A consensus document on the diagnostic criteria for BCR was published in 2006.<sup>29</sup> Required characteristics include bilateral disease, presence of at least three peripapillary lesions inferior or nasal to the optic nerve in at least one eye, low-grade anterior segment inflammation (less than or equal to 1+ cells), and low-grade vitreous inflammation (less than or equal to 2+ vitreous haze). Supportive findings include HLA-A29 positive, retinal vasculitis, and CME. Finally, exclusion criteria include presence of significant keratic precipitates, posterior synechiae, or diagnosis of

infectious, neoplastic, or inflammatory disease that may cause multifocal choroidal lesions.

### **Clinical Course and Prognosis.**

The disease is chronic in nature and does not regress. Again, symptoms of blurred vision, color deficiency, contrast sensitivity issues, and visual field problems may be present for years prior to the onset of fundus lesions. Visual acuity may be normal despite these complaints. It remains a poorly understood disease, and no consensus on management and treatment has been found. Many patients have a slow decline in vision despite treatment.<sup>10</sup> A final visual acuity of 20/40 or better in the best-seeing eye was reported in 75.1% of patients. However, 9.8% of patients were legally blind at follow-up (in the review of literature by Shah and colleagues<sup>10</sup>). Generally, macular edema was the commonest cause of visual decline in 50.5%.<sup>10</sup> Choroidal neovascular membranes developed in 5% of eyes.<sup>25,26</sup> These occur near the optic disc and can be bilateral. Finally, optic disc edema leading to atrophy can also affect visual prognosis. However, in a recent analysis of 46 patients, method of treatment was correlated with visual outcome.<sup>30</sup> Tomkins-Netzer and colleagues categorized patients as either having (1) no treatment, (2) short-term (less than/equal to 1 year) local or systemic treatment, or (3) systemic steroids with second-line immunosuppressants. They found that prognosis for central visual acuity and maintenance of visual fields was improved in patients on long-term immunosuppression compared to short-term therapy.<sup>30</sup>

## **Imaging**

### **Fluorescein Angiography.**

The creamy white spots have variable appearance on fluorescein angiography (FA), and the disease may be more evident clinically than with this mode of imaging (Fig. 79.3). The lesions can hypofluoresce in the early phase, and there can be diffuse hyperfluorescence in the late phases (Fig. 79.4). One theory suggests that the lesions are likely in the outer choroid and associated with large choroidal vessels, thus many of the lesions show neither

hypofluorescence or hyperfluorescence in any phase. The diffuse hyperfluorescence seen may represent a deep inflammatory focus that accumulates fluorescein.<sup>20</sup> Angiographic findings may include increased transit time, leakage from retinal vasculature leading to CME, optic disc hyperfluorescence (Fig. 79.5), and disc or retinal neovascularization.<sup>9,31,32</sup>

**FIG. 79.3** Color montage of right eye showing the distribution of spots.

**FIG. 79.4** Fluorescein angiography (FA) of periphery showing hyperfluorescence of lesions.

**FIG. 79.5** Fluorescein angiography (FA) showing hyperfluorescence of the optic nerve.

### **Indocyanine Green Angiography.**

Indocyanine green angiography (ICGA) is an important diagnostic test. In the active disease,<sup>32</sup> the birdshot lesions appear

hypofluorescent during the intermediate phase of angiography and appear to be bordered by medium-to-large vessels<sup>32-34</sup> (Fig. 79.6). Hypofluorescent lesions can occur prior to clinical lesions.<sup>35</sup> The choroidal vessels appear indistinct. Late in the ICGA, there is diffuse choroidal hyperfluorescence. Theories to explain this early hypofluorescence include choroidal ischemia versus blockage from inflammatory infiltrates. However, in birdshot chorioretinopathy it is agreed upon that the site of the pathology is primarily the choroid. In the acute stages, the inflammatory infiltrates may be denser and block fluorescence. In late stages of the disease, it is thought that the lesions become more atrophic and choroidal vasculature may become more visible. The lesions can become more isofluorescent in this phase of the disease, or they may remain hypofluorescent.<sup>31,32</sup>

**FIG. 79.6** Indocyanine green angiography (ICGA) showing hypofluorescent lesions exceeding the number seen clinically.

### Optical Coherence Tomography.

This mode of imaging has primarily been used to follow CME, which is the most common cause of vision loss in BCR<sup>36</sup> (Fig. 79.7). Photoreceptor loss is not a prominent finding early in the course of

this disease. Keane and colleagues created a protocol to scan extramacular retina using enhanced-depth imaging (EDI) optical coherence tomography (OCT).<sup>37</sup> They looked at four locations: superior and inferior to the major vascular arcades, temporal to the macula, and nasal to the optic nerve in addition to the macula. They found that there is significant thinning of the retina and choroid in the peripheral locations. There was a clear transition zone between the normal and abnormal retina. They suggest using this protocol and looking at the ellipsoid zone to monitor disease progression.<sup>37</sup> They also found discrete outer retinal and choroidal hyperreflective foci, which have been postulated to be inflammatory in nature.<sup>38</sup> Birnbaum and colleagues looked at the findings of 14 patients undergoing treatment and graded clinical symptoms as well as analyzed spectral domain (SD)-OCT with EDI.<sup>39</sup> They described a hyporeflectivity in the suprachoroidal space and found that if this “fluid” was present, it correlated directly to the presence of symptoms.<sup>39</sup> Another series of 11 patients looked at the features of the choroid on SD-OCT. Most patients were clinically inactive.<sup>40</sup> They found that despite clinical inactivity, patients had significantly thinner choroids than age-matched controls.<sup>40</sup>

**FIG. 79.7** Optical coherence tomography (OCT) showing cystoid macular edema and subfoveal fluid in a patient with birdshot chorioretinitis. (Courtesy of Deborah A.

Goldstein, MD.)

## Fundus Autofluorescence.

Giuliari and colleagues looked at fundus autofluorescence (FAF) of 18 eyes and found a spectrum of patterns.<sup>36</sup> They found that hypoautofluorescent lesions on FAF did not necessarily correspond to clinical birdshot lesions. Commonly (15/18 eyes) more FAF lesions denoting RPE defects were seen than clinical lesions. Koizumi and colleagues looked at eight patients. They found that some of these hypofluorescent lesions could be placoid in nature and involve the macula.<sup>41</sup> In addition, a perivascular (retinal) linear hypofluorescent FAF pattern was noted by both groups of investigators.<sup>36,41</sup> It was postulated that this finding may suggest that the retinal vessels may play a role in inflammatory-driven damage of the RPE and serve as a conduit for inflammatory factors. The observation that the clinical choroidal lesions did not always correspond to the FAF defects suggests that the choroid and RPE may be affected independently.<sup>41</sup> Furthermore, RPE defects in the macula could also be another cause of vision loss in these individuals. In another multicenter series of 76 patients who underwent wide-field FAF, 80% of patients were observed to have hypoautofluorescent lesions that correlated to decreased vision. They noted a diffuse involvement in the pigment epithelium.<sup>42</sup> FAF may be valuable in evaluating these patients as lesions may be clinically difficult to see.

## Electrophysiology

### Electroretinogram.

Electroretinography (ERG) is an important test for following BCR. Abnormal electroretinograms (ERGs) were reported in 88.8% of patients.<sup>10</sup> There appear to be two groups of patients: those who develop abnormal ERG early in the disease process and those that develop abnormal results late in the course.<sup>43</sup> Early ERGs may demonstrate supernormal ERG amplitudes, which may be related to retinal inflammation. In this stage, there may be a greater decrease in b-wave amplitude versus a-wave amplitude.<sup>24,43</sup> This is a negative ERG pattern and is not pathognomonic for BCR. It suggests that the Müller and bipolar cells are more affected than the

photoreceptor–retinal pigment epithelium complex. This has been seen in autoimmune retinopathy. Rod dysfunction may occur before cone dysfunction: the rod b-wave may be affected prior to photopic b-wave and flicker response in most patients. In late phases of the disease, there is a progressive decrease in a- and b-wave amplitudes. The 30 Hz flicker implicit time is abnormal in 70% of patients at baseline and is an important marker to follow.<sup>22,44</sup> ERG findings have been noted to improve with treatment.<sup>45</sup> Some authors argue that the reversible nature of the ERG abnormalities suggest a nonischemic etiology.<sup>17</sup> Inflammation of the retinal vasculature could lead to inner retinal dysfunction, while choroidal inflammation could be the cause of altered outer retinal function. Multifocal ERG has also been used and shows impairment as correlated with other functional tests.<sup>46</sup>

### **Electrooculogram.**

Shah and colleagues found that 66.5% of eyes reported in the literature with electrooculography (EOG) findings had abnormal results.<sup>10</sup> Decreased Arden ratios, representing RPE dysfunction, were reported.<sup>43</sup> These ratios further decline with disease progression.

### **Visual Field Testing**

Visual field abnormalities are present in patients with BCR. These include peripheral constriction, enlarged blind spot, central or paracentral scotomas, and generalized diminished sensitivity.<sup>9,19,20,23,47</sup> It is not certain whether these visual field defects occur due to ganglion cell, optic nerve, or outer retinal dysfunction, but it is unlikely that the birdshot lesions themselves cause blind spots.<sup>10</sup> Visual field abnormalities may be reversible with immunosuppression.<sup>48</sup> This is an important component to monitoring this disease.<sup>49</sup>

### **Systemic Associations**

There are no definitive systemic associations. Shah and colleagues'<sup>10</sup> review of the literature revealed hearing loss in some patients.<sup>8,50</sup> As mentioned earlier, cutaneous vitiligo associated with BCR has also

been reported in a few patients.<sup>9,20</sup> In addition, Priem and Oosterhuis reported an increased incidence of vascular disease in their series. Of 102 patients, 16 had hypertension, 5 had coronary artery disease, 2 had a history of cerebrovascular accident, and 2 had a central retinal vein occlusion.<sup>20</sup> These numbers are not impressive considering the age of the patients.

## **Pathogenesis**

The pathogenesis of BCR is unknown. Inflammation appears to be a primary feature. The histopathologic findings in a few eyes with BCR have been reported.<sup>51,52</sup> These suggest that the spots may be related to accumulation of lymphocytes in the choroid at multiple levels, occasionally associated with hemorrhage.<sup>51</sup> BCR appears to be a nongranulomatous nodular choroidal infiltration.<sup>52</sup> Some of the foci were adjacent to the choroidal vessels. The RPE, ciliary body, and iris were not involved. Some lymphocytes were found around the retinal blood vessels and in the optic disc. The lymphocytes were primarily CD<sup>8+</sup>T-lymphocytes. Inflammation is strongly associated with HLA-A29, which suggests a genetic predisposition to this disease. However, the fact that HLA-A29 is present in 7% of the white population and BCR is so rare tells us other factors are at work. Other genes are highly suspected. Increased interleukin (IL)-17 levels have been found in the aqueous and serum of patients.<sup>22,53</sup> This may represent a T-helper (Th)17-specific autoimmune process. However, initial studies of anti-IL-17 have not been efficacious.<sup>22</sup> Familial history of autoimmunity is likely.<sup>2</sup>

## **Differential Diagnosis**

Birdshot chorioretinopathy can usually be distinguished from other disorders by history and physical findings. However, entities such as pars planitis, intraocular B-cell lymphoma, syphilitic chorioretinitis, sarcoidosis, sympathetic ophthalmia, and other white spot diseases, especially multifocal choroiditis and panuveitis syndrome, should be considered. Indolent nonprogressive multifocal choroidal lesions also give a similar picture and should be considered when unilateral.<sup>54</sup> Sarcoidosis (see [Chapter 81](#), Sarcoidosis) and BCR may be the most difficult to distinguish from each other.<sup>10</sup>

## Management/Treatment

In the review of the literature by Shah and colleagues,<sup>10</sup> most cases were treated; however, no definitive guidelines for the initiation of treatment were given. This chronic progressive disease may not be sight-threatening in the early course, but macular edema with retinal damage, photoreceptor dysfunction, RPE atrophy, and optic nerve damage are the end results. Corticosteroids have been the mainstay of treatment. Oral, sub-Tenon, intraocular, and most recently sustained release fluocinolone acetonide<sup>55</sup> have been used. Corticosteroids can reduce CME,<sup>8,24,56,57</sup> inflammation,<sup>24</sup> and optic disc edema.<sup>56</sup> They have also been reported to decrease symptoms such as nyctalopia and issues with contrast sensitivity.<sup>12</sup> Systemic steroids carry their own risks. Local steroid injections increase the risk of cataract and cause glaucoma with repeated dosing. Implantation of a fluocinolone acetonide sustained-release device has been shown to eliminate the need for systemic therapy; however, it also has a high risk of cataract progression and glaucoma.<sup>55,58</sup>

## Immunosuppressive Therapy.

Conventional second-line immunosuppression is used when low-dose steroids are not sufficient at controlling disease and for long-term management of refractory cases.<sup>59</sup> The three classes of immunosuppressives have been used. Cyclosporine has been used as it inhibits T lymphocytes and prevents S-Ag-induced experimental uveitis.<sup>11</sup> Low-dose cyclosporine has proven to have positive visual effect in conjunction with steroids or alone.<sup>60</sup> Nephrotoxicity is the primary side-effect, and hypertension can be a problem.<sup>60</sup> Antimetabolites such as azathioprine, mycophenolate mofetil, and methotrexate have been adjunctive or used in monotherapy. Side-effects of these drugs include bone-marrow suppression and hepatotoxicity.<sup>61</sup> Methotrexate showed improved outcomes in one series compared with no treatment or steroid therapy.<sup>62</sup> The use of the alkylating agents cyclophosphamide and chlorambucil has also been reported. Side-effects such as bone-marrow suppression and development of malignancies must be weighed for this class. Daclizumab, a monoclonal antibody against the alpha-subunit of the IL-2 receptor of T cells, has been found to

have value in treating BCR.<sup>61,63</sup> The long-term efficacy of these agents needs to be determined and weighed against potential side-effects. Other biologics, such as infliximab and adalimumab, have also been used with evidence supporting efficacy.<sup>59</sup> A targeted IL-17 human monoclonal antibody, secukinumab, was not found to be effective in early trials.<sup>59</sup> Intravenous immunoglobulin G (IVIg) and interferons (IFNs) have also been studied.<sup>59</sup>

Anti-vascular endothelial growth factor (VEGF) therapy has been documented to be useful in treating CNV associated with inflammatory chorioretinal disorders.<sup>64</sup> Anti-VEGF may have some use in treatment of CME as well.<sup>65</sup> However, it has not been as effective in controlling the inflammatory component.<sup>59</sup> In following our patients, we recommend ERG yearly, Goldmann visual field examination at least yearly, close monitoring of visual acuity, OCT to evaluate epiretinal membranes and CME, and FA to assess disc and retinal vascular leakage.

## Summary

Birdshot chorioretinopathy is a bilateral, chronic progressive disease characterized by deep round lesions in a “birdshot” pattern. Symptoms include blurred vision, photopsias, scotomas, nyctalopia, and poor contrast sensitivity. These can develop years before the onset of fundus findings. The process is associated with a low-grade inflammation of the anterior and posterior segments. Visual prognosis is threatened by the ultimate development of CME, RPE, and photoreceptor atrophy, as well as optic nerve atrophy. Chronic immune suppression is the mainstay of therapy.

## Placoid Diseases

Acute posterior multifocal placoid pigment epitheliopathy (APMPPE), serpiginous choroiditis (SC), relentless placoid chorioretinitis (RPC), and persistent placoid maculopathy (PPM) are grouped together due to the “placoid” nature of the lesions. The pathophysiology of these lesions is still poorly understood. They share similarities on fluorescein and indocyanine green angiography; there exists a debate regarding the nature of the hypofluorescence that is seen in these studies. Some argue that

primary choroidal ischemia is the cause of the pathology, while others believe that this is blockage from swollen outer retina or RPE. In actuality, it may be a combination of these as newer OCT studies suggest that the outer retinal layer may be a site of primary insult. Attempts have been made, using new multimodal imaging, to separate these conditions. So far, the individual lesions look extremely similar, including OCT imaging. These conditions do, however, differ in their clinical courses and can almost always be separated from each other. APMMPPE shows multiple lesions, usually in both eyes, which heal rapidly without the development of marked retinal or choroidal atrophy. Serpiginous choroiditis is usually active in one eye; old scars are frequent. The lesions left untreated can develop more atrophy than the lesions of APMMPPE. Relentless chorioretinopathy shows continued development of new lesions (unlike the other entities) for many months. It requires immune suppression to stop this process. Persistent placoid maculopathy shows almost symmetric lesions that persist for months and sometimes longer. Although the pathophysiology of the individual lesions may be similar, these clinical findings allow their separation.

The diagnosis may dictate what therapy is necessary. APMMPPE shows marked healing, and although there may be permanent damage, it is often not severe. Many retinologists do not treat it, although some use corticosteroids. Serpiginous usually causes more retinal and choroidal atrophy. Immediate therapy is often indicated, usually corticosteroids. Relentless requires long-term immune suppression. Persistent placoid chorioretinopathy may show a response to immune suppression, but definitely requires treatment of the choroidal neovascularization, which often develops. For all of these entities, treatment of choroidal neovascularization is indicated, and where appropriate immune suppression should be used.

## Acute Posterior Multifocal Placoid Pigment Epitheliopathy

Acute posterior multifocal placoid pigment epitheliopathy (APMPPE) was first described in 1968 by Gass.<sup>66</sup> He presented three

healthy young female patients who developed the acute onset of bilateral central vision loss associated with multifocal placoid (plate-like) lesions at the level of the outer retina and the RPE, although he had also considered a primary choroiditis. Discussion regarding the site and etiology of the lesions would continue as the disease was further described in later years.<sup>67-76</sup>

## **Clinical Course**

### **Clinical Symptoms.**

Patients present with the onset of central vision loss that may be described as blurred vision, paracentral scotoma, metamorphopsia, “spots” in the vision, and photopsias.<sup>77</sup> Initial vision at presentation is 20/25 or worse in about 77% of eyes and 20/40 or worse in 58%.<sup>77</sup> Lesions can be unilateral or bilateral (more common 75%).<sup>78</sup> If unilateral, the second eye can become involved in a few days or weeks. Headaches, stiff neck, and malaise may accompany these ocular symptoms. A history of an antecedent viral syndrome or recent vaccination may be obtained.

### **Epidemiology.**

Males and females are equally affected, and generally this occurs in young adults, typically between age 20 and 50 with the mean age of onset being 26.<sup>77,78</sup> Recently, Taich and Johnson describe a syndrome resembling APMPE in older adults (over age 50).<sup>79</sup> These elderly individuals characteristically may have a worse outcome, with moderate or severe vision loss due to the development of geographic atrophy and CNV. These patients resemble the entity persistent placoid maculopathy (see below), and some may not have APMPE. Generally, APMPE is not a recurrent disease, but recurrence can rarely occur. A case of 11 recurrences in the span of 15 years has been described.<sup>80</sup>

### **Fundus Findings.**

Gass reported multiple round and confluent cream-colored, flat lesions with indistinct margins scattered in the posterior pole. Classically lesions have not been noted clinically anterior to the equator. However, with newer imaging modalities anterior lesions

can be seen.<sup>81</sup> The lesions are typically bilateral (Figs. 79.8 and 79.9). Fresh lesions can develop over the next few weeks; therefore lesions of differing ages can be visible. The placoid lesions tend to clear centrally initially leaving hypopigmentation. Later there is mild pigment mottling, which develops into condensation of the pigment. Finally an increasing degree of coarse pigment clumping occurs (Fig. 79.10). These lesions can enlarge. In the original article, there was no description of serous macular detachment associated with APMPE. However, later reports described localized serous retinal detachments,<sup>71,74,82-86</sup> and OCT imaging frequently reveals fluid. A superficial resemblance to Harada disease has been reported based on this feature.<sup>83,87-90</sup> Modern imaging techniques can easily differentiate these two entities. Recently, a staging scheme based on OCT classification has been proposed by Goldenberg and colleagues that correlates to the clinical findings just described.<sup>91</sup> In their four-stage classification system, lesions are described ranging from a subacute phase to resolution phase. Gass commented on how remarkably the choroid and retina remain relatively intact during the course of the disease. Spaide described choroidal infiltrations in the periphery<sup>92</sup> of a patient with acute APMPE. In addition, multiple authors have described an association with retinal vasculitis,<sup>93-95</sup> and retinal vein occlusion has also been seen.<sup>93,94</sup> Other findings can include subhyaloid hemorrhage<sup>94</sup> and rare CNV.<sup>96</sup> Case reports have also illustrated optic nerve involvement with disc edema.<sup>93,97</sup>

**FIG. 79.8** Fundus photo of the right eye showing placoid opacification during the acute phase.

**FIG. 79.9** Fundus photo of the left eye. Lesions of differing ages can be seen. Some mild pigment mottling can be seen (*arrow*).

**FIG. 79.10** Color fundus photo of healed acute posterior multifocal placoid pigment epitheliopathy.

### Other Ocular Findings.

Although vitritis is usually not a prominent component of APMPPE, the degree of ocular inflammation varies widely. An anterior uveitis<sup>98</sup> and granulomatous anterior uveitis<sup>99</sup> have been described. In addition, rare corneal stromal infiltrates<sup>100</sup> have been mentioned.

### Clinical Course and Prognosis.

Generally there is improvement of the visual symptoms within 2–4 weeks. APMPPE has a relatively good prognosis when compared with other placoid white spot syndromes. However, Fiore and colleagues<sup>77</sup> reviewed the literature as well as a cohort from their own institution and showed that approximately 50% of patients have an incomplete recovery of central vision and 25% of patients have 20/40 vision or worse. Sixty percent of eyes have residual visual symptoms. Foveal involvement at presentation is an important prognosticator. Eighty-eight percent of eyes without foveal involvement proceed to full central visual recovery in contrast to 53% of eyes that presented with foveal involvement. Unfortunately, approximately 70% of eyes present with foveal involvement. Photoreceptor involvement may ultimately limit

visual prognosis. Progressive improvement of visual acuity usually accompanies the resolution of the lesions. Gass initially reported that visual recovery could continue on for months after the lesions resolved, even up to 6 months.<sup>66</sup> However, most visual recovery occurs within 1 month.<sup>68,70,71,74,77,82</sup>

## Imaging

### Fluorescein Angiography.

Gass<sup>66</sup> described the lesions in the early phase as nonfluorescent (Fig. 79.11) and that the choroidal fluorescence is obstructed. Later in the angiogram there is a progressive, irregular staining of the lesions (Fig. 79.12). Ryan and Maumenee postulated that this could represent localization to the RPE or choriocapillaris rather than implying an infiltrate of the outer choroid.<sup>67</sup> Gass also stated that the underlying choroidal circulation appeared intact below the healing lesions.<sup>66</sup> However, later ICGA studies suggested that choroidal hypoperfusion did exist.<sup>101,102</sup> This is discussed below. As the process becomes inactive, hyperfluorescence corresponding to window defects in the mottled RPE develops and staining is no longer evident (Fig. 79.13). There may be visibility of the large choroidal vessels in areas of confluent atrophy. However, this does not exist in all areas, implying some RPE remains intact.<sup>72</sup> Either loss of the choriocapillaris or abnormal circulation in the confluent atrophied areas is suggested. In addition to these FA findings, there is also blocked fluorescence from pigment clumping.

**FIG. 79.11** Acute lesion: Fluorescein angiography (FA) shows early hypofluorescence of placoid areas.

**FIG. 79.12** Acute lesion: Fluorescein angiography (FA) in the late phases shows hyperfluorescence.

**FIG. 79.13** Healed lesion: early fluorescein angiography (FA). As the process becomes inactive, window defects develop. Pigment clumping is seen and blocks fluorescence as well.

The retinal vessels and optic nerve usually are normal;<sup>66,72</sup> however, some reports have described an association with retinal vasculitis, retinal vein occlusions, and disc edema.

### **Indocyanine Green Angiography.**

Since ICGA studies focus on the choroidal circulation, its findings in APMPE have been important in developing theories of pathogenesis.<sup>102-107</sup> Acute lesions show early hypofluorescence (Fig. 79.14). In the late phases, these lesions become more defined in shape. These areas are more numerous than the placoid lesions seen clinically. As the disease heals, the hypofluorescence in the late phase becomes less defined and smaller. This lends some support to the theory of choroidal ischemia as an underlying factor in the pathogenesis of APMPE. It is postulated that there is more hypofluorescence in the acute phase due to the additional presence of swollen outer retina or RPE cells in response to choroidal ischemia (clinically presenting as placoid lesions). As these disappear, there is less blockage and thus less hypofluorescence. Photoreceptor damage may also play a role in this as well, as elucidated by OCT studies and discussed below. Studies show that

the hypofluorescence in the late phases can also completely resolve,<sup>101</sup> suggesting that choroidal vasculopathy, if present, may be a transient process.

**FIG. 79.14** Acute lesion: Indocyanine green angiography (ICGA) shows hypofluorescent areas.

### Optical Coherence Tomography.

Many studies have described the OCT findings in APMMPPE.<sup>88,108–113</sup> Garg and Jampol reported outer retinal abnormalities in APMMPPE using time domain technology. A serous retinal detachment had reflective material within the subretinal fluid (SFR). It was postulated that this was either proteinaceous material or edematous RPE. There was rapid resolution of the serous detachment and the material disappeared.<sup>85</sup>

Lofoco and colleagues showed that in the acute phases the time domain OCT revealed a mild hyperreflective area above the RPE in the photoreceptor layer corresponding to the placoid lesions. Later the OCT scan revealed a nodular hyperreflective lesion in the plane of the RPE with mild underlying backscattering. They theorized that the hyperreflective areas may indicate inflammatory tissue and inflammatory cells or the presence of ischemic edema in the outer retinal layers.<sup>113</sup> As ultra-high resolution (UHR)-OCT developed,

Scheufler and colleagues showed disruption of the outer retina early in the disease (Fig. 79.15). RPE disruption occurs as the lesions heal.<sup>114</sup> Backscatter of lesions was observed in the acute inflammatory phase in UHR as well. They found photoreceptor atrophy as the lesions began to heal and persistence of it post resolution. They suggested that the backscattering of acute lesions in the outer retina represents inflamed or damaged photoreceptor cell bodies. In addition to illustrating photoreceptor and RPE degeneration, spectral domain OCT has also shown that in some patients with fluid associated with the placoid lesions, that there may actually be accumulation of intraretinal fluid (IRF) rather than an exudative retinal detachment.<sup>85,108</sup>

**FIG. 79.15** Subacute lesion: Optical coherence tomography (OCT) showing disruption of the outer retina.

### Fundus Autofluorescence.

FAF imaging is directed at the retinal pigment epithelial layer and is therefore especially useful in APMPE. Several studies have described FAF findings<sup>88,110,112,115,116</sup> (Fig. 79.16).

**FIG. 79.16** Subacute lesion: Fundus autofluorescence (FAF) shows areas of hyper- and hypoautofluorescence corresponding to clinical changes in pigmentation.

Spaide compared angiographic findings with autofluorescence. He noted that the early hypofluorescence seen on angiogram did not match up precisely with observable changes of the RPE, and he suggested this means there are choriocapillaris perfusion defects. In the late phase of the angiogram, there was staining of some of the lesions. These late-staining lesions matched the size and shape of lesions seen in fundus autofluorescence. As the lesions resolved clinically, they became pigmented centrally with a depigmented halo. On autofluorescence, centrally there was intense hyperautofluorescence, and the depigmented halo was hypoautofluorescent, implying atrophy. He postulated there was a centripetal contraction of the placoid lesions that produced this appearance. He noted the autofluorescence changes lagged behind the clinical appearance. In addition, he found that choroidal abnormalities seemed more numerous on fluorescein and indocyanine green angiography. He concluded the RPE abnormalities were a result of the choroidal abnormalities.<sup>116</sup>

## Adaptive Optics.

As an emerging technology, limited description of adaptive optics scanning laser ophthalmoscopy (AO-SLO) is provided in the literature. This imaging modality is currently best at analyzing the cone mosaic. The descriptions of APMPE show dark annulus corresponding to loss of the imaging of the cone cells in a case of acute APMPE.<sup>117</sup> They also describe hyperreflective flecks, which correspond to dome-shaped elevations on OCT. Further study is warranted to see the course of these cells as disease progresses.

## Electrophysiology

Although these functional studies are not essential in the diagnosis of APMPE, they do emphasize the role of RPE involvement as described by Fishman and colleagues. The electroretinogram is normal to minimally subnormal. However, abnormal light : dark ratios have been documented on EOG, suggesting a diffuse RPE problem. Furthermore, the ERG and EOG abnormalities can normalize, suggesting that this can be a transient RPE problem.<sup>72</sup> However, despite this good recovery, visual field abnormalities can persist in some cases.<sup>95</sup>

## Systemic Associations

APMPE has been linked to CNS manifestations<sup>118-120</sup> including cerebral vasculitis,<sup>95,121-127</sup> meningo-encephalitis,<sup>128</sup> and stroke.<sup>95,129-133</sup> Cases of APMPE associated with sixth cranial nerve palsy<sup>134</sup> and transient hearing loss<sup>135</sup> have also been cited. Headaches are a common symptom, and APMPE has mimicked migraine with aura.<sup>95,136</sup> Although many patients give a history of viral illness, the symptoms of malaise and headaches may thus be more related to a widespread underlying vasculitis. Cerebrospinal fluid analysis has shown pleocytosis,<sup>137</sup> which lends credence to this. The CNS associations are not benign and death, though uncommon, is possible. This has been described in association with a rapid taper of prednisone in one case.<sup>138</sup> There should be a low threshold for neurologic or rheumatologic consultation. MRI and CSF examination are important in these patients.<sup>95</sup> Steroids should be considered for CNS involvement.

Systemic vasculitis<sup>139</sup> has been implicated in APMPE-like patients and has been described in a P-ANCA-positive patient.<sup>140,141</sup> Other associations with erythema nodosum,<sup>68,76</sup> ulcerative colitis,<sup>142</sup> thyroiditis,<sup>143</sup> nephritis,<sup>144,145</sup> and juvenile rheumatoid arthritis<sup>146</sup> lead to an underlying immune-mediated or inflammatory link. Other associations include granulomatous diseases such as granulomatosis with polyangiitis,<sup>147</sup> pulmonary TB,<sup>148</sup> and sarcoidosis.<sup>121,149</sup>

## Pathogenesis

When Gass first described APMPE, he believed that the abnormalities were primarily at the level of the RPE. He believed that there was blockage of fluorescence due to damaged RPE cells, and these cells stained in the late phases. He stated that the retinal and choroidal circulations looked remarkably intact.<sup>66</sup> Van Buskirk and coworkers first described an alternate theory that choroidal perfusion was the primary problem and that the hypofluorescence seen with angiography was due to lack of perfusion of the choriocapillaris.<sup>76</sup> ICGA studies found that the choroid did appear hypoperfused as described above. However, Fishman and colleagues' study of ERG and EOG revealed that the ERG and thus the retina remained relatively intact compared to the EOG. Therefore, a diffuse RPE process was implicated in the acute phase of the disease. It also confirmed the transitory nature of this process as the EOG could normalize.<sup>72</sup> The fact that the ERG was generally normal did not favor a primary widespread choriocapillaris defect.

Currently, some believe that there is a vascular insult affecting the choroid that may cause partial choroidal ischemia leading to RPE changes and ultimately affect photoreceptors. In addition, the systemic associations of this disease suggest an underlying vasculitis. It is possible that a primary process involving the outer retina and RPE could secondarily cause choroidal abnormalities on angiography. There may be a trigger, either inflammatory or infectious in nature, that incites this process. Furthermore, an association with HLA-B7 and HLA-DR2<sup>150</sup> has been described, and this suggests there are certain individuals who are more susceptible to this process.

Although exact etiology is unknown, there have been

associations with viral illness,<sup>151</sup> specifically, mumps,<sup>152</sup> adenovirus,<sup>153,154</sup> and coxsackievirus B<sup>155</sup> have been mentioned. In half of the cases presented by Ryan and Maumenee, there was an overt viral illness prodrome.<sup>67</sup> In addition to viral infections, an association with bacterial infections has also been described. Two case reports implicate Lyme disease.<sup>156,157</sup> Another case report described APMMPPE post acute bacterial infection with group A streptococcus.<sup>158</sup> APMMPPE has also been found post various vaccinations such as influenza,<sup>159</sup> varicella,<sup>160</sup> meningococcal C conjugate,<sup>161</sup> and hepatitis B.<sup>162</sup> Molecular mimicry has been implicated in these cases of post-vaccination APMMPPE.<sup>159</sup> Sequence similarities between the introduced antigens and the eye could incite an immune reaction.

A delayed-type hypersensitivity (DTH) reaction may bring all these associations together.<sup>105</sup> In this process, there is an activation of sensitized T lymphocytes by various stimuli such as bacteria, viruses, and fungi. Previously primed T cells release lymphokines that then activate macrophages and cytotoxic T cells. Macrophages then give rise to epithelioid cells and giant cells that can lead to granulomas. The systemic associations such as CNS inflammation as mentioned above could be explained in this manner. The fluorescein and ICGA findings could also be explained by a choroidal DTH reaction causing choroidal vascular occlusion.

A thrombotic process of the choroid has also been postulated. Elevated anticardiolipin antibodies were found in a patient with acute APMMPPE. These levels were normal a year after resolution of the disease.<sup>163</sup> The association with retinal vein occlusion supports a prothrombotic state. Furthermore, elevated anticardiolipin antibodies have been associated with a number of viral infections and in many cases also associated with thrombosis.<sup>164</sup>

## **Differential Diagnosis**

The diagnosis of APMMPPE is made clinically based on examination, time course, and imaging characteristics. Other white spot placoid diseases are in the differential diagnosis and should be considered. These include serpiginous choroidopathy (which should be considered in recurrent, chronic cases), relentless placoid chorioretinitis, which should be thought of in severe, persistent,

and recurrent cases, and persistent placoid maculopathy. Other considerations include diffuse unilateral subacute neuroretinitis, Harada disease,<sup>83,87-89</sup> TB, sarcoid, fungal disease, choroidal metastasis, or lymphomatous infiltrate,<sup>67</sup> and especially syphilis.<sup>165</sup>

## Management/Treatment

Laboratory investigations are usually not necessary. Certain investigations may be useful in severe or questionable cases. Spinal fluid analysis for pleocytosis<sup>139</sup> and anticardiolipin antibodies<sup>163</sup> are among them.

No therapy in the management of acute APMPE has been proven with certainty. A review of the data from the literature on corticosteroids does not provide clear direction.<sup>77</sup> However, some support the use of steroids when there is central nervous system involvement.<sup>166</sup> Recently, the use of tumor necrosis factor (TNF) blockers has been reported in patients with severe APMPE.<sup>167</sup>

Rarely CNV can develop. Bruch's membrane appears less affected in APMPE compared to serpiginous choroiditis, and therefore CNV is less prevalent. Anti-VEGF agents have been found to be useful in treating the CNV.<sup>168,169</sup> Photodynamic therapy has been used as well; however, its use is cautioned as it can exacerbate inflammation and possible choroidal ischemia, which are present in the acute stages of APMPE.<sup>96</sup>

## Summary

APMPE is a bilateral inflammatory process involving the RPE, the choriocapillaris, and outer retina. There is an equal incidence in males and females. A viral prodrome is often associated with this entity. Headaches are a common symptom, and neurologic symptoms need to be addressed. There are characteristic findings on fluorescein angiography, including early hypofluorescence with late staining in the acute phase. This process becomes inactive over the period of weeks without intervention, and in comparison to other WSS it has a relatively good prognosis. The pathogenesis is controversial, and the outer retina may be the primary site of damage, but choroidal hypoperfusion leading to RPE and photoreceptor damage may play a role.

## Idiopathic Serpiginous Choroiditis

Serpiginous choroiditis (SC), also previously known as helicoid peripapillary chorioretinal degeneration,<sup>170</sup> geographic helicoid peripapillary choroidopathy,<sup>171</sup> and geographical choroidopathy,<sup>172</sup> is a rare disease of unknown etiology. It is usually eventually bilateral, chronic, and progressive. The lesions involve the outer retina, RPE, choriocapillaris, and large choroidal vessels.<sup>173</sup> Patients present with acute geographic or serpentine lesions that are gray or gray–yellow (due to disruption of the RPE and outer retina).

### Clinical Course

#### Clinical Symptoms.

Patients are often asymptomatic until a lesion affects the fovea. Blurred vision occurs at this point.<sup>174,175</sup> Although this is a bilateral disease, typically the patient becomes symptomatic unilaterally with foveal involvement. Small central or paracentral scotomas may be present. These are absolute in their acute stages and become relative with healing.<sup>175</sup>

#### Epidemiology.

Idiopathic SC is often a disease of healthy individuals. The onset is usually between the ages of 30 and 70. However, cases of SC have been reported in younger individuals.<sup>175</sup> Most reports of SC involve Caucasians; however, SC has also been reported in Asians,<sup>176</sup> African Americans,<sup>175</sup> and Hispanics.<sup>177</sup> The literature reflects a slight predilection for males.<sup>173</sup> No family history is elicited. One study done in a Finnish population showed a higher prevalence of HLA-B7 in patients with SC.<sup>178</sup>

#### Fundus Findings.

Two variants of idiopathic SC are seen. The classic appearance<sup>173</sup> starts with one or several geographic patches of gray or creamy yellow placoid lesions in the peripapillary region. It generally progresses with recurrences in a centrifugal manner with finger-like or serpentine projections. In one report, a centripetal direction was described.<sup>174</sup> Acutely, the outer retina appears edematous, and

serous retinal detachments may be seen.<sup>179,180</sup> As these active lesions resolve (with or without) treatment over the next several weeks, extensive RPE and choriocapillaris atrophy occurs (Fig. 79.17). SC has recurrences, and therefore it is common to see old and active lesions at the same time. Recurrences can occur at the edge of old scars (Fig. 79.18), but not always. As the disease becomes chronic, chorioretinal atrophy, subretinal fibrosis, and RPE clumping is seen.<sup>173</sup> Since most patients become symptomatic only when the fovea becomes involved, about two-thirds present with bilateral chorioretinal scarring.<sup>181</sup>

**FIG. 79.17** Fundus photo of serpiginous choroiditis showing the geographic projections in the inactive phase. (Courtesy Alice T. Lyon, MD.)

**FIG. 79.18** Fundus photo showing acute recurrence of serpiginous choroiditis near the edge of a scar.

Macular serpiginous choroiditis<sup>176,177</sup> is the second variant (Figs. 79.19–79.22). There is no difference in the lesions of macular serpiginous and peripapillary diseases except for location.<sup>178</sup> There is generally a poorer prognosis for the macular variant as the fovea is affected at the start. Vision loss may also be related to subsequent development of CNV.<sup>177</sup> However, Sahu and coworkers, in a more recent report, did not observe CNV in their series.<sup>182</sup> Macular SC may be misdiagnosed as macular degeneration, macular dystrophies, or toxoplasmosis.<sup>173</sup>

**FIG. 79.19** Fundus photo of subacute macular serpiginous choroiditis.

**FIG. 79.20** Subacute lesion: early fluorescein angiography (FA) shows hypofluorescence.

**FIG. 79.21** Subacute lesion: Indocyanine green angiography (ICGA) showing hypofluorescence centered in the macula.

**FIG. 79.22** Healed lesion: Optical coherence tomography (OCT) in macular serpiginous choroiditis shows outer retinal disruption.

### Other Ocular Findings.

Although idiopathic serpiginous choroiditis is not usually associated with a marked inflammatory response,

nongranulomatous anterior uveitis<sup>183,184</sup> has been seen. More commonly – estimated in about a third of patients – there are fine vitreous cells.<sup>180</sup> The eye is white. Additional retinal findings have been described. These include CNV, which affects 13–20% of eyes,<sup>185–190</sup> vein occlusions,<sup>191,192</sup> retinal vasculitis<sup>192</sup> (usually a periphlebitis), CME,<sup>193</sup> and bilateral full-thickness macular holes.<sup>194</sup> Optic nerve abnormalities such as optic disc edema<sup>174</sup> and disc neovascularization<sup>189</sup> can be seen at the active stage of serpiginous choroiditis.

### **Clinical Course and Prognosis.**

Serpiginous choroiditis is characterized by multiple recurrences at intervals of months to years. Healing of individual lesions takes place in 2<sup>178</sup> to 8 weeks,<sup>173</sup> but new lesions appear later.<sup>174</sup> Generally acute lesions are seen in one eye at a time.

Visual loss is correlated with proximity to the fovea. There can be some incomplete recovery, but due to the recurrences, 75% of untreated patients develop central visual loss in one or both eyes. Final visual acuity is less than 20/200 in up to 25%.<sup>195</sup>

## **Imaging**

### **Fluorescein Angiography.**

In the acute SC, the lesions show hypofluorescence during the early phase of the study<sup>171</sup> (Fig. 79.23). This is may be due to a of blockage by swollen outer retina and RPE and/or nonperfusion of the choriocapillaris. The borders of the lesion may be hyperfluorescent, representing intact choriocapillaris. As the study progresses, the previous hypofluorescent lesions become variably hyperfluorescent, and this intensifies over time, representing staining of the acute lesions (Fig. 79.24). Retinal vascular staining may be seen near active lesions. Pigmentary changes then develop, and there is gradual appearance of atrophy. Angiography at this stage shows mottled hyperfluorescence with increased fluorescence in the late phases representing leakage of dye from the damaged choriocapillaris at the periphery of the lesion. CNV can occur and appears as late leakage, usually at the edge of a scar.

**FIG. 79.23** Fluorescein angiography (FA) shows hypofluorescence corresponding to the new lesion (*arrow*). (Courtesy Alice T. Lyon, MD.)

**FIG. 79.24** Fluorescein angiography (FA) in the late phases shows that previously hypofluorescent lesions become variably hyperfluorescent.

## Indocyanine Green Angiography.

ICGA<sup>196-199</sup> is useful in evaluating SC. Giovannini and colleagues describe how ICGA allows a greater understanding of the disease. In particular, ICGA allowed (1) better staging of SC, revealing choroidal alterations when there was no clinical or FA evidence; (2) better identification of the active lesions, which appear to be larger at the choroidal level in comparison with the corresponding retinal lesions; and (3) persistence of choroidal activity even when the signs of retinal activity had disappeared.<sup>198</sup> The ICGA pattern is characterized by hypofluorescent areas persisting from early to late phases (Fig. 79.25). The hypofluorescence has been reported to be less pronounced in later phases, which may represent delayed perfusion rather than nonperfusion.<sup>200</sup> The hypofluorescent lesions appear more extensive on ICGA in comparison to clinical examination and fluorescein angiography.

**FIG. 79.25** Indocyanine green angiography (ICGA) of this patient with serpiginous choroiditis is characterized by persistent hypofluorescence. (Courtesy Manjot K. Gill, MD.)

## Optical Coherence Tomography.

OCT findings have been described.<sup>201-205</sup> Chronic changes seen with

spectral domain OCT illustrates development of retinal atrophy with disruption of the photoreceptor layers in affected areas. There is thinning of the RPE, and IRF including cystic changes can be seen.<sup>201</sup> There is increased reflectance of the choroid and the deeper retinal layers. Opacification of the outer nuclear layer and Henle's layer is seen. Disruption of the photoreceptor inner/outer segments can be seen in active and inactive lesions<sup>202</sup> (Fig. 79.26). It is noted that in acute lesions, the outer retina and choroid are involved with relative sparing of the inner retina. In late cases, due to RPE migration, the inner retina can also show changes.<sup>206</sup> OCT is useful for looking for cystoid macular edema, epiretinal membranes, and choroidal neovascularization, which occur with serpiginous choroiditis.<sup>206</sup>

**FIG. 79.26** Healed lesion: Optical coherence tomography (OCT) shows retinal atrophy and disruption of the photoreceptor layers. Cystic fluid is seen here as well. The fovea is spared.

### Fundus Autofluorescence.

As idiopathic SC affects the RPE, FAF<sup>202,205,207</sup> images are helpful in demarcating this disease. New lesions appear hyperautofluorescent, and old lesions are hypoautofluorescent (Fig. 79.27). Recurrences are characterized by hyperautofluorescent lesions at the borders of old hypoautofluorescent areas.<sup>207</sup> Hyperautofluorescence was detected 2–5 days after the appearance of acute lesions.<sup>205</sup> Piccolino and colleagues compared FAF to ICGA

and OCT and found that the acute hyperautofluorescent areas were less extensive than the apparent perfusion defect delineated by ICGA.<sup>205</sup> When compared to OCT, there was increased reflectance of the photoreceptor layer corresponding to the area of hyperautofluorescence. As the disease progressed, the hyperautofluorescent area became hypoautofluorescent and the photoreceptor changes persisted. This has been confirmed by later studies as well.<sup>208,209</sup> The lesions appear to be homogenous.<sup>207</sup>

**FIG. 79.27** Fundus autofluorescence (FAF) image shows hypoautofluorescent lesions corresponding to old lesions, the subacute lesions are more hyperautofluorescent. (Courtesy Manjot K. Gill, MD.)

## Electrophysiology

Results of ERG are normal,<sup>175,180</sup> and EOG is abnormal only when there is extensive disease.<sup>180</sup>

## Perimetry.

Goldmann visual field examination shows that scotomas corresponding to an area of activity may not be permanent.<sup>175</sup>

Scotomas corresponding to fundus lesions are present but are not absolute and usually are denser centrally and less peripherally. More recently, microperimetry<sup>210</sup> studies confirm this finding. Microperimetry may be able to detect subclinical lesions.<sup>206</sup>

## Systemic Associations

Reports have described SC in patients with various systemic diseases: Crohn's disease,<sup>211</sup> systemic lupus erythematosus (SLE),<sup>212</sup> celiac disease,<sup>213</sup> and extrapyramidal dystonia.<sup>214</sup> These are likely coincidental associations. Systemic vasculitides can cause choroidal ischemic syndromes, which may resemble SC.

## Pathogenesis

The pathogenesis of serpiginous choroiditis remains unknown. Postulated etiologies have included autoimmune, infectious, vascular, and degenerative.<sup>173</sup>

The inflammatory nature of the disease is supported by histopathology with inflammatory lymphocytic infiltrate in the choroid (more prominent at the margin of the lesion).<sup>188,215</sup> Clinically, the presence of anterior uveitis, vitritis, and retinal vasculitis also points to an inflammatory etiology. The report of an association with HLA-B7 suggests some individuals are more susceptible to this process.<sup>178</sup> Broekhuysse found a sensitization to S-antigen in SC patients.<sup>216</sup> Acute SC lesions respond to corticosteroids and immune modulating agents consistent with an immune-mediated process.

A microbial origin of SC has been suggested, but the evidence is not convincing. Herpesvirus has been found in aqueous humor,<sup>217</sup> and VZV and HSV DNA were detected in the aqueous of a subset of patients with serpiginous choroiditis, suggesting that these viruses may be involved. Conversely, Akpek and Chan described the lack of herpesvirus DNA in choroidal tissues at autopsy of a patient with SC.<sup>215</sup> No viral DNA was amplified, including HSV, CMV, EBV, VZV, or HHV-8. Furthermore, there are reports of recurrences while on antiviral therapy.<sup>195</sup> Pisa and colleagues studied five patients with SC to assess the presence of fungal infection by the presence of antibodies in human serum samples.<sup>218</sup> Antibodies against *Candida* were apparent in four of the patients.

Vasculopathy, either primary or secondary, has also been proposed.<sup>173,200,219</sup> The clinical presence of phlebitis and branch retinal vein occlusions supports this etiology. King and colleagues noted elevated factor VIII in association with SC.<sup>220</sup> This could lead to an occlusive vascular phenomenon due to vascular endothelial injury as seen in diseases such as scleroderma, Raynaud disease, polymyalgia rheumatica, and temporal arteritis. Fluorescein and ICGA also suggest vascular involvement. Hayreh's early work showed that closure of the cilioretinal vessels could produce lesions that look something like SC.<sup>221</sup> The lack of systemic vascular disease in SC does not support vasculopathy.

Finally, a degenerative etiology has been proposed. The nature of SC's chronic and progressive nature and later onset in life lends some support to this.<sup>173</sup> One case showed an association with unilateral extrapyramidal dystonia,<sup>214</sup> which could be supportive or coincidental. The presence of inflammation and lack of familial inheritance, the sporadic nature of SC, and occasional recovery of vision are not supportive of a degenerative condition.

## Differential Diagnosis

APMPPE must be considered. Patients with APMPPE are usually younger. The acute lesions are bilateral and scattered throughout the posterior pole. Recurrences are very rare. CNV is a rare complication in APMPPE compared to serpiginous choroiditis. Visual prognosis is better with APMPPE. Persistent placoid maculopathy and relentless placoid chorioretinitis should also be considered and will be discussed later in this chapter. Other white spot syndromes such as birdshot choroidopathy and multifocal choroiditis and panuveitis syndrome as well as presumed ocular histoplasmosis may also be considerations.

Other diagnostic considerations include tuberculous serpiginous choroiditis (discussed further below and [Chapter 85](#), Mycobacterial infections), sarcoidosis,<sup>222</sup> systemic non-Hodgkin lymphoma,<sup>223</sup> antiphospholipid antibody syndrome,<sup>224</sup> toxoplasmosis,<sup>225</sup> syphilis, and posterior scleritis.<sup>226</sup>

With macular SC, one must think about choroidal ischemia in the differential diagnosis.<sup>177</sup> This can occur with systemic vascular diseases such as systemic lupus erythematosus, toxemia of

pregnancy, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and malignant hypertension as an etiology for macular vision loss.

## Management/Treatment

Although the diagnosis is suspected by clinical history, examination, and imaging characteristics, a preliminary workup could include TB skin test, chest radiograph, quantiferon gold test if TB is suggested,<sup>227</sup> ACE, VDRL, fluorescent treponemal antibody absorption test, toxoplasma titers, and a viral screen. Abrez and colleagues suggest an aqueous tap if anterior chamber cells are noted with an evaluation by PCR for viral etiology.<sup>184</sup> Indications for doing a more extensive workup include the presence of multifocal lesions, lesions primarily involving the macula and sparing the peripapillary area and cells in the anterior chamber, as well as vitritis.<sup>206</sup> As serpiginous choroiditis is a rare disease, controlled trials comparing treatments are not available. Much of what we know comes from small case series.<sup>228</sup> Due to the relapsing and progressive nature of SC, treatments would ideally address both the acute inflammatory episode and preventing recurrences.

Corticosteroids have been a mainstay of acute treatment and multiple routes of administration have been described: oral prednisone,<sup>179</sup> sub-Tenon triamcinolone, intravenous pulse methylprednisolone therapy,<sup>229</sup> intravitreal triamcinolone acetonide,<sup>230-233</sup> and intravitreal fluocinolone acetonide implant.<sup>234</sup> Systemic prednisone therapy of 60–80 mg/day is a commonly prescribed therapeutic regimen. However, acute lesions in the fovea or threatening the fovea may benefit from immediate intravitreal corticosteroids. Aggressive corticosteroid therapy is useful in treating acute attacks, but since the corticosteroids are tapered, is not useful in preventing recurrences. Relapses are common after tapering the medication. A case report described using an intravitreal fluocinolone acetonide implant that resulted in ongoing control of the disease for 14 months postoperative follow-up.<sup>234</sup> This delivery route avoids the side-effects of systemic corticosteroids. However, cataract and glaucoma from this route of administration are often seen.

Corticosteroids can be used alone or in combination with other

immunosuppressive therapy.<sup>235,236</sup> T-cell inhibitor (cyclosporine),<sup>237,238</sup> antimetabolites (azathioprine),<sup>239</sup> and alkylating agents (cyclophosphamide and chlorambucil)<sup>240,241</sup> have been used. Cyclosporine alone has been used with mixed results. Triple-agent immunosuppression with cyclosporine, azathioprine, and prednisone was described by Hooper and Kaplan.<sup>242</sup> They reported five patients with bilateral SC in whom visual recovery was promoted by this regimen. The therapy was given for 8 weeks prior to tapering. Two patients relapsed. Another study reported four patients maintained on a low dose of triple therapy for 12–69 months. Three patients did achieve remission off the drugs.<sup>235</sup> Alkylating agents have shown some promise, but side-effects, including bone-marrow suppression, nausea, fatigue, as well as one case of development of transitional epithelial carcinoma of the bladder, did occur.<sup>240</sup> For this reason, these agents should probably be reserved for sight-threatening disease that has failed conventional immunosuppressive therapy.<sup>173</sup> Other more recent therapies have included infliximab<sup>243</sup> and interferon-alpha-2a.<sup>206,244</sup> They appear promising, but the risk of systemic side-effects should be weighed. Patients receiving systemic management for SC are often jointly managed with a rheumatologist, internist, or oncologist.

Treatment is also aimed at managing complications of SC. These include CNV and CME. Reports have described the use of anti-VEGF agents for inflammatory chorioretinal disorders.<sup>245–249</sup> CNV in SC appears to be responsive to this treatment. Photodynamic therapy<sup>250,251</sup> has also been used with some success; however, the clinician should be mindful that choroidal ischemia and inflammation is inherent in SC and could be exacerbated by this treatment. For extrafoveal CNV, thermal photocoagulation is possible.

Acetazolamide<sup>252</sup> may be useful in the management of CME related to SC. It is thought that CME develops due to RPE dysfunction. After 2 weeks of treatment, there was complete resolution of CME with improvement of visual acuity in one case report.

Follow-up can include Amsler grid use by the patient to monitor for relapses and foveal involvement.

## Tuberculous Serpiginous Choroiditis

Tuberculous serpiginous choroiditis can resemble idiopathic serpiginous choroiditis. Some may call this a serpiginous-like choroidopathy, but the term multifocal serpiginoid choroiditis (MSC) was suggested as a preferred term in a recent major review.<sup>206</sup> TB-related serpiginous choroiditis is associated with more vitritis compared to serpiginous choroiditis. In addition, patients with TB choroiditis have more multifocal lesions involving the periphery. SC has larger lesions compared to TB and is more likely to have lesions extending from the optic nerve head.<sup>253</sup> Fluorescein angiography does not distinguish between these two entities. Fundus autofluorescence may. Hypofluorescence corresponding to RPE loss in SC is more homogeneous compared to the variegated pattern and stippled hyperautofluorescence of tuberculous disease.<sup>205</sup> *Francisella tularensis* and *Bartonella henselae* have also been reported to give a clinical picture like SC.<sup>254</sup> These authors argue that both idiopathic SC and those with an infectious etiology should be grouped together on a spectrum as they give a similar clinical picture.<sup>254</sup> In developing countries, especially India, individuals with evidence of tuberculosis commonly may have serpiginous-like lesions. (See differential diagnosis section below and [Chapter 85](#), Mycobacterial infections). SD-OCT may be useful at differentiating tuberculous SC from idiopathic SC. Choroidal infiltration as has been reported in a case of tuberculous related disease and not in idiopathic SC.<sup>255</sup> FAF may help to distinguish the lesions of SC from TB-related disease. TB-related diseases in general have a stippled hypoautofluorescence corresponding to lesions, which is not as homogenous as SC.<sup>207</sup> (See [Chapter 85](#), Mycobacterial infections for more of a discussion on TB.)

## Summary

Idiopathic serpiginous choroiditis is a chronic, progressive, and often bilateral disease. The course of the disease includes destruction of the choriocapillaris, RPE, and atrophy of the overlying retina. Treatment is aimed at immune suppression and carries significant side-effects. Visual prognosis is determined by the proximity of active disease to the fovea. Tuberculous SC must be considered and ruled out.

## Relentless Placoid Chorioretinitis

Relentless placoid chorioretinitis (RPC) was described in 2000 by Jones and colleagues.<sup>256</sup> They reported six patients resembling both APMPPE and serpiginous choroiditis, but with an atypical time course and retinal distribution. The term ampiginous has been used to describe similar patients.<sup>257</sup> It is likely that some previous descriptions of multifocal serpiginous<sup>258</sup> and recurrent APMPPE represent this entity.<sup>259</sup>

### Clinical Course

#### Clinical Symptoms.

The commonest complaint is sudden painless blurring.<sup>260</sup> Patients also describe metamorphopsia, floaters, or can initially be asymptomatic.

#### Epidemiology.

Patients were aged 17–51 in the report by Jones and colleagues.<sup>256</sup> There was no gender predilection. In a series by Jyotirmay and colleagues, a male preponderance was found with a mean age of 34.<sup>260</sup> The patients have no consistent medical disorder or viral prodrome.

#### Fundus Findings.

In most cases, patients have bilateral posterior creamy-white lesions at the level of the RPE (Fig. 79.28). The lesions (in almost all cases) tend to be smaller than those of APMPPE (approximately one-half disc area)<sup>260</sup> (Fig. 79.29). Lesions can be active in both eyes simultaneously. As they heal, pigmented chorioretinal atrophy develops. Lesions can persist and grow. A hallmark of this disease is the eventual presence of numerous (>50 to hundreds) lesions with involvement anterior and posterior to the equator. This is in contrast to APMPPE, which is mostly limited to the posterior pole. One study found that lesions more commonly appear in the periphery first and in the posterior pole later.<sup>260</sup> The fovea is commonly involved.

**FIG. 79.28** Fundus photos of a patient with relentless placoid chorioretinitis documenting progression (A–D) of posterior creamy white lesions at the level of the retinal pigment epithelium over the course of one month.

**FIG. 79.29** Fundus photo of the same patient 2 years later. Healed lesions show pigmented chorioretinal

atrophy. The fovea is spared.

Other findings have included a mild vitritis, occasional SRF, and disc swelling.<sup>260</sup> In their study of 26 eyes in 16 patients, Jyotirmay and colleagues found subretinal fibrosis, as well as epiretinal membranes as rare findings.<sup>260</sup> Interestingly, CNV is not described.<sup>252,260,261</sup>

### **Other Ocular Findings.**

Jones et al. described a patient with herpetic keratitis and corneal infiltrates in their series. Iritis with keratic precipitates as well as episcleritis can also occur.<sup>256,261</sup>

### **Clinical Course and Prognosis.**

The clinical course is prolonged and relapsing. In four of the original six patients, active lesions were seen bilaterally and concurrently. This is in contrast to serpiginous chorioretinitis in which usually only one eye is active at a time. Pigmented chorioretinal atrophy develops within weeks. Throughout the long clinical course, lesions persisted and grew. There was also the appearance of new lesions for 5–24 months despite therapy, and involved eyes developed 50 or more lesions. Some patients showed recurrences months to years after onset. These can occur after significant periods of inactivity.

Permanent vision loss is usually mild. However, central vision was affected in all untreated cases. Vision dropped as much as 6 lines in the acute stage in Jones et al.'s study.<sup>256</sup> Some patients showed improvement in vision. Patients who received prolonged systemic steroids seemed to have decreased activity and improved visual outcome. Only two out of six patients had a final vision worse than 20/40 in the original series. Jyotirmay and colleagues report a favorable visual outcome in over 96% of their patients.<sup>260</sup>

## **Imaging**

### **Fluorescein Angiography.**

Similar to APMPE and SC, fluorescein studies reveal early hypofluorescence due to either blockage or choriocapillaris

nonperfusion. Later phases show staining.

### **Indocyanine Green Angiography.**

ICGA shows hypofluorescence in the areas corresponding to the clinical lesions. This persists into the late phases. Again this shows similarity to APMPE and SC.

### **Optical Coherence Tomography.**

There have been only limited reports. During the active stage of the disease with foveal lesions, the OCT showed subfoveal fluid.<sup>262</sup> In addition, a pigment epithelial detachment with hyperreflectivity of the inner and outer retinal layers was present. Another report described three zones of inflammation via SD-OCT in a patient.<sup>263</sup> Central to the lesion, a dome-shaped elevation involving the IS/OS junction with loss of the IS/OS band and thinning of the RPE associated with SRF was seen. Just peripheral to this, the IS/OS band was thickened and also associated with SRF. The outermost region showed a normal IS/OS band and mildly hyperreflective outer retinal layers. These were three concentric zones (Zone 1–3) that also corresponded to autofluorescence findings.<sup>263</sup> Choroidal thickness has also been reported in a study of three patients. They found that the choroid thickness was no different than the unaffected eye in the quiescent stage.<sup>264</sup> The authors felt that this was a distinguishing feature of RPC and different from other placoid diseases such as SC.<sup>264</sup> Further study is warranted.

### **Fundus Autofluorescence.**

FAF of RPC showed marked hypoautofluorescence in areas of widespread chorioretinal atrophy.<sup>265</sup> In another patient, a “cockade pattern” FAF was described.<sup>263</sup> Central in the lesion (Zone 1) there was dark hypoautofluorescence surrounded by a “white circle” of relative hyperautofluorescence (Zone 2), and the outermost concentric circle was hypoautofluorescent as well (Zone 3), but less so than in Zone 1. The authors correlate this directly to OCT findings as described above.<sup>263</sup>

### **Electrophysiology**

A decrease in the electrooculogram and electroretinogram results (scotopic, photopic, and flicker) has been reported.<sup>256</sup> Other reports do not show this finding.<sup>262</sup>

## Systemic Associations

In Jones and colleagues' case series, one patient had Hashimoto thyroiditis and aseptic meningitis. Two other patients presented with nonspecific upper respiratory tract infections.<sup>256</sup> Jyotirmay et al.'s series reported two patients with Hashimoto thyroiditis and one patient with type 1 diabetes mellitus.<sup>260</sup> There has been a recent case report of RPC associated with central nervous system lesions in a 20-year-old male.<sup>266</sup>

## Pathogenesis

The similarity to APMPE and serpiginous choroiditis suggests that there is some common pathophysiology. The reports of concurrent RPC in patients with thyroiditis may indicate inflammatory or immune processes.

Choroidal ischemia, either primary or secondary due to an inflammatory etiology, is a consideration, as it is in APMPE and SC. The presence of RPC in a patient with CNS lesions may indicate a small-vessel vasculitis.<sup>266</sup>

## Differential Diagnosis

APMPPE and serpiginous choroiditis are the main considerations (Table 79.1). Time course as well as the number and location of the lesions distinguish these diseases. There may be some resemblance to other white spot diseases including multifocal choroiditis and birdshot chorioretinopathy. Other processes such as Harada disease, neoplastic infiltration of the choroid, infections such as syphilis, and granulomatous diseases such as tuberculosis and sarcoidosis can also be considered.<sup>256</sup>

---

### TABLE 79.1

#### Comparison of APMPE, Serpiginous Choroiditis, and Relentless Placoid Chorioretinitis

---

	APMPPE	Serpiginous Choroiditis	Relentless Placoid Chorioretinitis
AGE	Young	Young to middle-aged	Young to middle-aged
COURSE	Lesions heal over weeks	Lesions heal over weeks to months	Continued activity, growth of lesions, new lesions
VISUAL OUTCOME	Good	Poor if fovea involved	Poor if fovea involved
OCULAR INVOLVEMENT	Usually posterior pole	Posterior pole, usually peripapillary	Posterior pole and anterior to equator
SYSTEMIC INVOLVEMENT	Headaches, CNS signs	None	None
RECURRENCES	Usually uniphasic	Recurrences contiguous with old lesions	Noncontiguous recurrences
TREATMENT	Often does well without treatment	Immunosuppression	Immunosuppression

CNS, central nervous system.

## Management/Treatment

The best regimen is as yet unknown. Jones et al. described decreased activity and improved vision in patients who were treated with prolonged steroids versus patients who were untreated or treated less aggressively.<sup>256</sup> Antiviral therapy was not effective. Immunosuppression with cyclosporine was also described, but recurrence was noted when it was tapered. Mycophenolate mofetil with prednisone was used in one patient who also had CNS lesions.<sup>267</sup> Jyotirmay and colleagues used steroids (including sub-Tenon) in combinations with azathioprine or cyclophosphamide.

## Summary

Relentless placoid chorioretinitis is a disease of unknown etiology that resembles APMPPE and serpiginous choroiditis. It has a prolonged and relapsing course. Many creamy lesions appear in the periphery, midperiphery, and macula. They grow in size and eventually heal leaving pigmented chorioretinal atrophy. Commonly active lesions are found bilaterally. A hallmark of this disease is the eventual presence of 50 to hundreds of lesions that are seen throughout the fundus. Despite the vast distribution, including foveal involvement, visual prognosis is fairly good. Aggressive prolonged immunosuppressive therapy appears indicated. The RPE and outer retina appeared involved when looking at the OCT and FAF. The choroid may not be as involved in

this disease based on a small cohort of this rare disease.<sup>264</sup>

## Persistent Placoid Maculopathy

Persistent placoid maculopathy (PPM) is a rare disease that superficially resembles macular serpiginous choroiditis but differs in its clinical course and visual prognosis.<sup>268</sup> It was originally described by Golchet and colleagues in 2006. More recently the same group and others have described series of patients using multimodal imaging.<sup>269,270</sup> Atrophy is a common feature of PPM and is a major cause of visual loss.<sup>270</sup> CNV frequently occurs.

### Clinical Course

#### Clinical Symptoms.

Patients present with gradual, painless, decreased vision, more commonly in one eye. Photopsias and decline in color vision can be seen.<sup>268</sup>

#### Epidemiology.

In the original description there were six patients. Five were men; the range of ages was 50–68. There were no consistent systemic medical problems.<sup>268</sup>

#### Fundus Findings.

Patients almost always have bilateral almost symmetric whitish plaque-like lesions at the level of the outer retina and RPE (Fig. 79.30). These lesions are centered in the fovea and not contiguous with the optic disc. There is a jigsaw pattern to margins of the lesions. During the course of the disease there is very gradual fading of the whitish lesions in all patients.<sup>268</sup> This can take months to years. This is a distinguishing feature from APMPPE.<sup>270</sup> In addition to the central lesions, satellite lesions have also been shown to occur.<sup>270</sup> RPE mottling and pigment clumping without CNV can develop. CNV can be seen leading to an increase in pigmentation, atrophy, or scarring.

**FIG. 79.30** Fundus photos of the right (A) and left (B) eye of a patient with persistent placoid maculopathy. Bilateral whitish plaques are seen. They are centered on the fovea. The left eye also shows a macular hemorrhage consistent with choroidal neovascularization.

### Other Ocular Findings.

Patients do not have cells in the anterior chamber, but vitreous cells have been described.<sup>270</sup>

### Clinical Course and Prognosis.

This macular disorder superficially resembles macular serpiginous. Vision is often minimally affected until the development of CNV or atrophy.

## Imaging

### Fluorescein Angiography.

In acute lesions, FA shows early hypofluorescence with hyperfluorescence ranging from filling to mild punctate hyperfluorescence in the late phase. No leakage or staining is seen, unless CNV is present (Figs. 79.31 and 79.32). Optic nerve hyperfluorescence was seen in one patient.<sup>269</sup> In healed lesions, FA is normal unless atrophy or scarring develops. However, some cases do have persistent hypofluorescence.<sup>270</sup>

**FIG. 79.31** Early fluorescein angiography (FA) of the right (A) and left (B) eye show hypofluorescence corresponding to the clinically seen macular lesions.

**FIG. 79.32** Late fluorescein angiography (FA) of the right (A) and left (B) eye shows that there may be some slight hyperfluorescence corresponding to the lesion. There are some focal areas of hyperfluorescence that corresponds to choroidal neovascularization.

### Indocyanine Green Angiography.

ICGA reveals persistent hypofluorescence throughout the angiogram (Fig. 79.33).<sup>270</sup> The large choroidal vessels in the affected areas are seen. In one case, the hypofluorescence showed partial resolution on follow-up.<sup>268</sup>

**FIG. 79.33** (A) Indocyanine green angiography (ICGA) shows classic central hypofluorescence with other scattered foci in the posterior pole. (B) Optical coherence tomography (OCT) shows opacification of the outer nuclear layer and some foveal thinning with a small amount of subretinal fluid and irregular retinal pigment epithelium.

### Optical Coherence Tomography.

Gendy et al. described the multimodal imaging of five patients.<sup>270</sup> The group found hyperreflectivity of the outer nuclear layer (ONL) and disruption of the ELM and the ellipsoid zone in all cases. In some cases there was a hyporeflective sliver at the level of the outer segments. In some cases there was a homogeneous solid isoreflective pattern of the choroidal capillaries underneath areas of

significantly disrupted RPE. In healed lesions a complete restoration of the outer retinal architecture could be seen if progression to atrophy did not occur.

### **Fundus Autofluorescence.**

Hypofluorescence correlating to RPE damage would be expected and has been seen in one case.<sup>271</sup> This was noted in a patient with concurrent CNV. In Gendy et al.'s series, hyperautofluorescence, hypoautofluorescence, and no changes were seen in acute lesions. Healed lesions showed mixed hyper- and hypoautofluorescence in atrophic lesions.<sup>270</sup> FAF can also reveal far peripheral lesions.<sup>269</sup>

### **Electrophysiology**

One patient had a normal electroretinogram.<sup>268</sup>

### **Systemic Associations**

No clear systemic associations are known. Hypertension was common.<sup>268,269</sup>

### **Pathogenesis**

There is similar speculation about pathophysiology as with other placoid white spot entities. Choroidal hypoperfusion,<sup>272</sup> blockage by swollen RPE cells, and inflammatory lesions in the outer retina, or a combination of these, have been suggested to explain the hypofluorescence on ICGA.<sup>272</sup> However, extensive choroidal hypoperfusion would not be expected in patients who maintain good vision. Nika and colleagues suggest that choroidal infiltrates are the primary pathology with secondary RPE and outer retinal changes based on multimodal imaging of a series of three patients treated with immunosuppression.<sup>269</sup>

### **Differential Diagnosis**

In addition to macular serpiginous choroiditis, other considerations include APMPE, relentless placoid chorioretinitis, and syphilitic posterior placoid chorioretinitis.<sup>268</sup> The time course visual outcome, symmetric white lesions, and common association with CNV distinguishes it from the other white spot entities. The fluorescein

angiogram in syphilis shows late staining unlike PPM, as well as clinical signs of inflammation due to the infectious etiology (see [Chapter 87](#), Spirochetal infections).

## Management/Treatment

Oral or periocular corticosteroids have been used with subsequent improvement in vision. More recent case series suggest significant improvement in at least one eye with high-dose steroids.<sup>269</sup> The role of steroids requires further investigation. Anti-VEGF agents have been used to treat CNV, with good results in a few reports.<sup>273–275</sup>

## Summary

Persistent placoid maculopathy is a unique placoid white spot entity. Bilateral almost symmetric white lesions centered in the macula and not contiguous with the optic nerve are seen. These fade over months to years. They may be associated with pigmentary changes and atrophy. Visual outcome is related to the development of CNV or atrophy, which are very common.

## Multifocal Choroiditis/Punctate Inner Choroidopathy

Idiopathic multifocal choroiditis (MFC) (including punctate inner choroidopathy [PIC]) is a condition characterized by inflammation at the level of the RPE and outer retina. Jampol and colleagues<sup>276,277</sup> have classified MFC and PIC as the same disease as their ophthalmoscopic appearance and clinical courses are similar. Multimodal imaging has further solidified this idea.<sup>277–279</sup>

Furthermore, MFC and PIC share haplotypic associations with IL10 and TNF loci.<sup>280</sup> For historic purposes, a brief introduction to each of the conditions is in order. MFC does not appear to be a pure choroiditis. Chorioretinal scars are left by the inflammation. The etiology and pathogenesis of MFC/PIC is unclear

## Multifocal Choroiditis

MFC was first described by Nozik and Dorsch in two young

patients in 1973.<sup>281</sup> They reported a chorioretinopathy that resembled presumed ocular histoplasmosis (POHS) but was associated with a bilateral anterior uveitis (see [Chapter 73](#), Ocular histoplasmosis). Later, Dreyer and Gass<sup>282</sup> coined the term multifocal choroiditis and panuveitis, describing 28 patients with uveitis and lesions at the level of the RPE and choriocapillaris. Deutsch and Tessler<sup>283</sup> reported a series of 28 patients in 1984 with what they termed inflammatory pseudohistoplasmosis. Their series included patients with concurrent systemic diseases such as tuberculosis, sarcoidosis, and syphilis. Morgan and Schatz,<sup>284</sup> 2 years later, described 11 patients with a recurrent idiopathic multifocal choroiditis. The term multifocal choroiditis should be further characterized as it is the subject of confusion. MFC can be secondary to other disease: either infectious bacterial (including TB, syphilis, fungal/POHS), viral, or noninfectious (sarcoid).<sup>278</sup> MFC as discussed in this chapter is idiopathic. However, even within the idiopathic category, there is MFC that presents with minimal anterior cell or vitritis and that has a significant cellular reaction – this latter category is sometimes characterized as multifocal choroiditis and panuveitis (MFCPU). MFCPU is commonly seen by our uveitis colleagues. We consider these a spectrum of disease.

## Punctate Inner Choroidopathy

PIC was first described in 1984.<sup>285</sup> Watzke reported 10 myopic women with blurred vision, photopsias, or paracentral scotomas with small yellow–white lesions of the inner choroid and RPE. These lesions were associated with overlying SRF. Acute lesions healed to atrophic scars and developed more pigmentation with time. Choroidal neovascular membranes developed in more than half of these individuals.<sup>286</sup> The lesions of PIC are classically limited to only the posterior pole ([Figs. 79.34](#) and [79.35](#)).

**FIG. 79.34** Fundus photo of the posterior pole showing small round lesions that are characteristic.

**FIG. 79.35** Expansion of scars in the inactive phase is common.

MFC and PIC are considered the same entity by many retina specialists and will be referred to as MFC/PIC or MFC in this chapter.<sup>276,277</sup> In general, PIC is used when the lesions/scars are limited to the posterior pole and MFC when scars are seen in the

periphery as well. However, these distinctions are arbitrary.<sup>277</sup> Some MFC lesions have a significant component of fibrosis that if severe have been called progressive subretinal fibrosis and uveitis syndrome.<sup>287</sup> We consider the fibrosis in the spectrum of the same disease process. MFC can present with photoreceptor loss apart from the focal lesions.<sup>288</sup> We consider this to be MFC with chorioretinal atrophy.<sup>289</sup> If severe, these cases were considered as part of Gass's AZOOR complex, but we now believe these are distinct from AZOOR on multimodal imaging.<sup>288,289</sup>

## **Clinical Course**

### **Clinical Symptoms.**

Patients present with decreased central vision, photopsias, floaters, metamorphopsia, paracentral or temporal scotomas, ocular discomfort, or photophobia. Asymptomatic lesions may be seen. Photopsias often correspond to lesions in the peripapillary area and indicate activity of the disease. Visual acuity can range from 20/20 to light perception. More than half present with vision less than 20/100 in the worse eye.<sup>282,284</sup>

In a survey of 77 people with PIC conducted by Gerstenblith and colleagues,<sup>290</sup> scotomas were the presenting complaint in 91% of patients, followed by blurred vision (86%), photopsias (73%), floaters (69%), metamorphopsia (65%), and decreased peripheral vision (26%). Most (85%) presented with unilateral symptoms.

### **Epidemiology.**

MFC has been reported predominantly in Caucasian,<sup>291</sup> myopic<sup>290</sup> women between the second and sixth decades of life.<sup>282,284</sup> Most affected patients are in their 30s. In addition, most have never lived in areas that are endemic for histoplasmosis. Mean refraction is  $-4.6$  diopters.<sup>292</sup>

### **Fundus Findings.**

In the acute phase, yellow round or oval lesions, ranging in number from one to scores, are seen in the outer retina and RPE. They range in size from 50 to 1000  $\mu\text{m}$ . They occur in the posterior pole, peripapillary region, and midperiphery. The nasal retina often

shows clustering.<sup>293</sup> When limited to the posterior pole<sup>290</sup> (Fig. 79.34), occasionally there is a linear pattern. The initial lesions are sub-RPE, and a neurosensory detachment may be present. These break out into the overlying retina. With time, these spots usually evolve into atrophic chorioretinal scars. After 2–3 years they become more distinct, pigment, and appear similar to the punched-out lesions of POHS (Fig. 79.35). Some lesions disappear without sequelae. CNV commonly develops. The lesions can also be arranged in linear scars (Schlaegel lines) parallel to the ora in the periphery<sup>294</sup> (Fig. 79.36). Previously, this linear appearance was thought to be pathognomonic for POHS.<sup>295,296</sup> Evanescent white lesions resembling MEWDS may be seen. Active lesions can be associated with SRF. As inflammation resolves, the lesions may disappear or become atrophic with a variable amount of pigment (“punched-out” appearance). They can also enlarge in size. There can be bridging subretinal scars between the disciform or atrophic scars.<sup>297</sup> Cantrill and Folk described five patients who developed sharply angulated subretinal scars as the lesions healed.<sup>298</sup> They noted broad scar formation in the macula as the lesions coalesced that could be related to serous and hemorrhagic macular detachment. During active phases, exudative retinal detachment may overlie areas of activity.

**FIG. 79.36** Linear scars parallel to the ora are seen in the periphery. (Courtesy of Medical University of Innsbruck, Austria.)

In recurrent episodes, new chorioretinal lesions may develop. Optic disc edema can be seen, and atrophy may occur. Optic disc neovascularization can very rarely be seen.<sup>283</sup> The peripapillary region may have a characteristic subretinal fibrosis<sup>299</sup> that has been described as a “napkin ring” configuration (Fig. 79.37). The midperiphery may have lobulated lesions resembling flowers. Retinal vessels may be narrowed. Periphlebitis may develop. Cystoid macular edema occurs in 10–20% of individuals. CNV develops in 25–30% of cases and can be the presenting sign.<sup>282,284,291</sup>

**FIG. 79.37** Fundus photo showing a characteristic subretinal fibrosis (“napkin ring”).

Multimodal imaging has helped characterize other variants of MFC. Jung and colleagues described 13 cases (21 eyes) of idiopathic MFC with discrete chorioretinal lesions associated with either diffuse (13 eyes), multizonal (6 eyes), or zonal (2 eyes) retinal or chorioretinal atrophy.<sup>288</sup> The outer retinal atrophy occurred around the optic nerve, geographic zones in the mid and far periphery, or diffusely. In diffuse disease, multiple pigmented chorioretinal scars were associated with confluent areas of atrophy and fibrous

proliferation. This occurred along the major vessels and in the peripapillary area. This more commonly occurred bilaterally. The atrophy progressed centripetally, but spared the macula until late in the disease. The atrophy correlated to Goldmann visual fields with either significant constriction or a large scotoma involving the blind spot. ERG showed rod and cone depression. Multifocal ERG showed signal preservation of the central macula but peripheral depression (Fig. 79.38). Multizonal disease was characterized by multiple, atrophic, pigmented chorioretinal scars and geographic atrophy that was hypopigmented. The atrophy was found throughout the fundus, including the peripapillary area and macula. In one patient, multizonal disease progressed to diffuse disease over the course of 14 years. Zonal disease occurred bilaterally in one patient. This patient had the typical lesions of MFC, but a visual field scotoma and a focal peripapillary zone of outer retinal atrophy. ICGA and FAF did not show any defect corresponding to the VF defect, but SD-OCT showed an attenuation of photoreceptors. This indicated a photoreceptor dysfunction rather than an RPE or choroidal dysfunction. Of note, no demarcation line of hyperautofluorescence between normal and abnormal retina occurred in any of these cases. This is an important distinguishing factor from AZOOR.<sup>288</sup> Munk and colleagues described a related variant of MFC with retinal or chorioretinal atrophy. They reported the findings of eight patients in whom MFC/PIC was associated with acute photoreceptor loss or dysfunction out of proportion to the clinically visible lesions.<sup>289</sup> In these patients, OCT showed the typical MFC lesions associated with large zones of attenuation of the external limiting membrane, ellipsoid zone, and interdigitation zones. These areas were hyperautofluorescent on FAF and corresponded to VF loss on formal testing. Full-field ERG often showed depression of both the rods and cones. Some anatomic recovery is possible, but the interdigitation zone remained affected.<sup>289</sup>

**FIG. 79.38** Color fundus photo of multifocal choroiditis with chorioretinal atrophy.

### **Other Ocular Findings.**

MFC/PIC may have no uveitis or a mild to moderate anterior uveitis. Nongranulomatous keratic precipitates and posterior synechiae can be present. Iris abnormalities, such as neovascularization or abnormal avascular areas on fluorescein angiography, have been reported.<sup>300</sup> Vitritis, if present, is usually mild or moderate. Findings may be asymmetric.

### **Clinical Course and Prognosis.**

MFC waxes and wanes, but vision loss can occur. Most patients have recurrent episodes that can involve the central or peripheral vision. These can resolve spontaneously or with the aid of immunosuppressants. Some patients retain excellent vision but have persistent photopsias. About 25% of patients have a more chronic course that involves more inflammation, or CNV. Recurrent inflammation may cause CME, vitreous haze, subretinal scarring, and swelling around old scars (Fig. 79.39). New lesions that are not

contiguous with old scars can develop. CNV is the most common cause of visual loss in MFC and can be seen with either inactive macular scars or recurrent inflammation. The long-term visual prognosis of MFC is variable. Brown and colleagues<sup>293</sup> followed 41 patients (68 eyes) for a mean of 39 months. They found that 66% of eyes ended up with 20/40 vision or better. Only 21% of eyes ended up 20/200 or worse. The majority of the cases with poor vision were due to CNV and less commonly CME. Foveal atrophy and uveitic neovascular glaucoma were other causes in their series. About one-third of patients developed CNV. Thorne and colleagues<sup>301</sup> studied 66 patients (122 eyes) and found that 55% of patients presented with vision worse than 20/50 and 38% presented with vision worse than 20/200. CNV was found in 22% of patients at presentation and was the most common cause of vision loss. Presence of epiretinal membrane and CME were other causes of vision loss. Use of immunosuppressive therapy was associated with an 83% reduction in the risk of posterior pole complications, including new or recurrent CNV. Brown and colleagues followed patients with lesions limited to the posterior pole for a mean length of 51 months.<sup>293</sup> They found that 77% of eyes had a final vision of 20/40 or better. Twenty-three percent had a vision of 20/50 or worse. Twenty percent had a vision of 20/200 or worse. The primary cause of this poor vision was CNV. Essex and colleagues<sup>292</sup> reported the clinical features and outcome of 136 patients (271 eyes) with lesions limited to the posterior pole (PIC) with a mean follow-up of 6.2 years. They found 63 fellow eyes that were normal at presentation. Of these, 56 (88%) remained unchanged. Only 3 (5%) developed lesions, and 4 (6%) developed CNV. In eyes with lesions, 49 of 74 eyes (66%) remained unchanged. New lesions developed in 9 eyes (12%), and CNV developed in 16 (22%). Generally, the prognosis for MFC limited to the posterior pole is very good.<sup>302</sup>

**FIG. 79.39** Fundus photos of the right (A) and left (B) eyes. The right eye shows subtle acute lesions (*arrow*). The left eye shows chronic disease. Bridging fibrosis is seen between scars (*thin arrow*).

## Imaging

### Fluorescein Angiography.

In the acute phase, the clinical lesions appear hypofluorescent on FA. Late in the angiogram, the lesions stain<sup>284</sup> (Figs. 79.40 and 79.41). CNV may be present in the peripapillary or macular areas. In the healed phase, the lesions become atrophic and show a window defect on angiography. A recent study of CNV in MFC revealed that most CNV is classic and clearly demonstrated unless blocked by subretinal blood.<sup>303</sup> The researchers looked at OCT (both stratus and spectralis) and found that CNV could be missed with this mode of imaging. They recommended FA be used in cases with suspected neovascularization. PIC lesions can appear hyperfluorescent in the arterial phase or may appear as blocked fluorescence (Fig. 79.42A). In later phases, the lesions stain<sup>285</sup> (Fig. 79.42B). More lesions are seen on FA than are clinically visible. Tiny punctuate hyperfluorescent lesions may be seen scattered in the posterior pole. In later stages of disease, as the RPE atrophies, window defects are seen. Leakage of fluorescein into the subretinal space is also possible.

**FIG. 79.40** Early fluorescein angiography (FA) of the right (A) and left (B) eye of a patient with new onset of symptoms in the right eye. The left eye has had poor vision for some time.

**FIG. 79.41** Late fluorescein angiography (FA) of the right (A) and left (B) eye shows an acute hyperfluorescent lesion in the right (*arrow*). The left eye shows staining of the scars.

**FIG. 79.42** (A,B) Fluorescein angiography shows increasing fluorescence (staining), and some slight leakage of lesions is seen.

Olsen and colleagues described CNV in six patients with PIC.<sup>304</sup> They found that a fibrotic response followed the development of CNV and there was often a dumbbell-shaped pattern of subretinal fibrosis.

### **Indocyanine Green Angiography.**

ICGA shows hypofluorescent round spots that may be far more numerous than seen on clinical examination and fluorescein angiography<sup>305-308</sup> (Fig. 79.43). The MFC/PIC lesions hypofluoresce in the early, middle, and late phases of ICGA<sup>309,310</sup> (Fig. 79.44). Tiffin and colleagues described choroidal vascular abnormalities.<sup>310</sup> In addition to the hypofluorescent lesions that, in some cases, corresponded to clinically seen lesions, larger choroidal vessels were seen crossing these areas. Several choroidal vessels also showed hyperfluorescence of the vessel wall. They postulated focal choroidal ischemia in the areas of hypofluorescence and possibly a vasculitis in the area of hyperfluorescence of the vessel walls.

**FIG. 79.43** Indocyanine green angiography (ICGA) shows numerous hypofluorescent round spots.

**FIG. 79.44** Indocyanine green angiography (ICGA) shows numerous hypofluorescent spots.

### **Optical Coherence Tomography.**

Characterization of the OCT findings of MFC/PIC have been the subject of many major papers.<sup>279,311-313</sup> Spaide and colleagues

describe the acute MFC/PIC lesions as nodular collections below the RPE that begin to rupture allowing the inflammatory material to enter the subretinal space and outer retina<sup>279</sup> (Fig. 79.45). Vance and colleagues describe SD-OCT imaging of acute lesions that showed drusen-like material between the RPE and Bruch's membrane, as well as a localized choroidal hyperreflectivity below the material.<sup>314</sup> These lesions disappear with treatment. Zhang and colleagues described a five-stage evolution of the lesions from choroidal infiltration, development of sub-RPE nodules, chorioretinal nodules, regression, and retinal herniation.<sup>312</sup> Focal choroidal excavation has been noted by us and other authors as well.<sup>315</sup> As discussed earlier, the MFC/PIC lesions can be associated with widespread loss of outer retinal elements beyond the nodular area.<sup>279,288,289</sup>

**FIG. 79.45** Optical coherence tomography (OCT) of the right eye shows a hyperreflective lesion in the outer retina corresponding to an acute lesion.

CNV is also seen on OCT and can usually be distinguished from the MFC/PIC lesions by the heterogenous nature of the signal, association with IRF/SRF, and larger size of the lesion in comparison to the more homogenous, smaller characteristic of a MFC/PIC lesion.<sup>316</sup> OCT angiography will likely be very useful in identifying CNV when it is uncertain with other testing.

## Fundus Autofluorescence.

Hyperautofluorescence was observed in the areas of fresh lesions. This resolved when immunosuppression was instituted. In the majority of patients, punctate hypoautofluorescent spots were seen on FAF corresponding to areas of chorioretinal atrophy (inactive lesions)<sup>317</sup> (Fig. 79.46). Larger plaques of hypoautofluorescence are seen when there is significant atrophy as seen in diffuse and multizonal disease.<sup>288</sup> Hyperautofluorescence is seen early in areas of photoreceptor involvement in patients with acute photoreceptor loss or dysfunction out of proportion to clinically visible lesions.<sup>289</sup>

**FIG. 79.46** (A,B) Fundus autofluorescence corresponding to inactive lesions that have developed chorioretinal scars.

## Electrophysiology

Dreyer and Gass<sup>282</sup> reported ERGs on 29 eyes of 16 patients. They observed normal or borderline results in 41% of patients, moderately reduced results in 17%, and severely reduced results in 21% of eyes. Oh and colleagues used multifocal ERG (mfERG) to study pre- and posttreatment results; however, due to the sensitivity of this test, it becomes almost extinguished with active MFC.<sup>318</sup> Furthermore, full-field ERG shows cone and rod depression in MFC with retinal and choroidal atrophy as well as when it is

associated with photoreceptor loss.<sup>288,289</sup> Electrophysiologic tests are not used commonly in the management of MFC.

## Visual Field Testing

Blind spot enlargement as a manifestation of multifocal choroiditis was described in 1991.<sup>319</sup> Enlarged blind spot in the setting of a normal optic nerve has been seen and called acute idiopathic blind spot enlargement (AIBSE). The enlargement is thought to be due to peripapillary retinal dysfunction rather than an optic nerve problem.<sup>320</sup> It can be seen in MFC and MEWDS. This is supported by the fact that color vision and pupillary responses have been reported to be normal in these patients. The enlarged blind spot can resolve with inactivity of disease. Visual field testing may also demonstrate scotomas related to areas of photoreceptor loss, chorioretinal scarring, or serous detachments related to active lesions. Visual fields are an important way to monitor MFC.

## Systemic Associations

An association between MFC and Epstein–Barr virus (EBV) has been suggested but never proven.<sup>321</sup> It was postulated that EBV triggers an immune response that starts a persistent intraocular inflammatory response. Immunoglobulin M antibodies directed against the viral capsid antigen or the Epstein–Barr early antigen were present in patients with MFC in one series with none in controls.<sup>321,322</sup> However, this could not be reproduced.<sup>323</sup> Some patients with MFC may also have or develop sarcoidosis. These individuals are often not distinguishable from those who have idiopathic MFC.

## Pathogenesis

The cause of MFC/PIC is not understood. It typically affects young, otherwise healthy myopic women. There are yellow lesions seen at the level of the outer retina as seen by OCT and beginning under the RPE. The lesions of MFC/PIC eventually atrophy and look similar to the punched-out lesions of POHS. CNV can develop, leading to bridging scars and subretinal fibrosis. Patients can also develop blind spots and scotomas that can improve with or without

treatment. Lesions resembling MFC have been reported to occur in patients with other white spot syndromes such as APMPE and MEWDS.<sup>324,325</sup> Jampol and Becker proposed a common genetic hypothesis for autoimmune involvement in these inflammatory processes.<sup>2</sup> The interplay of genetics, immune dysregulation, and environmental triggers may play a role in the different presentations of these clinical entities. Atan and colleagues<sup>280</sup> studied MFC and PIC and found similarities in the association with a IL-10 haplotype, and negative associations with a TNF haplotype. These genetic loci are known to be associated with noninfectious uveitis and autoimmunity. They state that definitive proof will necessitate genomewide sequence analysis. However, their data support the idea that genetic factors have a strong effect on clinical phenotype.

## Differential Diagnosis

The differential diagnosis for MFC/PIC includes presumed ocular histoplasmosis syndrome, sarcoidosis, Vogt–Koyanagi–Harada syndrome, sympathetic ophthalmia, myopic degeneration maculopathy, and other white spot syndromes such as serpiginous choroiditis and birdshot chorioretinopathy.

Infectious etiologies for multifocal choroiditis may be considered given the patient's history and health status. These include viral (herpes simplex, herpes zoster, Epstein–Barr, cytomegalovirus, Coxsackie), bacterial (syphilis, tuberculosis, *Borrelia burgdorferi*, septic choroiditis, metastatic endophthalmitis), fungal (histoplasmosis, *Cryptococcus*, coccidioidomycosis, *Candida*), protozoal (toxoplasmosis, *Pneumocystis carinii*), and worms (diffuse unilateral subacute neuroretinitis). Noninfectious etiologies include sarcoidosis, and neoplasias such as intraocular lymphoma can be considered as well.

## Differentiation of MFC and POHS

Both entities may show punched-out chorioretinal scars, peripapillary scarring, and CNV. Classically, the teaching is that the difference between these two entities is the presence of inflammation with MFC and absence with POHS. However, MFC can be present without signs of inflammation. Parnell and

colleagues<sup>297</sup> differentiated MFC from POHS based on clinical features, morphology of photographed fundus lesions, and fluorescein angiography. Clinically, MFC patients may develop photopsias and visual field defects. Clinically, distinctive features of MFC include multiple small white lesions clustered in the macula, nasal retina, or equator, a mixture of acute and inactive lesions, progressive growth of lesions, and subretinal fibrous metaplasia with bridging tissue between scars. Other changes include hyperplastic changes around the nerve (“napkin ring”), myopic-appearing nerve, sheathing of vessels or narrowed vessels, and inflammation seen as CME, vitritis, or disc edema (see [Chapter 73](#), Ocular histoplasmosis.)

## **Management/Treatment**

Treatment is aimed at inflammation and its sequelae (CME and CNV). Multifocal choroiditis may be associated with significant anterior and posterior inflammation. This can be managed with topical, periocular, intraocular, or systemic corticosteroids. Steroid-sparing agents are used when steroids are not tolerated or recurrence is frequent. Even if there is no significant visible inflammation, the MFC/PIC lesions do respond to immunosuppressive drugs. Immunosuppression should certainly be considered if there is progressive development of lesions and photoreceptor involvement.<sup>289</sup> CNV can be managed with anti-VEGF therapy with or without the use of corticosteroids. Anti-VEGF has become the standard management strategy. Amer and Lois<sup>286</sup> in their extensive review of literature on PIC suggest that PDT may best achieve closure of already formed neovascularization, while immunosuppressive agents may be most effective in the early stages of development of CNV. Anti-VEGF therapy has been found to be effective in several studies of CNV caused by MFC<sup>326–329</sup>/PIC.<sup>330–332</sup> An additional complication in these patients due to the demographics (young females) is concomitant pregnancy. Steroid therapy is possible during pregnancy; other agents may affect fertility, and teratogenicity is a risk.

## **Summary**

Multifocal choroiditis/punctate inner choroidopathy is an entity

that presents predominantly in young, healthy, myopic women. It may present unilaterally or bilaterally with lesions that are small and multifocal. With new imaging techniques, the outer retina and RPE seem to be the area of involvement. It has varied outcomes; visual prognosis is generally dependent on the status of the macula and development of CNV or fibrosis. Treatments are aimed at reversing these processes.

## Multiple Evanescent White Dot Syndrome

Multiple evanescent white dot syndrome (MEWDS), originally presented at ARVO in 1983 and in print in 1984,<sup>333</sup> is an acute, multifocal, usually unilateral retinopathy affecting young adults. Multiple white dots are seen at the level of the outer retina.

### Clinical Course

#### Clinical Symptoms.

Patients usually have an acute onset of blurred vision in one eye. They also may complain of a blind spot or “spots” in their periphery correlating to a temporal scotoma. Photopsias (especially temporally) are common. Patients also may relate flu-like symptoms.<sup>333</sup>

#### Epidemiology.

No particular racial or regional predisposition for MEWDS has been reported. There is a strong female predominance (75%). Initial visual acuity ranges from 20/20 to 20/300 and, after an average duration of approximately 6 weeks, almost always returns to normal levels. Patients are young, and cases of MEWDS have been reported in children as young as 10 years old and in patients as old as 67 years old.<sup>334,335</sup> Most patients, however, cluster near the mean age of 27 years. A high prevalence of myopes has been reported.<sup>336,337</sup>

#### Fundus Findings.

Numerous small (100–200  $\mu\text{m}$ ) white dots are seen ophthalmoscopically (Fig. 79.47). The white dots are mostly concentrated in the paramacular area, usually sparing the fovea itself, and are less prominent and numerous beyond the vascular arcades.<sup>333</sup> These small “dots” in the retina are distinguished from larger “spots” seen on multimodal imaging (ICGA, FAF), which appear deeper. The dots appear in late ICGA as small hypofluorescent lesions overlying larger hypofluorescent ones (spots).<sup>338</sup> This is discussed further below. Vitreal cells, retinal venous sheathing, and blurring of the disc margins are often present. The classic macular appearance is a granularity (Fig. 79.48). In atypical cases this may be the primary feature present.<sup>339</sup> The white dots disappear completely after a number of weeks or months. They may be replaced by mild pigment mottling, or rarely chorioretinal scarring resembling multifocal choroiditis. An appearance of transient brown areas has also been described after the white spots resolve. These resemble the lesions of AMN but are more numerous and widespread.<sup>340</sup> In the largest case series recently published, 27 of 32 patients also had optic nerve edema.<sup>337</sup> Rarely, a progressive geographic circumpapillary discoloration, appearing as a large white lesion, can be a presenting sign,<sup>341</sup> and peripapillary scarring may be seen after the acute lesions have healed.<sup>342</sup>

**FIG. 79.47** Fundus photo showing subtle numerous white spots. There are also blurred disc margins and foveal granularity.

**FIG. 79.48** Fundus photo showing granularity of the fovea. This may be the only presenting feature.

Rare instances of late CNV have also been noted with MEWDS.<sup>343,344</sup> Some “idiopathic” cases of CNV could represent MEWDS with resolution of other ocular changes before presentation.<sup>345,346</sup>

### **Other Ocular Findings.**

Mild iritis may be present. Vitritis may be variable.

### **Clinical Course and Prognosis.**

MEWDS is usually a self-limited disease, and recovery of visual function occurs over several weeks (3–10 weeks) with a concurrent dramatic improvement of the electroretinogram (ERG) and early receptor potential (ERP) amplitudes.<sup>333,347</sup> Cases of recurrent MEWDS occur, but determinants predisposing toward recurrence have not been identified.<sup>348</sup> Although usually unilateral, bilateral MEWDS has been reported. Bilateral involvement can be either simultaneous or sequential (seen as recurrence of MEWDS in the opposite eye). Bilateral cases may show asymmetric involvement,

with only one symptomatic eye, or simultaneous symptoms.<sup>337,349</sup> There is a chronic form of MEWDS with evidence of multiple recurrences over many years and involving both eyes.<sup>350</sup> Vision returns to baseline between recurrences in most patients. Some patients complain of visual field disturbances or photopsias even after vision has normalized. Fine and colleagues describe three cases of apparent MEWDS going on to develop a more permanent widespread photoreceptor loss resembling AZOOR.<sup>351</sup> If this occurs, it is extremely rare.

Multimodal imaging of a large series of patients has characterized MEWDS further.<sup>337</sup> OCT has shown that the inflammatory lesions of MEWDS are at the level of the outer retina. (see below). The change in the photoreceptor architecture noted acutely returns to normal.<sup>352,353</sup> The integrity of foveal cones specifically has been studied with OCT and foveal reflection analyzer, and also shows recovery.<sup>354</sup> The foveal granularity is associated with disruption of the IS–OS junction in the fovea with outer retinal swelling. A variety of foveal lesions on OCT have been described.<sup>337</sup> This recovers partially. Although clinical lesions are usually present in one eye, photoreceptor dysfunction has been found to be bilateral in some cases.<sup>353,355</sup> More recent emerging technology, adaptive optics, has been used to show photoreceptor disruption at the cellular level in the acute phase of MEWDS as well.<sup>356</sup> Photoreceptor recovery supports the good prognosis associated with MEWDS. CNV is very rare, but if present can affect visual prognosis.

## Imaging

### Fluorescein Angiography.

FA findings include early and late hyperfluorescence of the white dots often in a wreath-like pattern; diffuse, but patchy, late staining at the level of the RPE and retina; and disc capillary leakage. The wreath-like hyperfluorescence corresponds to the dots seen clinically, as well as lesions seen on ICGA and FAF.<sup>337</sup> A diffuse noncystoid leakage may be seen in the macula (Figs. 79.49 and 79.50). After resolution of the acute lesions, window defects may be noted in the macula corresponding to the clinical granularity seen

and, less often, elsewhere. Chorioretinal scars with blockage and window defects may occasionally be seen. Of note, in the subacute phase FAF and angiography can still show the lesions after they clinically have resolved.<sup>340</sup> Focal areas of vascular staining are sometimes noted.

**FIG. 79.49** Fluorescein angiography (FA) of the right eye (A) early and (B) late. There is subtle early and late hyperfluorescence of the white dots in a wreath-like pattern. There is late staining of the optic nerve.

**FIG. 79.50** Left eye fluorescein angiography (FA)

close-up of wreath-like pattern (*arrow*); a diffuse, noncystoid leakage is seen in the outer retina in the macula.

### Indocyanine Green Angiography.

ICGA in patients with MEWDS shows no abnormalities of large choroidal vessels in the early phase, but hypofluorescent lesions are evident in the late phase, corresponding to the white dots<sup>357</sup> (Fig. 79.51). There can be “spots” that are larger, deeper, and can be confluent appearing as a large plaque of deep retinal hypofluorescence. These hypofluorescent dots and spots are more numerous than those clinically seen. The hypofluorescence in the late phase suggests but does not prove that MEWDS may affect the choriocapillaris, as well as its well-known effect on the photoreceptors.<sup>358,359</sup> These lesions gradually disappear upon recovery,<sup>359,360</sup> but abnormalities on ICGA have been reported to be present up to 9 months after the initial presentation, even after clinical symptoms have resolved.<sup>361,362</sup> Since ICGA reveals lesions not seen clinically or by FA,<sup>363</sup> it has been recommended with some enthusiasm in the patients with MEWDS, mainly to help establish a diagnosis.<sup>364</sup> The blind spot enlargement of MEWDS corresponds to multiple peripapillary lesions, sometimes only detected with ICGA.

**FIG. 79.51** Indocyanine green angiography (ICGA) showing numerous hypofluorescent spots including confluent lesions around the disc.

Laser speckle flowgraphy (LSFG) was recently used to describe the changes to the choroidal circulation in patient with MEWDS.<sup>365</sup> They found that the choroidal blood flow (as defined by mean blur rate (MBR)), was decreased in the affected eye as compared to the unaffected eye. Furthermore, it increased in the affected eye by 20.2% at 1 month and 13.3% at 3 months, and this correlated with improving vision. There was no significant change in blood flow in the unaffected eye.<sup>365</sup> It is unclear if these changes are primary or secondary in the pathogenesis of MEWDS. Multimodal imaging analysis, however, strongly suggests that MEWDS is primarily a photoreceptor disease.<sup>337</sup>

### **Optical Coherence Tomography.**

OCT findings were first described using time domain technology. A dome-shaped reflective lesion in the subretinal space was seen corresponding to a clinical white dot. An increased reflectivity in the choroid was seen below this lesion in the acute phase. In the recovery phase, there was a decrease in size of the subretinal material and less reflectivity in the choroid. Ultimately, deep retinal lesions disappeared, but reflectivity was seen in the choroid for several months after active disease.<sup>366</sup> High-resolution OCT revealed disturbance in the ellipsoid zone (EZ also called the IS-OS junction).<sup>367-369</sup> In cases of recurrent MEWDS, a thinning of the outer nuclear layer was seen. RPE disturbance was not a prominent feature.<sup>369</sup> Li and colleagues emphasized that the disruption of the photoreceptor outer segments can be restored anatomically. Functional studies also showed recovery.<sup>353</sup> In addition, although lesions typically occurred unilaterally, the photoreceptor dysfunction is bilateral in most cases.<sup>353</sup> Focal disruption of the EZ<sup>339</sup> is seen even in atypical cases where white dots are not present. In a more recent analysis, these findings have been characterized further. OCT shows multifocal debris in the outer retina and centered on the EZ and also involving the interdigitation zone. In a multimodal analysis, these correspond to the dots seen on fundus photography, FA, and ICGA. Furthermore, confluent spots appear

as a plaque in the outer retina and may be pathognomonic and important in distinguishing MEWDS from other diseases. Protrusions of the hyperreflectant material towards the ONL correspond to the smaller dots seen on fundus photography<sup>337</sup> (Fig. 79.52). Therefore, this study is of particular importance in making the diagnosis of MEWDS (Fig. 79.53). Analysis of the choroid with enhanced-depth imaging suggested a trend towards transient choroidal thickening in the acute phase, and en face imaging showed an unremarkable choroid and choriocapillaris.<sup>337</sup> One published case described a patient with MEWDS who developed acquired focal choroidal excavation suggesting RPE/Bruch's membrane involvement.<sup>370</sup>

**FIG. 79.52** Fundus autofluorescence (FAF) illustrates smaller, more superficial dots (1) on larger, deeper spots (2) characteristic of multiple evanescent white dot syndrome (MEWDS).

**FIG. 79.53** Optical coherence tomography (OCT) shows small projections in the outer retina corresponding to “dots.” Near-infrared reflectance imaging highlights the granular fovea.

### Fundus Autofluorescence.

Dell’Omo and colleagues studied MEWDS in the acute and subacute phases and characterized specific FAF findings. Hypoautofluorescent areas were seen concentrated around the optic disc and posterior pole. Areas of hyperautofluorescence were seen as well, corresponding to the white dots.<sup>371</sup> Furino and colleagues described this as well.<sup>372</sup> In the recovery phase, many of the hypoautofluorescent lesions faded, while others persisted. The areas of hyperautofluorescence became smaller and more consolidated. They also retracted centripetally, becoming smaller with a ring of hypoautofluorescence around them, or became entirely hypoautofluorescent. In other cases, they disappeared altogether without becoming hypoautofluorescent.<sup>371</sup> These hypoautofluorescent spots generally correlate with the lesions seen with FA and ICGA.

Near-infrared autofluorescence (NIR-FAF) is a modality where a wavelength of 787 nm is used instead of the blue light used in traditional FAF. Some suggest that there may be additional value to seeing the white dots as hypoautofluorescent lesions in this modality<sup>373</sup> (Fig. 79.54).

**FIG. 79.54** Optical coherence tomography (OCT) through the fovea shows swelling of the outer retinal layers and granules at the level of the retinal pigment epithelium. (Courtesy of Medical University of Vienna.)

## Electrophysiology

Electrophysiologic studies in patients with acute MEWDS<sup>347</sup> have found reduced ERG a-wave and reduced ERP amplitudes that would suggest a primary involvement of the outer segments of photoreceptors. Focal ERG studies reveal delayed recovery of oscillatory potential (OP), which implies some inner retinal involvement.<sup>374</sup> Studies<sup>375</sup> have used foveal densitometry and color matching to show that, even with normal ERG findings, abnormalities exist during the active stage of MEWDS at the level of the cone photoreceptor outer segments. A transient metabolic disturbance at the level of the pigment epithelium–photoreceptor complex has been suggested. Multifocal electroretinography (mfERG) shows areas of depression that correspond to scotomas while full-field ERG shows a general depression. These abnormalities resolve after 6 weeks.<sup>376</sup> In addition, mfERG shows supernormal amplitudes of the first-order kernel of N1- and P1-wave amplitudes at the beginning of the disease; these values decrease to normal or subnormal values by 2 weeks and may be

helpful in detecting early stages of MEWDS or for follow-up.<sup>377</sup>

## Visual Field Testing

Visual field testing often shows an enlarged blind spot. Testing can range from normal to a generalized depression to cecentral or arcuate scotomas.<sup>378</sup> Visual field abnormalities may persist for an extended period beyond the resolution of clinical lesions.<sup>379</sup> Newer microperimetry testing also shows enlarged blind spots.<sup>380</sup> In addition, microperimetry has shown decreased retinal sensitivity in areas of EZ abnormalities, when correlated with SD-OCT.<sup>381</sup>

## Pathogenesis

We believe that with multimodal imaging we can clearly differentiate MEWDS from other WSS. The cause of MEWDS is unknown.

At the present time we do not have definite evidence for an infectious or immunologic cause for MEWDS. A single patient with chronic relapsing MEWDS was noted to respond to cyclosporine therapy.<sup>382</sup> Laatikainen and Immonen<sup>383</sup> described an increased level of protein in the cerebrospinal fluid in MEWDS patients. The occurrence of MEWDS following varicella infection,<sup>343</sup> vaccination for hepatitis A<sup>384</sup> or hepatitis B,<sup>385</sup> or most recently reported in a young girl after vaccination for human papilloma virus and meningococcus<sup>386</sup> suggests environmental triggers. One case of MEWDS from China with no previous or concurrent illness exhibited increased serum immunoglobulin M (IgM) and IgG values.<sup>387</sup> Recovery of vision in 3 weeks was coincident with the return of the IgM value to normal values. Data from this case suggested that MEWDS might be associated with a viral syndrome, although tests for herpes zoster, herpes simplex, mumps, and measles were inconclusive. Any explanation of the etiology of MEWDS must explain the strong female predominance, the occurrence of occasional chronic relapsing cases, and the excellent visual outcome in almost every case. The HLA locus may be important. A preliminary study found the frequency of HLA-B51 haplotype to be 3.7 times more common in patients with MEWDS than a normal control group.<sup>388,389</sup>

Our present suggestion is that a variety of relatively common

susceptibility genes may be responsible for MEWDS. These predispose to immune dysregulation. Precipitated by environmental triggers, MEWDS may develop. If this theory is true, then patients with MEWDS may demonstrate a family or personal history of autoimmunity. In investigating this, we have found an increased prevalence of autoimmunity in patients with white spot syndromes and their families, but the number of MEWDS cases was very small.<sup>2,4</sup> While the etiology of MEWDS is studied further, we believe that MEWDS is a distinct clinical entity that should not be confused with other WSS.

## **Differential Diagnosis**

The differential diagnosis of MEWDS includes acute posterior multifocal placoid pigment epitheliopathy (APMPPE) and birdshot chorioretinopathy. Other chorioretinopathies such as sarcoidosis and diffuse unilateral subacute neuroretinitis must be considered. In middle-aged or older patients, ocular infiltration by lymphoma must be ruled out.

Patients with MEWDS often present with signs and symptoms suggesting primary optic nerve disease, including disc edema, visual loss, afferent pupillary defect, enlarged blind spot, and other optic nerve field defects. Dodwell et al.<sup>390</sup> reported five cases that were initially misdiagnosed as primary optic nerve disease, as the white spots were subtle findings. Optic nerve involvement in MEWDS could theoretically contribute to the central visual loss, visual field loss, afferent pupillary defect, and even dyschromatopsia. MEWDS should be considered in the differential diagnosis of young, healthy patients who present with unilateral optic nerve dysfunction.<sup>391,392</sup>

The challenge of correctly diagnosing MEWDS lies in its variable, sometimes subtle, presentation and the rapid reversal of the visual loss with disappearance of the white dots. It should be noted that blind spot enlargement may be a feature of MEWDS, MCF/PIC, and perhaps other WSS

## **Management/Treatment**

The natural course of MEWDS is excellent, and no intervention is required. We do not support the use of steroids in MEWDS.

Although CNV is not common in MEWDS, anti-VEGF therapy has been used with success in a few cases.<sup>393,394</sup>

## Summary

MEWDS usually presents in young myopic females who may describe a viral prodrome. Generally, clinically the retinopathy is unilateral. Clinically there are three diagnostic findings: (1) grayish-white dots scattered in the posterior pole; (2) foveal granularity; and (3) optic nerve edema. Foveal granularity is the classic hallmark of this condition and defining feature. Multimodal imaging has shown that this is a photoreceptor disease.<sup>337</sup> The course is almost always good, and no intervention is required.

## Acute Zonal Occult Outer Retinopathy

Acute zonal occult outer retinopathy (AZOOR) has been linked by Gass to the white spot syndromes (AZOOR complex) although it has no white spots. In the early 1990s, Gass<sup>395</sup> described 13 patients with what he called acute zonal occult outer retinopathy. These were, in general, young, healthy patients, who abruptly developed photopsias and the presence of a scotoma in a local area of the retina. Examination initially showed minimal fundus changes; however, a dense scotoma could be plotted in the involved area. With the passage of time, these zones often developed pigment epithelial mottling, bone spicule pigmentation, and some choroidal atrophy (Fig. 79.55). The changes, when widespread, could resemble retinitis pigmentosa.<sup>396</sup>

**FIG. 79.55** Fundus photo of advanced acute zonal occult outer retinopathy. Pigment epithelial atrophy and bone spicule formation can be seen in continuity with the disc.

Gass<sup>5,397</sup> used the term AZOOR complex. Within this description he included MEWDS, AIBSE, AMN, PIC, and MFC. He felt that these diseases were somehow related; they demonstrated outer retinal dysfunction and usually occurred in young, healthy females. With the advent of multimodal imaging analysis, we believe that AZOOR is a distinct entity and can be distinguished from other white spot diseases.<sup>288,289,398</sup> The term AZOOR complex is thus outdated. The disease has recently been reviewed, and a classification based on multimodal imaging has been described by Mrejen and colleagues and is described in this section.<sup>398</sup>

## **Clinical Course**

### **Clinical Symptoms.**

Patients with AZOOR have the abrupt onset of a scotoma related to outer retinal dysfunction. Most have photopsias. They may complain of central visual disturbance and night vision difficulty.<sup>398</sup> There may be recurrences, new scotomas, or an increase in the size of the scotoma. The scotoma is often contiguous with the optic nerve. The disease may be unilateral initially but some progress to bilaterality.

## Epidemiology.

AZOOR is seen in all ethnic groups, although the literature shows a predominance of Caucasians. There is a marked predominance of women. Most patients are young, although occasionally elderly patients are involved. In the United States, a recent review showed a mean age of 47 years (range 17–86). A review of 38 cases in Japan showed a mean age of onset of 33.2 years (range of 15–47 yrs) with a high prevalence (92.3%) of myopia in their population.<sup>399</sup> Some of the patients relate a preceding viral illness. There is no definite association with any systemic diseases. Patients generally present with good vision.<sup>398</sup>

## Fundus Findings.

The fundus initially appears normal; subsequently the area of involvement will show retinal atrophy and mottling. The foveal cones appear to be relatively resistant to AZOOR accounting for good vision in many cases. If the onset of symptoms is recent, an abrupt transition can be seen. A gray–white line may be present at onset between normal and involved retina.<sup>398</sup> It is transient and can disappear within weeks. Gass and Stern described this acute annular occult retinopathy (AAOR) as a variant of AZOOR<sup>400</sup> (Figs. 79.56 and 79.57). We now believe these were cases of AZOOR. The gray–white line fades. An orange zone may develop between normal and abnormal retina.<sup>398</sup> The area of involvement is often peripapillary, but usually the central vision is good even if involvement extends to the fovea. Patients can have “skip” lesions with larger areas of involvement (typically peripapillary) and smaller areas elsewhere.<sup>398</sup> The arterioles attenuate with time (Fig. 79.58). The late appearance may resemble sectoral retinitis pigmentosa. The appearance can also resemble diffuse unilateral subacute neuroretinitis (DUSN). CNV is seen rarely.<sup>398,401</sup>

**FIG. 79.56** Fundus photo of acute annular occult outer retinopathy. A grey–white line (*arrow*) is present between the normal retina to the right and involved retina to the left. (Courtesy of Manjot K. Gill, MD.)

**FIG. 79.57** Optical coherence tomography (OCT) shows retinal thinning in the involved area. (Courtesy of Manjot K. Gill, MD.)

**FIG. 79.58** Fundus photo. Subtle fundus changes are seen. Arteriolar attenuation is present.

### Other Ocular Findings.

The eyes are quiet without evidence of anterior chamber reaction. There may be a few vitreous cells.<sup>398</sup> Disc leakage, retinal vascular staining (periphlebitis), and some CME may rarely be seen.

### Clinical Course and Prognosis.

Patients may show progression, with new areas of retinal involvement. Occasionally there may also be some improvement in visual function in the involved areas. Gass<sup>397</sup> suggested that most cases were active for about 6 months and then stabilized. In a Japanese case series with mean follow-up of 31 months, prognosis was reported to be very good with good visual outcomes and recurrence only in 9 of 38 patients.<sup>399</sup> However, there is little literature on the long-term follow-up of this disease. What we know from the existing literature is that chorioretinal atrophy may lead to severe vision loss, and prognosis is limited based on this.<sup>402</sup> There may exist a spectrum of severity with some showing little fundus change and reversal of abnormalities on imaging<sup>403</sup> to more severe disease that can resemble inherited dystrophies.

### Imaging

## Fluorescein Angiography.

Initially the fluorescein angiogram may be normal. Then window defects and abnormalities at the level of the pigment epithelium become apparent. Retinal arteriolar narrowing in the areas of involvement may be seen. Retinal vessel staining and leakage may be seen (Fig. 79.59).

**FIG. 79.59** (A,B) Fluorescein angiography (FA) shows peripapillary zonal retinal pigment epithelium abnormalities with window-type defects.

## Characteristic “Trizonal” Pattern of Azoor.

### Fundus Autofluorescence.

The AZOOR line, the transition from normal to involved retina, is best seen with FAF. It is hyperautofluorescent initially around the zonal area of involvement. With time, it can become discontinuous or beaded in appearance.<sup>398</sup> In some patients there is a diffusely hyperautofluorescent area that is surrounded by speckled hyperautofluorescence. Later these areas become hypoautofluorescent. The peripapillary area is most involved. The three zones of autofluorescence are (1) normal autofluorescence outside the delineating line; (2) speckled hyperautofluorescence bordering the affected area; and (3) hypoautofluorescence in a region of atrophy<sup>398,404,405</sup> (Fig. 79.60).

**FIG. 79.60** Fundus autofluorescence (FAF) shows the characteristic “trizonal” pattern of autofluorescence. Zone 1 – normal autofluorescence. Zone 2 – speckled hyperautofluorescence. Zone 3 – hypoautofluorescence.

### Optical Coherence Tomography.

Spectral domain OCT corresponds to the changes seen on FAF: (1) outside the AZOOR line, the OCT is normal; (2) inside the line, there is presence of subretinal hyperreflective material and there is an absence or irregularity of the ellipsoid zone; (3) with chronicity, atrophy of the RPE and thinning of the retina may be seen with the outer nuclear layer and then the inner nuclear layer thinning. Disruption may extend to the inner retina as well. Choroidal atrophy occurs ([Fig. 79.61](#)).<sup>398,405-407</sup>

**FIG. 79.61** Optical coherence tomography (OCT) shows absence of the ellipsoid zone line in the area of retinal involvement (*arrow*).

### Indocyanine Green Angiography.

ICGA may be normal or may show hypofluorescence in the area of involvement. This depends on the stage of disease. In chronic AZOOR, (1) ICGA is normal outside the involved area; (2) there is late extrachoroidal leakage inside the AZOOR line; (3) hypofluorescence is noted due to loss of choriocapillaris within the late lesion.<sup>398</sup>

### Visual Field Testing

Scotomas (usually peripheral and temporal) develop often in continuity with the optic disc. These are usually dense. With healing, some improvement may occur, but the functional loss is often permanent (Fig. 79.62).

**FIG. 79.62** Perimetry shows a dense zonal defect.

## Electrophysiology

Focal ERG demonstrates abnormalities in the area of the scotoma. Full-field ERGs are almost always abnormal, if large enough areas of the retina are involved.<sup>397</sup> EOG testing is usually abnormal.

## Adaptive Optics Scanning Laser Ophthalmoscopy

This modality is particularly useful in AZOOR as the photoreceptors are primarily involved. A case of a man presenting with AZOOR showed dark areas on AO-SLO corresponding to disruption of the ellipsoid zone on OCT, indicating decreased cone density. As the patient improved, there was reversal of the dark areas to a normal mosaic appearance.<sup>403</sup> In another series, 3 of 4 patients demonstrated focal cone loss and 1 patient demonstrated abnormal cones, but the rods appeared normal.<sup>408</sup> In another series of 12 eyes, 8 eyes had abnormally hyporeflective areas on near-infrared images that corresponded to an abnormal ellipsoid zone on SD-OCT. Cone mosaics were abnormal in the corresponding areas

on AO-SLO.<sup>409</sup>

## **Systemic Associations**

Systemic autoimmune diseases have been noted in some patients with AZOOR.<sup>396</sup> Like other white spot syndromes, it may be occurring in patients with immune dysfunction.<sup>2,4</sup>

## **Pathogenesis**

Mechanisms causing vision loss with the development of AZOOR remain obscure. Could this be an autoimmune attack on the retina? A possible association with systemic autoimmune disease suggests this.<sup>4</sup> In a recent study, three patients with acute AZOOR were evaluated with molecular biological methods and all were found to have antiretinal antibodies.<sup>410</sup> However, no specific antiretinal antibodies have been identified, and the presence of antibodies may be coincidental or a secondary phenomenon (epiphenomenon) not related to the underlying disease process.

Gass suggested that AZOOR is possibly a viral infection, with the virus entering the eye from the optic disc and thus producing peripapillary lesions.<sup>5</sup> There is no evidence supporting an infectious etiology of AZOOR at this point.

## **Differential Diagnosis**

The visual loss of AZOOR must be distinguished from optic neuropathies. OCT should show ellipsoid zone abnormalities in the involved area. It may initially be difficult to distinguish AZOOR from other entities with outer retinal dysfunction, but the characteristic trizonal pattern of multimodal imaging can distinguish these cases. Patients with hereditary retinal diseases (e.g., retinitis pigmentosa) develop changes that can possibly resemble AZOOR. These changes may be sectoral or asymmetric. Some of the patients with hereditary diseases have been shown to have antiretinal antibodies (the role these play in the pathophysiology of the diseases is unproven). Retinal dystrophies are usually bilateral, symmetric, and slowly progressive, distinguishing them from AZOOR. Patients with cancer-associated retinopathy (CAR) or melanoma-associated retinopathy (MAR)

may show outer or inner retinal dysfunction with autoantibodies against the retina. These cases can resemble AZOOR. A poorly defined group of patients have been felt to have “autoimmune retinopathies” without cancer where antiretinal antibodies or cell-mediated immunity may cause retinal dysfunction.<sup>411</sup> The clinical presentation of AZOOR – local and segmental, often peripapillary, or at least contiguous with the disc – helps in the diagnosis.

## **Management/Treatment**

No proven therapy exists. There is only meager evidence of an effect of systemic corticosteroids and other immunosuppressive drugs.<sup>343,412</sup> Antiviral drugs and antibacterial drugs have also been tried. Recently, Mahajan and Stone<sup>413</sup> reported the response of three patients to valaciclovir. Although these patients did show clinical improvement, they were early on in their course and their clinical appearances were not typical for AZOOR. The value of this drug for AZOOR remains uncertain, and we have not found it helpful in our hands.

## **Summary**

AZOOR is a disease of sectoral or zonal outer retinal dysfunction, often adjacent to the optic nerve. Characteristic features include a demarcating AZOOR line at the level of the outer retina, a trizonal pattern of sequential involvement of the outer retina, RPE and choroid (seen on FAF, OCT, and ICGA), and zonal progression. Although the fundus initially appears normal, the development of pigmentary changes occurs. Outer retinal and RPE changes are seen in most cases, and some inflammation may be seen. At the present time there is no definitive evidence of an infectious cause of AZOOR. Autoimmune disease is perhaps suggested by the female predominance. Differentiating this condition from hereditary retinal degenerations, CAR, MAR, and autoimmune retinopathies is necessary, and the trizonal multimodal imaging pattern is often helpful in this process.

# Acute Macular Neuroretinopathy

Acute macular neuroretinopathy (AMN) was first described in 1975 by Bos and Deutman.<sup>414</sup> It is an increasingly recognized condition that causes transient or permanent visual changes.<sup>415</sup> The distinct macular lesions of AMN are reddish-brown in appearance and wedge-shaped or flower-like pointing to or encircling the fovea. The level of the retina involved has been controversial. Originally it was thought to be a disease of the inner retina. Newer imaging techniques have shown the middle and outer retina are involved.<sup>416-421</sup> Fawzi and colleagues used multimodal imaging and found that the disease starts at the level of the outer plexiform layer and then rapidly involves the outer retina.<sup>422</sup> Multimodal imaging and clinical associations suggest that vascular compromise is the cause. In understanding this disease, it is important to review that there are three capillary layers of the retina. The superficial capillary plexus (SCP) is the innermost, and when compromised causes cotton-wool spots and hemorrhage. Next, the intermediate capillary plexus (ICP) may be associated with paracentral acute middle maculopathy (PAMM) (discussed further below) when it is ischemic. Finally, an outermost layer, deep capillary plexus (DCP) insult may cause AMN. Reports now appearing suggest that vascular ischemia can damage the three functional layers of the retinal capillaries. One, two, or three of these vascular beds may be involved on a given patient.

## Clinical Course

### Clinical Symptoms.

Patients complain of decreased vision and paracentral scotomas. A viral prodrome (recently dengue fever has been described),<sup>423</sup> sympathomimetic drug use, anemia, and thrombocytopenia among other associations are now recognized.

### Epidemiology.

AMN may occur in young women in the second to fourth decades of life.<sup>414</sup> In a review of the literature, Turbeville reported that 83%

of reported cases to 2002 were women with a mean age of 27 years.<sup>424</sup> Interestingly, 41 cases of AMN were published from 1975 to 2002. From 2002 till 2012, 43 cases were published in the English literature,<sup>425</sup> showing the increased recognition of this disease, largely due to multimodal imaging (especially OCT and near-infrared images).

### Fundus Findings.

One or several small lesions are seen surrounding the fovea at the level of the outer retina. These may be round, oval, or petaloid<sup>414,424</sup> (Fig. 79.63). They appear brown or dark red compared to the surrounding retina.<sup>414,418</sup> The lesions are best seen on red-free photography or near-infrared reflectance imaging. Retinal hemorrhages have been reported.<sup>424</sup> No abnormality is obvious in the retinal vessels or optic disc.

**FIG. 79.63** Fundus photo of a patient with acute macular neuroretinopathy. Subtle macular reddish-brown lesions are seen.

### Clinical Course and Prognosis.

The disease process may be unilateral or bilateral. Patients are often seen several days after the development of scotomas.<sup>424</sup> The lesions

may develop rapidly or over the course of days to weeks. Turbeville and colleagues noted a different time course in those cases that were related to viral prodrome and those that developed in association with epinephrine. Patients who reported an influenza-like illness had an onset of scotomas generally over days to weeks, though sudden onset was also possible. With time, some of the symptoms and lesions resolved, though patients remain mildly symptomatic. In contrast, all the epinephrine cases were sudden, bilateral, and did not seem to resolve with time. They postulated that this may represent different mechanisms.<sup>424</sup>

Recurrences may occur in one or both eyes. The acute retinal lesions fade but generally do not disappear completely. Complete recovery has been reported in a few cases.<sup>424</sup> Newer imaging techniques as further discussed below suggest that there are persistent anatomical changes in the outer retina despite subjective or clinical improvement.<sup>426</sup>

## Imaging

### Fluorescein Angiography.

Usually, FA results are normal. Sometimes there may be a slight hypofluorescence corresponding to blockage from the clinically seen lesions.<sup>414,418,427</sup>

### Indocyanine Green Angiography.

ICGA is normal.<sup>428</sup>

### Optical Coherence Tomography.

Much of the recent literature on AMN is devoted to OCT findings.<sup>415,417,428-435</sup> The infrared images seen with OCT highlight the lesions best. The reddish-brown clinical lesions correspond to focal changes in the photoreceptors<sup>422</sup> (Fig. 79.64). Early SD-OCT findings were described in a 29-year-old woman 3 hours after the onset of symptoms. An isolated hyperreflectivity at the posterior border of the outer plexiform layer was described. Seven days later she developed a wedge-shaped lesion with hyperreflectivity of the ONL and ellipsoid zone, and the outer plexiform layer (OPL) was no longer hyperreflective.<sup>436</sup> The findings on infrared reflectance

and OCT change rapidly over time in the first few weeks. Fawzi and colleagues described eight patients using multimodal imaging in 2012. Hyperreflective bands involving the OPL and ONL occurred acutely. Then disruption of the ellipsoid zone was seen. As the hyperreflectivity subsided, there was thinning of the ONL. The interdigitation line is also affected, and changes may persist even after the ellipsoid zone recovers.<sup>422</sup> En face SD-OCT has been characterized in a case report of bilateral AMN and correlates with Fawzi's description. The patient was imaged 5 months after the onset of symptoms and found to have a thinned ONL and disruption of the ellipsoid and interdigitation zones corresponding to the reddish lesions seen clinically.<sup>437</sup>

**FIG. 79.64** Optical coherence tomography (OCT) shows that the lesions correspond to focal interdigitation zone defects (*arrow*).

### **Fundus Autofluorescence.**

Subtle hypoautofluorescence corresponding to clinical lesions has been reported.<sup>415</sup>

### **Electrophysiology**

Multifocal ERG has shown decreased foveal peaks in affected eyes.<sup>416,434</sup> Researchers using mfERG localize the lesion to the outer

retina affecting the photoreceptor or bipolar cell layer. Changes may persist for longer durations.<sup>438,439</sup> ERG and EOG are generally normal.<sup>440</sup>

## Visual Field Testing

Paracentral scotomas are seen corresponding exactly to the shape and location of the clinical lesions. Patients can draw their scotomas on an Amsler grid.<sup>414</sup> When defects are very small, microperimetry may be helpful.<sup>441,442</sup>

## Adaptive Optics

AO-SLO has shown that cone photoreceptors are disrupted within areas of defects measured by microperimetry.<sup>443</sup> The area of decreased cone photoreceptor density has also been shown to be larger than the area that was seen on near-infrared imaging or SD-OCT, and it may not completely recover.<sup>444</sup>

## Systemic Associations

Oral contraceptive use, flu-like syndrome, dengue fever, anemia, thrombocytopenia, contrast media exposure, caffeine use, epinephrine use, trauma, history of headaches/migraines, postpartum hypotension, diabetes mellitus, and hypotensive shock have all been described in patients who developed AMN.<sup>423–425</sup>

## Pathogenesis

Retinal ischemia related to insult to the deep capillary plexus seems to be the etiology. Imaging shows involvement of the photoreceptors and the development of zones of outer retinal thinning. Turbeville and colleagues review theories of pathogenesis, which include hormonal predisposition, infectious processes (44% of reported cases to 2002 had a flu-like syndrome), decreased blood flow to the outer retina causing transient ischemia, and increased thoracic pressure causing a sudden increase in intravascular pressure damaging the blood–retina barrier.<sup>424</sup> The early involvement of the outer plexiform layer, as well as the vascular associations, suggest a vascular insult to the outer capillary network.<sup>422</sup> Given that the OPL is radially oriented, it would make

sense that an ischemic insult in this region could create a wedge-shaped defect.<sup>445</sup> A case report of a 15-year-old girl who presented with concomitant cotton-wool spots and IRF with reddish lesions in both eyes lends support to this theory. OCT imaging revealed typical hyperreflective plaques at the level of the OPL/ONL. The concurrence of cotton-wool spots and AMN lesions in this patient are supportive of a vascular insult as the etiology.<sup>445</sup>

## Differential Diagnosis

Entities included in the differential are central serous chorioretinopathy, old inner retinal infarcts, PAMM, and optic neuritis.

## Management/Treatment

The disease is self-limited. Visual acuity and visual field defects improve slowly over time, though subtle symptoms may persist. No treatment has been shown effective.

## Paracentral Acute Middle Maculopathy

In 2013, Sarraf and colleagues coined the term paracentral acute middle maculopathy (PAMM), a disease whose clinical presentation resembles AMN with reddish lesions and acute scotomas. However, multimodal imaging shows PAMM affects the middle macular layers above the OPL. These layers are bordered by the intermediate (ICP) and deep (DCP) capillary plexus<sup>421</sup> (Fig. 79.65). An association with retinal ischemia was suggested.<sup>421,446</sup> PAMM has been found in other vascular diseases such as diabetes and central retinal vein occlusion.<sup>420</sup> The OCT findings in PAMM show hyperreflectivity at the OPL/INL (inner nuclear layer) junction instead of OPL/ONL as in AMN. Thinning of the INL occurs with time, and no outer retinal abnormalities occur.<sup>421</sup> PAMM resembles AMN clinically; however, there is a different locus of injury. PAMM occurs more commonly than AMN in males, who are older (mean age 47.6 years), and often with vasculopathic risk factors.<sup>419</sup> The clinical similarities with AMN have given insight into a vascular insult of the retinal capillary plexus as a likely common etiology.

**FIG. 79.65** Optical coherence tomography (OCT) shows paracentral acute middle maculopathy lesion. Hyperreflectivity is at the level of the inner nuclear layer.

## Summary

AMN is an increasingly recognized condition and should be considered in patients with an acute onset of paracentral scotomas. The typical reddish-brown lesions are found in the macula and are best seen with red-free light or infrared reflectance. AMN involves the outer retina, as evidenced by OCT imaging, and can be distinguished from PAMM in this manner. It is a self-limited process, and no treatment has been proven effective.

## Acknowledgment

Evica Simjanoski, CRA, and the retina photographers at Northwestern Medicine for the imaging in this chapter. Lauren Nicosia MD, Northwestern Feinberg School of Medicine, for administrative support of this project.

Supported in part by a grant from Kevin Hitzeman and Mary Dempsey.

# Autoimmune Retinopathies

*Austin R. Fox, H. Nida Sen, Robert B. Nussenblatt, (posthumously)*

**Introduction**

**Epidemiology and Mechanisms**

**Clinical Features**

**Diagnosis**

**Differential Diagnosis**

**Treatment and Prognosis**

## Introduction

Autoimmune retinopathies (AIR) represent a group of inflammatory mediated retinopathies with otherwise unexplained vision loss associated with visual field deficits, photoreceptor dysfunction as evidenced on electroretinography (ERG), and the presence of circulating autoantibodies targeted against retinal antigens. Clinically, the fundus often appears normal, but some patients may show retinal vascular attenuation, diffuse retinal atrophy with or without pigmentary changes or waxy disc pallor. There are usually few or no intraocular inflammatory cells.<sup>1,2</sup>

AIR presumably results from an immunologic attack on the

retina by antibodies directed against retinal antigens. The first case of vision loss and photoreceptor degeneration associated with cancer was described by Sawyer et al. in 1976.<sup>3</sup> Paraneoplastic retinopathy, as a term, was first used by Klingele and associates in 1984 and has become the more general term used for autoimmune retinopathies associated with systemic malignancy since then.<sup>4</sup> Several forms of autoantibody-mediated retinopathy are described: cancer-associated retinopathy (CAR) syndrome, melanoma-associated retinopathy (MAR) syndrome, or autoimmune retinopathy of other types.<sup>3,5-11</sup> AIR can be categorized in two groups: (i) autoimmune retinopathy associated with cancer or other malignancies (paraneoplastic retinopathy or paraneoplastic autoimmune retinopathy); (ii) autoimmune retinopathy without any evidence of malignancy (nonparaneoplastic autoimmune retinopathy). Cancer-associated retinopathy and other paraneoplastic retinopathies will be covered in [Chapter 138](#) (Remote effects of cancer on the retina). Autoimmune retinopathy is the preferred term for an acquired, presumed immunologically mediated retinopathy caused by antiretinal autoantibodies in the absence of a malignancy. This chapter will emphasize the latter.

## Epidemiology and Mechanisms

The prevalence of AIR is unknown, but the condition is believed to be rare. Clinical reports of nonparaneoplastic AIR consist only of case reports and a few small cohorts.<sup>12-15</sup> AIR remains an ill-defined disorder and the lack of standardized diagnostic criteria may be contributing to the underestimation of its prevalence. Though circulating autoantibodies to retinal antigens have been shown to be associated with retinal dysfunction, the mechanisms by which these antibodies cause dysfunction are not entirely understood.<sup>16</sup> Multiple retinal proteins have been found to be antigenic, including recoverin, carbonic anhydrase,  $\alpha$ -enolase, arrestin, transducin- $\beta$  and - $\alpha$ , carbonic anhydrase II, TULP1, neurofilament protein, heat shock proteins, photoreceptor-cell-specific nuclear receptor (PNR), Müller-cell-specific antigen, transient receptor potential cation channel, subfamily M, member 1 (TRPM1), and many other yet-unidentified antigens<sup>17,18</sup> ([Table 80.1](#)). Some of these antigens are

retina-specific, such as recoverin and rhodopsin, while others can be found in nonretinal tissues as well, such as enolase. Among these, recoverin and enolase are the most extensively studied antigens in the context of AIR. Recoverin is a 23 kDa calcium-binding protein found in both rods and cones. Enolase is a 48 kDa glycolytic enzyme whose  $\alpha$ - and  $\beta$ -isoforms are found in many tissues, and  $\gamma$ -isoform in neuronal tissues.<sup>43</sup> In a large series, more than 30% of patients with antiretinal antibodies tested positive for antienolase antibody.<sup>44</sup> Antibodies against  $\alpha$ -enolase appear to be fairly ubiquitous; they are found in multiple autoimmune diseases and even in healthy subjects.<sup>45-48</sup> This has been, in part, attributed to the multifunctional nature of  $\alpha$ -enolase.<sup>16,26,49</sup>

**TABLE 80.1**  
**Proteins Targeted by Antiretinal Antibodies**

Recoverin (23 kD)	CAR, npAIR <sup>6,14,19-25</sup>
Alpha-enolase (46 kD)	CAR, npAIR <sup>14,22,26-29</sup>
Carbonic anhydrase II (CA II) (30 kD)	CAR, npAIR <sup>12,22,30</sup>
Tubby-like protein 1 (TULP-1) (65 kD)	CAR <sup>31</sup>
Heat shock protein 70 (HSC 70) (70 kD)	CAR <sup>21</sup>
Transducin- $\beta$ (35 kD)	MAR <sup>32</sup>
Transducin- $\alpha$ (40 kD)	CAR, MAR <sup>33</sup>
Arrestin (S-antigen) (48 kD)	MAR, npAIR <sup>22,34</sup>
Interphotoreceptor binding protein (IRBP) (141 kD)	npAIR, MAR <sup>22,35</sup>
Heat shock protein 60 (HSC 60) (61 kD)	CAR, npAIR <sup>36</sup>
Collapsin response mediator protein 2 (CRMP2) (62 kDa)	CAR, MAR, npAIR <sup>36</sup>
Unknown proteins	22 kD, 34 kD, 35 kD, 37 kD, 40 kD, 68 kD
	34 kD, 40 kD, 46 kD, 60 kD, 70 kD

Antibodies against the listed proteins were identified in the serum of patients with AIR or AIR-like clinical findings.

CAR, cancer-associated retinopathy; MAR, melanoma-associated retinopathy; npAIR, nonparaneoplastic autoimmune retinopathy.

Of all these antigens, recoverin and CAR has the strongest association. Recoverin has been shown to be expressed by the tumor cells of patients with CAR.<sup>50</sup> While antirecoverin antibody is most specific to CAR, it has also been found in patients with nonparaneoplastic AIR, as well as patients with small-cell lung carcinoma without any retinopathy.<sup>19,20,51</sup> Recoverin and  $\alpha$ -enolase have been shown to be highly expressed in cancer cells in patients with paraneoplastic AIR. It is plausible that the disease is triggered

by molecular mimicry between retinal proteins and tumor antigens in cases of paraneoplastic AIR and presumed viral or bacterial proteins in the case of nonparaneoplastic AIR.<sup>27,52,53</sup> Regardless of the presence or absence of malignancy, autoimmune retinopathies appear to share common clinical features.

Experimental studies have attempted to shed light on the pathogenic mechanisms of autoimmune retinopathy. In vitro studies have demonstrated that some of the antiretinal antibodies are, indeed, cytotoxic to retinal cells, and that the cellular internalization of the antibody leads to apoptosis.<sup>21,26,28,54–56</sup> This antibody-mediated apoptosis is independent of complement and involves caspase pathways and intracellular calcium influx. Similarly, in vivo studies showed that intravitreal injection of antirecoverin antibody causes apoptosis of retinal cells and a decrease in ERG responses.<sup>21,57,58</sup> Recoverin also acts as a uveitogenic antigen and can induce autoimmune retinopathy-like disease in animal models leading to reduced scotopic and photopic ERG responses.<sup>59,60</sup> Both in vitro and in vivo studies showed that antirecoverin antibody-triggered apoptosis occurs only in recoverin-positive cells.<sup>61</sup> Antirecoverin antibodies target photoreceptor cells, and anti- $\alpha$ -enolase antibodies appear to target ganglion cells. Antibodies targeting retinal bipolar cells have been associated with MAR. Additionally, injection of immunoglobulins isolated from serum of patients with MAR into the vitreous of monkeys led to ERG changes similar to those observed in MAR, indicating the pathogenicity of the antiretinal antibodies.<sup>62</sup> Evidence from these studies suggests that antiretinal autoantibodies can target virtually any retinal cell type – photoreceptor cells, ganglion cells, bipolar cells – and cause retinal dysfunction.<sup>14,54,63</sup>

It is still unclear, however, why some patients with antiretinal antibodies develop retinopathy while others do not. It has been suggested that antiretinal antibodies may be pathogenic when targeting specific epitopes, resulting in retinal cytotoxicity in CAR patients, while in healthy controls, antiretinal antibodies may target different epitopes without such a consequence.<sup>26</sup> On the other hand, it is a possibility that antiretinal antibodies are an epiphenomenon, resulting secondarily from the pathogenesis of AIR. In addition to studying the role of antiretinal antibodies, future studies are needed

to elucidate the role of cellular immunity in the pathogenesis of AIR, about which little is known.

Studies are also needed to explore other factors (i.e., genetics) potentially contributing to the pathogenesis of nonparaneoplastic AIR. Our group found significantly different frequencies of certain HLA alleles among 18 nonparaneoplastic AIR patients as compared to the general population, however, future studies of larger cohorts are needed to verify potential genetic associations.<sup>64</sup> As more nonparaneoplastic AIR patients are identified, genetic studies may provide insight into the pathogenesis and support the diagnosis of nonparaneoplastic AIR in the future.

## Clinical Features

Clinical features of AIR are quite variable. Serum antiretinal autoantibodies have been associated with loss of vision and visual field defects as well as electrophysiologic changes in patients with autoimmune retinopathy, but the exact mechanism has not been fully understood. In particular, the pathogenicity and specificity of these autoantibodies with respect to clinical findings have yet to be determined. Nevertheless, patients with AIR appear to share common clinical features despite the heterogeneity in the detectable circulating antiretinal antibodies.<sup>12,14,65</sup>

The clinical manifestations of nonparaneoplastic AIR is quite variable; there are no clear guidelines or consensus on the diagnosis of autoimmune retinopathy. Commonly recognized clinical manifestations include the following:<sup>12,13</sup>

1. Symptoms: acute or subacute onset of photopsia, dyschromatopsia, nyctalopia, photoaversion, scotomas, sometimes central vision loss.
2. Fundus findings: normal-appearing fundus or waxy disc pallor, attenuated retinal vasculature and retinal pigment epithelial (RPE) atrophy or mottling. There are few or no intraocular inflammatory cells.
3. Psychophysical tests:

- a. Visual fields: constricted visual fields, central or paracentral scotomas.
- b. Electroretinogram (ERG): ERG can show abnormalities in rods, cones, Müller cells, or bipolar cell responses or a combination of these.

Patients with nonparaneoplastic AIR present with acute or subacute vision loss. Patients typically complain of color vision changes, photosensitivity or photoaversion, and varying degrees of nyctalopia. Other presenting symptoms include floaters; photopsias; scotomas, most commonly paracentral; and constricted visual fields. Of these, photosensitivity, photoaversion, difficulty seeing in bright light, reduced visual acuity, dyschromatopsia and central scotomas are suggestive of cone dysfunction, whereas nyctalopia (night blindness) and midperipheral scotomas are suggestive of rod dysfunction. Depending on the extent and the distinct retinal cell involvement, visual acuity, particularly in the earlier stages, may be deceptively good. On presentation to a tertiary care center, most patients may have been diagnosed with nonspecific retinal degeneration or isolated cases of retinitis pigmentosa (RP). Fundus examination can be unremarkable or may show signs of retinal degeneration such as waxy disc pallor, attenuated retinal vasculature with or without pigmentary changes, or diffuse atrophy. Though atypical, one case of nonparaneoplastic AIR presenting with severe peripheral retinal vasoocclusion has been reported.<sup>66</sup> There may be mild or no inflammatory cells in the anterior chamber or the vitreous<sup>12,13,67</sup> (Fig. 80.1).

**FIG. 80.1** (A,B) Fundus photo of a 57-year-old patient with systemic lupus erythematosus and autoimmune retinopathy. Note the mild attenuation of retinal vasculature and mild optic nerve pallor.

Ancillary testing with fluorescein angiography (FA) or optical coherence tomography (OCT) may show mild retinal vascular staining or leakage, or cystoid macular edema (CME) in some cases.<sup>12,68</sup> Using spectral domain (SD) OCT, a few studies have identified outer retinal abnormalities and decreased central macular thickness in nonparaneoplastic AIR patients.<sup>69-71</sup> These abnormalities may include disruption or loss of the photoreceptor outer and inner segment junction (or ellipsoid zone), loss of the photoreceptor layer, disruption or loss of the external limiting membrane, and outer nuclear layer thinning. On FAF, a parafoveal hyperautofluorescent ring corresponds to these outer retinal abnormalities identified on SD-OCT.<sup>70,71</sup> Similar features on FAF and OCT have been noted in following 24 AIR patients here at the National Eye Institute.<sup>68</sup> However, abnormal FAF findings have not been consistently identified in all nonparaneoplastic AIR patients.

Visual field testing may confirm scotomas and constricted visual fields. While static visual field testing may be better for demonstrating and following central and paracentral scotomas, kinetic visual fields are better for measuring peripheral field constriction. However, kinetic visual fields have the disadvantage of examiner dependence, the need for patient cooperation, intertester variability, and lack of standardization of parameters.<sup>72,73</sup> ERG may demonstrate abnormal rod, cone, Müller cell, and bipolar cell responses and delay in implicit times.<sup>12,13,27,37</sup> However, the

majority of studies involving ERG findings in AIR come from paraneoplastic retinopathies (Fig. 80.2).

A

**FIG. 80.2** (A–C) Goldman visual field of an autoimmune retinopathy patient shows central and paracentral scotoma in the right (A) and left (B) eye. (C) Electroretinogram (ERG) responses of the same patient show reduced amplitudes for both rod- and

cone-mediated responses. Blue traces indicate baseline ERG recordings; red traces were recorded 1 month after treatment with rituximab (Rituxan®, Genentech, Inc., CA), a chimeric anti-CD20 antibody. Note the improvement in rod-mediated responses. ERGs were recorded according to ISCEV standards. Number indicates flash intensity (cd-s/m<sup>2</sup>). Note different scales for dark-adapted (DA) and light-adapted (LA) ERGs. (Courtesy of Brett Jeffrey, PhD.)

AIR is almost always bilateral, although involvement can be asymmetric. There is a female preponderance (63–66%), and average age at diagnosis appears to range from 51 years to 56 years.<sup>12–14</sup> The typical patient would be a middle-aged or older adult in their fifth to sixth decades with no history of visual problems prior to the onset of photopsias, scotomas, and other symptoms consistent with AIR, and no family history of RP. A personal or a family history of systemic autoimmune disease can be common among patients with nonparaneoplastic AIR.<sup>12,15</sup> In fact, cases of nonparaneoplastic AIR have been described in the setting of systemic lupus erythematosus and autoimmune polyglandular syndrome type 1 (APS 1).<sup>74–77</sup>

As might be expected for an entity with no consensus in diagnosis, retrospective studies in patients with nonparaneoplastic AIR showed that clinical features vary considerably. In one study, diffuse retinal atrophy was seen in the majority of patients (83%) and pigment deposits in only a small proportion (13%), and macular edema was present in approximately half of the cases, while another study showed pigmentary changes in approximately half of the patients and macular edema in 24%. The most common symptoms at onset were subacute vision loss, photopsias, and nyctalopia. Similarly, in a series of 12 patients with antienolase-associated retinopathy, clinical characteristics included visual loss, normal-appearing fundus except for vascular attenuation in most, optic nerve head pallor in some, and mainly abnormal cone responses. In all of these studies, however, there was a female predominance, and the age at onset was similar.<sup>12–14,27</sup>

# Diagnosis

The diagnosis of AIR is difficult as there are no definitive or standardized tests. The presumptive diagnosis relies on the presence of the above clinical manifestations, usually more than one, along with demonstration of serum antiretinal antibodies. Most patients will have more than one antiretinal antibody. If the clinical features of autoimmune retinopathy and the circulating antiretinal antibodies are present, and if there is no apparent cause of visual function abnormalities, including malignancy, at presentation or following a thorough investigation, a diagnosis of nonparaneoplastic AIR is made (Table 80.2).

**TABLE 80.2**

**Diagnostic Criteria for Nonparaneoplastic AIR<sup>a</sup>**

Essential Diagnostic Criteria <sup>b</sup>	Supportive Diagnostic Criteria
No apparent cause responsible for visual function abnormality <sup>c</sup>	Symptoms: photopsias, scotomas, dyschromatopsia nyctalopia, photoaversion
ERG abnormality	Systemic autoimmune disease: personal or family history
Presence of serum antiretinal antibodies (ARAs)	Rapidity of onset of vision change (acute or subacute)
Absence of fundus lesions and retinal degeneration or dystrophy that may explain visual function loss <sup>d</sup>	
Absence of overt intraocular inflammation <sup>e</sup>	

<sup>a</sup>Suggested diagnostic criteria following an expert consensus meeting in 2013 (unpublished data).

<sup>b</sup>All essential diagnostic criteria must be present. Supportive diagnostic criteria are not necessary to make the diagnosis of AIR.

<sup>c</sup>Including no evidence of malignancy.

<sup>d</sup>Absence of choroidoretinal lesions (other than incidental/small peripheral benign degenerations, such as pavingstone, lattice, etc., or old toxoplasmosis scar) or absence of retinal dystrophy, retinitis pigmentosa, or other hereditary eye disorders.

<sup>e</sup>Less than +1 intraocular cells/haze present.

In addition to an extensive review of systems and history to rule out any malignancy, a thorough physical exam and basic laboratory investigations accompanied by age- and gender-appropriate investigations are typically undertaken prior to starting treatment. These investigations are best performed or facilitated by an internist

or the primary care physician. Because the diagnosis of AIR is currently presumptive, it is very important that a clear communication between the ophthalmologist and the primary medical team is established regarding the uncertainty of the diagnosis and the possible overlap with paraneoplastic retinopathy, so an appropriate investigation can be undertaken. Imaging with MRI or CT should be guided by the review of systems and the patient's individual risk factors, and, as such, determined by the patient's primary medical team.

Demonstration of serum antiretinal antibodies can be done using various methods, including Western blot (WB), immunohistochemistry (IHC), or enzyme-linked immunosorbent assay (ELISA). Western blot is a protein immunoblot of patients' serum incubated with extracts of a normal donor human retina and shows antiretinal IgG bands. It identifies antibody activity based on size of the protein, and the interpretation relies on intensity of protein bands on a photographic film. The results may be affected by multiple technical factors and lack specificity. For example, a 23-kDa band on WB does not necessarily mean antibody against recoverin; there may be other antigens with the same size. The immunohistochemical detection of antiretinal antibodies, on the other hand, involves fixing patient serum against frozen donor human retina (or monkey or mouse retina) using immunohistochemical staining. Sections are then analyzed using light microscopy to determine which layers of the retina show binding of the antiretinal antibody. The advantage with IHC is the ability to localize the specific site of binding within the retina (Fig. 80.3). ELISA is similar, in principle, to WB and IHC and involves adding various dilutions of patient sera into wells coated with specific retinal proteins, and binding is detected using secondary antibodies.<sup>10,78</sup> All of these techniques, however, lack standardization.<sup>17</sup>

**FIG. 80.3** Immunohistochemistry performed using serum of autoimmune retinopathy patient against fresh-frozen human donor retina shows staining at the photoreceptor inner and outer segments as well as outer nuclear layer. (Courtesy of Chi Chao Chan, MD.)

To highlight the lack of standardization and variable methods between laboratories, one study compared the results of antiretinal antibody detection and measurement between two laboratories and found an overall concordance rate of detecting any antiretinal antibodies of 64%, yielding very poor interobserver agreement ( $\kappa = -0.13$ ),<sup>79</sup> and an ARA-specific concordance rate of 36%. Currently, there are few centers in the United States that perform antiretinal antibody testing, and only one center provides these services commercially through a CLIA (clinical laboratory improvement amendments) certified laboratory.<sup>80</sup>

Autoimmune retinopathy, similar to paraneoplastic retinopathy, can be associated with various antiretinal antibodies. Initially, detected autoantibodies in nonparaneoplastic AIR were antirecoverin antibodies.<sup>19</sup> Later, antibodies directed against the inner plexiform layer,<sup>11</sup> Müller cells (35 kDa), or other unidentified retinal proteins have been described.<sup>37,78</sup> One of the most commonly detected antibodies on WB in nonparaneoplastic AIR appears to be

one with a molecular weight of about 35 kDa, which was detected in about 25% of autoimmune retinopathies, whereas antirecoverin antibodies were more commonly associated with the paraneoplastic AIR. Anti- $\alpha$ -enolase antibodies were somewhat equally distributed in both groups.<sup>14</sup> Distinct profiles of multiple antiretinal antibodies, or antiretinal antibody signatures, have been explored and identified in paraneoplastic retinopathies, as well as in age-related macular degeneration (AMD), and it has been suggested that distinct signatures may correlate with a specific subtype or stage of disease.<sup>81-83</sup> As we learn more about antiretinal antibodies and the pathogenesis of nonparaneoplastic AIR, it is likely that unique antiretinal antibody signatures may be identified and aid in the management of nonparaneoplastic AIR.<sup>14</sup>

Moreover, it is important to remember that the mere presence of these autoantibodies does not warrant a diagnosis of AIR, nor does it mean they are pathogenic. Antiretinal antibodies have been detected in patients with other retinal diseases, uveitis, retinal degenerations including AMD, and even in normal controls.<sup>22,84-87</sup> Conversely, they can be negative in patients with clinical features considered typical of AIR.<sup>14</sup> In a large cohort, only 47% of patients who presented with signs and symptoms compatible with AIR had any detectable antiretinal antibodies. Of these, patients with a history of cancer were more likely to have detectable antiretinal antibodies (63.5%) than those who did not (41.1%).<sup>14</sup> The fact that half of patients with symptoms and signs compatible with AIR tested negative for any antiretinal antibody with the techniques currently available highlights the difficulty of diagnosis. The role of antiretinal antibodies in the pathogenesis of AIR has yet to be determined, but understanding such will aid in the diagnosis and management of AIR.

## Differential Diagnosis

Since there are no standardized tests for nonparaneoplastic AIR, the differential diagnosis is as challenging as its diagnosis. A variety of retinopathies are associated with the detection of antiretinal antibodies in serum. In addition, the clinical features seen in autoimmune retinopathy are not specific or unique to AIR and can

be seen in other forms of retinopathies.

The spectrum of disorders that may show clinical or laboratory similarities to AIR can be studied in four groups:

1. Paraneoplastic disorders (e.g., CAR, MAR).
2. White-dot syndrome spectrum disorders (e.g., acute zonal occult outer retinopathy).
3. Retinal degenerative disorders (e.g., retinitis pigmentosa, cone-rod dystrophy).
4. Noninfectious and infectious uveitis syndromes.

Paraneoplastic retinopathies, similar to nonparaneoplastic AIR, are characterized by vision loss, photopsias, nyctalopia, and scotomas. Cancer-associated retinopathy is typically associated with antirecoverin antibody, and most commonly associated with small-cell carcinoma of the lung. It is important to remember that a non-neoplastic form of antirecoverin antibody-associated retinopathy has also been described.<sup>6,7,19</sup> MAR occurs in patients with cutaneous melanoma and is characterized by a negative waveform on standardized full-field ERG due to reduction in b-wave amplitudes. In addition to similar symptoms as in nonparaneoplastic AIR, patients tend to have diffuse fundus depigmentation. Paraneoplastic retinopathies typically have a more rapid decline, with rapid progression of vision and visual field loss, as well as ERG changes; spontaneous recovery has not been observed. Vision loss can precede the identification of malignancy.<sup>65,67</sup> It is important to differentiate paraneoplastic retinopathy from nonparaneoplastic AIR because of significant implications for treatment. The features of paraneoplastic retinopathy are covered in detail in [Chapter 138](#) (Remote effects of cancer on the retina).

White dot syndromes such as acute zonal occult outer retinopathy (AZOOR) or multiple evanescent white dot syndrome (MEWDS) have been suggested to be associated with antiretinal antibodies.<sup>78,88</sup> AZOOR and MEWDS have overlapping features and cases of MEWDS evolving into AZOOR have been described.<sup>89</sup>

However, immunohistochemical testing of sera of patients with AZOOR yielded conflicting results in demonstrating antiretinal antibodies.<sup>90</sup> AZOOR can present with symptoms, visual field, and ERG findings similar to nonparaneoplastic AIR; it is typically bilateral but asymmetric, and the majority of patients either stabilize or show partial recovery without treatment. MEWDS, despite having similar symptoms, is a unilateral retinopathy which is characterized by afferent pupillary defect, optic nerve swelling, and spontaneous recovery, and hence is more readily differentiated from AIR. Both AZOOR and MEWDS may show enlarged blind spot on visual fields. In addition, the majority of eyes affected by AZOOR may show fundus autofluorescence abnormalities which have not been observed in AIR.<sup>15,91,92</sup>

Antiretinal antibodies have also been reported to occur in patients with RP, a hereditary retinal degeneration. However, up to 60% of patients with RP may lack a family history of retinal degeneration. Indeed, some patients who are eventually diagnosed as nonparaneoplastic AIR are initially diagnosed as isolated cases of RP. Approximately 10–37% of patients with RP may have circulating antiretinal antibodies.<sup>20,85</sup> Additionally, 90% of patients with RP and macular cysts have circulating antiretinal antibodies on WB, compared with 13% of patients with RP without macular cysts and 6% of controls.<sup>22</sup> Most commonly detected antibodies are targeted against carbonic anhydrase II and  $\alpha$ -enolase.<sup>22</sup> In some cases of RP, rapid progression of visual field loss and CME appears to be associated with presence of antiretinal antibodies.<sup>22,85</sup> In retinal degenerations, whether the antibodies precede the onset of retinopathy or whether antiretinal autoantibodies are a consequence of retinal damage is unclear. Additionally, whether the presence of these autoantibodies has a significant impact on clinical course has yet to be determined.

Antiretinal antibodies have also been found in patients with retinal vasculitis, uveitis patients with Vogt–Koyanagi–Harada syndrome (VKH), Behçet disease, and sympathetic ophthalmia. In patients with VKH, antibody reactivity to photoreceptors correlated with disease activity. However, all of these syndromes are characterized by significant intraocular inflammation in addition to their unique fundus findings, making the differentiation rather

unproblematic. Other rare cases of retinopathies associated with antiretinal antibodies include onchocerciasis and ocular toxoplasmosis. Antibodies to retinal pigment epithelium (RPE), neural retina, or photoreceptor layer have been described in these infectious retinopathies.<sup>65,87,93</sup> Typical fundus findings in these entities are helpful in differentiating them from nonparaneoplastic AIR. In all of the aforementioned diseases, it is unclear if the antibodies preceded the retinal disease or if the immune reactivity is simply a consequence of the retinal degenerative process.

## Treatment and Prognosis

Various forms of immunomodulatory approaches have been tried in an attempt to treat autoimmune retinopathy. Theoretically, because of the presumed autoimmune nature of the disease, immunosuppression for nonparaneoplastic AIR is the most sensible treatment strategy. However, because of the ambiguity in diagnosis and lack of standardization in therapeutic outcomes, management of AIR poses an enormous challenge. The immunosuppressive therapy can be considered empiric at this time because of our lack of understanding of this condition. If undertaken, a long-term treatment is needed in most cases, and therapy is not helpful once widespread retinal degeneration occurs. Most treatment-related case series and reports are regarding paraneoplastic retinopathy and include surgery to reduce tumor burden, chemotherapy, corticosteroids, intravenous immunoglobulin (IVIG), or plasmapheresis.<sup>23,94-99</sup> Recently, successful treatment of autoimmune retinopathy or associated cancer with more targeted biologic agents have also been reported.<sup>39,100-104</sup>

Immunosuppressive therapy should be administered by a rheumatologist, immunologist, or a uveitis specialist well versed in the management of such therapy. Immunosuppressive agents such as mycophenolate mofetil, cyclosporine, or corticosteroids may help improve visual function in some autoimmune retinopathy patients. In a cohort of 24 nonparaneoplastic AIR patients that received therapy with various combinations of prednisone, cyclosporine, azathioprine, mycophenolate mofetil, or periocular or intravitreal steroid injections, 15 of the 24 showed varying degrees of

improvement in visual acuity or visual field. CME improved in almost half of the patients; unfortunately, ERG was not routinely performed. More recently, remission of nonparaneoplastic AIR after minimal steroid treatment (50 mg daily for 2 weeks) has been observed.<sup>105</sup> Decrease in antiretinal antibodies following treatment may be seen in some cases;<sup>12,23,65,105</sup> however, clinical significance of this finding is unclear.

In addition to systemic and local corticosteroids, most commonly used immunosuppressive agents in the treatment of AIR include intravenous immunoglobulin (IVIG), antimetabolites such as mycophenolate mofetil, azathioprine, and T-cell inhibitors such as cyclosporine.<sup>12</sup> IVIG has multiple mechanisms of action, some of which are not completely understood. When used in the treatment of autoimmune disorders, its effect is believed to be due to its interaction with Fc receptors on effector cells or by acting as antiidiotypic antibodies directed against idiotypes on circulating autoantibodies. This mechanism may be at play in autoantibody-mediated diseases. Other mechanisms may involve clearance of immune complex deposits, presence of neutralizing antibodies in IVIG, or its effect on the number of T-cell subsets, proinflammatory monocytes, or regulatory T cells.<sup>106</sup> IVIG has been used in several uveitic syndromes refractive to conventional therapy. Its use is limited by cost and long infusions. The typical dose ranges between 1 and 2.5 g/kg each infusion, and the infusions can be administered every 4–8 weeks, although different protocols have been used. Major side-effects include hypersensitivity and anaphylactic reactions and thrombotic events.<sup>107</sup> Similarly, plasmapheresis has also been used in paraneoplastic autoimmune retinopathy. Plasmapheresis, also known as therapeutic plasma exchange, involves extracorporeal elimination of large molecular weight plasma proteins from the blood. The regimen for plasmapheresis is determined according to the pathologic substance desired to be removed. To replace volume, albumin, albumin–saline combination, or fresh-frozen plasma can be used; the latter is preferred to avoid depletion of coagulation factors and immunoglobulins. Its effect is believed to be due to removal of immune complexes and immune reactants. The effect may be rapid but is often short-lived; therefore, more sustainable

immunomodulation is often required. Major side-effects include paresthesias, muscle cramps, or urticarial and anaphylactic reactions.<sup>23</sup>

Less frequently, targeted B-cell therapy, such as anti-CD20 monoclonal antibody (Rituximab), has also been used in the treatment of AIR. Rituximab targets CD20 found on B cells, which are the precursors of antibody-secreting plasma cells.<sup>14,101</sup> Although there is anecdotal evidence, the benefit of immunosuppressive therapy in AIR is also not definite. There are no clear guidelines on how to institute and manage immunosuppressives in patients with AIR, owing to the rarity and ambiguity surrounding this entity. Therefore, the treating physician typically extrapolates from guidelines that are established for other ocular inflammatory disorders.<sup>108</sup> These drugs can take several weeks to have an effect, and it may take up to several months to observe a clinical effect in the form of improvement or stabilization on visual fields or ERG. More rapid improvement has been reported in CAR patients treated with IVIG.<sup>23</sup>

Adding to the challenges in the management is the lack of parameters to guide treatment. There have been no clear indicators for prognosis. Whether the autoantibodies would disappear in response to treatment, or whether their disappearance would be accompanied by clinical improvement is still unclear. Regardless, patients treated with immunosuppressives need to be closely monitored for side-effects. The most common side-effects with azathioprine and mycophenolate mofetil are gastrointestinal upset, nausea, and less commonly, vomiting. The most common severe side-effects are reversible bone-marrow suppression and hepatotoxicity. The most serious side-effects of cyclosporine are nephrotoxicity which occurs less commonly at lower doses (2–5 mg/kg per day), and hypertension. Regular complete blood count with differential and chemistry panel including hepatic and renal function tests should be performed during therapy. Patients should be encouraged to report any side-effects, as early intervention in the form of discontinuation or dose adjustments can be critical.

The response to treatment is very variable, with more favorable results achieved in paraneoplastic retinopathy, particularly CAR, with a combination of chemotherapy and immunomodulation. It

has also been suggested that those with a family history of autoimmune disorders may be less likely to respond to immunosuppression.<sup>12</sup> Our experience indicates that with treatment only a minority of patients with AIR show improvement in visual function, and some remain stable. This may be due to late presentation to our center with significant loss seen on both ERG and visual fields at presentation. Whether an earlier attempt to treat with immunosuppressives would be more beneficial is not clear. Early treatment attempts would require establishing a clear diagnosis using sensitive and specific assays and more definitive clinical criteria. While most of the immunosuppressives used in the treatment of AIR can be instituted and managed safely, a better understanding of the disease is needed to justify more aggressive and potentially beneficial treatment approaches.

Despite evolving research, the relationship between antiretinal antibodies and retinal dysfunction is not fully understood. Limitations in diagnostic assays also limit therapeutic investigations. Regardless, until more is known the mainstay of treatment remains immunosuppression following a thorough investigation to rule out malignancy. Clearly, additional studies are needed to identify the specificity and pathogenicity of antiretinal antibodies and the appropriate treatment. Efforts to establish diagnostic criteria, including more definitive clinical criteria and a standardized assay for antiretinal antibody detection, have been initiated with the goal to promote collaboration in order to advance understanding and future therapeutic investigations.

Established Therapy

Biologic Agents

### Conclusion

Sarcoidosis is a multisystem granulomatous disorder of unknown etiology characterized by intrathoracic involvement. The disease was first described as early as 1869 by Hutchinson, but its protean manifestations and clinical course still make sarcoidosis a diagnostic and therapeutic challenge for modern-day physicians. Ocular involvement is common and has been reported to occur in approximately 20–50% of patients with sarcoidosis.<sup>1,2</sup> Posterior segment manifestations may account for up to 28% of the lesions seen in patients with ocular sarcoid. Most large case series of patients with uveitis report that approximately 5% of patients with uveitis have biopsy-confirmed systemic sarcoidosis.<sup>3–6</sup>

## General Considerations

### Epidemiology

Sarcoidosis is worldwide in its distribution, but there is a striking difference in the prevalence between countries. In Japan, the prevalence is as low as 3.7 : 100,000 compared to Finland where the estimated prevalence is 28.2:100,000.<sup>7</sup> Although all races are affected, series in the United States generally show that the disease is more prevalent in blacks than in whites (three to four times more common). It has also been noted that the prevalence of sarcoidosis in black populations of Africa and South America is less than what has been observed in the African American population.<sup>8–10</sup> Both sexes are affected, with the overall frequency showing a slight excess of females (approximately 60%). Sarcoidosis is a disease of young adults, with almost three-fourths of cases occurring in those younger than 40 years of age. Children may be affected, but this is

uncommon.<sup>6,8-11</sup> The clinical course of childhood sarcoidosis is often atypical; that is, there is less frequent pulmonary involvement and more frequent extrathoracic disease.<sup>12,13</sup> A study of 46 Caucasian children from Denmark reported the four most-frequent presenting symptoms to be erythema nodosum (22%), iridocyclitis (22%), peripheral lymphadenopathy (15%), and cutaneous sarcoidosis (7%).<sup>14</sup> Among children, sarcoid-related uveitis must be differentiated from juvenile idiopathic arthritis and familial juvenile systemic granulomatosis.<sup>15-19</sup>

## Etiology and Pathogenesis

The etiology of sarcoidosis is unknown. Multiple etiologies have been proposed, including a variety of infectious agents, allergy to pine pollen and peanut dust, chewing pine pitch, and hypersensitivity to chemicals such as beryllium or zirconium. Cigarette smoking and tobacco exposure have also been proposed as independent risk factors for ocular sarcoidosis.<sup>20</sup> To date, there is no conclusive evidence to implicate any of these as an etiologic agent.

Familial studies and human leukocyte antigen (HLA) typing have suggested a possible genetic predisposition, but these studies are far from conclusive.<sup>21</sup> A cooperative multicenter study, A Case Control Etiologic Study of Sarcoidosis (ACCESS), enrolled 736 biopsy-confirmed cases from 10 centers in the United States and suggested a genetic predisposition for sarcoidosis, presenting evidence for the allelic variation at the HLA-DRB1 locus as a contributing factor to the disease. The most significant finding was the relationship between *DRB1\*0401* and eye involvement ( $p \leq .0008$ ; odds ratio [OR] 3.49) in the study population. Although only 2% of blacks had a *DRB1\*0401* allele, a similar OR was present in both blacks and whites.<sup>22</sup>

Patients with sarcoidosis are characterized by depression of delayed-type hypersensitivity, reflected by T-cell anergy, and skin tests that are often negative. Peripheral blood lymphocytes from patients with sarcoidosis show diminished responses to mitogens.

Bronchoalveolar lavage is useful to determine the immunologic events at the area of active disease in the lungs. These studies have

shown entirely different results from peripheral blood lymphocytes. In the lungs, there is an excess of helper-T lymphocytes (CD4<sup>+</sup>). These activated helper-T cells spontaneously secrete lymphokines, including interleukin-2 (IL-2), and will activate polyclonal B cells to produce immunoglobulins. These studies have been interpreted to show that an active T-cell-driven immunologic response occurs at the target organ, leading to granuloma formation.<sup>23,24</sup> Studies of bronchoalveolar lavage fluids have suggested that macrophages may also play a role in the pathogenesis of pulmonary sarcoidosis by inducing changes in the pulmonary microvasculature.<sup>25</sup>

Immunohistologic studies of biopsy tissue from patients with sarcoidosis have demonstrated the presence of cells of macrophage lineage and activated T cells in the granuloma. The vast majority of lymphocytes are T cells of the helper subset (CD4<sup>+</sup>) and express activation markers, including class II antigens and the IL-2 receptor.<sup>26-28</sup>

## Clinical Features

The organs most frequently involved in sarcoidosis are the lungs, lymph nodes and spleen, skin, eyes, nervous system, and the musculoskeletal system<sup>1,21,29-31</sup> (Table 81.1).

**TABLE 81.1**

**Organ System Involvement in Sarcoidosis**

Organ System	Frequency (%)
Intrathoracic	84-93
Hilar nodes	60-77
Lung parenchyma	40-56
Lymph nodes	23-37
Eyes	11-32
Skin	12-27
Erythema nodosum	4-31
Spleen	1-18
Bones	2-9
Parotid	5-8
Central nervous system	2-7

## Intrathoracic Sarcoidosis

Several series have demonstrated that intrathoracic involvement is the most common manifestation of sarcoidosis and occurs in approximately 90% of patients. An abnormality on chest radiograph examination is evident at the onset of sarcoidosis in almost all patients. Chest radiograph abnormalities have been classified according to a simple staging system, which closely correlates with the eventual outcome. Stage 0 is characterized by a normal chest radiograph; stage 1 is characterized by bilateral hilar lymphadenopathy without pulmonary infiltration and is seen in 65% of patients with pulmonary sarcoidosis; stage 2 is characterized by hilar lymphadenopathy associated with pulmonary infiltration and is seen in 22% of patients with sarcoid; stage 3 sarcoid is characterized by pulmonary infiltration with fibrosis but without bilateral hilar adenopathy and occurs in 13% of patients. The overall rates of radiographic resolution are 59%, 39%, and 38% for disease stage 1, 2, and 3, respectively.<sup>1</sup>

## **Extrapulmonary Lesions**

Involvement of the reticuloendothelial system, particularly the extrapulmonary lymph nodes or spleen, or both, is common and occurs in 23–37% of patients with sarcoidosis. Biopsy of a palpable lymph node is often used for histologic confirmation of the diagnosis of sarcoidosis (see below). Skin lesions occur frequently in sarcoidosis and include erythema nodosum, lupus pernio, maculopapular rashes, cutaneous plaques, and subcutaneous nodules. Lupus pernio (dusky-purple infiltration of the skin of the nose) and sarcoid plaques are typically associated with chronic disease, whereas erythema nodosum (especially in the presence of polyarthritis) is typically associated with acute sarcoid or Löfgren syndrome.<sup>32</sup> Neurosarcoidosis occurs in 2–7% of patients with sarcoid. Facial palsy is the most frequent manifestation of neurosarcoidosis. Other presentations include other cranial nerve palsies, papilledema, peripheral neuropathy, meningitis, space-occupying cerebral lesions, cavernous sinus syndrome,<sup>33</sup> and endocrine disorders such as hypopituitarism or diabetes insipidus resulting from space-occupying lesions. Musculoskeletal involvement includes bone cysts in patients with chronic sarcoid, polyarthralgias, and peri-arthritis in patients with acute sarcoid,

and, less commonly, myopathy from granulomatous lesions within muscles.<sup>1,21,31,33–37</sup>

## Investigations

### Radiologic Evaluation

#### Chest X-Ray.

The single best test for the evaluation of patients with suspected sarcoidosis is the chest film, since it may be abnormal in approximately 90% of patients with sarcoid. Although the chest film is the best test for detecting the presence of sarcoidosis, it does not unequivocally establish the diagnosis, though neither does a negative chest radiograph rule out the disease. Among patients with negative chest radiographic, bronchoalveolar lavage may have a high diagnostic value for detecting sarcoid-related uveitis.<sup>38</sup>

#### High-Resolution Computed Tomography (CT).

The CT findings in sarcoidosis can be divided into three main categories:

1. Parenchymal findings.
2. Large and small airway findings.
3. Mediastinal findings.

The presence of diffuse nodular opacities (1–5 mm) with irregular borders in the perilymphatic distribution typically in the upper and middle lung zones is the most common and almost universal finding in the lung parenchyma.<sup>39</sup> The presence of architectural distortion is also exclusive to sarcoidosis as opposed to other diseases with perilymphatic distribution.<sup>40</sup> “Sarcoid galaxy sign,” which is a collection of multiple granulomas and gives the impression of an opacity, is present in 10–20% of patients with pulmonary sarcoidosis.<sup>41</sup> Extensive fibrosis, mostly distributed in the upper and middle zones associated with architectural distortion, is also seen in 20–25% of cases. The presence of air trapping at end expiration has been reported frequently. Terasaki et

al.<sup>42</sup> reported air trapping on expiration in 45 (98%) of their study patients. Davies et al.<sup>43</sup> demonstrated that the extent of air trapping on expiration was correlated with the pulmonary function of the patient.

Large-airway involvement is seen in 1–3% of patients with pulmonary sarcoidosis. This typically presents with tracheal stenosis due to granuloma formation within the tracheal mucosa or submucosa or secondary to lymph node compression from the outside. More than 60% of patients with sarcoidosis are reported to have smooth thickening of the smaller airways.<sup>39</sup>

The classic radiologic finding in the mediastinum of a sarcoid patient is symmetric bilateral hilar adenopathy with some form of paratracheal adenopathy. Symmetry is an important diagnostic feature of the sarcoid hilar adenopathy as it is uncommon in the major diagnostic alternatives, including tuberculosis and lymphoma.<sup>39</sup>

### **Gallium Scan.**

Gallium-67 is a radioactive isotope with a half-life of 78 hours and is administered intravenously to patients as Ga-citrate. The Ga uptake is detected by gamma cameras 48 hours after injection and is assessed in the liver, spleen, thorax, eyes, and lacrimal and salivary glands. Ga scanning has been suggested as a useful diagnostic test for sarcoidosis. The test is again nonspecific, and gallium uptake is seen in other diseases, including Sjögren syndrome, tuberculosis, radiation therapy, and lymphoma. However, signs such as lambda (Ga uptake of parahilar and infrahilar bronchopulmonary lymph nodes) and panda (Ga uptake of lacrimal and salivary glands) on Ga scanning along with bilateral symmetrical hilar lymphadenopathy may be highly specific for sarcoidosis, obviating the need for invasive procedures such as biopsy.<sup>44,45</sup> In addition, it has been proposed that the combination of gallium scanning and an elevated angiotensin-converting enzyme (ACE) level is highly specific for sarcoidosis, but these studies have employed patients specifically chosen for very active sarcoid.<sup>46</sup> As such, these tests may be of less utility in a patient with presumed sarcoid uveitis and no obvious evidence of systemic sarcoidosis. The best use of these tests may be in following patients with active disease.<sup>47,48</sup>

In a study of 22 patients with sarcoid uveitis compared to 70 patients with uveitis secondary to other disorders, Power et al.<sup>49</sup> reported that the sensitivity and specificity of an elevated ACE alone in diagnosing sarcoidosis were 73% and 83%, respectively, and that the sensitivity and specificity of the gallium scan alone were 91% and 84%, respectively. Using the combination of a gallium scan and an elevated serum ACE, the specificity for diagnosing sarcoidosis was 100% and the sensitivity was 73%. The authors concluded that the combination of serum ACE level and whole-body gallium scan might be useful for diagnosing sarcoidosis in patients with uveitis. However, because of the study design inherent in investigating the values of these tests, their actual utility in patients with normal chest radiographs and without clinical evidence of sarcoid remains uncertain. Furthermore, because the reported prevalence of sarcoid uveitis is approximately 5% among patients with biopsy-confirmed systemic sarcoidosis,<sup>3-6</sup> routine screening of all patients with uveitis by both ACE levels and gallium scan may have a low positive predictive value and, therefore, may be misleading. Nevertheless, in selected patients in whom sarcoidosis is highly likely, these tests may be useful.

## **Magnetic Resonance Imaging (MRI) and Positive Emission Tomography Scan (PET)**

Fluorodeoxyglucose PET (<sup>18</sup>F-FDG PET) scanning has become of great importance in the study and follow-up of patients with cancer. However, in recent years, its role in the diagnosis and management of other conditions such as sarcoidosis has been explored. Although the sensitivity of a whole-body PET scan to detect sarcoid lesions is 80–100%, the findings are nonspecific and histology is required to confirm or rule out sarcoidosis. F-FDG PET/CT may show intense uptake in eyes with active sarcoidosis.<sup>50</sup> In addition, a decrease in FDG uptake correlates well with changes in the magnitude and extent of inflammatory activity among patients with sarcoidosis receiving treatment.<sup>51</sup> Thus, F-FDG PET may be a valuable adjunct in the management of ocular and systemic sarcoidosis.<sup>52</sup>

MRI has been successfully used in the evaluation of organ-specific damage in patients with sarcoidosis, especially cardiac and

musculoskeletal tissue.<sup>46,49,53–56</sup>

## Histology

Histologic confirmation (Table 81.2)<sup>57–75</sup> may be required to establish the diagnosis of sarcoid. Sites most often biopsied include the lungs, mediastinal lymph nodes, skin, peripheral lymph nodes, liver, and conjunctiva. Biopsy of clinically evident skin lesions or palpable lymph nodes is frequently performed because of the high yield and low morbidity. Fiberoptic bronchoscopy with transbronchial lung biopsy is positive in 80% of patients with intrapulmonary sarcoidosis. This procedure is routinely performed by pulmonary physicians and has a relatively low morbidity. The next step in such a scenario is cervical mediastinoscopy, which is both highly invasive and an expensive procedure. The requirement of general anesthesia further increases the chances of complications from the procedure. From the patient's perspective it is important that further possibilities of minimally invasive techniques for the diagnosis of sarcoidosis are explored.

**TABLE 81.2**

### Yield of Different Biopsy Sites in the Diagnosis of Sarcoidosis

Technique	Study	Positive/Total	(%)
Liver biopsy	Branson and Park (1954) <sup>57</sup>	48/63	76
	Israel and Sones (1964) <sup>58</sup>	22/24	92
	Klatskin (1976) <sup>59</sup>	17/23	94
Scalene lymph node biopsy	Beahrs et al. (1957) <sup>60</sup>	20/34	59
	Rochlin and Enterline (1958) <sup>61</sup>	27/34	79
	Williams and Webb (1962) <sup>62</sup>	32/39	82
Scalene fat pad biopsy	Romer et al. (1973) <sup>63</sup>	115/142	81
	Rasmussen and Neukirch (1976) <sup>64</sup>	41/99	52
Mediastinoscopy	Carlens (1964) <sup>65</sup>	118/123	96
	Palva (1964) <sup>66</sup>	27/28	96
	Romer et al. (1973) <sup>63</sup>	47/48	98
Lung biopsy, transbronchial	Koerner et al. (1975) <sup>67</sup>	21/23	91
Bronchoscope	Koontz (1978) <sup>68</sup>	74/104	71
Conjunctival biopsy	Crick et al. (1961) <sup>69</sup>	20/79	25
	Bornstein et al. (1962) <sup>70</sup>	16/64	25
	Kahn et al. (1977) <sup>71</sup>	20/60	33
	Solomon et al. (1978) <sup>72</sup>	8/15	57
	Garver (unpublished, 1980)	10/21	48
	Nichols et al. (1980) <sup>73</sup>	30/55	55
	Karcioglu and Brear (1985) <sup>74</sup>	14/28	50
Minor salivary gland biopsy	Nessan and Jacoway (1979) <sup>75</sup>	44/75	58

Modified from Green WR. Inflammatory diseases and conditions of the eye. In: Spencer WH, editor. *Ophthalmic Pathology: An Atlas and Textbook*, vol. 3. Philadelphia, PA: WB Saunders; 1986.

Development of linear echoendoscopes and subsequent procedures (endoscopic ultrasound-guided fine-needle aspiration [EUS-FNA] and endobronchial ultrasound-guided transbronchial needle aspiration [EBUS-TBNA]) has opened new diagnostic possibilities for sarcoidosis. Both techniques allow real-time monitoring of the needle. Several investigators have reported a high sensitivity of 72–85% for EBUS-TBNA and minimal complications. In a randomized control trial Tremblay et al.<sup>76</sup> have shown that the diagnostic yield of EBUS-guided TBNA (95.8%) versus the conventional TBNA (73.1%) was 22.7% greater. Sensitivity and specificity were 60.9% and 100%, respectively, in the standard TBNA group, and 83.3% and 100%, respectively, in the EBUS-guided TBNA group (absolute increase in sensitivity of 22.5%). EUS-FNA was used for diagnosis of sarcoidosis and had a yield of 82% and sensitivity of 89–94% by assessing noncaseating granulomas in mediastinal nodes.<sup>77</sup> The liver biopsy is often positive in patients with sarcoidosis, but the finding of granulomatous lesions on liver biopsy must be interpreted with caution, as they can be produced by other disorders. Other potential biopsy sites include peripheral lymph nodes and minor salivary glands. Minor salivary gland biopsy is a minimally invasive and easier means for the diagnosis of sarcoidosis.

Conjunctival biopsies are positive in 25–57% of patients with histologically documented sarcoidosis. Variations in these reports are the result of whether clinically evident lesions are biopsied or whether a “blind” conjunctival biopsy is performed. However, the yield can be increased by techniques such as bilateral conjunctival biopsies and serial sectioning of the specimens, and careful inspection of the conjunctiva for any visibly evident nodules which can be biopsied. Transconjunctival lacrimal gland biopsy can also be used for histologic diagnosis, but the procedure is not performed routinely.<sup>47,78</sup>

## Immunology

The Kveim skin test was a simple, specific, outpatient skin test

using human sarcoid tissue. It was positive in 78% of patients with sarcoidosis and was helpful in delineating multisystemic sarcoidosis from other granulomatous disorders. The antigen was a saline suspension of human sarcoid tissue prepared from the spleen of a patient suffering from active sarcoidosis. This material was injected intradermally, and the site inspected for nodule formation after 3–6 weeks. A palpable nodule was biopsied, and the finding of noncaseating granulomas on biopsy established the diagnosis of sarcoid.<sup>21,58,79</sup> Concerns about the injection of human tissue, with its potential for disease transmission, have essentially eliminated the use of the Kveim test.

Studies suggest that CD4/CD8 ratios in the vitreous fluid may be high among patients with ocular sarcoidosis. This finding is similar to the observations of higher CD4 cell counts in the bronchoalveolar lavage fluid in patients with pulmonary sarcoidosis.<sup>26–28</sup> In a study of 51 eyes of 38 patients with ocular sarcoidosis (confirmed by International Workshop on Ocular Sarcoidosis [IWOS] criteria), peripheral blood and vitreous T lymphocytes (obtained by pars plana vitrectomy) were analyzed using polymerase chain reaction, and flow cytometry. CD4/CD8 ratios were high among patients with sarcoidosis compared to nonsarcoid controls with a high sensitivity and specificity of 100% and 96.3%, respectively.<sup>80</sup>

## Noninvasive Tests

Multiple attempts have been made to find noninvasive tests that could be both sensitive and specific in the diagnosis of sarcoidosis. These have included measurement of serum calcium, urinary calcium, serum lysozyme, and serum immunoglobulins. Although all these may be abnormal in patients with sarcoid, they are nonspecific and nondiagnostic. The serum ACE level has been touted as a useful measurement in the diagnosis of sarcoidosis. The ACE level is frequently abnormal in patients with active sarcoidosis and appears to reflect the total-body granuloma content in such patients. As such, it may be useful in following patients with active sarcoid.<sup>48,58,81</sup> However, it is not diagnostic of sarcoidosis and appears to be of limited utility in the diagnostic dilemma of patients with possible sarcoid uveitis but a normal chest film.

For following patients with active intrapulmonary sarcoid, pulmonary function tests, particularly forced vital capacity, forced expiratory volume, and diffusing capacity, are far more useful. Changes in pulmonary function tests are often used to follow patients with sarcoidosis and to adjust the corticosteroid dosage.<sup>29</sup>

Jabs and Johns<sup>82</sup> reported that over 80% of patients with ocular sarcoid had their ocular lesions at the time of diagnosis of sarcoidosis, and Hunter and Foster<sup>56</sup> reported that 3% of patients with uveitis were diagnosed as having sarcoid after the initial evaluation for a systemic disease revealed no diagnosable systemic disorder. Although patients who present with uveitis should be evaluated for sarcoid, repetitive workups appear to have limited value unless new symptoms arise.

## Course and Prognosis

There appear to be two distinct paradigms of sarcoidosis, acute and chronic, with differences in onset, natural history, course, prognosis, and response to treatment. Acute sarcoidosis tends to have an abrupt, explosive onset in young patients and to go into spontaneous remission within 2 years of onset. Acute iritis is often seen in acute sarcoidosis. The response to systemic corticosteroids is generally quite good, and the manifestations may quickly disappear within a week of therapy initiation. The long-term complications of sarcoidosis are minimal. Löfgren syndrome comprises erythema nodosum, bilateral hilar adenopathy, and acute iritis; it generally has a good long-term prognosis.<sup>1,21,31</sup>

Chronic sarcoidosis is defined as disease persistence of greater than 2 years. The disease may have a more insidious onset and generally has intrapulmonary involvement with chronic pulmonary disease as a major source of morbidity. Corticosteroid therapy is generally required and may be prolonged. Chronic ocular disease, particularly chronic uveitis, may be a feature of chronic sarcoidosis.<sup>1,21,29,31,82</sup>

The overall mortality from sarcoidosis is 3–5%, but neurosarcoidosis is associated with a mortality of 10%.<sup>55</sup> Corticosteroids are the mainstay of treatment. Patients with hilar adenopathy without abnormalities of pulmonary function and

without intrapulmonary infiltration may not need systemic corticosteroid treatment.

## Ocular Manifestations

Multiple studies have documented the common occurrence of ocular involvement in sarcoidosis and the various ocular manifestations of sarcoid. Frequency estimates vary and have ranged as high as 50%.<sup>55</sup> However, most series report rates that are generally closer to 15–28%.<sup>1,21,31,34,82,83</sup> These differences undoubtedly relate to case ascertainment methods, the patient population studied, definitions of ophthalmic involvement, and the nature of the evaluation conducted. Racial differences influence not only the mode of presentation for ocular sarcoidosis but also the frequency of patients with ocular involvement. When the same diagnostic criteria were applied, Japanese patients with sarcoidosis were found to have ocular disease six times more frequently than Finnish patients, and they were also more likely to present with ocular symptoms of sarcoidosis. In the United States the black population is twice as likely to have ocular disease as opposed to white patients. Furthermore, high frequencies of ocular involvement are reported when keratoconjunctivitis sicca is sought carefully and included as evidence of lacrimal involvement in sarcoidosis.<sup>55</sup>

Sarcoidosis may affect most of the ocular structures, as well as the orbit and adnexa. Ocular lesions described in sarcoidosis include anterior uveitis, iris nodules, conjunctival nodules, scleral nodule,<sup>84,85</sup> and corneal disease with either band keratopathy or interstitial keratitis; posterior segment disease, including chorioretinitis, periphlebitis, chorioretinal nodules, vitreous inflammation, and retinal neovascularization; and orbital disease, including involvement of the lacrimal gland, nasolacrimal duct, optic nerve, and orbital granulomas. The various ocular lesions along with the prevalence estimates are outlined in [Table 81.3](#).

---

**TABLE 81.3**

**Ocular Manifestations of Sarcoidosis**

---

Ocular Manifestations	Frequency in Patients With Ocular Sarcoid (%)
-----------------------	---

ANTERIOR SEGMENT DISEASE	
Anterior uveitis	66–70
Acute	15–32
Chronic	39–53
Iris nodules	11–16
Conjunctival lesions	7–47
CORNEA	
Band keratopathy	5–14
Interstitial keratitis	1
POSTERIOR SEGMENT DISEASE	
Vitritis	3–25
Periphlebitis	10–17
Chorioretinitis	11
Choroidal nodules	4–5
Retinal neovascularization	1–5
Orbital and other disease	26
Lacrimal gland	7–60
Keratoconjunctivitis sicca	5–60
Enlargement	7–28
Orbital granuloma	1
Optic nerve granuloma	<1–7

Sarcoidosis accounts for nearly 5% of all the adult uveitis cases and 1% of the pediatric cases. Anterior uveitis is the most common ocular manifestation and occurs in approximately two-thirds of patients with ocular sarcoid. The uveitis may be an acute iridocyclitis or a chronic granulomatous uveitis. Acute iridocyclitis with mutton-fat keratic precipitates is most often seen in patients with acute sarcoid but can be seen in those with chronic sarcoid as well. The prognosis is worse for those with chronic disease, who may develop complications such as secondary glaucoma, cataracts, macular edema, and visual loss. Iris nodules are occasionally seen in association with anterior uveitis in patients with sarcoidosis.

Conjunctival and corneal lesions such as band-shaped keratopathy are less common. These are generally described as conjunctival nodules, which on biopsy reveal the characteristic granuloma formation of sarcoidosis. Occasionally a nonspecific or phlyctenular keratoconjunctivitis is described in association with other mucocutaneous lesions of sarcoidosis. In addition, occasional cases of interstitial keratitis in association with sarcoidosis have been described.

The frequency of orbital, and particularly lacrimal gland, lesions varies widely among series and depends on the patient selection and investigations used. Clinical enlargement is present in less than one-third of patients with ocular sarcoid, but when sought,

keratoconjunctivitis sicca may be present in a greater percentage.<sup>31,34,55,82-84</sup> Orbital granuloma, independent of the lacrimal gland, occurs infrequently.<sup>86-88</sup> Massive lacrimal gland enlargement simulating a lacrimal gland tumor may occur and require orbitotomy and biopsy. Sarcoid granulomas may also manifest as a pseudotumor, affecting the orbital muscles along with the lacrimal gland resulting in swelling, diplopia and restriction of ocular motility.<sup>89-91</sup>

## Posterior Segment Disease

Posterior segment lesions are reported to occur in approximately 14–28% of patients with ocular sarcoid.<sup>6,14,31,34,54,55,82,83,92,93</sup> The actual frequency may be higher, since most patients with posterior segment disease also have anterior uveitis. Posterior lesions include vitritis, chorioretinitis, periphlebitis, vascular occlusion, retinal neovascularization, and optic nerve head granulomas.

Vitreous infiltration in patients with sarcoidosis can appear as cellular infiltration, often as a nonspecific vitritis. More classically, however, the lesions demonstrate clumping and an accumulation of vitreous debris, called either “snowballs” or a “string of pearls” (Fig. 81.1). These lesions may be somewhat similar in appearance to those seen in pars planitis, although snowball formation is generally not seen in sarcoid uveitis. Sarcoid granulomas can also present in the optic nerve, peripheral retina, pars plana, and anterior choroid and can be imaged by high-resolution ultrasound biomicroscopy as different forms of uveal thickening.<sup>94</sup>

**FIG. 81.1** Vitreous inflammation in a patient with sarcoidosis. (Courtesy of Vishali Gupta, MD).

Perivascular sheathing is the second most common finding and occurs in 10–17% of patients with ocular sarcoid. It is generally a midperipheral periphlebitis without significant vascular occlusion (Figs. 81.2 and 81.3). However, a few series have documented the occasional occurrence of occlusive retinal vascular disease, particularly branch retinal vein occlusion (Fig. 81.4). Central retinal vein occlusion is much less common. Histologic studies have demonstrated vascular compromise by the granulomatous inflammatory material.<sup>95,96</sup> More severe forms of periphlebitis have been called “candle-wax drippings” (*taches de bougie*). Arteriolar involvement is very unlikely in patients with sarcoidosis. Sanders and Shilling<sup>97</sup> have described an “acute retinopathy of sarcoidosis” with extensive perivascular sheathing, vascular occlusion, and intraretinal hemorrhages. These cases were complicated by subsequent retinal neovascularization.

**FIG. 81.2** (A, B) Perivascular sheathing in a patient with sarcoidosis. (Reproduced with permission from Green WR. Inflammatory diseases and conditions of the eye. In: Spencer WH, editor. Ophthalmic pathology: an atlas and textbook, vol. 3. Philadelphia, PA: WB Saunders; 1986.)

Inflammatory diseases and conditions of the eye. In: Spencer WH, editor. Ophthalmic pathology: an atlas and textbook, vol. 3. Philadelphia, PA: WB Saunders; 1986.)

**FIG. 81.4** Perifoveal branch vein occlusion in a patient with sarcoidosis.

Deeper chorioretinal lesions have also been reported. These can vary in size from small “Dalen–Fuchs-like” granulomas to large choroidal nodules simulating a metastatic tumor.<sup>98,99</sup> If located in the macular region, these lesions can cause severe visual loss. Exudative retinal detachments are rarely seen in patients with sarcoid uveitis but do occur in those patients with large nodular chorioretinal granulomas. These detachments appear to be an overlying detachment of the neurosensory retina.<sup>5,100</sup>

Visual loss can occur from epiretinal membrane formation and cystoid macular edema in patients with sarcoidosis. Once the inflammation has been controlled, pars plana vitrectomy with membrane peeling may have a beneficial effect on restoring vision, although development of cataract and membrane recurrence may require additional surgeries.<sup>101,102</sup> In one small uncontrolled case series, triamcinolone acetonide was injected into the vitreous cavity to assist the visualization of the vitreous for the vitrectomy,<sup>103</sup> but the role of this approach is uncertain. Complications of ocular sarcoidosis such as epiretinal membranes and macular edema may also be treated effectively using microincision vitrectomy (23- or 25-gauge systems) resulting in remission of ocular inflammation and improvement in visual acuity.<sup>104</sup>

Peripheral retinal neovascularization or neovascularization of the

optic nerve head is present in less than 5% of patients with ocular sarcoid, but can be associated with significant visual loss due to vitreous hemorrhage. Peripheral retinal neovascularization is generally seen in patients with a defined vaso-occlusive disorder such as a branch retinal vein occlusion. The peripheral neovascular lesions may even simulate a sea fan, similar to that seen in sickle-cell disease. Neovascularization of the disc may also develop after a branch or central vein occlusion. The rare occurrence of peripapillary choroidal neovascularization in the absence of uveitis or optic nerve disease has been reported, and described to be responsive to oral corticosteroids.<sup>103</sup> Doxanas and coworkers<sup>105</sup> described a patient with sarcoidosis and a steroid-responsive neovascularization of the optic nerve head without retinal nonperfusion (Fig. 81.5). Hoogstede and Copper<sup>96</sup> described one case of subretinal neovascularization, which they attributed to sarcoid uveitis. Duker et al.<sup>106</sup> reported the clinical features of proliferative sarcoid retinopathy in 11 eyes of seven patients. In these cases the new retinal vessels were associated with concomitant peripheral retinal capillary nonperfusion. The authors suggested that in these patients capillary nonperfusion secondary to microvascular shutdown, rather than a direct effect of inflammation, was the stimulus for the formation of retinal neovascularization.

**FIG. 81.5** Neovascularization of the optic nerve in a patient with sarcoidosis. Fundus photograph (A) and fluorescein angiogram (B) of the left eye, and fundus photograph (C) and fluorescein angiogram (D) of the right eye of a young female diagnosed with sarcoidosis. (Courtesy of Vishali Gupta, MD).

It has been reported that when posterior-segment involvement is seen in patients with sarcoid uveitis, there is an increased frequency of CNS involvement. In a retrospective review of the literature, Gould and Kaufman<sup>107</sup> suggested that the prevalence of CNS involvement increased from 2% to 30% when fundus lesions were found. However, Spalton and Sanders<sup>108</sup> found no such association, thus leaving the association not well confirmed.

Optic nerve involvement, particularly multiple granulomas of the optic nerve head, occur in 0.5–7.0% of patients with ocular sarcoid<sup>31,34,79,82,108</sup> (Fig. 81.6). Histologic descriptions have shown granuloma formation<sup>79,109</sup> (Fig. 81.7). Optic disc edema without granulomatous invasion of the optic nerve head may be seen in

patients either with chronic uveitis or with papilledema<sup>36</sup> from CNS sarcoid, mimicking conditions such as malignant hypertension.<sup>110</sup> Other manifestations include optociliary shunt vessels and macroaneurysms.<sup>111</sup> Occasionally, isolated sarcoid optic neuropathy (optic atrophy, optic neuritis, optic disc edema) may occur and may be the first manifestation of neurosarcoidosis.<sup>112-114</sup>

**FIG. 81.6** Optic nerve mass in a patient with sarcoidosis. (Courtesy of Robert Nussenblatt, MD.)

**FIG. 81.7** Granulomatous inflammatory mass coming from the optic nerve head in a patient with sarcoidosis (hematoxylin and eosin,  $\times 35$ ). (Reproduced with permission from Green WR. Inflammatory diseases and conditions of the eye. In: Spencer WH, editor. Ophthalmic pathology: an atlas and textbook, vol. 3. Philadelphia, PA: WB Saunders; 1986.)

In addition to these conventionally observable lesions, Mizuno and Takahashi<sup>115</sup> have used cycloscopy to document the common occurrence of lesions in the ciliary processes of patients with intraocular sarcoidosis. In their series, nodules of the ciliary processes were seen in 41% of eyes, waxy exudates in 24%, and cyclitic membrane-like exudates in 3%. Only 20% of eyes with intraocular sarcoid had no observable lesions.

## Diagnosis

Ocular sarcoidosis can present as a myriad of signs and symptoms. Such variability in presentation makes the diagnosis challenging and clinicians often need to resort to invasive diagnostic techniques in order to rule out or establish the diagnosis. In 2006 the scientific community came together at the first IWOS in Tokyo, Japan and established criteria for the diagnosis of ocular sarcoidosis when ocular changes are present in the presence or absence of clinical signs of systemic disease. These have been subsequently revised in

2009. The IWOS diagnostic criteria allow ophthalmologists to arrive at one of the following four conclusions with a minimally invasive approach: (1) definite; (2) presumed; (3) probable; and (4) possible ocular sarcoidosis. A summary of the 2006 IWOS diagnostic criteria and laboratory investigation is given in [Table 81.4](#). A proposed outline to the approach in evaluating a patient for possible ocular sarcoid is shown in [Fig. 81.8](#).

**TABLE 81.4**

**Clinical Signs, Laboratory Investigations, and Diagnostic Criteria Proposed by the International Workshop on Ocular Sarcoidosis (2006)**

<b>CLINICAL SIGNS SUGGESTIVE OF OCULAR SARCOIDOSIS</b>
<ol style="list-style-type: none"> <li>1. Mutton-fat KPs (large and small) and/or iris nodules at pupillary margin (Koeppe) or in stroma (Bussacca)</li> <li>2. ALAT, alanine aminotransferase; ASAT, aspartate aminotransferase; BCG, bacillus Calmette-Guérin; CT, computed tomography; GGT, gamma-glutamyl transferase; KPs, keratic precipitates; LDH, lactate dehydrogenase; PPD, purified protein derivative.

**FIG. 81.8** Schematic outline for the evaluation of patients with suspected sarcoidosis.

A survey of 24 uveitis specialists from around the world has suggested that a significant number of ophthalmologists use the IWOS criteria to establish a diagnosis of ocular sarcoidosis.<sup>116</sup> A recent study compared the ocular (such as tent-shaped peripheral anterior synechiae) and systemic findings (such as lung function

tests and bronchoalveolar lavage) findings in both biopsy and nonbiopsy proven cases of ocular sarcoidosis with the criteria proposed by IWOS ( $n=83$ ). The study results showed that employing the IWOS criteria provides high reliability in diagnosing ocular sarcoidosis.<sup>117</sup> Employing the IWOS diagnostic criteria allows for diagnosis in the absence of a biopsy, provides information for both the clinician and patient with regard to prognosis, and encourages nonspecialists to consider sarcoidosis as a putative diagnosis. Although there are limitations of the IWOS diagnostic criteria, they certainly help to limit the investigations that a patient with suspected sarcoidosis may have to undergo and help the caregiver to formulate a standardized approach towards establishing the diagnosis.

As is the case in any other form of uveitis, there needs to be a systematic approach to establishing a diagnosis of ocular sarcoidosis and ruling out its major differentials. Patients may present with no systemic disease. After carefully ruling out the possibility of an infectious cause of the uveitis, ophthalmologists may follow the IWOS criteria for diagnosis. However, if the clinical and ancillary evidence is not enough to commit to a diagnosis or rule out the possibility in patients with ocular sarcoidosis, a biopsy may be performed. It is important for the ophthalmologist to consider referring patients with suspected sarcoidosis to an internist whenever there is evidence of extrapulmonary involvement or the diagnosis of systemic disease needs to be confirmed.

## Course and Prognosis

Karma and coworkers<sup>83</sup> classified the course of ocular sarcoidosis as monophasic, relapsing, or chronic. The three different courses of uveitis correlated with visual outcome. Patients with monophasic uveitis retained 20/30 or better visual acuity in 88% of eyes, with relapsing uveitis in 72% of eyes, and with chronic uveitis in none of the six eyes. Similarly, those with monophasic uveitis had a visual acuity of 20/70 or worse in 12% of eyes, with relapsing uveitis in 28% of eyes, and chronic uveitis in 67% of eyes. Hence the course of uveitis appears to correlate with the long-term visual outcome.

The development of secondary glaucoma in association with sarcoid uveitis appears to be a poor prognostic sign and is associated with severe visual loss. In one series,<sup>82</sup> most of these patients had a panuveitis with both anterior- and posterior-segment involvement associated with the development of secondary glaucoma, suggesting a more severe ocular disease. Treatment should be directed towards promptly suppressing the inflammation and minimizing any potential ocular complications.

In a retrospective study of 60 patients with sarcoid-associated uveitis who were followed at a subspecialty eye care and referral center, Dana et al.<sup>118</sup> identified prognostic factors for visual outcomes in sarcoid uveitis. The factors most strongly associated with both a lack of visual acuity improvement and a final visual acuity worse than 20/40 were (1) delay in presentation to a uveitis subspecialist of greater than 1 year; (2) development of glaucoma; and (3) presence of intermediate or posterior uveitis. There was a substantial increase in the relative odds of both visual improvement and the likelihood of achieving a visual acuity of at least 20/40 among patients in whom systemic corticosteroids were used for treatment. Because patients with more severe disease are more likely to receive systemic corticosteroid therapy, this result strongly supports the use of systemic corticosteroids for selected patients with sarcoid uveitis. Miserocchi et al. evaluated the risk factors for visual outcomes in 44 patients retrospectively, and their multivariate results suggest that only the presence of cystoid macular edema was significantly associated with worse visual outcome.<sup>119</sup>

## Therapy

Treatment of any form of uveitis depends upon the initial presentation of the patient, severity of the disease, and accompanying complications. Nonetheless, the goals of therapy remain the same and include preservation of visual acuity, prompt identification of all sources of inflammation, zero tolerance toward any degree of inflammation, and proper management of complications such as macular edema, cataract, and glaucoma. The management of uveitis can be quite complex and may involve

employment of multiple therapeutic options, some of which do have potential significant and serious side-effects. A proposed outline for the management of ocular sarcoidosis is shown in Fig. 81.9. However, it is of the utmost importance to recognize that the approach to the management of each patient should be individualized. The proposed scheme only serves as a generalized recommendation. If there are any concerns regarding the diagnosis and management of a patient with ocular sarcoidosis, it may be beneficial for the patient if he/she can be referred to a uveitis specialist who is experienced in managing the disease.

**FIG. 81.9** Proposed treatment algorithm for patients with ocular sarcoidosis.

## Established Therapy

Treatment of the anterior uveitis associated with sarcoidosis is generally achieved with intensive topical corticosteroids, which may require several months to reach quiescence. In some patients with refractory anterior uveitis, the judicious use of oral corticosteroids may be necessary to suppress the inflammation. Patients with sarcoidosis generally respond to corticosteroid therapy, but chronic therapy may be necessary. Posterior-segment lesions in sarcoidosis generally require the use of systemic corticosteroids. Dosages are often in the range of prednisone 40–80 mg/day initially. Maintenance therapy with systemic corticosteroids should be less than 5 mg/day of prednisone or equivalence. Posterior-segment lesions such as perivascular sheathing and peripheral chorioretinal nodules that are not associated with visual loss may not mandate oral corticosteroid therapy. However, vascular occlusion, neovascularization, macular mass lesions, and optic disc lesions may produce profound visual loss and most likely require corticosteroid therapy.

Although corticosteroids are very effective in controlling inflammation initially, their long-term use is often associated with significant complications and side-effects. The use of steroid-sparing agents is indicated if chronic steroid usage ( $\geq 5$  mg of prednisone or equivalent daily) is required to control the inflammation. Corticosteroid-sparing agents such as hydroxychloroquine, methotrexate, azathioprine, mycophenolate mofetil, or cyclosporine may be useful in patients with corticosteroid-dependent sarcoidosis in whom corticosteroid side-effects are problematic;<sup>120–123</sup> however, their usages may not be without risk. Patients being treated with these agents, including corticosteroids, require very thorough and experienced clinical oversight by specialists (such as uveitis specialists, rheumatologists, or oncologists) who are familiar with employing such classes of drugs.

Methotrexate,<sup>124</sup> azathioprine,<sup>125,126</sup> and mycophenolate<sup>127</sup> have been widely employed as steroid-sparing agents in the management of chronic uveitis. In a retrospective series of 386 patients, methotrexate was found to control uveitis in 66% of patients.<sup>128</sup> A delay of up to 6 months in response to therapy with methotrexate has also been reported, which has prompted the use

of intraocular injections of the drug.<sup>125</sup> Azathioprine has been reported to be beneficial in patients with ocular sarcoidosis who do not respond to methotrexate. However, in a retrospective study of patients with intermediate uveitis, a 25% rate of discontinuation was noted within the first year of therapy due to toxicity. The use of azathioprine is permitted in pregnant women with several precautions. Mycophenolate mofetil has shown promising results in terms of low toxicity. Deuter et al.<sup>127</sup> reported a success rate of 86% in patients with chronic uveitis treated with mycophenolate with a discontinuation of only 5% due to toxicity. A small series of seven patients diagnosed with sarcoidosis has also reported the drug to be beneficial.<sup>129</sup> Galor et al. reported a response rate of 70%, 42%, and 58% at 6 months for mycophenolate mofetil, methotrexate, and azathioprine, respectively, in 321 patients with nonspecific ocular inflammation.<sup>130</sup> Although the time to response for azathioprine and mycophenolate was similar, the former had more toxicity-related events reported.

Other immunomodulatory therapeutic agents have been employed in the management of sarcoidosis. Baughman and Lower reported a 58% complete and 28% partial improvement in patients with ocular sarcoidosis when treated with leflunomide. Only two of the 28 patients discontinued therapy due to toxicity in this study.<sup>131</sup>

## Biologic Agents

Biologics, antagonists of tumor necrosis factor (TNF) such as adalimumab (humanized monoclonal antibody), infliximab (chimeric monoclonal antibody), and etanercept (soluble TNF receptor antagonist) have been reported in small studies to benefit patients with chronic uveitis.<sup>132-136</sup> However, there is a lack of evidence from clinical trials supporting the use of adalimumab and infliximab, while it has been shown in a double-masked randomized clinical trial that etanercept is no better than placebo when treating chronic uveitis.<sup>92,93</sup> Several groups have also reported the development of uveitis in patients receiving anti-TNF therapy<sup>135,137-139</sup> at a significantly higher rate, with etanercept followed by infliximab and adalimumab.<sup>140</sup> Although the mechanism of this phenomenon is not yet fully understood, several

reports of anti-TNF therapy leading to a sarcoidosis-like reaction suggest that a very cautious approach should be taken when using these agents to treat ocular sarcoidosis.

## Conclusion

Sarcoidosis is a multiorgan disease with protean manifestations, including ocular involvement. Throughout the years, significant advancements have been made toward the understanding of the pathogenesis of sarcoidosis; however, the etiology of the disease is not completely elucidated. Evidence suggests that the pathophysiology most likely involves T cells. Sarcoid is one of the most common causes of uveitis of all types – anterior, intermediate, and/or posterior. Therefore, it is important for ophthalmologists to recognize that ocular manifestations may be the initial presentation of a patient with sarcoidosis.

The IWOS has established criteria for the diagnosis of ocular sarcoidosis when ocular changes are present in the presence or absence of clinical signs of systemic disease. Such criteria are helpful and should be considered in establishing the diagnosis and asserting its certainty. Managing a patient with ocular sarcoid will depend on whether the disease is unilateral or bilateral, whether there is presence or absence of systemic involvement, and how such involvements are at the time of the ocular disease. It is important for ophthalmologists caring for patients with ocular sarcoid to collaborate with internists, pulmonologists, and sarcoid specialists to provide patients with comprehensive and complete care.

There are existing therapeutic options and approaches that may be used in bringing the disease into quiescence, which should be the goals for both ocular and systemic diseases. In addition, potential new drugs are currently in development that may lead to disease quiescence with fewer side-effects and complications in the future.

## **Introduction**

## **Epidemiology and Demographics**

## **Presentation and Clinical Findings**

## **Imaging**

## **Differential Diagnosis and Workup**

## **Histopathology and Pathophysiology**

## **Treatment**

## **Clinical Course and Complications**

## **Introduction**

Intermediate uveitis is defined anatomically, according to the Standardized Uveitis Nomenclature working group, as intraocular inflammation in which the primary site is the vitreous, but it commonly involves the peripheral retina as well.<sup>1</sup> The origin of the inflammatory cells includes the ciliary body pars plana, the peripheral retinal vessels, and the peripheral choroid. Previously used terminology for this entity includes pars planitis, peripheral uveitis, peripheral cyclitis, hyalitis, and vitritis. The term “pars planitis” now specifically refers to a subcategory of idiopathic intermediate uveitis characterized by the presence of snowbanks

and snowballs, which will be described in more detail below.

## Epidemiology and Demographics

Because the currently used nomenclature for uveitis was agreed upon in 2005, prevalence and incidence figures for this anatomic category of uveitis are sparse. Although various groups have reported the frequency of intermediate uveitis in their uveitis practices, ranging from 4 to 15.4%, these figures are subject to referral bias since the reports originate from tertiary care referral clinics.<sup>2-6</sup> In pediatric uveitis, it accounts for up to 25% of cases.<sup>7,8</sup> The overall population prevalence of different types of uveitis based on anatomic location, including intermediate uveitis, has been investigated in several population studies since 2005. Gritz and Wong found a prevalence ratio for intermediate uveitis of 4.0 per 100,000 persons in a cross-sectional retrospective study using a database of individuals in northern California receiving care through a single large health-maintenance organization.<sup>9</sup> The incidence was 1.5 per 100,000 person-years. These figures were reported with the stipulation that the prevalence may have been underestimated because a significant proportion of included patients did not have dilated fundus examinations, and the anatomic uveitis location was, therefore, unknown. Another study utilizing the Veterans Affairs database in the Pacific Northwest region found that the prevalence of intermediate uveitis was approximately 3.3 per 100,000 persons.<sup>10</sup> The annual incidence of pars planitis in Olmstead County, Minnesota, was 2.08 per 100,000 persons.<sup>11</sup>

Although intermediate uveitis can occur at any age, it tends to occur in a younger age range. Average age of onset was 31 years (range 8–64 years) in one study,<sup>12</sup> and 30 years (range 6–76 years) in another.<sup>13</sup> There appears to be no gender predilection for this anatomic subtype of uveitis, although certain entities that can cause intermediate uveitis, such as sarcoidosis, have a strong female bias.<sup>14</sup> In certain uveitis practices, such as that reported by Thorne and colleagues, intermediate uveitis appears to be slightly more common in women (66.4%).<sup>13</sup> Racial predilection likely depends on the etiology, but there appears to be no race preference in pars

planitis.

## Presentation and Clinical Findings

The most common symptoms of intermediate uveitis include blurry vision and floaters, whereas pain, redness, and photophobia are less common than in other types of uveitis. Although typically bilateral over time (74.5–80% bilateral),<sup>3,12,13,15</sup> it is frequently asymmetric and may begin unilaterally. Findings on clinical examination at onset include anterior vitreous cells or diffuse vitreous haze, and, to a lesser extent, anterior chamber involvement. Vitreous haze is graded on a scale of 0–4+ based on the level of optic nerve and retinal vessel obscuration.<sup>16</sup> Snowballs (see below for discussion on histopathology) are whitish inflammatory vitreous opacities in clusters frequently found in the inferior vitreous cavity (Fig. 82.1). Snowbanks are identified as whitish-gray confluent preretinal membranes most commonly seen along the inferior pars plana, and peripheral retina (Fig. 82.2A). Over time, these may develop into organized fibrovascular membranes that are prone to vitreous hemorrhage and retinal detachment. The vascular component of this snowbank is continuous with the retinal vessels (Fig. 82.2B). Commonly, a peripheral vasculitis manifested by perivascular sheathing is seen in intermediate uveitis and may indicate an increased probability of associated systemic disease.<sup>12</sup> According to one study, periphlebitis in the setting of intermediate uveitis was associated with an increased rate of multiple sclerosis (MS) or optic neuritis (Fig. 82.3).<sup>17</sup> It is important to note that sarcoidosis can also present as an isolated periphlebitis or as granulomatous inflammation in the form of snowballs. Periphlebitis in sarcoidosis can present with a wide spectrum of appearances, from scant focal periphlebitis to exudative candle-wax drippings (taches de bougie) (Fig. 82.4). Yellowish peripheral punched-out chorioretinal lesions that might represent active or old choroidal granulomas are highly suspicious for sarcoidosis, although once these are present, the anatomical designation is panuveitis rather than intermediate uveitis. Obliterative peripheral vasculitis may result in peripheral neovascularization and resultant vitreous hemorrhage (Fig. 82.5). Cystoid macular edema (CME) is a common finding, occurring in

over 40% of individuals at diagnosis of intermediate uveitis (Fig. 82.6).<sup>13</sup> Campbell et al. demonstrated that peripheral vascular leakage (PVL) seen on ultra-wide-field fluorescein angiography in eyes with uveitis, including those with intermediate uveitis, may be associated with higher rates of ocular complications such as CME, at least at the time of discovery of the PVL.<sup>18</sup> Clinically apparent optic nerve edema also occurs in a small percentage of patients with intermediate uveitis. Other noteworthy complications include retinoschisis (Fig. 82.7), which occurs in pars planitis frequently, and exudative retinal detachment.<sup>19</sup>

**FIG. 82.1** Snowballs seen in the inferior and mid-vitreous cavity in a 14-year-old boy with pars planitis.

**FIG. 82.2** Inferotemporal pars plana snowbank in a patient with idiopathic unilateral pars planitis. (A) Ultrawide-field fundus image. Snowbank noted by *white arrow*. (B) Retinal vessel (*red arrow*) incorporated into snowbank in magnified view of snowbank from same patient as in panel A.

**FIG. 82.3** Ultrawide-field fluorescein angiography of (A) right and (B) left eyes of a 31-year-old woman presenting with bilateral asymmetric intermediate uveitis, who was later diagnosed with multiple sclerosis. In panel A *white arrows* show peripheral vascular leakage. In panel B *red arrows* show peripheral nonperfusion (*long solid arrow*) and early retinal neovascularization (*short dotted arrow*). Panel B also demonstrates diffuse retinal venular leakage.

**FIG. 82.4** (A) Focal periphlebitis (*arrows*) in a patient with sarcoid intermediate uveitis. (B) Granulomatous exudative periphlebitis (candle-wax drippings or taches de bougie in intermediate uveitis due to sarcoidosis).

**FIG. 82.5** Peripheral nonperfusion and neovascularization (NV) in 2 patients with sarcoidosis-associated intermediate uveitis. (A) Wide-field fluorescein angiography showing severe peripheral nonperfusion (*short arrows*) and an early neovascular tuft (*long arrow*). (B) Advanced peripheral NV (*arrow*).

**FIG. 82.6** Spectral domain optical coherence tomography demonstrating unilateral cystoid macular edema in a patient with intermediate uveitis before (A) and after (B) treatment with a posterior sub-Tenon Kenalog injection. This patient also has an epiretinal membrane causing a stellate configuration of thickening of the retina.

**FIG. 82.7** (A) Pars plana snowbank and schisis demonstrated by ultrasound biomicroscopy, and retinoschisis on B-scan ultrasound (B), both from the same 7-year-old boy with pars planitis.

## Imaging

Although the majority of cases of intermediate uveitis are diagnosed by clinical examination, various imaging modalities give useful adjunctive information to guide diagnosis and management. For instance, in the setting of media opacity from cataract, ultrasound biomicroscopy (UBM) can be used to detect pars plana exudates (Fig. 82.7). Identification of cyclitic membranes by UBM can be of great value in preoperative planning. B-scan ultrasonography can be used to diagnose and measure macular thickening with a great degree of accuracy, sensitivity, and specificity in the setting of media opacity or intolerance to

fluorescein angiography and optical coherence tomography (OCT).<sup>20</sup> B-scan can also be used to document the extent of retinoschisis (Fig. 82.7). Fluorescein angiography is useful to detect CME, vasculitis, peripheral nonperfusion, and peripheral neovascularization (see Fig. 82.3). OCT is important to identify and follow CME as a gauge of disease activity in intermediate uveitis.<sup>21</sup> In some cases, concentric macular retinal thickening without frank CME, as determined by OCT, can be used to monitor response to treatment.<sup>22</sup>

## Differential Diagnosis and Workup

The cause of intermediate uveitis can be determined by investigating the presence of systemic findings or historical clues. Although the vast majority of cases are idiopathic (nearly 70%),<sup>23</sup> the most common known inflammatory etiologies include sarcoidosis and MS, whereas infectious causes can include syphilis, Lyme disease, and tuberculosis (Box 82.1). Pars planitis is, by definition, idiopathic intermediate uveitis characterized by the presence of snowbanks and snowballs. Thorne et al. found that 36% of their intermediate uveitis patients had pars planitis.<sup>13</sup> In one study by Rodriguez et al., 22.2% of cases of intermediate uveitis at a referral center were due to sarcoidosis, whereas 8.0% were due to MS.<sup>23</sup> One out of 112 cases at this center was due to Lyme disease.

**Box 82.1** In other studies, 14.8 and 16.2%, respectively, had MS.<sup>17,24</sup>

## Differential Diagnosis of Intermediate Uveitis

### Infectious

- Lyme disease (*Borrelia burgdorferi*)
- Syphilis (*Treponema pallidum*)
- Toxocariasis (*Toxocara canis*)
- Toxoplasmosis (*Toxoplasma gondii*)

- Tuberculosis (*Mycobacterium tuberculosis*)
- Cat-scratch disease (*Bartonella, Rochalimaea*)
- Whipple's disease (*Tropheryma whippelli*)
- HTLV-1
- Hepatitis C
- Epstein–Barr virus
- Endophthalmitis (*Propionibacterium acnes*, indolent fungal infection)

### Immune

- Sarcoidosis
- Multiple sclerosis
- Inflammatory bowel disease
- Behçet disease
- Idiopathic
- Pars planitis

### Masquerade

- Lymphoma (usually B-cell, NHL)
- Leukemia
- Amyloidosis
- Other neoplasms: retinoblastoma, uveal melanoma
- Irvine–Gass syndrome (CME with subtle inflammation)

HTLV-1, human T-lymphotropic virus-1; NHL, non-Hodgkin's lymphoma; CME, cystoid macular edema.

Tests that warrant investigation in all patients with intermediate uveitis include rapid plasma reagin and fluorescent treponemal antibody absorption test to test for syphilis, chest radiography, angiotensin-converting enzyme (ACE), and tuberculin skin test with anergy panel to evaluate sarcoidosis and tuberculosis. If clinical suspicion is high for sarcoidosis in the setting of a negative ACE and chest radiograph, one should consider a gallium scan, pulmonary function tests, or a chest computed tomography scan. A careful review of systems should be performed to determine if there are risks associated with MS, including urinary retention, neurologic weakness or symptoms, or evidence of previous optic neuritis (Table 82.1).<sup>25</sup> In a significant number of patients, as is the case in our experience, pars planitis can be the first manifestation of a central nervous system demyelinating process, so it is important to elicit the appropriate history and keep a low threshold for the diagnosis of MS. Because there is growing evidence that early treatment of MS with systemic interferon therapy may reduce long-term disability, it is important to consider this systemic association seriously upon initial presentation.<sup>26–28</sup> Evaluation by a neurologist, magnetic resonance imaging (MRI) of the brain, and cerebrospinal fluid studies should be considered in new-onset intermediate uveitis, even without the above symptoms, given that early disease can be asymptomatic.

**TABLE 82.1**  
**Systemic Symptoms and Signs of Multiple Sclerosis by Site**

Anatomic Location	Symptoms	Signs
Cerebrum	Cognitive impairment	Deficits in attention, reasoning, and executive function; dementia (late)
	Depression	Flat affect
	Hemisensory and motor	Upper motor neuron signs
Optic nerve	Unilateral vision loss	rAPD, Uhthoff phenomenon (exacerbation in hot temperatures), Pulfrich effect (difficulty judging path of oncoming cars)
Cerebellum	Tremor	Action tremor
	Clumsiness and poor balance	Gait ataxia

Brainstem	Diplopia, oscillopsia	INO, nystagmus
	Vertigo	
	Impaired swallowing	
	Impaired speech	
Spinal cord	Weakness	Spasticity, Lhermitte's sign (painful electric-shock sensation down spine upon neck flexion)
	Stiffness and painful spasms	
	Bladder dysfunction	
	Retention	
	Frequency, urgency	
Other	Pain	
	Fatigue	
	Temperature sensitivity and exercise intolerance	

INO, internuclear ophthalmoplegia; rAPD, relative afferent papillary defect.

Modified from Compston A, Coles A. Multiple sclerosis. *Lancet* 2008;372:1502–17.

If there is a history of exposure to deer or ticks, especially if the patient lives or travels in an endemic area, and there is an associated history of a target lesion or systemic flu-like symptoms, then *Borrelia burgdorferi* antibody should be tested. Exposure to cats might prompt serum antibody testing for *Bartonella*.<sup>29</sup> In the elderly population, intraocular lymphoma should be suspected and there should be a lower threshold to perform diagnostic vitrectomy, especially if there is limited response to corticosteroids.<sup>30,31</sup> If intraocular lymphoma is highly suspected, a lumbar puncture for cytologic evaluation of the cerebrospinal fluid and neuroimaging are adjunctive diagnostic tests to consider. Bilateral pars planitis has been found in patients who have human T-cell lymphotropic virus type 1 (HTLV-1) infection, which is endemic in Japan, the Caribbean islands, parts of Central Africa, and South America.<sup>32</sup> The latter can be diagnosed with serologic testing for antibodies against HTLV-1. Gastrointestinal disturbances associated with a pars planitis-like clinical presentation should prompt referral to a gastroenterologist since it has been reported in association with inflammatory bowel disease and Whipple's disease.<sup>33,34</sup> Other masquerade syndromes, such as intermediate uveitis secondary to tumor necrosis from retinoblastoma or uveal melanoma or even metastasis from other types of systemic cancer, must be evaluated in the appropriate clinical settings.<sup>35</sup> Finally, mild vitritis and CME in the setting of recent cataract surgery should prompt consideration of pseudophakic CME. One should consider indolent

endogenous or exogenous endophthalmitis as a possibility if there is a poor response or worsening with corticosteroids in the setting of the appropriate risk factors, such as immunocompromised state or recent intraocular surgery.

## Histopathology and Pathophysiology

On histopathologic examination, snowballs are isolated vitreous granulomas consisting of lymphocytes, macrophages, epithelioid cells, and multinucleated giant cells.<sup>36</sup> Snowbanks consist of collapsed vitreous collagen, membranous fibroglial cells, blood vessels, and lymphocytes, as well as hyperplastic pars plana nonpigmented epithelium.<sup>37</sup> Periphlebitis is denoted by lymphocytic infiltration and cuffing of the peripheral retinal venules.<sup>36</sup> Because the term “intermediate uveitis” is an anatomic designation, one should avoid assigning a single etiologic or pathophysiologic process to it given that various systemic diseases and infectious processes can result in inflammation in this anatomical location. The pathogenesis of the autoimmune causes of intermediate uveitis involves overlapping principles, as well as some distinguishing characteristics, and will be discussed here for pars planitis and sarcoidosis.

### Pars Planitis

Although it is thought that noninfectious intermediate uveitis arises from an autoimmune response, the antigenic stimulus has not yet been clearly identified. Bora et al. described a novel 36 kDa nucleopore complex protein that was found to be six to eight times higher in the sera of 81% of active pars planitis patients compared with controls ( $p < .05$ ).<sup>38</sup> The exact function of this protein and its role in the pathogenesis of pars planitis are unknown, although there are indications that other nucleopore complex proteins may be involved in myeloid leukemogenesis and autoantibody formation.<sup>39,40</sup> Wetzig et al. found that endstage idiopathic intermediate uveitis in a familial case of bilateral intermediate uveitis was characterized immunopathologically by a predominance of CD4<sup>+</sup> T lymphocytes and overwhelming

predominance of glial cells in the pars plana snowbank; the latter is a characteristic unique to this type of uveitis.<sup>41</sup> It has been proposed that pars planitis represents a similar pathoetiologic entity as MS, although with expression either isolated to the eye or starting in the eye.<sup>42</sup> Indeed, patients with MS have increased circulating CD54<sup>+</sup> lymphocytes and antibodies that recognize glial proteins.<sup>43</sup> Raja et al.<sup>24</sup> discovered that a human leukocyte antigen (HLA)-DR15 allele, which is known to be associated with MS, was significantly associated with pars planitis compared with controls (odds ratio, 2.86;  $p=0.004$ ). Although no specific autoantigen has been clearly determined, components of vitreous, in addition to the glial elements mentioned above, have been implicated. Circulating lymphocytes isolated from pars planitis patients appear to proliferate in response to type II collagen.<sup>37</sup> Furthermore, Hultsch produced a clinical entity similar to pars planitis by giving owl monkeys multiple intravitreal injections of hyaluronic acid.<sup>44</sup>

Interleukin (IL-)8, a cytokine that is involved in neutrophil and T-lymphocyte recruitment, and soluble intercellular adhesion molecule 1 (sICAM-1), which is expressed at sites of inflammation to aid in leukocyte adhesion and migration, were elevated in the blood of patients with intermediate uveitis compared to controls. Furthermore, elevated sICAM-1 and IL-8 were associated with development of systemic disease. Elevated IL-8 was associated with signs of inflammatory activity such as periphlebitis and the presence of vitreous exudates. Rather than explaining the pathogenesis of this ocular condition, these markers may be indicators of systemic disease or activity, even in the absence of systemic symptoms.<sup>45,46</sup>

## Sarcoidosis

Sarcoidosis is also thought to be a CD4<sup>+</sup> T-lymphocyte-mediated process in the eye and in other actively affected tissues. Efforts to elucidate an infectious cause for sarcoidosis have met with little success. Patients with active sarcoidosis have a predominantly Th1 cytokine profile with elevated levels of IL-2 and interferon-gamma, and diminished levels of IL-4. Despite the predominance of CD4<sup>+</sup> T cells in ocular tissues affected by the disease, elevated peripheral

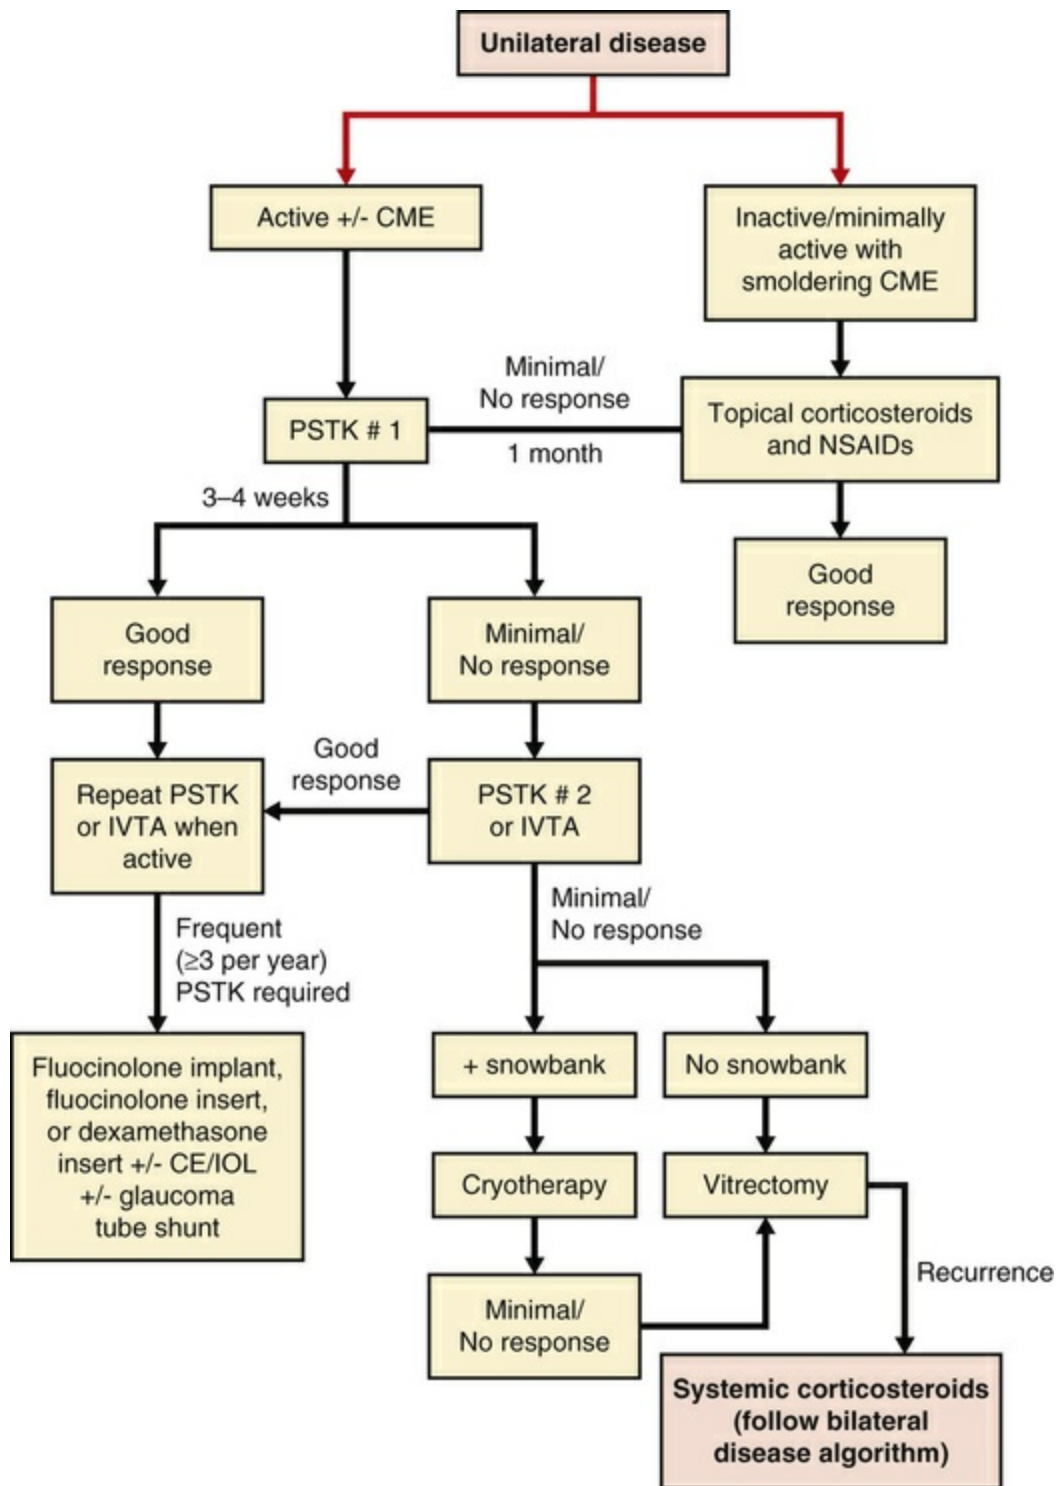

levels of immunoglobulin, B-cell hyperactivity in the peripheral blood, and a loss of delayed-type hypersensitivity to the tuberculin skin test (anergy) argues for an unusual partitioning of the immune response.<sup>43,47</sup> We have found that approximately 50% of patients with sarcoid-associated uveitis are anergic to delayed-type hypersensitivity testing.<sup>48</sup> The latter observations underline the importance of an anergy panel to accompany a tuberculin skin test in the initial workup of intermediate uveitis. HLA associations in sarcoidosis also differ from pars planitis and have not been clearly elucidated. In one study by Rossman et al., ocular sarcoidosis was associated with the HLA-DRB1\*0401 allele in both blacks and whites.<sup>49</sup>

## Treatment

### Unilateral Disease

Once an infectious cause has been ruled out, the primary treatment of choice is corticosteroids. If an underlying systemic condition is suspected, then systemic treatment with appropriate referral to a rheumatologist or infectious disease specialist is warranted. For unilateral noninfectious intermediate uveitis in the absence of systemic disease, periocular corticosteroids are initiated (Fig. 82.8), although some clinicians utilize systemic steroids. In our practice, posterior sub-Tenon Kenalog is given at 40 mg/mL, 1 mL total. If there is little to no response in 3–4 weeks, a second injection can be given, or alternatively, if the patient is pseudophakic and does not have glaucoma, an intravitreal injection of preservative-free triamcinolone acetonide can be offered. If smoldering uveitic CME is present without other evidence of active inflammatory disease, a trial of topical corticosteroids in combination with nonsteroidal antiinflammatory drops can be applied prior to considering either periocular or intravitreal corticosteroids.<sup>50</sup> Topical difluprednate is also very effective in treating uveitic CME associated with intermediate uveitis, but causes a higher rate of elevated intraocular pressure than prednisolone acetate and was as high as 50% in pediatric uveitis patients in one study.<sup>51</sup> Alternatively, bevacizumab has been investigated for its efficacy in treating uveitic CME. In a

study comparing intravitreal bevacizumab with intravitreal triamcinolone acetonide for uveitic CME, after removing the effect on cataract formation the triamcinolone group appeared to have significantly better visual acuity outcomes. Triamcinolone was also more effective in reducing macular thickness than bevacizumab.<sup>52</sup>

**FIG. 82.8** Treatment algorithm for unilateral disease. CME, cystoid macular edema; PSTK, posterior sub-Tenon Kenalog; IVTA, intravitreal triamcinolone acetonide; CE/IOL, cataract extraction with intraocular lens implant; NSAIDs, nonsteroidal antiinflammatory drugs.

If the patient has benefited from periocular or intraocular corticosteroid, but has documented recurrence when the corticosteroids have waned, then a corticosteroid intravitreal implant can be considered, especially if the patient is already pseudophakic (Fig. 82.9). If the patient is phakic, combined lens extraction, intraocular lens implantation, and insertion of a fluocinolone acetonide sustained drug delivery system (Retisert) can be performed.<sup>53</sup> If the patient has known glaucoma, then combined glaucoma tube shunt and fluocinolone implant surgery should be considered and has been found to be effective.<sup>54</sup> In young patients, combined surgery should proceed only after achieving relative quiescence given the robust inflammatory response after incisional surgery and careful consideration of the loss of accommodation that will occur after removing the crystalline lens. Alternatively, a dexamethasone intravitreal insert (Ozurdex)<sup>55</sup> or the fluocinolone acetonide nonbiodegradable insert (Iluvien) can be injected through the pars plana into the vitreous cavity to circumvent the need for incisional surgery, although the latter is not yet FDA approved for the treatment of uveitis. If there is little to no response after two corticosteroid injections (either posterior sub-Tenon or intravitreal), then therapeutic/diagnostic vitrectomy can be considered. If a snowbank is present, cryotherapy can be applied but tends to be more effective if applied to 3 clock-hours or less of snowbanking.<sup>56</sup> Peripheral laser photocoagulation has also been used to treat pars planitis, resulting in a decrease in the amount of corticosteroid needed and in decreased vitritis, although the rate of epiretinal membrane increased.<sup>57</sup> If peripheral neovascularization occurs, then targeted peripheral laser to areas of nonperfusion is indicated. Finally, oral prednisone can be used, applying the algorithm for bilateral disease below.

**FIG. 82.9** Fluocinolone acetonide implant placement.

## Bilateral Disease

Bilateral disease usually warrants treatment with systemic corticosteroids, starting at 1 mg/kg per day tapered to the lowest levels required to achieve quiescence over a 2-month period. If greater than 10 mg of oral prednisone is required for longer than 4 months, or when treating children, in whom long-term corticosteroids can cause growth retardation, steroid-sparing immunosuppressives should be initiated (Fig. 82.10). If one is not aware of the systemic risks or does not choose to monitor appropriately for systemic risks, referral to or co-management with an internist or rheumatologist is highly recommended.

**FIG. 82.10** Treatment algorithm for bilateral disease.

We have had good success treating sarcoidosis-associated intermediate and panuveitis with methotrexate starting at 12.5–15 mg PO weekly and escalating to 25 mg PO weekly, along with folic acid, 1 mg/day. Dosage is based on treatment response and tolerability. Because of its relative safety in children, methotrexate is often used as a first-line agent with a short course of bridging corticosteroids. It should be noted that methotrexate should not be used in pregnancy given its teratogenicity and fetal abortive effects. Common side-effects of methotrexate include nausea, vomiting, and oral stomatitis. If gastrointestinal side-effects prevent oral dosing, intramuscular or subcutaneous injections can be administered instead. Hepatotoxicity, cytopenia, and interstitial pneumonitis can also occur with methotrexate use. Liver function tests and complete blood counts are evaluated before initiation of therapy and should be monitored every 8–12 weeks thereafter. The

dose of methotrexate should be reduced if the aspartate aminotransferase or alanine aminotransferase level is more than twice normal on two separate occasions, but any elevation may warrant at least dose reduction. In the first study on the use of methotrexate in ocular sarcoidosis, 100% of 11 patients decreased their dosage of corticosteroids, 86% successfully discontinued prednisone, and 90% had preserved or improved visual acuity, although all patients in this study had panuveitis rather than isolated intermediate uveitis.<sup>58</sup> In a multicentered retrospective study in which methotrexate was used to treat noninfectious uveitis patients of all anatomical subtypes, methotrexate was found to be moderately effective in controlling inflammation, although the side-effect profile was beneficial.<sup>59</sup> Information regarding the effectiveness of methotrexate on the intermediate uveitis subgroup in the latter study was difficult to interpret given that 76.2% were inactive at the time of starting methotrexate.

In patients unable to tolerate methotrexate or who fail to achieve treatment success on this agent, other antimetabolites, including azathioprine or mycophenolate mofetil, can be initiated. Galor et al. compared the three antimetabolites in the treatment of noninfectious ocular inflammation in a retrospective cohort study. They suggested that mycophenolate mofetil controlled inflammation more rapidly than methotrexate, when “control of inflammation” was defined by quiescent inflammation on  $\leq 10$  mg oral prednisone.<sup>60</sup> There were several caveats in the latter study, however, including significantly younger age in the methotrexate group and the use of prior immunosuppressive drug therapy in the azathioprine and mycophenolate groups. If antimetabolites are minimally effective, a course of cytotoxic agents (cyclophosphamide or chlorambucil) or T-cell inhibitors (cyclosporine) can be given with close attention to toxic side-effects. Alternatively, the tumor necrosis factor-alpha (TNF- $\alpha$ ) inhibitors adalimumab or infliximab can be initiated in combination with methotrexate,<sup>61</sup> although it is important to note that there are a number of reports of these biologics causing demyelinating disease such as MS and progressive multifocal leukoencephalopathy.<sup>62</sup> Because they have also been implicated in the reactivation of latent tuberculosis,<sup>63</sup> an updated tuberculin skin test should be performed

prior to initiating these drugs. If the patient is anergic to the tuberculin skin test due to sarcoidosis, a quantiFERON tuberculosis test can be performed.<sup>64</sup>

The anti-IL-2 receptor biologic daclizumab and infliximab have both been used to treat ocular sarcoidosis with success.<sup>65,66</sup> Etanercept is a TNF-alpha inhibitor that is no longer used as often in the treatment of uveitis since it has been associated with increased inflammation or lack of ocular inflammation control. In one study of 22 uveitis patients who received anti-TNF- $\alpha$  therapy, infliximab was more effective than etanercept in controlling ocular inflammation.<sup>67</sup> It is possible that other biologics targeting additional inflammatory cytokines such as IL-6 (e.g., tocilizumab), may prove to be successful in the treatment of noninfectious intermediate uveitis as well.<sup>68</sup>

The results of the Multicenter Uveitis Steroid Treatment trial, comparing systemic antiinflammatory therapy with the fluocinolone acetonide surgical implant for intermediate, posterior, and panuveitis<sup>69</sup> demonstrated no significant difference in visual acuity outcome at 24 months, but improved control of uveitis activity, vitreous haze, and a trend towards better control of CME in the implant group. The rate of ocular complications, such as elevated intraocular pressure requiring glaucoma surgery or cataracts, was significantly higher in the implant group, as expected, whereas adverse systemic events, while infrequent in both groups, were slightly lower in the implant group, although the risk of hospitalization did not differ between the two groups.<sup>69</sup> The MUST follow-up study showed similar results out to 54 months, although a 21% crossover rate from systemic immunosuppression to the implant after the initial study ended suggests possible underestimation of the advantages of the implant group.<sup>70</sup> Also, while the implant group had a more rapid reduction in macular edema at 6 months, by 48 months the two groups were similar. The irreversible damage that can occur to the retina with macular edema would argue for faster control with the implant. Given the relative costs of the two treatment paradigms, it would be reasonable to consider implant therapy for unilateral noninfectious intermediate, posterior, or panuveitis cases in which there are no systemic manifestations of disease, or any cases in which systemic

treatment fails or is intolerable, as long as ocular side-effects such as glaucoma are treated aggressively.

## Diagnostic and Therapeutic Vitrectomy

Diagnostic and therapeutic vitrectomy is considered in patients who are not responsive to the above treatment regimens or if intraocular lymphoma is highly suspected. In a prospective randomized study, Tranos et al. demonstrated better visual acuity and improved fluorescein angiographic CME characteristics after vitrectomy, compared with standard medical therapy consisting of systemic corticosteroids and immunosuppressives. However, this study was underpowered to achieve statistical significance.<sup>71</sup> A number of other studies also appear to show a moderate level of success in treating CME with pars plana vitrectomy, which is thought to be effective by debulking soluble and cellular vitreous inflammatory mediators and by allowing easier access to the vitreous cavity of aqueous inhibitory molecules such as transforming growth factor- $\beta$  and alpha-melanocyte-stimulating hormone.<sup>72-74</sup> We perform a diagnostic vitrectomy if an infectious source such as herpetic viral infection or toxoplasmosis is suspected but cannot be confirmed using other methods, or if intraocular lymphoma is suspected, in which case the specimen is sent for cytopathologic evaluation and/or flow cytometry. If intraocular lymphoma is diagnosed, a neurologic workup and MRI may be necessary to determine if there is central nervous system disease. If isolated to the eye or in the setting of central nervous system lymphoma with a recurrence restricted to the eye, orbital irradiation or intravitreal rituximab alone or in combination with methotrexate can be administered with success.<sup>75-77</sup>

## Clinical Course and Complications

### Clinical Course

Patients with inflammatory intermediate uveitis often have a favorable visual acuity outcome. In one study of patients with pars planitis, mean visual acuity after 10 years of follow-up was 20/30,

75% maintained a visual acuity of 20/40 or better, and one-third maintained normal visual acuity without treatment.<sup>11</sup> In a study by Kalinina Ayuso and colleagues, younger age at onset decreased the visual prognosis and increased the rates of complications;<sup>78</sup> however, another study showed higher rates of remission in patients who presented at a younger age. Mean time to remission in the latter study, which occurred at a rate of 34%, was 8.6 years.<sup>12</sup>

## Complications

Causes of vision loss in intermediate uveitis include CME, uveitic glaucoma, retinal detachment, vitreous hemorrhage, cataracts, and epiretinal membranes. Band keratopathy, especially prominent in children with chronic intermediate uveitis, can also cause vision loss. Chronic CME accounts for most cases of permanent visual loss, and occurred at a rate of 41.2% over 15 years according to one large retrospective cohort study, and at a rate of 45.7% in a separate study.<sup>11,13</sup> Concentric retinal macular thickening can also be seen in patients with intermediate uveitis, although it does not necessarily need to be treated.<sup>22</sup> The 15-year rates of cataract and epiretinal membranes were 34.2% and 44.4%, respectively, in the report by Donaldson et al.<sup>11</sup> An increased rate of CME appears to be associated with cigarette smoking. In one large case-control study, the odds ratio of a smoker (versus a nonsmoker) having intermediate uveitis with CME was 8.4 compared with an odds ratio of 1.5 in intermediate uveitis without CME.<sup>4</sup> In the report from Thorne et al., the odds ratio of having CME at presentation was 3.9 compared with a reference group of patients who had never smoked.<sup>13</sup>

In the late stages of intermediate uveitis peripheral neovascular and fibrous membranes can extend on to the ciliary body to form cyclitic and/or retrolenticular membranes, resulting in ciliary body detachment and hypotony. Prevention of progression to this stage is the mainstay of management. Once this develops, surgical intervention can be attempted to remove the cyclitic membrane and reverse hypotony to prevent phthisis, but success in improving visual outcome is poor.<sup>79</sup> Retinal detachment in the setting of active inflammatory disease should be repaired after relative quiescence is

achieved, if possible. Combined surgery with fluocinolone implant and placement of silicone oil can be considered given the lipophilic nature of fluocinolone and its ability to be dispersed throughout the silicone oil.<sup>80</sup>

# Rheumatic Disease

*Alastair K. Denniston, Benjamin Rhodes, Mary Gayed, David Carruthers, Caroline Gordon, Philip I. Murray*

**Introduction**

**Disease-Specific Section**

**Ocular Complications of Rheumatologic Therapies**

## Introduction

### An Approach to the Assessment of the Patient With Possible Rheumatic Disease

Patients may present to the ophthalmologist with a known rheumatic disease, and it may be assumed that the ophthalmic problem is a manifestation of their rheumatic disease. Alternatively, patients may present who do not have a known diagnosis of rheumatic disease. In this group it is important to know which ophthalmic conditions are associated with rheumatic disease and to be aware that some are common to many rheumatic diseases, such as keratoconjunctivitis sicca, and scleritis. Therefore, one must have knowledge of those diseases and how to differentiate between them. This will involve taking a full ophthalmic and medical history, performing a detailed examination, and ordering appropriate investigations.

# Common Ocular Presentations of Rheumatic Disease

## Keratoconjunctivitis Sicca and Other Corneal Presentations

Keratoconjunctivitis sicca (KCS, or “dry-eye syndrome”) is a common ocular manifestation of a number of rheumatic diseases including rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), scleroderma, and relapsing polychondritis. Symptoms vary from slight irritation and burning in mild disease to severe pain and blurred vision arising from increasing corneal involvement. Clinical examination using slit-lamp biomicroscopy reveals a small or absent tear meniscus with a tear film break-up time of less than 10 seconds. Corneal abnormalities, which may be highlighted with fluorescein drops and a cobalt blue light, include punctate epitheliopathy, mucus filaments, strands, and plaques. Additional staining with Rose Bengal or Lissamine Green drops reveals a characteristic interpalpebral pattern, with greatest staining nasal and temporal to the corneal limbus. Tear production, as measured by Schirmer's test, is reduced. Wetting of the test strip by less than 5 mm after 5 minutes in the unanesthetized eye indicates severe tear deficiency. It should be noted that the correlation of dry eye symptoms with observed disease is poor. Many more patients report “dry eyes” than have visible disease, and many asymptomatic patients do have some degree of keratoconjunctivitis sicca.<sup>1</sup>

Other less common corneal presentations of rheumatic disease include the sight-threatening peripheral ulcerative keratitis (PUK). The etiology is uncertain, but it has been suggested that immune complex deposition at the corneal limbus results in an obliterative vasculitis and stromal melt. It is most commonly associated with RA or systemic vasculitis, in particular granulomatosis with polyangiitis (previously known as Wegener's granulomatosis).<sup>2,3</sup> Clinical features include variable pain and redness and reduced vision, uni/bilateral peripheral corneal ulceration with epithelial defect and stromal thinning, associated limbal inflammation, and scleritis.

## Scleritis/Episcleritis

### Scleritis.

Inflammation of the sclera is an extremely painful, potentially blinding condition. It may be classified according to location (anterior – 90%, or posterior – 10%), distribution (diffuse or nodular), and destruction (necrotizing or non-necrotizing). The majority of anterior scleritis is non-necrotizing (diffuse or nodular), and necrotizing disease may occur with and without inflammation.

Scleritis is associated with systemic disease in around 40–50% of patients, of which most are cases of a rheumatic disease, such as RA, granulomatosis with polyangiitis, relapsing polychondritis, SLE, sarcoidosis, polyarteritis nodosa, inflammatory bowel disease, psoriatic arthritis, ankylosing spondylitis, and gout.<sup>4</sup> It is commonest in middle-aged women. Scleritis is bilateral in 50% of cases, but both eyes may not be affected at the same time.<sup>5</sup> The pain (constant/deep/boring) can be so severe that it may wake the patient at night. The eye has an intense red/dark red appearance. The globe may be very tender to touch. A bluish hue implies scleral thinning from previous active scleritis due to the underlying blue/black uveal tissue showing through the translucent sclera. Scleral thinning can eventually result in high degrees of astigmatism. The degree of redness and scleral thinning is more easily seen under room light or in daylight than by the slit lamp. Topical phenylephrine 2.5% causes blanching of the more superficial episcleral vessels but does not change the engorgement of deeper scleral vessels and can often help differentiate between scleritis and episcleritis. The most severe type is necrotizing anterior scleritis with inflammation. Apart from the severe pain and redness, there may be tearing and photophobia. White avascular areas surrounded by injected edematous sclera are present that may lead to scleral necrosis. An associated anterior uveitis suggests advanced disease. Complications of scleritis include peripheral ulcerative keratitis, acute stromal keratitis, sclerosing keratitis, uveitis, cataract, astigmatism, glaucoma, and globe perforation.

Posterior scleritis is uncommon but is probably underdiagnosed. It is a potentially sight-threatening condition. It may be overlooked on account of more obvious anterior scleral inflammation or

because there is isolated posterior disease and thus the eye appears white and quiet (often despite severe symptoms). It is associated with systemic disease (usually RA or systemic vasculitis) in up to one-third of cases. There is mild–severe deep pain (may be referred to brow or jaw), reduced vision, diplopia, and hypermetropic shift. The eye is white (unless anterior involvement) but may be associated with lid edema, proptosis, lid retraction, restricted motility, shallow anterior chamber, choroidal folds, annular choroidal detachment, exudative retinal detachments, macular edema, and optic disc edema. Diagnosis (and response to therapy) may be assisted by B-scan ultrasonography with measurement of scleral thickening and fluid in the Tenon space (T-sign).

### **Episcleritis.**

This common condition is a benign, recurrent inflammation of the episclera. Being superficial it is easily distinguished from deeper scleral inflammation, in that it is less painful and the involved vessels blanch on instillation of topical phenylephrine 2.5%. It is more common in young women, often self-limiting, and may require little or no treatment. It is not usually associated with any systemic disease, although around 10% may have an underlying rheumatic disease.<sup>6</sup>

## **Uveitis**

### **Acute Anterior Uveitis.**

In acute anterior uveitis (AAU) patients typically present with pain, photophobia, redness, and blurred vision. Examination findings are of anterior segment inflammation, including circumlimbal injection, keratic precipitates (especially inferior), anterior chamber (AC) flare, cells, and fibrin (fibrin is a key feature in HLA-B27-associated uveitis). A hypopyon is suggestive of HLA-B27-associated disease, Behçet disease, or severe intraocular infection.<sup>7</sup> Posterior synechiae are common in both idiopathic and HLA-B27-associated AAU, and every effort should be made to break them at time of presentation. Vitreous cells may be seen as “spill-over” inflammation, but vitritis is not a dominant feature. Occasionally cystoid macular edema (CME) may be seen (especially in HLA-B27 disease), but this is

more commonly a feature of intermediate, posterior, or pan-uveitis. It is estimated that up to one-third of patients with AAU have ankylosing spondylitis (AS).<sup>8</sup> Treatment is with intensive topical corticosteroid and mydriatic. If severe, subconjunctival corticosteroid and mydriatic, oral corticosteroid or even intravenous corticosteroid may be given. Recurrent disease (especially if frequent or severe) may be an indication for maintenance systemic treatment.

### **Chronic Anterior Uveitis.**

In chronic anterior uveitis (CAU) patients are typically asymptomatic, so the condition may be picked up on routine optometric review or in screening in the context of juvenile idiopathic arthritis (JIA). Anterior chamber cells and flare are noted, and with time posterior synechiae, cataract, band keratopathy, and secondary glaucoma are common.

### **Intermediate Uveitis.**

This is defined anatomically as the predominant amount of inflammation being in the vitreous. Patients typically present with floaters but may have reduced vision in the context of associated CME. Examination findings include vitritis, retinal periphlebitis, snowball vitreous opacities, and snowbanks at the vitreous base. It is commonly idiopathic but may be associated with systemic disease; the main rheumatic disease association is with sarcoidosis, but multiple sclerosis is also a recognized cause.

### **Posterior Uveitis.**

Patients typically present with visual symptoms, arising from retinal and/or choroidal inflammation; an associated retinal vasculitis may be seen. A number of rheumatic diseases may be associated with posterior uveitis, including Behçet disease and sarcoidosis.

### **Panuveitis.**

In panuveitis (inflammation involving anterior chamber, vitreous, and retina/choroid) the presentation is usually with visual problems (reduced acuity, floaters) with redness, photophobia, and pain

being a more minor feature.

## **Other Retinal Presentations**

Retinal vasculitis may be associated with Behçet disease, sarcoidosis, systemic vasculitis, and SLE, but may also be associated with infections (herpesviruses, toxoplasma) and nonrheumatic systemic diseases (such as multiple sclerosis).

## **Orbital Presentations**

Rheumatic diseases – notably ANCA-associated vasculitis (ANCA = antineutrophil cytoplasmic antibodies) and SLE – may be associated with orbital inflammation or periorbital edema. Orbital inflammation may present with reduced vision, acute proptosis, lid edema, conjunctival injection and chemosis, reduced ocular motility, and raised intraocular pressure. It may be misdiagnosed as orbital cellulitis, thyroid-associated ophthalmopathy, or another form of orbital inflammation. Inflammation sometimes includes a myositis that may be demonstrated by imaging using CT and B-scan ultrasound (enlargement of extraocular muscles).

## **Neuro-Ophthalmic Presentations**

Neuro-ophthalmic complications of rheumatic disease are most commonly seen in the systemic vasculitides and include optic neuropathy, ocular motility abnormalities, and retrochiasmal lesions. They are discussed in more detail under the specific rheumatic diseases (see below).

## **Investigations**

The investigations ordered will depend on the history and examination findings. A baseline set of tests might include full blood count, erythrocyte sedimentation rate, C-reactive protein, urea and electrolytes, liver function tests, rheumatoid factor, antinuclear antibody, antineutrophil cytoplasmic antibody, angiotensin-converting enzyme, uric acid, syphilis serology, chest radiograph, and urinalysis.

## Therapeutic Considerations

Many patients will require systemic treatment, such as corticosteroids, immunosuppressants (methotrexate, azathioprine, mycophenolate mofetil, cyclosporine), and biologics (anti-TNF, rituximab – anti-CD20) for their rheumatic and ophthalmic disease. Where possible this should be undertaken in conjunction with a rheumatologist who has an expertise in this type of therapy. Ophthalmologists should prescribe these drugs only if they have a detailed knowledge of their action, route of administration, side-effects, and how to monitor for them, as the treatments themselves have potentially serious complications. Most patients with sight-threatening disease are likely to be prescribed oral corticosteroid, and these have numerous, well-recognized side-effects, including glucocorticoid-induced bone disease.<sup>9</sup> Fortunately, in patients with ocular inflammation the commonly used immunosuppressants do not appear to increase overall or cancer mortality.<sup>10</sup>

## Disease-Specific Section

### Rheumatoid Arthritis

#### General Considerations

Rheumatoid arthritis (RA) is a chronic disease which is characterized by synovial inflammation that typically affects the small joints of the hands and feet in a symmetrical distribution. It can lead to joint destruction and may be associated with systemic features including sight-threatening ocular disease. Early treatment of disease is felt to be important to limit long-term damage.

#### Epidemiology

RA is the commonest of the inflammatory arthritides, with an incidence of around 3 in 10, 000 per annum and a prevalence of 1% among adults in industrialized nations.<sup>11-13</sup> Epidemiologic risk factors include age (increases with age), female gender (3–5 times greater risk than male),<sup>13</sup> and smoking.<sup>14</sup>

#### Articular and Systemic Disease

The diagnosis of rheumatoid arthritis requires the presence of chronic polyarticular joint inflammation, which is characterized by pain and stiffness, tenderness, and joint swelling. In contrast to noninflammatory degenerative arthritis such as osteoarthritis, patients commonly complain of morning stiffness that improves with exercise.<sup>15</sup> All synovial joints may be affected including the metacarpophalangeal joints (MCPJs), proximal interphalangeal joints (PIPs), the interphalangeal joint of the thumb, metatarsophalangeal joints (MTPJs), wrist, elbows, hip joints, knees, and the atlantoaxial joint.<sup>15</sup> Typically, however, there is symmetric involvement of the wrists, MCPJs, PIPJs, and MTPJs with sparing of the distal interphalangeal joints.

Damage to joints and periarticular structures due to uncontrolled inflammation can, with time, give rise to the classical deforming appearances of advanced rheumatoid arthritis including ulnar deviation, "Swan-neck," and Boutonniere deformities ("rheumatoid hands").

Numerous extraarticular features have been reported in rheumatoid arthritis.<sup>16</sup> The commonest, affecting up to 30%, are solid lesions within the subcutaneous tissues of extensor surfaces known as rheumatoid nodules. Pleural disease, often asymptomatic and presenting as pleural thickening or small pleural effusion, is also reasonably common.<sup>17</sup> More serious extraarticular manifestations include pulmonary fibrosis, vasculitis, vasculitic neuropathy, and pericarditis. Other systemic complications include systemic amyloidosis and a chronic anemia and/or leucopenia. The combination of RA, splenomegaly, and leucopenia is known as Felty syndrome.<sup>18</sup> It is now recognized that rheumatoid arthritis is an important risk factor for atherosclerosis and premature cardiovascular mortality.<sup>19</sup> The incidence of severe, nonpulmonary extraarticular features of rheumatoid arthritis, particularly vasculitis, appears to be declining.<sup>16</sup> Whether this is related to changing treatment regimens is uncertain.

In addition to clinical assessment, the diagnosis of rheumatoid arthritis may be supported by systemic investigations such as the measurement of inflammatory markers, rheumatoid factor, and anticitrullinated protein antibodies (ACPA). ACPA in particular has high sensitivity and specificity for rheumatoid arthritis and may

predict the development of destructive disease.<sup>20</sup> New American/European classification criteria for rheumatoid arthritis were published in 2010, which reflect the clinical emphasis on early disease identification prior to the development of joint damage, combined with the clinical utility of anti-CCP antibodies (Box

**Box 83.1**

**The 2010 American College of Rheumatology (ACR)/European League Against Rheumatism (EULAR) Classification Criteria for Rheumatoid Arthritis**

The criteria are aimed at classification of newly presenting patients. In addition, patients with erosive disease typical of rheumatoid arthritis (RA) with a history compatible with prior fulfillment of the 2010 criteria should be classified as having RA.

**Target Population (Who should be tested?)**

1. Patients that have at least 1 joint with definite clinical synovitis (swelling)
2. Patients with the synovitis not better explained by another disease

**Classification Criteria for RA**

(Score-based algorithm: add score of categories A–D; a score of >6/10 is needed for classification of a patient as having definite RA.)

	<i>Score</i>
<b>A. Joint Involvement</b>	
1 large joint	0
2–10 large joints	1
1–3 small joints (with or without involvement of large joints)	2
4–10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint)	5
<b>B. Serology</b> (at least 1 test result is needed for classification)	
Negative RF <i>and</i> negative ACPA	0
Low-positive RF <i>or</i> low-positive ACPA	2
High-positive RF <i>or</i> high-positive ACPA	3
<b>C. Acute-Phase Reactants</b> (at least 1 test result is needed for classification)	
Normal CRP <i>and</i> normal ESR	0
Abnormal CRP <i>or</i> abnormal ESR	1
<b>D. Duration of Symptoms</b>	

<6 weeks	0
≥6 weeks	1

## Ocular Disease

In RA, anterior segment disease is more common than posterior segment disease. Common anterior segment disease includes keratoconjunctivitis sicca, Sjögren syndrome, episcleritis, scleritis, and various forms of keratitis.

Scleritis occurs in 1–6% of patients with RA and in up to 14% of patients with rheumatoid vasculitis.<sup>2,4,5</sup> Scleritis in the context of RA may present with severe pain and may be diffuse or nodular, anterior or posterior, and necrotizing or non-necrotizing in pattern.<sup>6</sup> Of greatest concern is scleromalacia perforans, in which scleral destruction is not typically painful and not associated with visible signs of inflammation.<sup>2,6</sup> Episcleritis may also be seen in the context of RA.<sup>6,22</sup>

Corneal complications of RA are wide-ranging with varying risk of perforation. Marginal keratitis without apparent inflammation may result in peripheral thinning giving rise to the appearance of “contact lens cornea.” More significant are peripheral ulcerative keratitis and keratolysis (“corneal melt”), both of which have a high risk of perforation.<sup>2</sup> Necrotizing keratitis or scleritis in the context of RA are associated with increased mortality.<sup>23</sup>

Posterior segment lesions in RA include posterior scleritis and rarely a retinal vasculitis. Retinal vasculitis is probably underdiagnosed. In one study of 60 patients with RA the rate of retinal vasculitis was 18% even in the absence of clinical features of retinal vasculitis.<sup>24</sup> This study is supported by a number of case reports describing typical retinal vasculitis associated with fluorescein angiographic evidence of leakage and a single case of retinal exudation in the context of scleritis that the authors attribute to vasculitis.<sup>25,26</sup>

Treatment-related ocular complications of RA include cataract (corticosteroid), elevated intraocular pressure (corticosteroid), and retinopathy (chloroquine and to a lesser extent

hydroxychloroquine).

## **Treatment**

### **Treatment of Systemic Disease.**

The goals of treatment in RA are to alleviate symptoms, including pain and loss of function, and to prevent joint damage. Comprehensive management guidelines were published by the American College of Rheumatology (ACR) in 2012 and the European League Against Rheumatism in 2013, and these largely agree in their management recommendations.<sup>27,28</sup> Current best practice is to treat early and aggressively, with frequent therapy escalation until disease activity is low or absent. First-line treatment is typically with methotrexate used as monotherapy or in combination (concurrently or sequentially) with other traditional synthetic disease-modifying agents. Patients who fail to respond to this approach will escalate to a targeted biologic DMARD (typically an anti-TNF biologic as first line with tocilizumab (anti-interleukin-6), rituximab (anti-CD20), and abatacept (fusion protein of CTLA-4 and IgG) as alternatives). Tofacitinib, a synthetic janus kinase inhibitor, is available in the United States.

### **Treatment of Ocular Disease.**

Mild superficial ocular disease (such as mild keratoconjunctivitis sicca or episcleritis) may be adequately controlled with topical therapies such as artificial tear substitutes.<sup>29</sup> Non-necrotizing anterior scleritis may be managed with oral NSAIDs, but necrotizing disease frequently requires systemic corticosteroid. Uncontrolled ocular inflammation warrants escalation of systemic treatment that should be coordinated with a rheumatologist. In addition, sight-threatening inflammation such as necrotizing scleritis or corneal melt requires urgent rescue therapy such as pulsed intravenous methylprednisolone.<sup>2</sup> In our practice we administer up to three pulses of 500–1000 mg methylprednisolone on consecutive days that is usually followed by commencing or increasing a course of oral corticosteroid (in addition to DMARD/biologic therapy).

# Seronegative Spondyloarthropathies

## General Considerations

Spondyloarthropathy (SpA) is a term used to describe a group of interrelated inflammatory arthropathies affecting the axial skeleton, synovium, and extraarticular sites (Box 83.2).<sup>30,31</sup> This group of conditions includes ankylosing spondylitis, reactive arthritis, inflammatory bowel disease-related arthritis, juvenile spondyloarthropathies, and psoriatic arthritis. Clinical manifestations include inflammatory back pain, sacroiliitis, enthesitis (inflammation of the entheses, where tendons or ligaments insert into the bone), dactylitis (inflammation of an entire digit), uveitis, and usually an asymmetric arthritis that affects lower limbs. These diseases are often subclassified as either axial SpA (where disease predominantly affects the back and sacroiliac joints) or peripheral SpA (where enthesitis, arthritis, and dactylitis predominates).<sup>30,31</sup> Overlapping or undifferentiated disease patterns are well recognized. There is a strong association with the class I MHC molecule HLA-B27. Based on a systematic review, which included nearly 30,000 patients, the mean prevalence of uveitis in spondyloarthropathies has been estimated at 33% overall, with anterior uveitis being the most common type seen.<sup>32</sup>

## The Assessment of Spondyloarthritis International Society (ASAS) Criteria for Axial and Peripheral Spondyloarthritis<sup>30,31</sup>

### Axial Spondyloarthropathy

Consider in patients aged <45 years with  $\geq 3$  months back pain *and*

- *Either* – Sacroiliitis on imaging\* +  $\geq 1$  spondyloarthritis clinical features<sup>†</sup>
- *Or* – HLA-B27 positive +  $\geq 2$  spondyloarthritis clinical features

### Peripheral Spondyloarthropathy

Consider in patients with arthritis or enthesitis or dactylitis *and*

- *Either*  $\geq 1$  of psoriasis, inflammatory bowel disease, preceding

infection, HLA-B27, uveitis, or sacroiliitis on imaging

- Or  $\geq 2$  of arthritis, enthesitis, dactylitis, history of inflammatory back pain, or a positive family history

### \*Sacroiliitis on Imaging

- Definite radiographic sacroiliitis according to modified New York criteria (radiographic axial spondyloarthropathy)
- Active inflammation on MRI highly suggestive of sacroiliitis associated with spondyloarthropathy (if radiographic features absent then termed nonradiographic spondyloarthropathy)

### †Spondyloarthritis Clinical Features

- Inflammatory back pain
- Arthritis
- Enthesitis (heel)
- Uveitis
- Dactylitis
- Psoriasis
- Inflammatory bowel disease
- Good response to NSAIDS
- Positive family history for spondyloarthritis
- HLA-B27
- Elevated CRP

## Epidemiology

Spondyloarthropathies occur particularly in individuals who are

positive for HLA-B27, but additional environmental factors are also thought to play a role. Spondyloarthropathies as a whole have a prevalence of 0.5–1.9% of the population.

## **Ankylosing Spondylitis**

### **General Considerations.**

Ankylosing spondylitis (AS) is an HLA-B27-associated chronic inflammatory axial arthritis typically presenting in young men with a strong association with anterior uveitis. The traditional classification scheme (the Modified New York criteria) required the presence of radiographic sacroiliitis along with the symptoms and signs of inflammatory back pain. The increasing use of sensitive modalities such as MRI has identified a group of patients with inflammatory disease but no radiographic changes, and this has led to a concept of nonradiographic axial SpA and a new set of classification criteria for axial SpA that incorporates this concept (Box 83.2).<sup>30</sup> Whether patients with nonradiographic axial SpA will all inevitably develop ankylosing spondylitis is currently unknown.

### **Epidemiology.**

AS is the commonest of the spondyloarthropathies. Its prevalence varies between 0.1 and 0.4% of the population, depending on the frequency of HLA-B27 in that population. This results in significant geographic variation with low rates of in South Africa and Japan, higher rates in Germany compared to other European countries, and very high rates in the natives of Eurasia and the North American circumpolar/sub-Arctic areas.<sup>33</sup> AS is commoner in males, with a male : female ratio of 2–3 : 1, although it has been suggested that it may be underdiagnosed in females due to them having milder disease.<sup>34</sup>

### **Articular and Systemic Disease.**

The hallmark of AS is inflammatory back pain that presents with buttock pain and early morning stiffness (minimum 30 minutes), that is relieved by exercise and NSAIDs, and worse with rest.<sup>35</sup> The shoulders and hips are regarded as axial joints and are affected in up to 50% of patients.<sup>36</sup> In AS an asymmetric oligoarthritis is

uncommon but may be a predictor of more severe disease if it presents early in the disease course.<sup>36</sup>

Enthesitis can occur at any enthesis but is most commonly seen in the foot at the insertion of the Achilles tendon and of the plantar fascia onto the calcaneus. The classic cardiac abnormalities in AS are aortitis, aortic regurgitation, and conduction abnormalities, but symptomatic disease is rare.<sup>37</sup>

Disease is monitored using a combination of instruments, including BASDAI (Bath Ankylosing Spondylitis Assessment Index), BASFI (Bath Ankylosing Spondylitis Function Index), inflammatory markers (CRP/ESR), Visual Analogue Scale, swollen joint count, and radiographs of spine and pelvis.

### **Ocular Disease.**

The commonest ocular complication of AS is recurrent AAU. It is almost always unilateral but may affect both eyes sequentially (described as “flip-flop” pattern). Rarely the anterior uveitis may become persistent. The presentation is of typical AAU, but inflammation is classically more severe (often with fibrin in the anterior chamber) and recurrences more frequent than in idiopathic AAU.<sup>38-40</sup> Hypopyon may also be present in severe cases. AAU may lead to sight loss via recurrent or persistent CME, secondary glaucoma, and cataract.<sup>38-40</sup> Treatment-related ocular complications of AS include cataract and elevated intraocular pressure (secondary to corticosteroid usage).

## **Treatment**

### **Treatment of Systemic Disease.**

The goal of treatment in AS is to relieve pain and to restore and maintain posture and movement to as near normal as possible. This is achieved through lifelong physical therapy and medical treatment. NSAIDs (nonsteroidal antiinflammatory drugs) are an effective treatment and are recommended as first-line therapy in many national guidelines.<sup>41,42</sup> There is little evidence to support the use of steroids or DMARDs (disease-modifying antirheumatic drugs such as sulfasalazine and methotrexate) in axial SpA, although they may be some use in treating peripheral

manifestations.<sup>43</sup> Five TNF-inhibitors (etanercept, infliximab, adalimumab, certolizumab, and golimumab) are authorized for the treatment of ankylosing spondylitis, and are typically used when active disease is not adequately controlled after a trial of a number of NSAID agents. Meta-analyses strongly support the efficacy of these agents in axial SpA.<sup>43,44</sup>

### **Treatment of Ocular Disease.**

The mainstay of treatment for AS-associated AAU is intensive topical corticosteroids and a mydriatic (as for idiopathic AAU), but it should be noted that subconjunctival treatment and oral corticosteroids are more commonly required to adequately control inflammation in HLA-B27-associated versus idiopathic AAU. Anti-TNF agents, such as infliximab, etanercept, and adalimumab, as part of studies for the treatment of the underlying AS can also reduce the frequency of AAU recurrences.<sup>45,46</sup>

## **Reactive Arthritis (Previously Known as Reiter Syndrome)**

### **General Considerations.**

Reactive arthritis (ReA) is a sterile inflammation of the joints triggered by an infection, associated with frequently occurring extraarticular symptoms.

### **Epidemiology.**

There are a few population-based studies which have estimated the incidence to be between 1 and 30 per 100,000 per annum.<sup>47</sup> HLA-B27 is positive in 60–80% of patients with reactive arthritis. The most commonly associated infections are urogenital (*Chlamydia trachomatis*) or gastrointestinal (*Yersinia*, *Salmonella*, *Shigella*, and *Campylobacter*).<sup>47–50</sup>

### **Articular and Systemic Disease.**

Characteristically patients will have an asymmetric oligoarthritis of the large lower limb joints, with involvement often occurring in an additive or migratory pattern. The upper limbs and small joints

(usually PIP joints) can also be affected. Other features include inflammatory lower back pain similar to AS, dactylitis, enthesitis, erythema nodosum, keratoderma blennorrhagica (skin lesions on the soles of feet that mimic pustular psoriasis), and a distinctive genital rash called circinate balanitis.<sup>47,48</sup>

### **Ocular Disease.**

The commonest ocular complication of ReA is anterior segment disease. Conjunctivitis forms part of the classical triad of ReA but is usually only seen at first presentation and early in the disease. Of more consequence is recurrent AAU that may occur in up to 50% of patients, although in only up to 20% patients at the initial attack.<sup>40,48</sup> As described for other forms of AAU, these attacks may be associated with spillover vitreous cells and CME, and very rarely optic disc edema.

Rarely ReA may be associated with panuveitis or multifocal choroiditis;<sup>51,52</sup> the rarity of such cases is underlined by many series of ReA patients in which no cases of panuveitis or posterior uveitis were identified.<sup>48,53</sup>

### **Treatment**

#### **Treatment of Systemic Disease.**

The underlying infection should be treated as appropriate.<sup>47,54</sup> Acute arthritis can be treated with NSAIDs and intraarticular corticosteroids. DMARDs such as sulphasalazine or methotrexate should be considered in patients with a prolonged disease course, while case reports suggest anti-TNF biologic drugs may be helpful in severe resistant cases.<sup>47,54</sup>

#### **Treatment of Ocular Disease.**

ReA-associated AAU is treated as for idiopathic AAU with intensive topical corticosteroids and a mydriatic. As noted previously for other HLA-B27-associated AAU, subconjunctival treatment and oral corticosteroids may be required to adequately control inflammation. Rare cases of posterior segment inflammation are likely to require systemic immunosuppression.

# Inflammatory Bowel Disease

## General Considerations.

Peripheral and axial arthritis are associated with inflammatory bowel disease (IBD), especially Crohn's disease and ulcerative colitis.

## Epidemiology.

The incidence of peripheral arthritis is reported to be between 5% and 10% in ulcerative colitis and 10% and 20% in Crohn's disease, respectively.<sup>55</sup> Men and women are affected equally. Spondylitis occurs in 1–26% of patients with IBD, and males are more often affected than females. In addition, the prevalence of AS in IBD (1–6%) is higher than in the general population.<sup>55</sup>

## Articular and Systemic Disease.

IBD-related arthritis is often a clinical diagnosis as radiology is often normal with no joint erosion or deformity. Some authors have classified two distinct types of arthritis: type 1 (pauciarticular) and type 2 (polyarticular).<sup>55,56</sup>

## Ocular Disease.

Ophthalmic complications are estimated to occur in 3.5–12% of patients with IBD, occurring more commonly earlier in the disease.<sup>57</sup> The commonest ocular complications of IBD are uveitis, episcleritis, and scleritis.

Uveitis is usually of recurrent AAU type, occurring in around 5% of IBD patients, but in up to 50% of IBD patients who are also positive for HLA-B27.<sup>58</sup> Less commonly, a chronic bilateral anterior uveitis may be seen, which has a female gender preponderance.<sup>59</sup> Scleritis is a well-recognized feature of IBD and has been reported to parallel the activity of the bowel disease. Scleritis is usually anterior but may be posterior; it may be non-necrotizing or necrotizing, leading to a risk of scleromalacia perforans.<sup>60</sup> Retinal artery occlusions and ischemic optic neuropathy are reported and may reflect the prothrombotic tendency seen in some patients with IBD. Other reported associations with IBD include keratitis, retinal vasculitis, posterior uveitis, cystoid macular edema, optic neuritis,

neuroretinitis, Brown's syndrome, and orbital myositis.<sup>60</sup> A recent community survey also suggested that there is a high prevalence of “dry eye” (up to 42%), which was associated with 5-aminosalicylate use, although it was not clear if this was causative or a surrogate marker of disease activity.<sup>61</sup> Interestingly, a family history of IBD has been proposed as an independent risk factor for the development of idiopathic ocular inflammation, including uveitis.<sup>62</sup>

## Treatment

### Treatment of Systemic Disease.

Treatment depends on the severity of symptoms. Patients with mild oligoarthritis usually respond to relative rest, physiotherapy, and intraarticular corticosteroid injections.<sup>55,56</sup> Most of the patients respond to NSAIDs because they control the symptoms and joint and enthesitis inflammation, but they do not stop joint destruction, and they may have significant side-effects including exacerbation of IBD and produce small intestine and colon ulcers. Hence, they are recommended for patients with mild exacerbations, to control symptoms in arthritis flares, but their use must be limited to the minimal effective dose and time.<sup>55,56</sup>

Type 1 arthritis is related to disease activity and therefore therapy of the underlying IBD is the treatment of choice. Treatment of type 2 IBD arthritis and axial arthropathies generally requires long-term treatment with a DMARD, such as sulfasalazine or methotrexate. In addition, treatment with systemic or intraarticular corticosteroids can be used.<sup>55</sup> A number of IBD patients will also be using anti-TNF agents to control their bowel symptoms.

### Treatment of Ocular Disease.

IBD-associated AAU is treated as for idiopathic AAU with intensive topical corticosteroids and a mydriatic; it should be noted that the more chronic form of anterior uveitis may require more prolonged treatment.<sup>63</sup> The treatment of scleritis will depend on the pattern and severity of disease seen but will often require immunosuppression.<sup>63</sup>

## Psoriatic Arthritis

## General Considerations.

Psoriatic arthritis (PsA) is traditionally diagnosed by the combination of an inflammatory arthritis (peripheral arthritis and/or sacroiliitis or spondylitis), psoriasis, and the absence of serologic tests for rheumatoid factor.<sup>30</sup> In 2006, however, the CASPAR (CLASSification Criteria for Psoriatic ARthritis) was developed (Box 83.3). This has been demonstrated to have high **Box 83.3** and specificity for the diagnosis of PsA (see below).<sup>30,64</sup>

## The CASPAR Criteria for Psoriatic Arthritis

### Presence of

Inflammatory articular disease (joint, spine or enthesis)

**and**

**At least 3 points scored from the following**

Current psoriasis (2 points), a personal history of psoriasis (1 point), or a family history of psoriasis (1 point)

Typical psoriatic nail dystrophy (1 point); this includes onycholysis, pitting, hyperkeratosis

Dactylitis (1 point): current or previous episode noticed by rheumatologist

Juxtaarticular new bone formation (1 point): hand or foot X-rays

Rheumatoid factor-negative (1 point): preferably by enzyme-linked immunosorbent assay

Modified with permission from Taylor W, Gladman D, Helliwell P, et al. Classification criteria for psoriatic arthritis: development of new criteria from a large international study. *Arthritis Rheum* 2006;54:2665–73.

## Epidemiology.

Psoriatic arthritis (PsA) can occur at any age but is commonest between 30 and 50 years of age. It affects males and females equally.<sup>30,65</sup> The exact prevalence of PsA is unknown, but it is estimated to affect 0.3–1% of the US population and 7–42% of

patients with psoriasis.<sup>30,65,66</sup>

### **Articular and Systemic Disease.**

PsA can cause a variety of articular symptoms, varying from an isolated monoarthritis to an extensive destructive arthritis.

Articular involvement can be divided into five subtypes: DIP (distal interphalangeal) joint involvement, mono/oligoarticular, symmetric polyarthritis, arthritis mutilans, and spondyloarthropathy. It is important that patients with long-standing PsA have cervical spine radiographs before a general anesthetic, as there can be a clinically silent erosive/inflammatory arthritis causing atlantoaxial or subaxial instability, as in RA.<sup>67</sup> Dactylitis or “sausage digit” occurs in 30–40% of patients with PsA. In addition 20–40% of patients have symptomatic enthesitis generally affecting the foot at the insertion of the Achilles tendon and of the plantar fascia onto the calcaneus.<sup>64,68</sup> There appears no correlation between the severity of skin psoriasis and joint involvement, but skin symptoms do tend to precede joint symptoms. Psoriasis can be assessed using a variety of tools including PASI (Psoriasis Area and Severity Index), health assessment questionnaires, and Psoriatic Arthritis Response Criteria (PsARC).

### **Ocular Disease.**

Ophthalmic complications are estimated to occur in 10% of patients with psoriasis<sup>69</sup> and 31% of patients with PsA.<sup>70</sup> The most common presentations are conjunctivitis (up to 20%) or uveitis (7%).<sup>70</sup> Paiva and coworkers compared the nature of uveitis in PsA to that seen with a previous cohort of spondyloarthropathy patients.

Interestingly this suggested that PsA-associated uveitis was more likely to be insidious in onset (19% vs. 3%), bilateral (38% vs. 7%), chronic in duration (31% vs. 6%), or posterior (44% vs. 17%).<sup>71</sup>

Episcleritis, scleritis, keratoconjunctivitis sicca, and keratitis are also reported.<sup>69,70</sup>

## **Treatment**

### **Treatment of Systemic Disease.**

NSAIDs are normally used for musculoskeletal symptoms, based

on the evidence from other rheumatic diseases.<sup>72</sup> Intraarticular corticosteroid can be used, but oral corticosteroids should be used cautiously as they can be associated with a “poststeroid flare” of cutaneous disease. Typically, nonbiologic disease-modifying drugs (for example methotrexate, sulfasalazine, and leflunomide) are used as first-line treatment, with methotrexate also being an effective treatment for cutaneous psoriasis.<sup>43</sup> Clinician experience suggests these can be effective for many people, and they continue to feature in the majority of treatment guidelines; however, reviews, meta-analyses, and a randomized controlled trial of methotrexate really fail to demonstrate a clear statistical benefit from these agents, so there remains some uncertainty over their role.<sup>73</sup>

All licensed anti-TNF agents (etanercept/infliximab/adalimumab/certolizumab/golimumab) are effective at treating peripheral arthritis, as well as enthesitis, and dactylitis and cutaneous psoriasis.<sup>43</sup> They are recommended for use in patients with an active peripheral arthritis despite traditional treatment. Where access is available, two other treatment options have been approved in psoriatic arthritis: ustekinumab, a monoclonal antibody targeting the common p40 subunit of IL-12/IL-23 inhibitor, and apremilast, an oral inhibitor of phosphodiesterase 4, which has immunomodulatory effects.<sup>43</sup>

### **Treatment of Ocular Disease.**

PsA-associated AAU is treated as for idiopathic AAU with intensive topical corticosteroids and a mydriatic, but more persistent anterior uveitis may require prolonged treatment. Cataract, which may be associated with chronic intraocular inflammation, corticosteroid usage, and possibly P-UVA treatment,<sup>74</sup> requires surgical treatment with appropriate immunosuppressive perioperative care.

## **Juvenile Idiopathic Arthritis**

### **General Considerations**

Juvenile idiopathic arthritis (JIA) is the most common rheumatic disease occurring in childhood. It is characterized by persistent inflammation of the joints, with onset prior to age 16 years.

## Epidemiology

The reported incidence of JIA varies between 0.8 to 23 per 100, 000 per annum, with a prevalence rate between 7 and 400 per 100, 000 children. There are reported differences between different ethnic groups: JIA is more frequent in children of European descent than in children of African, Asian, or East Indian origin.<sup>75</sup>

## Articular and Systemic Disease

JIA is classified using the ILAR (International League of Associations of Rheumatologists) classification (Box 83.4). The main clinical feature of JIA is defined as “swelling within a joint or limitation in range of movement with joint pain or tenderness, which persists for a minimum of 6 weeks, observed by a physician and which is not due to primary mechanical disorders or to other identifiable causes.”<sup>76</sup>

## The International League of Associations of Rheumatologists (ILAR) Classification of Juvenile Idiopathic Arthritis

### Systemic Arthritis

*Definition:* Arthritis in one or more joints with or preceded by fever of at least 2 weeks' duration that is documented to be daily (“quotidian”) for at least 3 days, and accompanied by one or more of the following:

1. Evanescent (nonfixed) erythematous rash
2. Generalized lymph node enlargement
3. Hepatomegaly and/or splenomegaly
4. Serositis

*Exclusions (below):* a, b, c, d

### Oligoarthritis

*Definition:* Arthritis affecting 1–4 joints during the first 6 months of disease. Two subcategories are recognized:

1. Persistent oligoarthritis: Affecting not more than 4 joints throughout the disease course
2. Extended oligoarthritis: Affecting a total of more than 4 joints after the first 6 months of disease

*Exclusions (below): a, b, c, d, e*

### **Polyarthritis (Rheumatoid Factor Negative)**

*Definition:* Arthritis affecting 5 or more joints during the first 6 months of disease; a test for RF is negative.

*Exclusions (below): a, b, c, d, e*

### **Polyarthritis (Rheumatoid Factor Positive)**

*Definition:* Arthritis affecting 5 or more joints during the first 6 months of disease; two or more tests for RF at least 3 months apart during the first 6 months of disease are positive.

*Exclusions (below): a, b, c, e*

### **Psoriatic Arthritis**

*Definition:* Arthritis and psoriasis, or arthritis and at least two of the following:

1. Dactylitis
2. Nail pitting or onycholysis
3. Psoriasis in a first-degree relative

*Exclusions (below): b, c, d, e*

### **Enthesitis-Related Arthritis**

*Definition:* Arthritis and enthesitis, or arthritis or enthesitis, with at least two of the following:

1. The presence of or a history of sacroiliac joint tenderness and/or inflammatory lumbosacral pain
2. The presence of HLA-B27 antigen

3. Onset of arthritis in a male over 6 years of age
4. Acute (symptomatic) anterior uveitis
5. History of ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis in a first-degree relative

*Exclusions (below): a, d, e*

## Undifferentiated Arthritis

*Definition:* Arthritis that fulfills criteria in no category or in two or more of the above categories.

## Exclusions

The principle of this classification is that all categories of JIA are mutually exclusive. This principle is reflected in the list of possible exclusions for each category:

- a) Psoriasis or a history of psoriasis in the patient or first-degree relative
- b) Arthritis in an HLA-B27-positive male beginning after the 6th birthday
- c) Ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis, or a history of one of these disorders in a first-degree relative
- d) The presence of IgM rheumatoid factor on at least two occasions at least 3 months apart
- e) The presence of systemic JIA in the patient

The application of exclusions is indicated under each category and may change as new data become available.

Reproduced with permission from Petty RE, Southwood TR, Manners P, et al. International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision, Edmonton, 2001. *J Rheumatol* 2004;31:390–2.

## Ocular Disease

The major ocular manifestation of JIA is uveitis. Uveitis is present in around 10% of JIA patients at presentation but may occur in up to one-third of patients at some point during their disease although the exact estimate depends on the type of population sampled.<sup>77-81</sup> Inflammation is typically a chronic anterior uveitis with a white eye, which is usually bilateral (70%) but may initially present with unilateral disease. Recurrent acute anterior uveitis is less commonly seen and when it does occur is usually in the context of HLA-B27.

The risk of developing uveitis in association with JIA has been stratified according to age of onset, type of arthritis, and the presence of ANA, with uveitis occurring in up to half of the highest-risk group (oligoarticular – persistent and extended, ANA-positive disease). Interestingly, a recent study has suggested that age and ANA status may be less useful in predicting risk in boys (versus girls).<sup>82</sup> It should be noted that the gold standard for determining ANA is via immunofluorescence on HEp-2 cells; ELISA-determined ANA was not found to be predictive.<sup>83</sup> Antihistone antibodies are also associated with risk of uveitis but are less widely used in clinical practice.<sup>83</sup> Since the chronic anterior uveitis has minimal if any of the symptoms commonly associated with inflammation, screening is recommended. The recommendations of the American Academy of Pediatrics are summarized in [Table 83.1](#).<sup>84</sup>

**TABLE 83.1**

### American Academy of Pediatrics Guidelines on Frequency of Ophthalmologic Examination in Patients With Juvenile Idiopathic Arthritis

Type	ANA	Age at Onset (yr)	Duration of Disease (yr)	Risk Category	Eye Examination Frequency (mth)
Oligoarthritis or polyarthritis	+	≤6	≤4	High	3
	+	≤6	>4	Moderate	6
	+	≤6	>7	Low	12
	+	>6	≤4	Moderate	6
	+	>6	>4	Low	12
	–	≤6	≤4	Moderate	6
	–	≤6	>4	Low	12
	–	>6	NA	Low	12
Systemic disease	NA	NA	NA	Low	12

(fever, rash)					
---------------	--	--	--	--	--

Recommendations for follow-up continue through childhood and adolescence.

ANA, antinuclear antibodies; NA, not applicable; mth, month; yr, year.

Reproduced with permission from Cassidy J, Kivlin J, Lindsley C, Nocton J. Ophthalmologic examinations in children with juvenile rheumatoid arthritis. *Pediatrics* 2006;117:1843–5.

JIA-associated uveitis is more commonly seen in girls,<sup>81</sup> but male gender is a risk factor for worse disease, with significantly higher rates of CME by 5 years of follow-up (50% vs. 4%) and need for cataract surgery (59% vs. 32%). Other reported predictors of worse outcome are uveitis present at time of diagnosis<sup>85,86</sup> and elevated laser flare values.<sup>87</sup>

The key sight-threatening complications of JIA-associated uveitis are band keratopathy (60%), cataract (40%), glaucoma (10–25%), and CME (10%). Posterior synechiae are present in most cases.<sup>77,88,89</sup> Less commonly, vitritis and a peripheral retinal vasculitis are reported.<sup>77,80,88,89</sup>

## Treatment

### Treatment of Systemic Disease.

The management of JIA is based on a combination of medical treatment, physical and occupational therapy, and surgical management. NSAIDs can be used for all types of mild JIA, to treat pain and stiffness. Oral corticosteroids must be used minimally in children because of the effects on bone and growth; the main indications are severe fever, serositis, and macrophage activation syndrome. Intraarticular corticosteroids can be used, and encouraging results have been reported in children with monoarthritis.<sup>90</sup> Methotrexate is used for patients with polyarthritis; other DMARDs that have been shown to be effective include sulfasalazine and leflunomide. Etanercept can be used in patients who fail to respond to methotrexate therapy and has been demonstrated to be effective in both the short- and long-term management of JIA.<sup>91–93</sup> Infliximab was not shown to be superior to placebo in polyarticular JIA.<sup>94</sup> Adalimumab is licensed for use in JIA and was found to be effective in children with polyarticular JIA.<sup>95</sup> Abatacept is an alternative biologic agent which is a selective

T-cell co-stimulator inhibitor. In randomized controlled trials (RCTs) abatacept was superior to placebo in children with polyarticular arthritis, including those who were anti-TNF treatment failures.<sup>96,97</sup> There is some concern regarding the potential increased risk of cancers in children using anti-TNF agents.<sup>98</sup> Further studies are being undertaken to investigate the potential future role of other biologics, including rituximab, IL(interleukin)-1, and IL-6 antagonists.

### **Treatment of Ocular Disease.**

Systemic immunosuppression is usually required to control both the systemic disease and its ocular manifestations, although some children may require only topical corticosteroid and a mydriatic. What constitutes a “safe” level of topical corticosteroid usage in children is controversial. In a recent retrospective study by Thorne and coworkers, topical corticosteroid use was associated with development of cataract, and this was independent of active uveitis or presence of posterior synechiae.<sup>99</sup> Importantly, there appeared to be no significant increase of cataract when chronic administration was no more than twice daily.<sup>99</sup> The need for frequent topical corticosteroid to control the uveitis usually requires the introduction of methotrexate often given by the subcutaneous route weekly rather than orally. If methotrexate cannot adequately control the inflammation, then it requires the addition of an anti-TNF agent; adalimumab appears to be the drug of choice, with effective control of the uveitis in 16/18 children in one study.<sup>100</sup> There are some reports of uveitis occurring in association with etanercept.<sup>101</sup>

Cataract surgery is challenging and requires very careful preparation, perioperative care, and intensive postoperative management. It is vital that the patient's carers are fully aware of the importance of adherence to prescribed therapy and follow-up visits. Traditionally cataract removal for these patients was by pars plana vitrectomy/lensectomy followed by aphakia, but it is now more common to use intraocular lenses at the time of surgery.<sup>102-104</sup> Postoperative posterior synechiae and intraocular lens deposits are common, but overall visual improvement is encouraging, with a recent series of 17 eyes reporting an improvement in visual acuity

of 2 lines or more in all patients with no increase of CME, glaucoma, or hypotony,<sup>103</sup> but it should be noted that other studies do report significant rates of secondary glaucoma and CME.<sup>104</sup>

## Systemic Lupus Erythematosus

### General Considerations

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease predominantly affecting women of childbearing age. The 1997 American College of Rheumatology classification criteria remain widely used (Box 83.5), although an alternative set of classification criteria were proposed by the Systemic Lupus International Collaborating Clinics (SLICC) group in 2012.<sup>105,106</sup> Although similar in outline, the SLICC criteria have greater sensitivity, at the expense of some specificity, by considering a broader range of clinical manifestations (especially in dermatologic and neurologic categories) and immunologic manifestations (for example low complement). By requiring the presence of at least one immunologic feature, the SLICC criteria do not support the concept of “seronegative lupus.”

### The 1997 Updated American College of Rheumatology Criteria for Systemic Lupus Erythematosus

For the purposes of clinical trials, a diagnosis of SLE is made on the presence of at least four out of 11 criteria being present simultaneously or sequentially.

1. **Malar rash**

Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds

2. **Discoid rash**

Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions

3. **Photosensitivity**

Skin rash as a result of unusual reaction to sunlight, by patient

history or physician observation

**4. Oral ulcers**

Oral or nasopharyngeal ulceration, usually painless, observed by physician

**5. Nonerosive arthritis**

Involving 2 or more peripheral joints, characterized by tenderness, swelling, or effusion

**6. Pleuritis or pericarditis**

(a) Pleuritis: convincing history of pleuritic pain or rubbing heard by a physician or evidence of pleural effusion

*or*

(b) Pericarditis: documented by electrocardiogram or rub or evidence of pericardial effusion

**7. Renal disorder**

(a) Persistent proteinuria  $> 0.5$  g per day or  $>$  than 3+ if quantitation not performed

*or*

(b) Cellular casts: may be red cell, hemoglobin, granular, tubular, or mixed

**8. Neurologic disorder**

(a) Seizures: in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance

*or*

(b) Psychosis: in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance

**9. Hematologic disorder**

At least one of the following:

(a) Hemolytic anemia – with reticulocytosis

(b) Leucopenia  $<4000/\text{mm}^3$  on  $\geq 2$  occasions

(c) Lymphopenia  $<1500/\text{mm}^3$  on  $\geq 2$  occasions

(d) Thrombocytopenia  $<100,000/\text{mm}^3$  in the absence of offending drugs

**. Immunologic disorder**

At least one of the following:

(a) Anti-DNA: antibody to native DNA in abnormal titer

(b) Anti-Sm: presence of antibody to Sm nuclear antigen

(c) Positive finding of antiphospholipid antibodies on:

1. An abnormal serum level of IgG or IgM anticardiolipin antibodies

2. A positive test result for lupus anticoagulant using a standard method, *or*

3. A false-positive test result for at least 6 months confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test

### . Positive antinuclear antibody

An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of potential drug causes

Modified from Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1997;40:1725.

## Epidemiology

SLE has a prevalence of around 28 cases per 100,000,<sup>107</sup> predominantly affecting women of child-bearing age (15–45 years); the female : male ratio peak is 12 : 1. SLE is more common in non-Caucasians, in whom it is both more severe and earlier in onset.

## Articular and Systemic Disease

SLE is a systemic disease that can cause constitutional or organ-specific symptoms. The skin, mucous membranes, joints, kidney, brain, serous membranes, lung, heart, and occasionally the gastrointestinal tract may all be involved.<sup>105,107</sup> Arthritis in SLE can be divided into a deforming and nondeforming arthropathy. Constitutional symptoms consist of fever, malaise, fatigue, weight loss, lymphadenopathy, and anorexia.<sup>107</sup> There are multiple cutaneous manifestations of lupus: commonly these include photosensitivity (>50% of patients), butterfly/malar rash, painful/painless oral ulcers, diffuse alopecia, and livedo reticularis.<sup>107</sup>

Renal disease is one of the most serious SLE manifestations and a prognostic indicator of disease severity. Renal biopsy is used to determine the class of nephropathy as classified by the International Society of Nephrology (ISN)/Renal Pathology Society

(RPS) guidelines.<sup>108</sup>

Neuropsychiatric SLE (NPSLE) is a major diagnostic and treatment problem. The ACR has provided classification criteria, describing central and peripheral types of neurologic involvement that may be found in lupus patients.<sup>107</sup>

Pulmonary features of SLE include pleurisy, pneumonitis, pulmonary hemorrhage, pulmonary embolism, pulmonary hypertension, and diaphragmatic weakness causing shrinking lungs. Pericarditis is the most common cardiac manifestation; others include myocarditis, endocarditis, accelerated atherosclerosis, and, rarely, pericardial tamponade.<sup>107</sup>

Abdominal pain, nausea, vomiting, and diarrhea occur in up to 50% of SLE patients. Gastrointestinal involvement includes mesenteric vasculitis (high risk of death), aseptic peritonitis (with or without ascites), subacute bowel obstruction, hepatitis, sclerosing cholangitis, protein-losing enteropathy, pancreatitis, and ascites.<sup>109</sup>

Cytopenias, including anemia, leucopenia, or thrombocytopenia, are commonly associated with SLE; they may be immune-mediated or due to other factors, e.g., menstrual losses. Antiphospholipid antibodies and lupus anticoagulant are found in about 30–40% of patients, associated with venous and arterial thrombosis, recurrent fetal loss, preeclampsia, headache, and epilepsy.<sup>107</sup>

A firm diagnosis of lupus is made based on appropriate clinical findings and the measurement of at least one antibody. There are a number of antibodies associated with SLE, the most common being ANA (antinuclear antibody). Other associated autoantibodies include anti-dsDNA (double stranded DNA) in approximately 60% of patients, the highly specific anti-Sm antibody (Smith proteins) in 10–30% of patients, and anti-RNP (ribonucleoprotein) also in 10–30% of patients.<sup>105–107</sup>

## **Ocular Disease**

Ophthalmic complications are common in SLE, affecting up to one-third of patients. The commonest complication is keratoconjunctivitis sicca, but sight-threatening posterior segment and neuro-ophthalmic disease is also seen (reviewed by Sivaraj and coworkers).<sup>110</sup>

Common ocular surface diseases related to SLE include KCS

(25% of SLE patients).<sup>111,112</sup> Peripheral ulcerative keratitis is a rare but serious complication requiring urgent immunosuppression.<sup>2</sup>

Episcleritis is observed in 1–2% and scleritis in 1% of patients with SLE.<sup>6,113</sup> Scleritis may be anterior or posterior, necrotizing or non-necrotizing, and may indicate activity of the underlying disease.

Occasionally SLE may cause orbital inflammation and present with acute proptosis, lid edema, conjunctival injection and chemosis, reduced ocular motility, and elevated intraocular pressure, with myositis and panniculitis also reported.<sup>114,115</sup> Orbital inflammation may also be associated with posterior scleritis.

Lupus retinopathy was first described by Bergmeister in 1929. Its prevalence is estimated at around 10%, although this is variable depending on the population studied.<sup>116</sup> The classic clinical picture is of cotton-wool spots, retinal hemorrhages, and vascular abnormalities (arterial narrowing with capillary dilation, and venous dilation and tortuosity) (Figs. 83.1–83.3). Additional features may include retinal edema, hard exudates, and microaneurysms. Retinopathy is usually bilateral but may be asymmetric.<sup>117</sup>

**FIG. 83.1** Acute lupus retinopathy with cotton-wool spots, arterial narrowing, venous dilation, and tortuosity.

**FIG. 83.2** Fundus fluorescein angiography of the same patient: (A) early, (B) arteriovenous, and (C) late phases demonstrating capillary “dropout,” vessel wall staining, and leakage.

**FIG. 83.3** Detail of the same patient showing venous beading.

Severe vaso-occlusive retinopathy is much less common but potentially devastating. Whereas mild retinopathy may be picked up as an incidental finding, vaso-occlusive retinopathy usually presents with visual symptoms such as reduced acuity, visual field loss, and distortion. In addition it is strongly associated with the life-threatening complication of CNS lupus.<sup>118</sup> The clinical appearance is of widespread arteriolar occlusion and capillary nonperfusion. Subsequently neovascularization is common (up to 72% cases) (Figs. 83.4 and 83.5)<sup>118</sup> and may be complicated by vitreous hemorrhage (up to 63%), retinal traction, and detachment (up to 27%).<sup>118</sup> The occurrence of vaso-occlusive disease is strongly associated with the presence of antiphospholipid antibodies (up to fourfold increased risk).<sup>119</sup> Primary antiphospholipid syndrome (i.e., antiphospholipid antibodies in the absence of SLE or any other systemic disease) may be associated with a similar severe vaso-occlusive retinopathy but with cotton-wool spots being less common. The severe vaso-occlusive retinopathy is sometimes described as a retinal vasculitis, but this is not generally supported by histologic examination.<sup>120</sup>

**FIG. 83.4** The same patient one year later, showing resolution of cotton-wool spots. Careful examination,

however, reveals two areas of abnormal neovascularization.

**FIG. 83.5** Fundus fluorescein angiography of the same patient: (A) early, (B) arteriovenous, and (C) late phases demonstrating the presence of active new vessels. These did not resolve with immunosuppression and required sectoral laser photocoagulation.

Occlusion of the larger retinal vessels may occur and again is associated with the presence of antiphospholipid antibodies. Manifestations include branch retinal arteriolar or central retinal artery occlusion (B/CRAO) (Fig. 83.6), branch or central retinal vein occlusion (B/CRVO), and combined retinal arterial and venous occlusions.<sup>118,120</sup>

**FIG. 83.6** Branch retinal arteriole occlusion in a patient with systemic lupus erythematosus and antiphospholipid syndrome.

Other retinal manifestations of SLE include an unusual bilateral pigmentary retinopathy that may resemble retinitis pigmentosa but is proposed to be ischemic in origin.<sup>121</sup> Coexisting systemic hypertension may result in features of hypertensive retinopathy. Choroidal involvement in SLE (lupus choroidopathy) may also cause significant visual morbidity. Choroidopathy results in single or multifocal serous detachments of the retina and retinal pigment epithelium (RPE), which may mimic idiopathic central serous chorioretinopathy (CSC).<sup>122</sup> The degree of visual symptoms depends on the anatomic location of the detachment(s). These serous detachments may become extensive over time but conversely may reverse with control of the underlying systemic disease.<sup>122</sup> Fluorescein angiography (and indocyanine green angiography) is helpful as it not only demonstrates typical CSC-like leakage from the choroid into the subretinal and sub-RPE spaces but also demonstrates the degree of choroidal ischemia.

Optic nerve disease is uncommon (about 1% patients with SLE). The spectrum of disease described includes anterior and posterior ischemic optic neuropathy, and acute optic neuritis (which is also thought to be ischemic in origin).<sup>123</sup> Bilateral optic disc swelling in

SLE may arise due to either idiopathic intracranial hypertension or accelerated systemic hypertension, both of which are more common in SLE.

Other neuro-ophthalmic complications of SLE include ocular motility abnormalities (causes include brain stem infarcts, cranial neuropathies, tenosynovitis, myositis, and Miller–Fisher syndrome), nystagmus, ptosis, and migraine.<sup>110</sup>

Finally, it should be noted that patients with SLE are immunosuppressed (both due to disease and treatment) and may present with severe intraocular infections. Retinal necrosis due to herpes simplex virus, varicella-zoster virus, and cytomegalovirus have been reported. Other ocular infections include tuberculous choroidal abscess and nocardia endophthalmitis.<sup>124,125</sup>

## Treatment

### Treatment of Systemic Disease.

The treatment of SLE is tailored to the severity of disease. General lifestyle advice includes avoidance of sunlight and use of sun block. Patients should have regular disease assessments and be screened for SLE complications, such as infection, diabetes, hyperlipidemia, and hypertension. Women of childbearing age should be advised regarding the importance of good disease control before conception, the need for close monitoring during pregnancy, and the risk of postpartum disease flare.

Mild cases with intermittent rashes, arthritis, and other mucocutaneous features can usually be treated with corticosteroid creams, short courses of NSAIDs, and hydroxychloroquine (<6.5 mg/kg per day). Patients with more severe disease manifestations (such as nephritis, gastrointestinal vasculitis, or central nervous system disease) are likely to need azathioprine, methotrexate, mycophenolate mofetil, or cyclophosphamide as immunosuppressive agents, combined with a variable dose of oral steroid. If conservative treatment and traditional DMARDs fail, then biologics should be considered.

Rituximab is a monoclonal antibody against the B-lymphocyte marker CD20 expressed on B cells, it has been used in SLE patients since 2002, but not without controversy. Although two randomized

controlled trials failed to demonstrate statistical efficacy, most clinicians regard it as an effective treatment strategy for antibody-mediated disease manifestations such as arthritis and nephritis, and this is supported by a large meta-analysis of open-label registries.<sup>126</sup> It may also have significant “steroid-sparing” effects, allowing a lower dose of concomitant steroid to achieve disease control.<sup>127</sup> It therefore remains widely used, particularly in refractory nephritis. An alternative biologic agent, belimumab, neutralizes soluble B-lymphocyte stimulator (BLyS – also known as BAFF), a B-cell activating factor that induces B-cell proliferation and maintains survival. Efficacy in patients with moderately active nonrenal lupus was assessed in two masked, randomized, placebo-controlled trials.<sup>128</sup> It has been approved for use in the United States but has not yet obtained worldwide authorization in all publically funded healthcare systems.

### **Treatment of Ocular Disease.**

In SLE, control of the systemic disease often improves the ophthalmic disease. The presence of severe ophthalmic disease should prompt the rheumatologist to look for evidence of systemic activity, and warrants escalation of systemic therapy. Additional local and regional treatments may also be indicated depending on the type of ocular complication. For example, KCS may benefit from a range of treatments, including tear replacement therapy (preservative-free preparations preferred), punctal occlusion, lid hygiene, topical corticosteroids or cyclosporine, and environmental measures.<sup>110</sup>

Mild anterior segment inflammation may respond to topical corticosteroids (keratitis or anterior uveitis) or topical NSAIDs (episcleritis). In more severe anterior segment inflammation, such as scleritis or disease affecting the posterior segment or orbit, systemic treatment is required. Non-necrotizing scleritis may respond to oral NSAIDs, but most severe inflammatory disease will require high-dose systemic corticosteroid often in combination with the immunosuppressive agents listed above. Significant retinal vascular occlusions associated with antiphospholipid antibodies may be treated with warfarin or low-dose acetylsalicylic acid (in addition to immunosuppression). Retinal neovascularization

usually requires panretinal photocoagulation. Persistent vitreous hemorrhage or traction retinal detachment may require vitreoretinal surgery.<sup>110,118</sup>

## **Sjögren Syndrome**

### **General Considerations**

Sjögren syndrome is a slowly progressive, inflammatory autoimmune disease primarily affecting the exocrine glands.

### **Epidemiology**

Sjögren syndrome predominantly affects females in the fourth to fifth decade of life. The female : male ratio is 9 : 1. In a population-based study in Minnesota, incidence of Sjögren syndrome was estimated to be 3.9 per 100, 000 per year.<sup>129</sup>

### **Articular and Systemic Disease**

Sjögren syndrome is clinically characterized by sicca symptoms: dry eyes and mouth due to failure of the salivary and mucosal glands. Sjögren syndrome may be primary or secondary to a preexisting disorder such as SLE, rheumatoid arthritis, systemic sclerosis, vasculitis, autoimmune thyroid disease, or primary biliary cirrhosis.<sup>130,131</sup>

The primary syndrome is associated with hypergammaglobulinemia with very high total IgG levels and strongly positive antinuclear antibody, rheumatoid factor, and anti-Ro and anti-La antibody levels. The extraglandular manifestations include arthralgia, Raynaud phenomenon, peripheral neuropathy, myositis, liver and interstitial nephritis, or renal tubular acidosis. Immune complex deposition resulting from ongoing B-cell hyperactivity is associated with increased morbidity and lymphoma risk.<sup>130</sup>

### **Ocular Disease**

The cardinal ocular sign of Sjögren syndrome is keratoconjunctivitis sicca (KCS), which may range from mild irritation in its early stage to severe tear deficiency with ocular surface inflammation and

damage resulting in severe visual loss.<sup>1</sup> Assessment of tear production, tear stability, and careful examination of the ocular surface are key.<sup>1</sup> Posterior segment disease is rare. Rosenbaum and Bennett described a series of eight patients with Sjögren syndrome and uveitis, reporting that in all cases the disease was bilateral and chronic; in their report they describe anterior and posterior disease (but no chorioretinitis) with posterior synechiae, cataract, and pars plana exudation being common.<sup>132</sup>

## **Treatment**

### **Treatment of Systemic Disease.**

Sjögren syndrome is a chronic disease with a wide clinical spectrum, making it necessary for regular follow-up. Treatment of sicca symptoms is essential and includes general measures such as avoidance of dry atmospheres, humidification of rooms, and chewing sugarless chewing gum.<sup>131</sup> Hydroxychloroquine can be effective for treating the subgroup of Sjögren sufferers who have inflammatory myalgias and arthralgias. Anti-TNF- $\alpha$  agents have not shown clinical efficacy. Rituximab also did not show a statistically significant effect in a recent randomized controlled trial, although further trials are due to report shortly.<sup>131,133</sup>

### **Treatment of Ocular Disease.**

The treatment of KCS is predominantly with frequent use of preservative-free tear substitutes, with a range of viscosities to suit the patient, their visual needs, and even the time of day. RCTs have shown topical 0.05% cyclosporine to be beneficial for patients with moderate to severe dry eye disease.<sup>134,135</sup> In the presence of associated inflammation of the ocular surface, topical glucocorticoids may be required.<sup>29</sup>

## **Sarcoidosis**

This is dealt with separately in [Chapter 81](#) (Sarcoidosis).

## **Familial Juvenile Systemic Granulomatosis**

## (Blau Syndrome)

### General Considerations

Familial juvenile systemic granulomatosis (Blau syndrome or Jabs syndrome) is a rare autosomal dominant disorder, associated with mutations in the *NOD2/CARD 15* gene.<sup>136-139</sup> It was described by Blau in 1985, as a triad of polyarthritis, iritis, and granulomatous papulosquamous rash.

### Epidemiology

Little is known about the epidemiology of familial juvenile systemic granulomatosis. It is thought to occur worldwide, with equal gender and race distribution.<sup>138</sup> All affected members carry one of a number of *NOD2/CARD 15* mutations.<sup>138, 140</sup> Not all affected individuals have the complete triad of symptoms.

### Articular and Systemic Disease

Familial juvenile systemic granulomatosis presents with a polyarticular arthritis, associated with synovial and tenosynovial cysts, resulting in swelling of the affected joints and tendons.<sup>138</sup> Camptodactyly (multidigit contracture of the interphalangeal joints) can occur secondary to inflammation.<sup>138</sup>

Familial juvenile systemic granulomatosis can be distinguished from childhood sarcoidosis by the absence of pulmonary involvement.<sup>138,141</sup> The rash is described as papuloerythematous and usually affects the trunk and extremities.<sup>138</sup> In addition, familial juvenile systemic granulomatosis can be associated with a large vessel vasculitis and cranial nerve palsies;<sup>138</sup> Crohn's disease is reported to occur in 30% of patients.<sup>142</sup>

### Ocular Disease

The cardinal ocular sign of familial juvenile systemic granulomatosis is a chronic anterior uveitis or panuveitis with multifocal choroiditis.<sup>143</sup> Complications of uveitis are common, including cataract, glaucoma, band keratopathy, and CME. Also reported are subepithelial corneal infiltrates, optic disc edema, ischemic optic neuropathy, and retinal vasculopathy.<sup>143,144</sup>

## Treatment

### Treatment of Systemic Disease.

Treatment for familial juvenile systemic granulomatosis is largely empirical. Prednisone can be used (dose will be dependent on the severity of disease).<sup>138,139</sup> Immunosuppressive agents, such as methotrexate and azathioprine, have been used with little effect.<sup>138,139</sup> There are also isolated reports of benefit from infliximab and anakinra (IL-1 receptor antagonist) in refractory cases.<sup>138,139</sup>

### Treatment of Ocular Disease.

Due to the chronicity of disease, long-term immunosuppression is generally required<sup>144</sup> that may be supplemented with topical and local treatment (as described previously) when needed for flares of ocular disease.

## Systemic Sclerosis

### General Considerations

Systemic sclerosis (also called scleroderma) is a multisystem disease of unknown etiology, with immunologic, vascular, and fibrotic abnormalities. There is characteristic tissue thickening and fibrosis, often with involvement of internal organs. The most recent classification criteria were published in 2013.<sup>145</sup>

### Epidemiology

The precise estimate for the incidence and prevalence of systemic sclerosis are unknown. This is likely due to a combination of true variation over different populations and differences in case ascertainment and disease classification.<sup>146</sup> Reported prevalence estimates in North America have varied from 13.8 cases per 100,000 from 1950 to 1979 to 28.6 cases per 100,000 in 1985, while a Canadian study estimated the prevalence in Quebec in 2003 to be 44.3 cases per 100,000.<sup>146,147</sup> Systemic sclerosis is more common in women, with a female : male ratio of 4–6 : 1. Multiple studies have demonstrated increased incidence and severity of scleroderma in people of African descent.

## Articular and Systemic Disease

Cutaneous manifestations may initially present with inflammation, edema, and reduced sweat and oil production. The characteristic cutaneous features include sclerodactyly, scleroderma, Raynaud phenomenon, digital ulceration, telangiectasia, calcinosis, and perioral radial furrowing. Gastrointestinal effects include esophageal dysmotility, gastroesophageal reflux disease (GORD), and intestinal dysmotility.<sup>145</sup>

Pulmonary disease (including pulmonary fibrosis and pulmonary arterial hypertension) is the leading cause of mortality in systemic sclerosis.

Systemic sclerosis patients will for the most part have a positive ANA (85–90%). The mutually exclusive presence of scleroderma-associated antibodies (including anticentromere, antitopoisomerase-1 (Scl-70) and anti-RNA polymerase III) are increasingly recognized as having important prognostic implications.<sup>148</sup>

## Ocular Disease

Ocular involvement is common, particularly of the eyelids and anterior segment. Lid involvement occurs in up to two-thirds of patients, resulting in progressive skin tightness, blepharophimosis, and occasionally lagophthalmos. Small lid telangiectasia occurs in up to 21% of patients.<sup>149,150</sup> Ocular surface disease is also very common, with KCS affecting up to 79% patients. KCS may occur as part of secondary Sjögren syndrome. It should be noted when interpreting IOP measurements in scleroderma that central corneal thickness increases during the first eight years of disease and may affect IOP readings.<sup>151,152</sup>

Although retinopathy may be seen in patients with scleroderma, it is usually in the context of secondary hypertension, and is of a clinical appearance typical of hypertensive retinopathy (cotton-wool spots, exudation, neuroretinal edema, hemorrhages). Milder retinal changes may also occur in normotensive patients with scleroderma, as shown by Ushiyama et al. where 34% of normotensive scleroderma patients (vs. 8% controls) had retinal findings such as hard exudates and vascular tortuosity.<sup>116</sup> Other reported retinal features include combined CRVO and CRAO,

bilateral CRVO, BRVO, and parafoveal telangiectasia. Interestingly, fundus fluorescein angiography (FFA) studies suggest that abnormality of the choroidal vasculature occurs in around one-third of patients, with hyperfluorescence in the late phase corresponding with areas of hypopigmentation.<sup>153</sup> Other reported ocular complications include cranial nerve palsies, Brown syndrome, and ophthalmoplegia.<sup>154</sup>

## **Treatment**

### **Treatment of Systemic Disease.**

Systemic sclerosis is a heterogeneous condition, with varying degrees of severity. Treatment strategies are aimed at the vascular, immunologic, or fibrotic manifestations of disease and need to be individualized depending on the patient and their disease manifestations.<sup>155</sup> Digital ulceration is typically managed with conventional vasodilators, escalating to sildenafil (phosphodiesterase type V inhibitor) and bosentan (endothelin receptor antagonist) in severe cases. Sildenafil, bosentan, and intravenous prostacyclin are used for pulmonary hypertension. Corticosteroids are commonly used at low doses for inflammatory arthritis, but there is no convincing trial evidence. Methotrexate has been demonstrated to be effective for skin manifestations in early disease and may help joint disease, while mycophenolate mofetil is an effective alternative for skin, lung, and joint disease. The efficacy of cyclophosphamide for scleroderma-associated lung fibrosis has been demonstrated and subsequently replicated in a clinical trial setting.<sup>156</sup> In patients with severe diffuse cutaneous systemic sclerosis, autologous hematopoietic stem cell transplantation has proven more effective than cyclophosphamide for skin and lung disease, albeit with considerable procedure-related mortality and morbidity.<sup>157,158</sup>

Tocilizumab (anti-interleukin-6) is another agent showing early promise in systemic sclerosis, and its role needs to be clarified in larger clinical trials.

### **Treatment of Ocular Disease.**

Keratoconjunctivitis sicca may usually be controlled with topical

therapy as previously described.<sup>29</sup> In addition to systemic immunosuppression, treatment of blood pressure is an important factor in preventing or treating retinopathy.

## Polymyositis and Dermatomyositis

### General Considerations

Polymyositis and dermatomyositis are inflammatory myopathies, characterized by proximal muscle weakness and often a variety of cutaneous and systemic features.

### Epidemiology

Several classification criteria have been proposed; the most frequent are the Bohan and Peter criteria (Box 83.6).<sup>159</sup> The precise incidence of myositis is unknown but is estimated to be between 2 and 10 new cases per million persons at risk per year.<sup>160</sup> The reported female : male incidence ratio is 2.5 : 1.<sup>160</sup> Similar to SLE and systemic sclerosis, there is a higher incidence in people of African descent, **Box 83.6** younger age of onset.

### The Bohan and Peter Criteria for the Diagnosis of Polymyositis and Dermatomyositis

#### Individual Criteria

1. Symmetric proximal muscle weakness
2. Muscle biopsy evidence of myositis
3. Increase in serum skeletal muscle enzymes
4. Characteristic electromyography pattern
5. Typical rash of dermatomyositis

#### Diagnostic criteria

Polymyositis:

Definite: all of 1–4

Probable: any three of 1–4

Possible: any two of 1–4

Dermatomyositis:

Definite: 5 plus any three of 1–4

Probable: 5 plus any two of 1–4

Possible: 5 plus any one of 1–4

Modified from Bohan A, Peter JB. Polymyositis and dermatomyositis (first of two parts). *N Engl J Med* 1975;292:344–7.

Myositis can be associated with other autoimmune conditions, particularly scleroderma and mixed connective tissue disease, and occasionally in SLE, RA, and Sjögren syndrome. Recent interest has focused on a range of myositis-associated autoantibodies that may have utility for classification and prognostication in the inflammatory myositides.<sup>161</sup> There is an increased risk of malignancy in both polymyositis and dermatomyositis. The greatest risk is in dermatomyositis (standardized incidence ratio (SIR): 3.0) which is associated with ovarian, lung, pancreatic, stomach, colorectal, and non-Hodgkin lymphoma. Antitranscriptional intermediary factor 1  $\gamma$  (anti-TIF-1 $\gamma$ ) antibodies may be seen in cancer-associated dermatomyositis. Polymyositis is associated with a significant but lower increased risk (SIR: 1.2–1.5), of malignancy, particularly non-Hodgkin lymphoma, and lung and bladder cancer.<sup>162</sup>

### **Articular and Systemic Disease**

Myositis often presents as a subtle, progressive, painless symmetrical weakness over 3–6 months, affecting proximal more than distal muscles.<sup>163</sup> Dermatomyositis is associated with

characteristic skin manifestations including a heliotrope rash (purplish rash over the periorbital area), Gottron papules (scaly or erythematous papules and plaques over bony prominences, particularly elbows and knees), and an erythematous rash over anterior chest and upper back and shoulders. Subcutaneous calcinosis (nodules or plaques of calcification over the elbows, forearms, knuckles, axillae, or buttocks), occurs particularly in juvenile dermatomyositis, but occasionally also in adult cases.<sup>163</sup>

Arthralgias and synovitis of small or large joints may occur in patients with myositis, even without an associated connective tissue disease. A deforming arthropathy of the proximal and distal interphalangeal joints occurs typically in patients with inflammatory myopathy and antisynthetase antibodies.<sup>163</sup> Interstitial lung disease is also more likely to develop in patients with anti-Jo-1 or other antisynthetase antibodies. Subclinical cardiac involvement including myocarditis, pericarditis, arrhythmias, and congestive cardiac failure have been reported. Gastrointestinal tract musculature involvement may occur, causing dysphonia, dysphagia, pseudo-obstruction, or malabsorption.<sup>163</sup>

## Ocular Disease

The classic heliotrope eyelid eruption of dermatomyositis is a familiar periocular sign of disease. Actual ocular involvement with myositis of the extraocular muscles is rare.<sup>164</sup> A retinopathy with cotton-wool spots is described in both these conditions, most commonly seen in children and usually (but not exclusively) in the context of systemic vasculitis. Retinopathy is usually mild, but in its severe retinal vasculitis form may lead to permanent visual loss.<sup>165,166</sup> Conjunctivitis, anterior uveitis, and episcleritis are also reported.<sup>166,167</sup>

## Treatment

### Treatment of Systemic Disease.

There are no large RCTs exploring the treatment of myositis, so treatment is based on case series, open-label trials, and small RCTs. General measures for treating are rehabilitation, avoidance of aspiration, and sun protection. Primary initial therapy is oral

corticosteroid.<sup>163,168</sup> Initially patients should be treated with prednisone 1 mg/kg, daily for 4–6 weeks before tapering the dose, but in more severe disease intravenous methylprednisolone up to 1 g/day for three consecutive days is recommended. Immunosuppressant therapy at an early stage may be required to facilitate corticosteroid reduction and side-effects from corticosteroids, and the first choice agents are methotrexate and azathioprine. In severe cases, in particular those associated with vasculitis or interstitial lung disease, cyclophosphamide has been recommended.<sup>163,168</sup> Intravenous immunoglobulin has been proposed in patients with rapidly progressing disease, and alternative agents include cyclosporine and mycophenolate mofetil. In a randomized controlled trial of Rituximab for inflammatory myopathy, no statistical difference was seen in comparison with placebo when looking at the primary endpoint, but 83% in the treatment group did improve.<sup>169</sup> Anti-TNF biologics are ineffective or may even worsen outcome.

### **Treatment of Ocular Disease.**

Systemic immunosuppression is required to control both the systemic disease and its ocular manifestations. Vasculitis regimens such as intravenous cyclophosphamide and methylprednisolone are commonly used.<sup>167</sup>

## **Relapsing Polychondritis**

### **General Considerations.**

Relapsing polychondritis is a rare autoimmune disease of unknown etiology, primarily affecting cartilaginous structures throughout the body.

### **Epidemiology.**

Relapsing polychondritis has an estimated incidence rate of 3.5 per million per annum; the peak onset is between 40 and 60 years. Equal frequency has been reported in both genders and all racial groups. Over 30% of cases are associated with existing autoimmune and hematologic conditions, including RA, SLE, Sjögren syndrome,

AS, lymphoma, and IBD.<sup>170</sup>

## Articular and Systemic Disease

Relapsing polychondritis is a multisystem disease that can affect the cartilaginous structures in the eyes, ears, nose, laryngotracheobronchial, and costal cartilages (Table 83.2). It causes inflammation of hyaline cartilage with a predilection for ear cartilage.<sup>171</sup> Involvement of the parasternal joints, including the sternoclavicular, costochondral, and manubriosternal articulations, is typical for this condition. Peripheral joint disease is reported in 70% of patients and is usually nonerosive and asymmetric.<sup>171</sup>

**TABLE 83.2**

### Systemic Features of Relapsing Polychondritis

Organ Involvement	Clinical Manifestation
Ear	External inflammation, loss of hearing, tinnitus, vertigo
Eye	Episcleritis, scleritis, ulcerative keratitis, uveitis, proptosis
Nose	Crusting, rhinorrhea, epistaxis, saddle nose
Large airways	Hoarseness, aphonia, wheezing, inspiratory stridor, nonproductive cough, dyspnea
Joints	Parasternal joints, peripheral joints (mono- or oligoarticular)
Heart	Aortic and mitral valvular disease
Skin	Aphthous ulcers, purpura, papules, nodules or ulcerations

Reproduced with permission from Lahmer T, Treiber M, von Werder A, et al. Relapsing polychondritis: an autoimmune disease with many faces. *Autoimmun Rev* 2010;9:540–6.

## Ocular Disease

Ophthalmic disease occurs in around half of patients with relapsing polychondritis. In a series of 112 patients, Isaak and coworkers reported that 19% patients had ocular symptoms at the onset of disease, with 51% developing ocular symptoms during the course of disease. Episcleritis (39%) and scleritis (14%) are common.<sup>172</sup> Anterior uveitis was reported as just 9% in the Isaak series but has been reported to be as prevalent as 30% in other series.<sup>173</sup> Other anterior segment findings include KCS and peripheral ulcerative keratitis.<sup>174</sup> The commonest posterior segment presentation is posterior scleritis, which may be severe and be associated with

serous retinal detachments and frank proptosis.<sup>175–177</sup> Retinopathy consisting of cotton-wool spots and intraretinal hemorrhages is reported to occur in up to 9% of patients. Other posterior segment features are branch or central retinal vein occlusions and ischemic optic neuropathy.<sup>172</sup> Cranial neuropathies may also be seen.

## **Treatment**

### **Treatment of Systemic Disease.**

First-line therapy for relapsing polychondritis is corticosteroid, initially started at 1 mg/kg prednisone daily; if necessary, three pulses IV methylprednisolone can be administered.

Immunosuppressives should be used for severe disease causing organ compromise or where corticosteroids have not provided a satisfactory response within a few weeks. The choice of immunosuppressant is empirical; the most commonly used agents are cyclophosphamide, azathioprine, cyclosporine, and methotrexate.<sup>170</sup> There are case reports reporting success with anti-TNF agents (etanercept/infliximab/adalimumab), anakinra, and rituximab.<sup>178</sup>

### **Treatment of Ocular Disease.**

Systemic immunosuppression is required to control both the systemic disease and its severe ocular manifestations. Vasculitis regimens may be required. Anterior uveitis, episcleritis, and KCS may be additionally controlled with topical therapy as previously described.

## **Primary Systemic Vasculitis**

The vasculitides are a heterogeneous group of diseases involving inflammation of blood vessels with subsequent tissue destruction and/or organ damage. The vasculitides can be considered to be primary or secondary (commonly associated with another connective tissue disease or infection). They are predominantly arterial in nature, though capillaries and less commonly veins are involved. Local tissue disruption is caused by inflammatory cell infiltrate in the vessel wall and subsequent tissue ischemia from

vessel occlusion. The primary systemic vasculitides are an uncommon group of diseases (combined annual incidence >100 new cases per million).<sup>179</sup> Classification is usually based on the predominantly affected vessel (Box 83.7). Recently the term ANCA-associated vasculitis (AAV) has been used to describe those small vessel conditions where there are similar immunopathologic tissue mechanisms: granulomatosis with polyangiitis (GPA, Wegener's granulomatosis), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA, Churg–Strauss

**Box 83.7** (Continued).<sup>180,181</sup>

## Classification of Vasculitides According to the Chapel Hill Consensus

### Primary Vasculitides

#### Large artery

Giant cell arteritis

Takayasu arteritis

#### Medium artery

Polyarteritis nodosa

Kawasaki disease

#### Small artery and vein

Granulomatosis with polyangiitis (Wegener's granulomatosis)<sup>a</sup>

Microscopic polyangiitis\*

Eosinophilic granulomatosis with polyangiitis (EGPA,

Churg–Strauss syndrome)

Henoch–Schonlein purpura

Leukocytoclastic vasculitis

Essential cryoglobulinemic vasculitis

**Other**

Behçet disease

Cogan syndrome

### **Secondary Vasculitides**

Connective tissue disease

Hepatitis B/C

Human immunodeficiency virus (HIV)

Recently, Watts et al. have suggested a possible fourth category, no predominant vessel size, to describe Behçet disease, primary central nervous system (CNS) vasculitis and Cogan syndrome.<sup>180</sup>

---

<sup>a</sup>These vasculitides are associated with ANCA.

Modified from Jennette JC, Falk RJ, Andrassy K, et al. Nomenclature of systemic vasculitides. Proposal of an international consensus conference. *Arthritis Rheum* 1994;37:187–92.

In parallel with advances in our understanding of the immunobiology of the vasculitides, it is becoming increasingly recognized that therapy for vasculitis needs to be tailored to the specific diagnosis and the phase of disease in that individual. An understanding of the natural history of the specific conditions and

assessment to identify the extent and activity of disease is required to achieve this.

## **Progression and Prognosis of Primary Systemic Necrotizing Vasculitis**

Classification of the vasculitides is most often based on the size of vessel involved (Box 83.7).<sup>182</sup> The initial and predominant inflammatory process is granulomatous in some cases, with the vasculitic phase of the illness only presenting later. This is typical of GPA, where constitutional and upper respiratory symptoms may be present for several years prior to diagnosis, thus delaying the commencement of appropriate therapy and adding to the morbidity and mortality of the condition.

Though the vasculitides are characteristically relapsing diseases, the frequency of relapse depends on the specific underlying diagnosis. In polyarteritis nodosa (PAN) the risk is low, which contrasts with ANCA-associated vasculitides where relapse is as high as 50%.<sup>183</sup> Prior to the introduction of effective therapy, the 5-year survival of systemic necrotizing vasculitis (SNV) was only 15%; corticosteroids improved this figure to 48%, while the combination corticosteroids and cyclophosphamide (CP) gave a significant improvement, with 5-year survival reaching 80%. However, this improved survival came at a cost, with recurrent flares of disease activity leading to the accumulation of organ damage, with appreciable morbidity also related to drug toxicity.

### **Aims of Therapy**

The aim of therapy in SNV must be to suppress disease activity so that organ damage is limited.

Clinical tools to assess disease activity and damage are used to aid in assessment and management of these complex diseases. These scoring systems have predictive value for severe disease where patients are at higher risk of mortality, thus supporting a more aggressive approach to therapy. The Birmingham Vasculitis Activity Score (BVAS) provides a weighted numeric score based on the specific organ involved and the severity of that involvement. A high score reflects either critical organ involvement or multisystem

disease and predicts a higher mortality.<sup>184</sup> The Vasculitis Damage Index (VDI) is a cumulative score where items of organ damage must be present for a period of at least 3 months and be attributable to effects of the disease, its therapy, or other undefined causes. A high VDI score identifies a subgroup of patients with more severe or fatal disease.<sup>185</sup>

Thorough clinical assessment to differentiate vasculitis localized to a single organ (such as ocular vasculitis) from more systemic disease is important, as the former group may not require systemic immunosuppression. Use of a systematic approach in clinical assessment, such as that provided on the BVAS form, can help clinicians identify previously unsuspected disease symptoms or signs, such as purpura or vascular bruits. Urinalysis is a simple critical investigation to identify renal involvement. Laboratory tests may provide supportive evidence of active systemic disease. A rise in C-reactive protein indicates active inflammation in the absence of infection. The presence of ANCA supports a diagnosis of one of the AAV but should not on its own prompt introduction of immunosuppressive therapy without appropriate clinical features. MPO-ANCA is seen in MPA and EGPA, while PR3-ANCA is most commonly seen in GPA. Tissue samples for histopathologic examination may be needed to confirm a diagnosis and exclude alternatives such as infection or malignancy. Therefore, a combination of clinical tools and laboratory investigations can help support a diagnosis of SNV and help differentiate disease activity, where immunosuppressive therapy may be required, from irreversible organ damage, where more therapy may be potentially harmful.

A diagnosis of vasculitis is not an indication to commence aggressive therapy in every patient. Some small vessel disease, such as Henoch–Schonlein purpura (HSP) or isolated leukocytoclastic vasculitis (LCV), where an initiating event is identified, may be self-limiting and need no therapy. Corticosteroids alone may be enough for the large vessel vasculitides. It is the AAV and PAN where a more aggressive approach is indicated to minimize organ damage. The approach outlined below can also be applied to other vasculitides where there is critical organ-threatening disease (such as sight-threatening scleritis in rheumatoid vasculitis).

## Induction Stage.

Cyclophosphamide in combination with corticosteroids are the drugs of choice for remission induction. Continuous oral cyclophosphamide (2 mg/kg daily) in conjunction with oral prednisone (1 mg/kg reducing to 10 mg daily by 3 months) induces remission in most by 3 months.<sup>186</sup> Remission induction takes longer in some patients, increasing the risk of drug-related toxicity. A safer and equally effective approach is to use intermittent pulses of intravenous cyclophosphamide.<sup>187</sup> The pulse interval is an important factor and a suggested induction regimen has been provided (Table 83.3).

**TABLE 83.3**  
**Pulse Cyclophosphamide Induction Regimen**

Drug Doses	Methylprednisolone 10 mg/kg plus Cyclophosphamide 15 mg/kg
Dose interval	0, 2, 4, 7, 10, 13 weeks Switch after six pulses to consolidation phase with monthly infusions ×3. If in remission, maintenance treatment with methotrexate or azathioprine can be commenced
Dose reductions	Age (>70 years), renal impairment, infection, neutropenia
Toxicity	Nausea, alopecia, neutropenia, infertility, hemorrhagic cystitis

## Maintenance Stage.

At 6 months, cyclophosphamide should be switched to milder maintenance therapy, such as azathioprine (2 mg/kg daily) or methotrexate. Cotrimoxazole has also been shown to reduce the relapse rate in GPA, possibly by eliminating nasal carriage of *Staphylococcus aureus*. Other maintenance agents that have been used in small series include cyclosporine, leflunomide, and mycophenolate mofetil. The duration that maintenance therapy should be continued is not clear, but in diseases where the relapse rate is high (e.g., AAV) therapy should probably be continued for 3–5 years.

## Adjuvant Therapy.

Where disease control is proving difficult and in the presence of severe organ involvement, pulses of methylprednisolone (1 g on

three consecutive days) may be used but should not delay the commencement of cyclophosphamide. Plasma exchange and intravenous immunoglobulin are other potential treatment modalities.

### **Treatment of Relapse.**

Fewer items of damage accumulate after relapse than at first presentation,<sup>185</sup> but for major relapses a short course of cyclophosphamide (six pulses), with an early transfer to maintenance methotrexate, azathioprine, or cyclosporine, is one approach. Patients with recurrent relapses may be exposed to several courses of cyclophosphamide, increasing the risk of drug-related toxicity (bladder cancer, infertility, myelodysplasia). Methotrexate may be used as an alternative to cyclophosphamide for less severe relapse.

### **Alternative Approaches to Therapy.**

A number of alternative therapies have been trialed. A short course of higher-dose pulsed cyclophosphamide may induce an early remission, but has an increased risk of neutropenia and infection. Autologous stem cell transplantation after intensive immunosuppression has been successfully carried out in a few patients with severe unremitting disease. Anti-T-cell monoclonal antibodies (Campath-1H and anti-CD4) have produced dramatic responses in some patients. Anti-TNF agents have not shown any benefit over standard therapy,<sup>188</sup> although several case reports suggest a benefit in some cases of treatment-resistant vasculitis. More promising results have been shown using the B-cell depleting anti-CD20 antibody rituximab, which is now used in some cases for remission induction or maintenance therapy.<sup>189</sup>

## **Large Vessel Vasculitides**

### **Giant Cell Arteritis**

#### **General Considerations.**

Giant cell arteritis (GCA) or temporal arteritis is a vasculitis that typically affects elderly patients, and is highly corticosteroid-

responsive. Symptoms tend to begin insidiously, most commonly headaches, scalp tenderness, myalgias, fever, anorexia, and weight loss.<sup>190</sup> In some cases, however, disease can present abruptly with a major complication such as loss of vision.<sup>191</sup>

### **Epidemiology.**

GCA is predominantly a disease of the elderly. It rarely affects those under 50 years, with a mean age of presentation of 70–75 years. There is a 2 : 1 female : male ratio. It is estimated to affect approximately 220 patients per million per year.<sup>180,192,193</sup>

### **Articular and Systemic Disease.**

GCA targets branches of the external carotid artery; patient symptoms include headaches, scalp tenderness, and jaw and tongue claudication. There is an increased risk of transient ischemic attack (TIA) or stroke, as a result of arteritis of the vertebral and basilar arteries. Systemic features of GCA, such as fever, malaise, fatigue, weakness, anorexia, weight loss, and depression are present in 40–50% of patients. The arteritic process can involve other large vessels and subclavian or brachial arteries presenting with upper limb claudication or an aortitis (thoracic > abdominal) is well recognized in 10–20% of patients. There is thought to be an association with polymyalgia rheumatica.<sup>194</sup>

### **Ocular Disease.**

Many patients present with temporal headache but no visual loss, but anterior ischemic optic neuropathy (AION) due to arteritis of the short posterior ciliary arteries is the major complication of GCA, and typically presents as acute painless loss of vision. The diagnosis is straightforward when seen with devastating loss of vision (often perception of light), a relative afferent pupillary defect, and typical optic disc edema in the context of systemic features typical of the disease. With time, optic atrophy ensues with complete loss of vision. Nevertheless in some patients it is difficult to distinguish between an arteritic and nonarteritic cause of AION. Failure to differentiate these two can be catastrophic as involvement of the second eye in arteritic AION ranges from 10% if treated to 95% if untreated. A detailed ocular and general history is essential and

examination reveals a tender, thickened, nonpulsatile superficial temporal artery. Characteristically there is an elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). A definitive diagnosis is made on temporal artery biopsy (TAB), but a positive biopsy is not always required to make a diagnosis (American College of Rheumatology classification criteria for GCA – [Box 83.8](#)).<sup>195</sup> Nevertheless, all patients with a clinical and/or laboratory diagnosis, or where the diagnosis is in doubt, should have therapy instigated and a TAB performed. A TAB is normally performed within 48–72 hours of commencing corticosteroid therapy. A recent study has shown that on 459 cases of biopsy-proven GCA the odds of a positive biopsy were 1.5 times greater with an ESR of 47–107 mm/h, 5.3 times greater with a CRP >2.45 mg/dL, and 4.2 times greater with platelets >400 / $\mu$ L.<sup>196</sup>

### **The American College of Rheumatology 1990 Criteria for the Classification of Giant Cell Arteritis**

The presence of *three or more* of the following five criteria is associated with 93.5% sensitivity and 91.2% sensitivity for giant cell arteritis (GCA).

1. Age  $\geq$ 50 years at disease onset
2. New onset of localized headache
3. Temporal artery tenderness or decreased pulse
4. ESR  $\geq$ 50 mm/h
5. Arterial biopsy with necrotizing arteritis with a predominance of mononuclear cell infiltrates or granulomatous process with multinucleate giant cells

Reproduced with permission from Hunder GG, Bloch DA, Michel BA, et al. The American College of Rheumatology 1990 criteria for the classification of giant cell arteritis. *Arthritis Rheum* 1990;33:1122–8.

More problematic are those presenting with posterior ischemic optic neuropathy (with an apparently normal optic disc in the acute

phase) and who may not report typical features; in the series by Hayreh, around 10% of the IONs seen were posterior ischemic optic neuropathy (PION).<sup>191</sup> The estimates of visual loss from GCA vary widely from 13% to 70%, with lower estimates being seen in a recent series that may reflect improved diagnosis and earlier treatment. The visual loss is usually severe (<20/200), and visual recovery is uncommon despite appropriate therapy.<sup>197</sup> Visual field loss may be complete, altitudinal, or occasionally an arcuate (Bjerrum-type) scotoma. Amaurosis fugax may be a warning of impending ION or other serious ischemic pathology. An ischemic retinopathy with cotton-wool spots (and sometimes retinal hemorrhages) may be seen and can precede optic nerve involvement.<sup>198,199</sup> Other ophthalmic complications of biopsy-proven GCA include cilioretinal artery occlusion (CRAO), and ocular ischemic syndrome occurring in about 14%, 20%, and 1%, respectively, of patients. Occasionally there is extraocular muscle dysfunction with symptoms of transient or permanent diplopia.<sup>191</sup>

### **Treatment.**

Corticosteroids are the mainstay of treatment, with almost all patients who present to a rheumatologist responding to 40–60 mg oral prednisone. Those patients presenting to an ophthalmologist with or without vision loss should have three intravenous pulses of methylprednisolone 1 g for 3 days, then oral prednisone 1 mg/kg daily. Corticosteroid taper can occur after 4 weeks with resolution of symptoms and a fall in inflammatory markers.<sup>200</sup> It is reasonable to aim for a dose of 15 mg by 3 months of therapy. In addition, low-dose aspirin (to reduce the risk of arterial thrombus and visual loss) and bone protection (bisphosphonates and calcium and vitamin D supplementation) with or without a proton pump inhibitor could be considered.<sup>200</sup> On average, 18 months of corticosteroid treatment is required, but up to 40% may need long-term therapy due to relapsing disease. A corticosteroid sparing agent may need to be introduced, such as methotrexate, azathioprine, and leflunomide. There is no evidence that they are beneficial when used at disease onset but may be helpful in relapsing disease to minimize corticosteroid dose and thus side-effects. Recently, encouraging results have been demonstrated with the biologics infliximab,

etanercept, rituximab, and tocilizumab.<sup>201-203</sup>

## Takayasu's Arteritis

### General Considerations.

Takayasu's arteritis is a rare inflammatory disease of unknown etiology, characterized by granulomatous vasculitis affecting large arteries, in particular the aorta and its main branches.

### Epidemiology.

Takayasu's arteritis is very rare, with an annual incidence of 2.6 per million in North America and 1.2 per million in Japan. It is classically described in women of childbearing age of Southeast Asian, South African, and Latin American background<sup>204-206</sup> (see **Box 839**).

### The American College of Rheumatology Criteria for the Classification of Takayasu Arteritis

For purposes of classification, a patient is said to have Takayasu arteritis if *at least three* of these six criteria are present. The presence of any three or more criteria yields a sensitivity of 90.5% and a specificity of 97.8%.

1. Age at disease onset <40 years  
Development of symptoms or findings related to Takayasu arteritis at age under 40 years
2. Claudication of extremities  
Development and worsening of fatigue and discomfort in muscles of one or more extremities while in use, especially the upper extremities
3. Decreased brachial artery pulse  
Decreased pulsation of one or both brachial arteries
4. BP difference >10 mmHg  
Difference of >10 mmHg in systolic blood pressure between arms

5. Bruit over subclavian arteries or aorta  
Bruit audible on auscultation over one or both subclavian arteries or abdominal aorta
6. Arteriogram abnormality  
Arteriographic narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities, not due to arteriosclerosis, fibromuscular dysplasia, or similar causes; changes usually focal or segmental

Reproduced with permission from Arend WP, Michel BA, Bloch DA, et al. The American College of Rheumatology 1990 criteria for the classification of Takayasu arteritis. *Arthritis Rheum* 1990;33:1129–34.

### **Articular and Systemic Disease.**

At the time of diagnosis, 10–20% of patients are clinically asymptomatic and the disease is diagnosed incidentally on vascular examination. The most common findings on examination are hypertension, bruits, diminished or absent pulses, and asymmetric blood pressure readings in the extremities. Of symptomatic patients, 80–90% can present with either systemic or vascular symptoms, or a combination of both. Systemic features include fever, malaise, weight loss, arthralgia, and night sweats.<sup>204–206</sup>

Vascular symptoms are more common and are as a result of active vasculitis or vascular damage from previous inflammation resulting in stenosis or aneurysm formation. Involvement of the carotid and vertebral arteries can lead to central nervous system involvement. Clinically patients may be asymptomatic or have symptoms including transient ischemic attacks, stroke, dizziness, syncope, headache, or visual changes. Mesenteric involvement is common. The most common cardiac manifestation is aortic regurgitation. Cutaneous manifestations such as erythema nodosum and pyoderma granulorum have been observed in 3–28% of patients.<sup>204–206</sup>

### **Ocular Disease.**

Ophthalmic disease occurs in around one-third of patients with Takayasu arteritis. The most common ocular complication is hypertensive retinopathy (16–30%), followed by Takayasu

retinopathy (13–15%) and ocular ischemic syndrome (around 4%).<sup>208,209</sup> Takayasu retinopathy may progress from small vessel dilation (stage 1), to microaneurysms (stage 2), arteriovenous anastomoses (stage 3), and finally additional complications, such as retinal neovascularization and vitreous hemorrhage (stage 4).<sup>208</sup> Other recognized complications include AION, PION, and neovascular glaucoma. The presence of ischemic ocular complications is associated with nonrecordable right upper limb blood pressure.<sup>209</sup>

### **Treatment.**

Corticosteroids are the mainstay of treatment. Initially it is recommended that prednisone is started at 1 mg/kg daily (maximum 60 mg/day), for a month then tapered gradually.<sup>210,211</sup> If patients have severe disease or refractory disease, steroid-sparing agents need to be considered.

Corticosteroid-sparing agents that can be considered are azathioprine (2 mg/kg daily) and methotrexate (20–25 mg/week).<sup>210,212</sup> Other agents with limited data available include cyclophosphamide, mycophenolate mofetil, leflunomide and minocycline, and the biologic agents infliximab, tocilizumab, and abatacept.<sup>210,212</sup>

Nonmedical interventions such as angioplasty, stent insertion, arterial reconstruction, and bypass grafting may also be required.<sup>210,211</sup>

## **Medium Vessel Vasculitides**

### **Polyarteritis Nodosa**

#### **General Considerations.**

Polyarteritis nodosa (PAN) is a necrotizing inflammation of medium vessels with or without glomerulonephritis, which can be secondary to hepatitis B, and is ANCA-negative.

#### **Epidemiology.**

PAN is a very uncommon disease, being estimated to occur at less than 1 per million per year (United Kingdom data). The major

environmental risk factor is hepatitis B; other associated viruses are HIV and parvovirus B19.<sup>193</sup>

### **Articular and Systemic Disease.**

PAN has a wide spectrum of disease, ranging from very mild limited disease to life-threatening organ involvement. Arthralgia or arthritis may be present in up to 50% of patients. An intermittent, asymmetric, predominantly lower limb, nondeforming arthritis may occur in up to 20% of cases. Myalgias may occur in up to 50% of patients.<sup>213,214</sup>

Cutaneous features are seen in 25–60%: these include infarctions, ulcerations, livedo reticularis, subcutaneous nodules, and ischemic changes of distal digits.<sup>215</sup> Peripheral neuropathy or mononeuritis multiplex may be seen. CNS involvement with headaches, seizures, cranial nerve dysfunction, stroke, and cerebral hemorrhage are less common. Renal involvement can result in hypertension as a result of renal artery stenosis or renal impairment/failure due to multiple microaneurysms and infarcts as a consequence of vascular occlusion. Abdominal pain, which can occur in up to 70% of patients as a result of gastrointestinal involvement, can be severe, with bowel ischemia occurring.<sup>213,214</sup>

### **Ocular Disease.**

Ophthalmic disease occurs in around 10–20% of patients with PAN and may reflect direct ocular involvement or be secondary to its systemic effects (notably hypertension from renal disease). Retinal disease includes retinal vasculitis and hypertensive retinopathy. Other ophthalmic complications include peripheral ulcerative keratitis, episcleritis, scleritis (both anterior and posterior), serous retinal detachments, ischemic optic neuropathy, cranial neuropathies, and cerebral disease resulting in visual field defects.<sup>216–218</sup>

### **Treatment.**

Pulsed intravenous cyclophosphamide and corticosteroids has been found to achieve better disease control and sustained remission compared to corticosteroids alone, but the long-term survival remains unchanged.<sup>219,220</sup> Patients with hepatitis-associated PAN are

recommended to have high-dose corticosteroid therapy tapered over 2 weeks, followed by antiviral agents and plasma exchange.<sup>219,220</sup>

## **Kawasaki Disease**

### **General Considerations.**

Kawasaki disease predominantly affects young children and is the most common cause of acquired heart disease in the United States and Japan. It is the second commonest vasculitis of childhood after Henoch–Schonlein purpura.

### **Epidemiology.**

The highest incidence rate is in Japan – 216 cases per 100,000 per year in children under 5 years of age – with a peak incidence at between 9 and 11 months of age.<sup>221</sup> There are possible familial and infectious links.<sup>193</sup>

### **Articular and Systemic Disease.**

Kawasaki disease is usually defined as a persistent fever for a minimum of 5 days with a minimum of four out of the following: (1) polymorphous rash; (2) bilateral conjunctival injection without exudates; (3) oropharyngeal involvement, including red fissured lips, strawberry tongue, and red pharynx without exudates; (4) peripheral changes including edema of extremities, sole erythema, and periungual desquamation; and (5) cervical lymphadenopathy. Arthritis of the small joints is common and is associated with a bluish discoloration over the PIPs. Axial arthropathy and effusions can also occur, but the articular symptoms will usually resolve after the acute phase.<sup>222,223</sup>

The most serious manifestation is that of the cardiovascular system, which can result in aneurysms (especially the coronary arteries), myocarditis, and congestive cardiac failure. Other clinical manifestations include gastrointestinal manifestations, urethritis, facial nerve palsy (rare), and sensorineural hearing loss.<sup>222,223</sup>

### **Ocular Disease.**

Bilateral conjunctival injection without purulent discharge is one of

the hallmarks of Kawasaki disease. Additionally, bilateral anterior uveitis is common in the first week of illness.<sup>224</sup> Rare ocular manifestations include optic neuritis and ophthalmic artery obstruction.<sup>225</sup>

### **Treatment.**

Kawasaki disease is treated with a single intravenous (IV) dose of immunoglobulin and high-dose aspirin. The aspirin dose can be reduced once the fever finishes. If patients fail to respond to the first dose of IV immunoglobulin, treatment options include a repeat infusion, infliximab, IV methylprednisolone, and plasmapheresis.<sup>226–229</sup>

## **Small Vessel Vasculitides**

### **Granulomatosis With Polyangiitis (Wegener's Granulomatosis)**

#### **General Considerations.**

Granulomatosis with polyangiitis (GPA) is a multisystem disease of unknown etiology, characterized by granulomatous inflammation, tissue necrosis, and varying degrees of vasculitis. It can affect any organ, but has a predilection for the upper respiratory tract, lungs, and kidneys.

#### **Epidemiology.**

GPA has a slight male predominance, and is more common in Caucasians. GPA is a rare disease, with a prevalence ranging from 3 per 100,000 in the United States to up to 16 per 100,000 in Northern Europe.<sup>230,231</sup> GPA predominantly affects older individuals, but 15% of cases have been reported in childhood.<sup>232</sup> GPA is highly associated with PR3 (proteinase 3) ANCA.<sup>233</sup>

#### **Articular and Systemic Disease.**

Musculoskeletal symptoms can occur in up to 60% of patients. Commonly a migratory polyarthritis affecting the large joints or a polyarthritis can occur.

Presenting symptoms in up to 75% of patients will be of upper

respiratory tract disease (nasal, sinus, tracheal, and/or ear abnormalities). The “saddle nose deformity” results from nasal bridge collapse, and other nasal manifestations include nasal pain, stuffiness, crusts, epistaxis, mucosal erosion, and septal perforation. A characteristic feature of mouth involvement is “strawberry gums,” an intense gingivitis that responds to systemic treatment. A serious complication is subglottic stenosis secondary to tracheal inflammation and scarring, as this may require a tracheostomy.<sup>3</sup> Nonspecific systemic features may occur, particularly during active disease, which include fever, malaise, arthralgias, anorexia, and weight loss.<sup>3</sup>

Pulmonary involvement may present as cough, hemoptysis, dyspnea, or pleuritic or other forms of chest pain; however one-third of patients with pulmonary lesions have asymptomatic disease. Renal involvement occurs in about 80% of GPA patients.

### **Ocular Disease.**

Ophthalmic disease occurs in around 50% of patients in this condition and is an important cause of morbidity and blindness, with vision loss occurring in around 8%.<sup>3</sup> Although orbital disease is the most common ocular complication of the disease, almost any part of the ophthalmic system may be affected.

Orbital disease occurs in up to 20% of patients with GPA. It may present with acute or subacute proptosis, and may be associated with ocular motility disturbance (resulting in diplopia), and optic nerve compression or infiltration potentially leading to blindness. Severe proptosis may also lead to sight-threatening exposure keratopathy. It should be noted that although proptosis is common in these patients, chronic orbital inflammation may lead to orbital socket contraction with enophthalmos, restrictive ophthalmopathy, and chronic pain.<sup>234</sup>

Important nonorbital presentations of GPA include scleritis (7–10% of patients), peripheral ulcerative keratitis, and an ulcerative conjunctivitis with a chronic cicatrizing course.<sup>235</sup> The scleritis may be anterior or posterior; necrotizing scleritis is often associated with corneal disease (marginal corneal ulcer/PUK). Uveitis is uncommon (around 3%). Anterior, posterior and panuveitis have all been described in this context and may be isolated or associated with

scleritis.<sup>236,237</sup> Retinal vasculitis may occur and ranges in severity from cotton-wool spots to severe vaso-occlusive disease, with neovascularization and related consequences. Neuro-ophthalmic consequences most commonly occur secondary to orbital involvement, but may also arise due to vasculitis causing ischemic optic neuropathy. In a study of 59 patients with ANCA-associated vasculitis and ocular inflammation, 75% had scleritis, and with time these patients had a 2.75-fold higher mortality than other patients with inflammatory eye disease.<sup>238</sup>

### **Treatment.**

Like other vasculitides, the suggested treatment to induce remission is pulsed intravenous cyclophosphamide with oral steroids.<sup>219,239</sup> Corticosteroid-sparing agents that can be substituted for cyclophosphamide once remission has been achieved are methotrexate or azathioprine. If disease is limited, then methotrexate in combination with oral corticosteroid can be used rather than cyclophosphamide.<sup>219</sup> Biologics are now increasingly used in the management, initially infliximab and more recently rituximab.<sup>240</sup> Rituximab is used for remission induction when cyclophosphamide is contraindicated and as remission maintenance in those where risk of relapse is high. It has been used in sight threatening ocular and orbital disease.<sup>189,241</sup> Treatment is primarily directed against the systemic disease, although it should be noted that the severity of ophthalmic involvement may be an important factor in escalating therapy.

## **Microscopic Polyangiitis**

### **General Considerations.**

Microscopic polyangiitis (MPA) is a necrotizing vasculitis, predominantly affecting small vessels, associated with MPO (myeloperoxidase) ANCA.

### **Epidemiology.**

MPA has an incidence of 5 per million per year, with a peak age of onset of between 65 and 75 years; it is more common in men.<sup>231</sup>

## Articular and Systemic Disease.

Renal involvement is very common, affecting up to 90% of patients. Rapidly progressive glomerulonephritis may occur, resulting in acute renal failure necessitating renal dialysis. Varying degrees of pulmonary involvement can occur; these can range from mild dyspnea to life-threatening pulmonary hemorrhage. Involvement of both the central and peripheral nervous system is described and includes peripheral neuropathy, mononeuritis multiplex, cerebral hemorrhage/infarction, seizures, or headache. Other systemic manifestations include cardiac, gastrointestinal, otorhinolaryngeal, and venous thromboembolism.<sup>215,242,243</sup>

## Ocular Disease.

Ophthalmic disease is rare in MPA, with one series noting ocular involvement in only 1 of 85 patients with MPA.<sup>242</sup> In small case series and isolated reports the following ophthalmic complications have been noted: scleritis, anterior uveitis with hypopyon, retinal vasculitis (ranging from cotton-wool spots to neovascularization and vitreous hemorrhage), and peripheral nonulcerative keratitis.<sup>244,245</sup>

## Treatment.

Recommended treatment for severe MPA is oral corticosteroid with pulsed intravenous cyclophosphamide to induce remission.<sup>219,239</sup> In milder active disease (no threatened vital organ disease or damage), methotrexate or azathioprine and oral corticosteroid can be used, but there is a higher risk of relapse.<sup>239</sup> If patients have failed to achieve remission and have persistent low activity, IV immunoglobulin can be used to achieve remission.<sup>219</sup> There is increasing data on the use of biologics, mainly rituximab for the same indications as for GPA.<sup>246</sup>

## Eosinophilic Granulomatosis with Polyangiitis

### General Considerations.

Eosinophilic granulomatosis with polyangiitis (EGPA, Churg–Strauss syndrome) is a primary, multisystem, eosinophilic vasculitis

associated with upper and lower respiratory tract disease and ANCA.

### **Epidemiology.**

EGPA is estimated to have a prevalence of 10 to 15 per million. The mean age of diagnosis is 55 years. It has equal gender incidence.<sup>247</sup>

### **Articular and Systemic Disease.**

EGPA can affect virtually any organ system in the body. Systemic symptoms include fever, weight loss, arthralgias, and, rarely, arthritis.<sup>247</sup>

Pulmonary involvement is nearly universal in EGPA with 96–100% having asthma. Other pulmonary manifestations include pulmonary infiltrates, pulmonary hemorrhage, and pleural effusions.

Peripheral neuropathy occurs commonly (65–75%), usually with mononeuritis multiplex. CNS involvement may include cranial nerve palsies, ischemic optic neuropathy, cerebral hemorrhage or infarction, convulsions, coma, and psychosis.

Abdominal pain is the most common gastrointestinal symptom. Cardiac involvement includes eosinophilic endomyocarditis, coronary vasculitis, valvular heart disease, congestive heart failure, hypertension, and pericarditis. Skin lesions are common and typically include nonthrombocytopenic palpable purpura, with erythematous, maculopapular, or pustular lesions being reported. Renal involvement is fairly typical, but unlike other necrotizing vasculitides such as GPA or microscopic polyangiitis, renal failure is rare.<sup>247–249</sup>

### **Ocular Disease.**

Ophthalmic disease may arise from two processes: vasculitis and granuloma formation. Clinical presentations include conjunctival nodules,<sup>250</sup> peripheral ulcerative keratitis, episcleritis, scleritis, uveitis (rare), retinal vasculitis,<sup>251</sup> retinal artery occlusion, ischemic optic neuropathy, cranial neuropathies,<sup>252</sup> and orbital disease (presenting with an orbital inflammatory syndrome).<sup>251</sup>

### **Treatment.**

As with other ANCA-positive vasculitides, remission induction is normally achieved with oral corticosteroids and cyclophosphamide or with a DMARD such as methotrexate or azathioprine in less severe disease.<sup>219,239</sup> Rituximab is currently undergoing clinical trials, but there have been promising results published.<sup>253</sup>

## Ocular Complications of Rheumatologic Therapies

### General

Ocular complications of rheumatologic therapies may relate to (1) direct drug-specific toxic effects, such as chloroquine retinopathy, (2) indirect drug-specific side-effects, such as corticosteroid-induced ocular hypertension resulting in secondary glaucoma, and (3) drug nonspecific complications relating to immunosuppression, such as opportunistic infections.

### Corticosteroids

Most treatment-related visual morbidity is associated with corticosteroid treatment. The association between posterior subcapsular cataract and exogenous corticosteroids is well established.<sup>254</sup> Cataract surgery in patients with rheumatic diseases is generally successful, although there must be strict control of any intraocular inflammation prior to surgery and in the postoperative phase. Prognosis will be worse if there is visually significant posterior segment disease. Increased intraocular pressure due to exogenous corticosteroids may occur in up to 30% of the normal population, with 5% experiencing an increase of more than 15 mmHg (reviewed by Clark<sup>255</sup>). Corticosteroid-induced ocular hypertension must be monitored and treated where there is a risk of progression to secondary glaucoma.

### Antimalarials

The aminoquinolines chloroquine and hydroxychloroquine have been widely used in the treatment of SLE. These drugs can cause a

reversible, visually insignificant keratopathy (cornea verticillata) and, more importantly, an irreversible sight-threatening maculopathy. Clinical progression is of loss of the foveal reflex followed by a fine granular appearance of the macula and finally a “bull's-eye” maculopathy presenting as a central scotoma. Endstage disease includes generalized atrophy, peripheral pigmentation, arteriolar attenuation, and optic atrophy.<sup>256</sup>

Retinopathy is rare with hydroxychloroquine when used at currently recommended doses (<6.5 mg/kg daily), but increases markedly towards 1% after 5–7 years of usage or a cumulative dose of 1000 g of hydroxychloroquine.<sup>257,258</sup> The risk with chloroquine is thought to be significantly greater, with an increased risk at over 460 g chloroquine. In both cases, risk increases with increasing dose, increasing duration, and reduced renal function. The American Academy of Ophthalmology (AAO) 2011 guidelines recommend screening for all patients at baseline or within first year of use, and to start annual screening after 5 years of use (or earlier if additional risk factors).<sup>258</sup> Assessments should include dilated retinal examinations and white 10–2 automated visual field testing which should be interpreted with a low threshold for abnormality and with retesting if abnormalities are seen. Additionally, they recommend that one or more of the following should be performed where available: spectral domain optical coherence tomography, multifocal electroretinography, or fundus autofluorescence.<sup>258</sup> High-risk patients include those on a dose of >6.5 mg/kg, with a duration of >5 years, obese patients, those with renal or hepatic disease, those with preexisting retinal disease, or those over the age of 60 years.<sup>258</sup> Amsler grid testing is no longer recommended. Although fundus examinations are advised for documentation, the aim is to detect changes before visible maculopathy. The AAO authors stress the importance of counseling patients regarding the risk of toxicity and the rationale for screening.

## Introduction

Acquired immunodeficiency syndrome (AIDS) is a potentially fatal multisystem syndrome characterized by profound disruption of the immune system and a propensity for various opportunistic infections and neoplasms. AIDS is caused by either of two human immunodeficiency viruses (HIV-1 [formerly HTLV-3] or HIV-2).<sup>1-3</sup> HIV-1 entered humans from chimpanzees nearly a century ago and, after passing unrecognized among West Africans,<sup>4,5</sup> came to the United States via Haiti in the 1970s. AIDS was recognized first in 1981 as outbreaks of usual opportunistic infections (OIs) in homosexual men in three American cities.

Ocular involvement occurs in up to 73% of AIDS patients,<sup>6,7</sup> with the most common lesions being a retinal vasculopathy consisting of cotton-wool spots, retinal hemorrhages, and infectious retinopathy such as cytomegalovirus (CMV), herpetic, toxoplasmic, or luetic retinitis.

## Epidemiology of HIV Infection and AIDS

By 2012, an estimated 1.2 million people were living with HIV in the United States.<sup>8</sup> Since 1996 AIDS has been converted from an inevitably progressive and fatal disease into a manageable chronic condition by three-drug regimens referred to as highly active or combination antiretroviral therapy (HAART or CART). HIV is spread by homosexual and heterosexual intercourse, blood exposures through shared needles among intravenous drug users, or peripartum or by breast-feeding of infants.<sup>9-11</sup>

## Occupational Exposure to HIV

The average risk of HIV transmission in healthcare workers after percutaneous exposure to HIV-infected blood is approximately 0.3% without treatment.<sup>12,13</sup> This risk is further lowered by double-gloving and is probably much lower in the ophthalmic setting.<sup>14</sup> Postexposure prophylaxis (PEP) with two or three antiretroviral

drugs appears likely to dramatically reduce the transmission of HIV even after high-risk injuries.<sup>15</sup> Because PEP should be started as soon as possible after injury, healthcare institutions should have well-developed procedures that provide for expert consultation and ready access to a combination of drugs for persons at high risk of injuries, such as surgeons, invasive proceduralists, and phlebotomists.

Currently, for percutaneous injuries, the US Public Health Service recommends 4 weeks of treatment with a two-drug regimen if the exposure is less severe (solid needle and superficial injury) and the source patient has asymptomatic HIV infection or known low viral load (<1500 RNA copies/mL [class I patient]). An expanded three-drug regimen is recommended if the exposure is severe (large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient's artery or vein) or if the source patient has symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load (class II patient). The recommended two-drug regimens for HIV/PEP are (1) tenofovir plus emtricitabine or (2) zidovudine plus lamivudine. Tenofovir is generally better tolerated, but should not be used in persons with renal insufficiency. Three-drug regimens involve adding ritonavir-boosted (/r) lopinavir/r or darunavir/r. Alternatives for constructing an expanded regimen in cases of resistance, drug interactions, or intolerance include darunavir/r, atazanavir/r, or raltegravir. For mucous membrane or nonintact skin exposures, the two-drug regimen is recommended for all small volume exposures (a few drops) and large volume (major blood splash) exposure in a class I patient, with three-drug expanded regimens recommended for large volume exposure in a class II patient.<sup>13</sup>

## HIV Virology and Pathogenesis

HIV infection usually gradually depletes CD4 lymphocytes, resulting in decreased blood levels of this crucial subset of “helper” T cells.<sup>16</sup> AIDS patients typically become ill only after CD4<sup>+</sup> helper T cells reach less than 200/ $\mu$ L, a level that no longer supports cell-mediated immunity at levels needed to contain infections by select opportunistic viral, bacterial, or fungal pathogens.

Understanding of HIV infection was revolutionized by the development in the mid-1990s of assays that measured the levels of HIV in the blood. All stages of HIV infection were seen to be characterized by a high rate of viral replication in most patients. Levels of plasma HIV-1 RNA predict the rate of clinical progression in HIV patients.<sup>17-23</sup> Both high replication and an error-prone reverse transcription process promote frequent mutations in the HIV genome that result in the emergence of variants that can better resist either control by the host's antibody and cell-mediated immune responses or by antiretroviral drugs, if drugs are present in insufficient numbers or at low blood levels that fail to fully suppress HIV replication. Under selective pressure from antiretroviral agents, mutations that confer a decreased sensitivity to individual drugs are selected and stored in latent cells where they last for decades.<sup>24-27</sup>

## Therapy of HIV Infections

Treatment of HIV has evolved rapidly, with the development of more than 30 drugs (as of 2011) that fall into at least four classes based on which of the steps in HIV replication they inhibit ([Table 84.1](#)). These steps include (1) binding to receptors and entry into the host cell; (2) reverse transcription of HIV RNA to proviral DNA; (3) integration of proviral DNA into the host cell genome; and (4) maturation of HIV after budding by the action of HIV protease.<sup>28</sup> Coadministration of drugs from several of the classes delays or prevents the emergence of drug-resistant HIV by minimizing viral replication. However, HIV may develop resistance to all available therapy because (1) patients have difficulty maintaining high levels of adherence over long periods and (2) cross-resistance is common to drugs within a class.<sup>29-32</sup> After failure of a regimen, the next combination of drugs is less likely to be successful in fully suppressing HIV replication, which is the necessary condition for prolonged success. For details of recent expert guidelines on HIV therapy consult *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*, which is constantly updated and available at this NIH website: <http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf>

**TABLE 84.1****Currently Licensed Antiretroviral Drugs in the United States in 2011 by Class**

<b>Brand Name</b>	<b>Generic Name</b>	<b>Manufacturer Name</b>
<b>MULTICLASS COMBINATION PRODUCTS</b>		
Atripla	efavirenz, emtricitabine, and tenofovir disoproxil fumarate	Bristol–Myers Squibb and Gilead Sciences
<b>NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTIS)</b>		
Combivir	lamivudine and zidovudine	GlaxoSmithKline
Emtriva	emtricitabine, FTC	Gilead Sciences
Epivir	lamivudine, 3TC	GlaxoSmithKline
Epzicom	abacavir and lamivudine	GlaxoSmithKline
Retrovir	zidovudine, azidothymidine, AZT, ZDV	GlaxoSmithKline
Trizivir	abacavir, zidovudine, and lamivudine	GlaxoSmithKline
Truvada	tenofovir disoproxil fumarate and emtricitabine	Gilead Sciences, Inc.
Videx EC	enteric-coated didanosine, ddI EC	Bristol–Myers Squibb
Videx	didanosine, dideoxyinosine, ddI	Bristol–Myers Squibb
Viread	tenofovir disoproxil fumarate, TDF	Gilead
Zerit	stavudine, d4T	Bristol–Myers Squibb
Ziagen	abacavir sulfate, ABC	GlaxoSmithKline
<b>NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTIS)</b>		
Edurant	rilpivirine	Tibotec Therapeutics
Intelence	etravirine	Tibotec Therapeutics
Rescriptor	delavirdine, DLV	Pfizer
Sustiva	efavirenz, EFV	Bristol–Myers Squibb
Viramune (immediate release)	nevirapine, NVP	Boehringer Ingelheim
Viramune XR (extended release)	nevirapine, NVP	Boehringer Ingelheim
<b>PROTEASE INHIBITORS (PIs)</b>		
Agenerase	amprenavir, APV	GlaxoSmithKline
Aptivus	tipranavir, TPV	Boehringer Ingelheim
Crixivan	indinavir, IDV,	Merck
Fortovase	saquinavir (no longer marketed)	Hoffmann–La Roche
Invirase	saquinavir mesylate, SQV	Hoffmann–La Roche
Kaletra	lopinavir and ritonavir, LPV/RTV	Abbott Laboratories
Lexiva	fosamprenavir calcium, FOS-APV	GlaxoSmithKline
Norvir	ritonavir, RTV	Abbott Laboratories
Prezista	darunavir	Tibotec, Inc.
Reyataz	atazanavir sulfate, ATV	Bristol–Myers Squibb
Viracept	nelfinavir mesylate, NFV	Agouron Pharmaceuticals
<b>FUSION INHIBITORS</b>		
Fuzeon	enfuvirtide, T-20	Hoffmann–La Roche & Trimeris
<b>ENTRY INHIBITORS – CCR5 CO-RECEPTOR ANTAGONIST</b>		
Selzentry	maraviroc	Pfizer
<b>HIV INTEGRASE STRAND TRANSFER INHIBITORS</b>		
Isentress	raltegravir	Merck & Co., Inc.

## Clinical Spectrum of HIV

HIV infection and disease is highly variable in presentation and includes asymptomatic, various chronic or recurring constitutional signs and symptoms, and a plethora of opportunistic conditions. The “acute retroviral syndrome,” that is, early or primary infection with HIV, is characterized by fever, pharyngitis, skin rash, arthralgias, malaise, mucosal ulcerations, and neurologic manifestations such as aseptic meningitis.<sup>33</sup>

Patients chronically infected with HIV may present with a prodrome of generalized, nontender lymph node enlargement, fevers and night sweats, weight loss, and diarrhea for weeks or months, formerly termed AIDS-related complex (ARC). Nearly all HIV-seropositive patients will progress to AIDS, but a small minority, called “long-term nonprogressors” or “elite controllers,” suppress their infections naturally (without treatment) to the point of very low or undetectable levels of plasma HIV. Although highly active antiretroviral therapy (HAART) often reduces plasma viremia of HIV-1 to undetectable levels, latent viral reservoirs of resting CD4 lymphocytes persist for years and reappear in the blood if therapy is stopped.<sup>34</sup>

Opportunistic infections are responsible for the deaths of most AIDS patients, but consequences of coinfections with hepatitis C and B, such as hepatic insufficiency or hepatocellular carcinoma, have become increasingly important, in part because HIV promotes progression of these infections.<sup>35</sup> The most common pathogens encountered in AIDS patients are cytomegalovirus (CMV), *Candida albicans*, *Pneumocystis jiroveci* (formerly *carinii*), *Mycobacterium tuberculosis* and *M. avium-intracellulare*, *Cryptococcus neoformans*, herpes simplex virus (HSV), *Cryptosporidium* spp., *Toxoplasma gondii*, and varicella-zoster virus (VZV).<sup>3,36</sup> CMV retinitis can be the initial sign of tissue-invasive systemic CMV infection in these patients, although it is restricted to patients with advanced immunosuppression (CD4<sup>+</sup> count less than 50/ $\mu$ L). CMV may present also in the gastrointestinal tract, brain and spinal cord, or other organs.<sup>37</sup>

## Infection Control Related to HIV

The US Centers for Disease Control and Prevention (CDC) recommendations for universal precautions to prevent the occupational transmission of HIV and other bloodborne viruses in the healthcare setting were provided in 1988 and have not been amended.<sup>38</sup>

The CDC provided specific guidelines for ophthalmologic examinations in addition to the general recommendations. The use of gloves (especially if the skin of the examiner is compromised in any way) and good handwashing technique after procedures or examinations involving the eye are recommended because HIV may be present in tears.

Sterilization of all instruments and equipment that come into contact with the eye in all patients is necessary using gas or steam autoclaving or a 5- to 10-minute soak in one of the following solutions: 3% hydrogen peroxide solution, 10% solution of sodium hypochlorite (common household bleach), or 70% ethanol or isopropanol. Instruments disinfected in this manner should be rinsed in water and dried before reuse.<sup>39,40</sup> Damage to tonometer tips has been reported with the use of 70% isopropanol; thus a 5- to 10-minute soak in 3% H<sub>2</sub>O<sub>2</sub> or 1 : 10 dilution of household bleach may be preferable.<sup>41</sup> It should be noted that there is no evidence of HIV transmission through contact with tears or instruments used to examine these patients.<sup>39</sup>

Contact lenses used in trial fittings on all patients should be disinfected by use of any commercially available cleaning method or solution.<sup>42</sup> Inactivation of HIV by various disinfectants on surfaces has been reviewed.<sup>43</sup> Guidelines for preventing transmission of HIV through transplantation of human tissue and organs (including corneal transplants) have been set forth.<sup>44</sup> Specific recommendations for postexposure management of needlestick injuries or mucosal membrane exposures to secretions from patients with HIV infection have been published.<sup>45</sup>

## Ocular Findings in AIDS: An Overview

HIV has been detected in the cornea,<sup>46</sup> conjunctival epithelium,<sup>47</sup>

and in tears,<sup>46</sup> but at very low titers. Ocular manifestations of AIDS may be seen in up to 100% of patients. They are less common, but may be seen in patients with earlier, symptomatic HIV infection.<sup>48</sup> Most common are cotton-wool spots and other noninfectious retinopathies,<sup>49</sup> CMV retinitis, and conjunctival Kaposi sarcoma, followed less frequently by herpes zoster ophthalmicus,<sup>50,51</sup> retinal toxoplasmosis, choroidal *P. carinii* infection, herpes simplex and herpes zoster retinitis (acute retinal necrosis [ARN]), and cryptococcal choroiditis.<sup>6,52-59</sup>

Iritis may occur in association with viral retinitis but especially with CMV; it is mild. Acute iritis may be associated with the use of oral rifabutin (used for the treatment and prophylaxis of mycobacterial infections) or intravenous cidofovir used for CMV retinitis.<sup>60</sup>

Choroidal infection with *Cryptococcus*, *Pneumocystis*, *M. tuberculosis*, *Aspergillus*, *Toxoplasma*, *Histoplasma*, and *M. avium-intracellulare* usually is associated with systemic infection.<sup>61,62</sup> *Histoplasma capsulatum* chorioretinitis and endophthalmitis,<sup>63</sup> *Paracoccidioidomycosis brasiliensis* chorioretinitis,<sup>64</sup> keratitis sicca, cranial nerve paralysis, Roth's spots, papilledema, perivasculitis, and fungal corneal ulcers are rare but have been reported.<sup>65</sup>

## Noninfectious Retinopathy

Noninfectious retinopathy refers to cotton-wool spots, retinal hemorrhages, and microvascular abnormalities that do not progress, enlarge, or cause visual symptoms. No infectious cause of these lesions has been demonstrated, and they appear to represent nonspecific retinal microvascular disease. A correlation between the number of cotton-wool spots and decreased cerebral blood flow (as shown by technetium 99<sup>m</sup> hexamethylpropyleneamine oxime single photon emission computed tomography) was shown in 25 patients with AIDS or symptomatic HIV infection.<sup>66</sup>

Cotton-wool spots are the most common ocular lesion seen in AIDS, occurring in 25–50% of patients<sup>6,67</sup> and in up to 75% of cases by autopsy examination.<sup>57</sup> In one study, up to 92% of AIDS patients were found to have evidence of retinovascular disease when examined using fluorescein angiography.<sup>67</sup> Cotton-wool spots seen

by ophthalmoscopy are a result of microinfarction of the nerve fiber layer of the retina. In AIDS these lesions usually are confined to the posterior pole near the optic disc<sup>67</sup> (Fig. 84.1). Histopathologic study of retinal cotton-wool spots in AIDS patients has demonstrated that these lesions have pathologic features identical to those seen in cotton-wool spots of other cause. Similar to the cotton-wool spots seen in other systemic diseases, this lesion in AIDS demonstrates no associated inflammation, no cells in the vitreous, and no vascular leakage on fluorescein angiography (Fig. 84.2). Attempts to isolate organisms from cotton-wool spots in the hope of explaining their cause in AIDS as infectious have been unsuccessful, and the cause of this lesion in AIDS remains elusive.<sup>6,57,68,69</sup>

**FIG. 84.1** (A) Retinal cotton-wool spot seen inferotemporal to the disc. (B) Early fluorescein angiogram shows blockage and possible nonperfusion. (C) Late angiogram shows staining, presumably from damaged retinal microvasculature.

**FIG. 84.2** Photomicrograph of retinal cotton-wool spot shows cytooid bodies and swelling of the nerve fiber layer of the retina. Retinal cellular elements are seen at the top of the photograph.

Cotton-wool spots have been speculated to be harbingers of CMV retinitis or perhaps sites of susceptibility to CMV infection, but substantiation of these ideas is lacking. Histopathologic studies of eyes at autopsy have failed to show clear evidence of a viral cause of cotton-wool spots.<sup>70-72</sup>

We have reported that noninfectious retinopathy is not seen in HIV-seronegative men and is rare in ARC, but it is very common in patients with AIDS even in the absence of active opportunistic ophthalmic infection.<sup>48</sup> It is striking that this lesion may be seen in 50–75% of AIDS patients, and studies using multiple examinations indicate that the more frequently these patients are examined, the higher the incidence may be.<sup>6,49</sup> Cotton-wool spots probably are ophthalmoscopically visible for 6–12 weeks, and owing to the transient nature of the lesion and its apparent noninfectious cause, treatment is not indicated at this time.<sup>73</sup> On in vivo imaging they cause the “hyper-reflective sign”<sup>74</sup> followed by inner retina thinning years after their disappearance.<sup>75</sup>

In a cross-sectional study, the median CD4 count (per microliter [ $\mu$ L]) in patients with cotton-wool spots was 14 cells (range 0–160) and was 8 cells (range 0–42) in patients with CMV retinitis.<sup>76</sup> In the absence of other systemic vascular disease, such as hypertension or diabetes mellitus, AIDS must be considered in the differential diagnosis of cotton-wool spots owing to their very high prevalence

in these patients. Whether these lesions are an early manifestation of AIDS remains to be elucidated, but they may be apparent in HIV-infected persons before the onset of opportunistic infections.<sup>48</sup>

Morphologic studies have shown that the number of retrobulbar optic nerve fibers in patients with AIDS is decreased compared with the number of optic nerve fibers in normal control eyes as a result of axonal degeneration and an associated decrease in the number of optic nerve axons.<sup>77-80</sup> Infarctions of the nerve fiber layer develop in most patients with AIDS, and the number of such infarctions increases over time.<sup>6,49</sup> Visual dysfunction associated with multiple nerve fiber layer infarctions may be manifested by defects in color-vision and contrast-sensitivity testing in patients with AIDS.<sup>81-83</sup>

Interestingly, *in vivo* studies of the retinal nerve fiber layer have shown both broad and slit-like defects, suggesting that retinal nerve fiber loss and optic nerve fiber loss are related to subclinical vision loss in HIV patients without infectious retinitis.<sup>74,84</sup>

Electroretinographic studies of HIV patients without retinitis also have shown retinal dysfunction.<sup>85,86</sup> The complex of above-mentioned vision abnormalities has been termed HIV neuroretinal disorder with an incidence in HIV patients between 16% to 50% after 20 years of AIDS diagnosis.<sup>87,88</sup> The molecular biology of HIV retinopathy and possible pathophysiology of HIV neuroretinal disorder has been published recently.<sup>89</sup>

Retinal hemorrhages are seen in AIDS in association with CMV retinitis, cotton-wool spots, and as an isolated finding. These lesions have been reported in up to 30%<sup>52,67,90</sup> of AIDS patients, and autopsy evidence of retinal hemorrhages has been reported to be as high as 40%. Retinal hemorrhages usually take the form of flame-shaped lesions in the posterior pole, dot-blot hemorrhages, or as punctate intraretinal hemorrhages peripherally (Fig. 84.3). Occasionally the hemorrhage is manifested as Roth's spots (hemorrhage with a white central area).<sup>52,67</sup> The pattern of retinal hemorrhages changes over time. The hemorrhages do not appear to be related to a bleeding diathesis or coagulopathy, but rather seem to be a manifestation of AIDS itself.<sup>6</sup> Vision loss from retinal hemorrhage has not been described, and treatment is conservative if the lesions are not associated with CMV retinitis or septicemia.

**FIG. 84.3** White, centered retinal hemorrhage (Roth spot) seen in an HIV-infected patient. These lesions do not progress.

Microvascular pathologic findings in AIDS, as demonstrated by fluorescein angiography, include microaneurysms, telangiectasias, focal areas of nonperfusion, and capillary loss.<sup>67</sup> These changes are similar to the changes seen in diabetes mellitus. The histologic findings of periodic acid–Schiff (PAS)-positive thickening of blood vessels and precapillary arteriolar closure also correlate with the findings in diabetes mellitus.

Branch or central retinal vein occlusion, branch retinal artery occlusion, and ischemic maculopathy have been reported in HIV patients without infectious retinitis. The incidence is unknown. It is possible that the cause may be related to lupus anticoagulant and other clotting abnormalities seen in HIV-infected patients.<sup>91,92</sup> Abnormalities of retinal blood flow have also been reported in HIV patients and may contribute to the pathogenesis of microvascular abnormalities.<sup>93–96</sup>

## Infectious Retinopathy

### Cytomegalovirus Retinitis

#### Pathogenesis, Diagnosis, and Clinical Manifestations

CMV infection is a major cause of morbidity and mortality in AIDS. CMV retinitis has been reported to occur in 15–40% of AIDS patients with the rate declining since the arrival of HAART.<sup>37,52,97,98</sup> In contrast to the noninfectious lesions of AIDS, CMV retinitis demands aggressive treatment to prevent severe visual loss.<sup>6,99,100</sup> Patients with active CMV disease may have systemic symptoms of fever, arthralgia, and pneumonitis, or leukopenia, retinitis, or hepatitis; blood cultures and urine specimens may be positive for CMV. CMV retinitis often is the presenting sign of systemic CMV infection, and all patients should be thoroughly evaluated for systemic disease.

The clinical presentation of CMV retinitis in AIDS is similar in many respects to CMV retinitis found in iatrogenically immunosuppressed patients and infants with cytomegalic inclusion disease.<sup>101,102</sup> Correlation of the clinical and typical pathologic findings at autopsy has been demonstrated.<sup>103</sup> Specifically, it is known that CMV is a neurotropic virus with a tendency to infect neural tissues and the retina. Necrosis of the retina in AIDS-associated CMV retinitis is typical, with pathognomonic cytomegaly and minimal inflammatory cells present in the lesions. Choroidal involvement is rare, and whether vascular endothelium is involved is unclear. These lesions also may appear as noncontiguous patches rather than the more commonly seen contiguous spreading lesion. Antigens to CMV have been found by immunofluorescence, immunoperoxidase staining, and DNA hybridization techniques.<sup>104,105</sup> The most distinctive anterior segment finding is the presence of fine stellate keratic precipitates on the corneal endothelium.<sup>106</sup> Retinal vascular nonperfusion and retinal neovascularization resulting from CMV retinitis and choroiditis also have been reported.<sup>107</sup>

CMV is a slowly progressive necrotizing retinitis that may affect the posterior pole, the periphery, or both, and may be unilateral or bilateral. Involved retinal areas appear as white intraretinal lesions, areas of infiltrate, and often necrosis along the vascular arcades in the posterior pole. In addition, prominent retinal hemorrhages often are present within the necrotic area or along its leading edge (Fig. 84.4). Peripherally, CMV retinitis occurs commonly; it tends to have a less intense white appearance, with areas of granular, white

retinitis that may or may not demonstrate associated retinal hemorrhage (Fig. 84.5). As the retinitis progresses, an area of atrophic, avascular retina may remain with underlying retinal pigment epithelial atrophy or hyperplasia.<sup>6,37,108</sup> Peripheral CMV retinitis is common in AIDS patients who initially may report only floaters with or without a visual field deficit. Wide-angle fundus photography and fluorescein angiography may be of benefit if the diagnosis is uncertain. These techniques may be used to document progression of retinitis, and fluorescein leakage in areas of retinitis may be helpful in confirming the diagnosis (Fig. 84.6).

**FIG. 84.4** CMV retinitis with hemorrhagic areas are seen superior to the fovea and a more dense area just below the fovea. Borders are opaque and associated with variable amounts of hemorrhage.

**FIG. 84.5** (A) Peripheral cytomegalovirus (CMV) retinitis without retinal hemorrhage is characterized by white areas of retinal necrosis. (B) After healing, CMV retinitis leaves behind a glial scar without opacification (not same eye as in panel A). Often only minimal pigmentary changes are seen.

**FIG. 84.6** Fluorescein angiogram of cytomegalovirus (CMV) retinitis lesion shows lack of perfusion and blockage, as well as staining and leakage of fluorescein from damaged retinal vessels.

Reactivation of CMV retinitis is characterized by reopacification of the border of the lesion followed by advancement. Smoldering

retinitis (Fig. 84.7) and subtle reactivation may be difficult to recognize without prior fundus photographs. Several studies have shown that wide-angle fundus photographs are a more sensitive indicator of retinitis progression than is clinical examination by indirect ophthalmoscopy.<sup>109,110</sup>

**FIG. 84.7** Smoldering cytomegalovirus (CMV) retinitis is a low grade of retinitis border activity that is associated with slow progression of retinitis. It may be difficult to diagnose without fundus photographs. (A) Low grade CMV lesion. (B) Lesion has progressed slowly over 2 months.

Several investigators have shown that untreated CMV retinitis is inexorably progressive in AIDS patients.<sup>6,52,102,104,110,111</sup> As in our experience, untreated CMV becomes bilateral in the vast majority of patients. In an observational study of 26 patients treated for CMV retinitis, vision scores decreased with greater abnormalities found on ophthalmologic examination. Visual symptoms were most strongly related to findings in the worse eye. Patients reported considerable impairment, including blurred vision (42%), difficulty reading (40%), difficulty driving (44%), treatment interference with social activities (40%), and substantial trouble with vision (50%).<sup>112</sup> Treatment of AIDS-related CMV retinitis minimizes loss of vision and may protect previously uninfected eyes, prolonging visual independence.<sup>113</sup>

Recurrent CMV retinitis exhibiting a foveal-sparing pattern within 1500  $\mu$ m of the foveola has been described and occurs primarily in patients with recurrent CMV retinitis resistant to

treatment (“clinically resistant”), particularly that which has arisen temporally. Despite its foveolar proximity and ultimate significant loss of function, the pattern of progression allows for preservation of useful foveal vision for longer periods than would have been expected.<sup>114</sup>

Other manifestations of CMV retinitis include retinal edema, attenuated vessels, perivascular sheathing, and exudative retinal detachment<sup>115</sup> (Fig. 84.8). In addition, vitritis and anterior uveitis are often seen, and optic atrophy may occur as a late manifestation resulting from widespread retinal destruction. CMV occasionally may be demonstrated in vitreous biopsy specimens in these patients.<sup>103</sup> The yield may be higher in the presence of marked vitritis because CMV is a cell-associated virus. Other causes of retinitis, including herpes simplex retinitis,<sup>101,116</sup> toxoplasmosis,<sup>62</sup> candidal infection, Behçet disease, syphilis, acute retinal necrosis,<sup>117,118</sup> and subacute sclerosing panencephalitis, usually can be distinguished from CMV on clinical grounds, although this may not be the case in retinitis caused by other members of the herpesvirus family.<sup>117</sup> CMV has a very characteristic clinical appearance, but the lesions in CMV retinitis vary from patient to patient, and it is important to maintain a high index of suspicion for the above infections, especially in light of frequent superinfection of AIDS patients with multiple organisms.<sup>6,90,91</sup>

**FIG. 84.8** Cytomegalovirus (CMV) affecting the

perifoveal area or the optic nerve can result in an exudative retinal detachment often involving the macula. If there has not been actual involvement of a vital structure, treatment may result in improvement of central vision.

CMV retinitis is a reflection of underlying active systemic CMV infection. In almost all cases it is a blinding disease if not controlled. Thus, in the face of changing mental status, development of focal signs on neurologic examination, or other symptoms consistent with subacute encephalitis in AIDS patients, a comprehensive ophthalmologic examination is indicated, and an increased index of suspicion of CMV infection of the CNS and possible CMV retinitis is warranted. There is also evidence that patients with CMV retinitis, especially peripapillary disease, have a much higher incidence of CMV encephalitis. CMV infection of the brain, optic nerves, and retinas from 47 consecutive autopsies of patients with AIDS was examined.<sup>119</sup> Immunocytochemistry demonstrated CMV infection in 11 (23%) brains, 2 (2%) of 94 optic nerves, and 38 (40%) of 94 retinas. Ten (91%) of 11 patients with CMV encephalitis had concurrent retinitis. While 10 (42%) of 24 patients with CMV retinitis had CMV encephalitis, when the retinitis included the peripapillary region, 75% had encephalitis. The optic nerve parenchyma usually was not infected histologically despite extensive peripapillary retinitis. The strength of these associations suggests that CMV retinitis defines a group of patients with AIDS at risk for development of CMV encephalitis (relative risk, 9.5%), especially when the retinitis involves the peripapillary region (relative risk, 13%). Furthermore, in patients with AIDS without CMV retinitis, central nervous system symptoms are unlikely to be attributable to CMV encephalitis.<sup>119</sup> The pathologic correlation between ocular and cerebral lesions in patients with AIDS has been reviewed.<sup>120</sup>

CMV retinitis is less frequent in children with AIDS, with reported rates of approximately 5–6%, though rates of extraocular CMV are higher than in adults. CMV retinitis has been reported in young children with high absolute CD4 counts, though these counts are low relative to the child's age. Older children tend to have low absolute CD4 counts, similar to adults. There is a higher incidence

of bilateral and posterior pole disease in children, however this is likely due in part to delays in diagnosis in children from lack of subjective vision complaints.<sup>120-123</sup>

## **Screening Techniques for Retinal and Systemic CMV Infection**

Screening for CMV retinitis is a difficult problem. Many patients who are CMV-viremic or -viruric may not have end-organ disease, and studies employing quantitative CMV polymerase chain reaction (PCR) in plasma or CMV antigenemia have not been able to definitively predict the development of CMV retinitis.<sup>124</sup> Currently no laboratory marker exists that reliably predicts the occurrence of clinical CMV retinitis.

Urine is culture-positive for CMV in more than 50% of homosexual men and the majority of AIDS patients; thus urine culture may not be of diagnostic value. Serology in AIDS patients is nonspecific, and documentation of rising CMV titers is unusual.<sup>6,104</sup> Studies of newly diagnosed CMV retinitis patients indicate that many are CMV culture-negative in the blood. Positive blood cultures for CMV, fever, and weight loss are associated with more extensive CMV retinitis at the time of diagnosis.<sup>125</sup> The results of virologic blood assays for CMV also have been associated with clinical outcome in patients with CMV retinitis.<sup>126</sup> Therefore assays for the detection of CMV antigenemia may be a simple and rapid means of identifying those patients with unilateral retinitis at highest risk of developing CMV retinitis of the fellow eye or of visceral CMV disease if intravitreal injections or implants are used as the sole treatment for CMV retinitis.<sup>127</sup>

A positive PCR result supports the clinical diagnosis and may be useful for monitoring response to antiviral treatment. By prospective monitoring for increases in plasma CMV DNA copy number, it may be possible to identify HIV-seropositive patients who are at imminent risk for development of symptomatic CMV retinitis.<sup>128</sup>

It is also reasonable and practical to use the CD4 cell count as a threshold below which to screen patients, since the risk of CMV retinitis increases at CD4 cell counts below 50/ $\mu$ L.<sup>74</sup> The incidence and prevalence of CMV retinitis in a cohort study of patients with

CD4 cell counts below  $0.10 \times 10^9/L$  ( $100/\mu L$ ) revealed a 25% chance for the development of CMV retinitis by 4 years of follow-up. Among those subjects in whom CMV retinitis developed, about 19% had retinitis before a CD4 cell count of less than  $0.05 \times 10^9/L$  ( $<50/\mu L$ ) was observed, and 81% had CMV retinitis after the CD4 cell count reached this threshold.<sup>129</sup> In the HAART era, some patients may develop CMV retinitis with CD4 counts above  $100/\mu L$ , probably because of incomplete restoration of the immune repertoire against CMV.<sup>130</sup>

A technique for screening for central CMV retinitis, entoptic perimetry, which employs patient visualization of moving particles on a computer monitor, appears to have a very high sensitivity and specificity (over 90%) in detecting CMV retinitis within the central 30-degree radius of fixation<sup>84</sup> (Fig. 84.9).

**FIG. 84.9** Entoptic perimetry can allow detection of cytomegalovirus (CMV) retinitis lesions. (A) The patient is asked to view particle motion programmed on a monitor. (B) An overlay of the CMV lesion (dotted white border) and the patient's own sketch of the scotoma seen (black line).

Techniques for detection of CMV DNA based on PCR are increasingly being applied to ocular fluids; however, the clinical significance of such findings can sometimes be unclear. The application of PCR-based methods to ocular fluids made a useful contribution to the treatment of the patients.<sup>131</sup>

This appears to be a sensitive and specific diagnostic assay that could assist in the diagnosis of CMV retinitis.<sup>132</sup> PCR detection of CMV DNA has been reported to be a more sensitive method than

analysis of locally produced antibodies by calculating a Goldman–Witmer coefficient to determine local ocular antibody production. There is also an immune predisposition to the development of CMV retinitis in patients with AIDS.<sup>133,134</sup>

## **Treatment of CMV Retinitis**

The treatment of CMV retinitis has been reviewed.<sup>135,136</sup> Treatment may be systemic, local, or a combination of the two. There are currently four medications approved by the US Food and Drug Administration (FDA) for the treatment of CMV retinitis: ganciclovir, valganciclovir, cidofovir, foscarnet. Fomivirsen, the first antisense drug with a relatively long duration of action, is no longer available in the United States.

## **Systemic Therapy of CMV Retinitis.**

CMV retinitis may be treated systemically or intravitreally. However, systemic treatment is associated with less spread of CMV retinitis from one eye to the other.<sup>136</sup> In addition, local treatment including the sustained release ganciclovir implant has been shown to be associated with higher risk of the development of systemic CMV.<sup>137,138</sup>

Systemic CMV may cause gastrointestinal disease, with colitis being the most common manifestation as well as esophagitis. Systemic CMV diagnosis may be difficult and usually requires histopathologic evidence of CMV infection. The cumulative incidence of systemic CMV disease that becomes clinically apparent is approximately 25%.<sup>139</sup> Therefore, although systemic CMV disease may not be clinically apparent at the time of diagnosis of CMV retinitis, some experts believe that initial systemic therapy may be warranted despite the inconvenience, expense, and potential toxicities.

## **Intravenous Ganciclovir.**

Ganciclovir is a nucleoside analog of 2-deoxyguanosine, similar to acyclovir.<sup>140</sup> Despite its structural similarities with acyclovir, ganciclovir is much more active in vitro against CMV than acyclovir.<sup>141</sup> Ganciclovir inhibits all herpesviruses, including CMV,

by preventing DNA elongation. CMV lacks the virally specified thymidine kinase (TK) that converts ganciclovir (or acyclovir) to its monophosphate form.<sup>142</sup> TK-altered strains resistant to acyclovir are as sensitive to ganciclovir as the unaltered parent strains. Thus ganciclovir is phosphorylated to its triphosphate form much more efficiently than acyclovir which accounts for the greater activity of ganciclovir against CMV.<sup>143</sup>

The majority of AIDS patients treated with ganciclovir respond within 2–4 weeks with decreased retinal opacification and stabilization of the retinitis<sup>97</sup> (Fig. 84.10). Ganciclovir is commercially available as an intravenous and oral formulation (and also is included in an intraocular device), and indefinite maintenance therapy is necessary as long as the patient remains in immune failure with a CD4 count below 50/ $\mu$ L. An intravenous loading dose of 5 mg/kg every 12 hours for 14–21 days should be followed by maintenance doses of 5 mg/kg per day. If the drug is discontinued, retinitis often recurs within 10–21 days, continuing its progression at the borders of healed areas.<sup>97</sup> Recurrences have been common, even during maintenance therapy, being reported 3 weeks to 5 months after institution of therapy and occurring in 30–40% of patients.<sup>97</sup> Many investigators have found that discontinuation or delay of ganciclovir therapy results in nearly 100% recurrence of retinitis, at which time reinstatement of the loading dose regimen often is necessary.<sup>142,144,145</sup> Multiple series in patients with AIDS and CMV retinitis have shown response rates of 80–100%, with 60–80% of patients achieving a remission with ganciclovir therapy.<sup>37,145–149</sup>

**FIG. 84.10** (A) Active peripheral cytomegalovirus (CMV) retinitis with secondary retinal vasculitis. (B) The area is healed after intravenous ganciclovir therapy. Note absence of border opacification. Also seen are pigmentary changes characteristic of healed CMV.

The treatment of CMV retinitis usually includes an induction phase followed by a maintenance phase to prevent relapse. Before the advent of HAART, relapse occurred almost universally, given a sufficiently long period after induction courses of ganciclovir. Therapy therefore continued for a lifetime. The median time to relapse in patients treated with just an induction dose is 3–4 weeks.<sup>145</sup>

Most clinicians use a 14-day induction course of intravenous ganciclovir consisting of 5 mg/kg per day every 12 hours and indefinite maintenance of 5 mg/kg per day. Lower doses and every-other-day dosing schedules have been associated with high rates of early relapse. Since treatment may be lifelong if the patient's CD4 count cannot be elevated with anti-HIV therapy, usually a permanent or semipermanent indwelling venous catheter is placed at the onset of therapy if intravenous therapy is chosen as maintenance therapy. Ganciclovir requires modification of dosing in the presence of renal insufficiency.

Side-effects of ganciclovir include granulocytopenia, neurologic dysfunction, abnormal liver function tests, and rarely, thrombocytopenia. The most serious toxicity is granulocytopenia, which may occur in up to one-third of patients when defined as less than 500 neutrophils per microliter.<sup>145</sup> Granulocytopenia is generally reversible, and this adverse effect is exacerbated when used with AZT.<sup>150</sup> The use of colony-stimulating factors rGM-CSF (recombinant granulocyte–macrophage colony-stimulating factor) and rG-CSF (recombinant granulocyte colony-stimulating factor) for reversing or preventing neutropenia may be useful.

The prevalence of CMV resistance to ganciclovir is unknown, but ever-increasing induction regimens may be necessary to control CMV retinitis. Strains of CMV that develop resistance to ganciclovir may remain susceptible to foscarnet. Because of the question of ganciclovir resistance, a trial of combined vs. alternating foscarnet–

ganciclovir maintenance therapy has been reported to be effective.<sup>151</sup>

Visual acuity depends on the location of the involved retina, and involvement of the fovea or optic nerve may result in decreased visual acuity even if there has been a response to therapy. Ganciclovir has been shown to be effective in preserving visual acuity. For example, 73% of eyes maintained a visual acuity of 20/40 or better when treated with ganciclovir.<sup>152</sup>

### **Oral Ganciclovir.**

Oral ganciclovir (FDA approved, 1994) can be used for maintenance therapy of CMV retinitis after it has been healed with intravenous ganciclovir therapy. Studies using this drug regimen have shown efficacy, but it is clear that oral ganciclovir is less effective than intravenous ganciclovir for many patients.

Perhaps the most common use of oral ganciclovir is in patients being treated with intravitreal therapy (injections of cidofovir or ganciclovir implant) to prevent systemic CMV disease. Such use of oral ganciclovir also may reduce the incidence of CMV in the fellow eye if it is not involved.<sup>153,154</sup> Oral ganciclovir for prophylaxis or treatment of CMV retinitis has been replaced by oral valganciclovir, which provides much higher blood levels.

### **Valganciclovir.**

Valganciclovir, the valine ester of ganciclovir, is an orally administered formulation of ganciclovir. The valine ester confers enhanced permeability and absorption of the molecule through the cell membranes of the gut. Once in the bloodstream, the valine ester is cleaved from the molecule by esterases, rendering plasma levels of ganciclovir comparable to those achieved with intravenous ganciclovir administration. A single-dose randomized crossover pharmacokinetic study reported the absolute ganciclovir bioavailability after oral valganciclovir administration is 60.9% compared to 5.6% bioavailability of oral ganciclovir.<sup>155</sup> A randomized crossover dose-ranging study determined that plasma levels of ganciclovir after an 875 mg dose of valganciclovir are similar to the plasma levels achieved with a dose of 5 mg/kg of intravenous ganciclovir (AUC 24.8 mg/ml per hour vs. 26 mg/ml

per hour). The authors suggested the 900 mg dose of valganciclovir would approximate the AUC value of the 5 mg/kg dose of IV ganciclovir.<sup>156</sup>

Valganciclovir has been studied for induction therapy for CMV retinitis. Martin et al. (Valganciclovir Study Group) reported a multicenter randomized, controlled clinical trial comparing oral valganciclovir 900 mg twice a day for 3 weeks' induction therapy followed by 900 mg daily for 1 week maintenance therapy with intravenous ganciclovir 5 mg/kg twice a day for 3 weeks' induction therapy followed by 5 mg/kg once daily for one week of maintenance therapy. After 4 weeks both groups received continued maintenance therapy with 900 mg valganciclovir daily. Eighty patients with newly diagnosed CMV retinitis were randomized to each group in a 1 : 1 ratio. Primary endpoint was photographically determined progression of CMV retinitis within 4 weeks after the initiation of treatment. In the valganciclovir group, 9.9% of patients had progression of CMV retinitis within the first 4 weeks compared to 10.0% of patients assigned to IV ganciclovir. This 0.1 percentage point difference was not significant (95% CI -9.7 to 10.0). Secondary endpoints included the achievement of a prospectively defined successful response to induction therapy and the time to progression of CMV retinitis. Seventy-seven percent of patients receiving IV ganciclovir and 71.9% of patients receiving oral valganciclovir achieved a satisfactory response to induction therapy. This 5.2 percentage point difference was not significant (95% CI -20.4 to 10.1). The median times to progression of retinitis were 125 days in the IV ganciclovir group and 160 days in the oral valganciclovir group. The relative risk of progression of retinitis in the valganciclovir group compared to the ganciclovir group was 0.90 (95 CI 0.58-1.38). Diarrhea was the most common adverse effect during the study and occurred more frequently in the valganciclovir group compared to the ganciclovir group (19% vs. 10%,  $p=.11$ ). Neutropenia occurred with similar frequency in each group. Catheter-related side-effects were seen more frequently in the IV ganciclovir group than in the valganciclovir group.<sup>157</sup> No clinical trials have been published specifically comparing efficacy of valganciclovir for maintenance therapy of CMV retinitis.

Lalezari et al. (Roche Valganciclovir Study Group) reported a

large safety study of valganciclovir. The adverse event profile was similar to that reported from previous studies of intravenous and oral ganciclovir. Adverse events of note were diarrhea (38%), nausea (23%), fever (18%), neutropenia (absolute neutrophil count <500 cells/ $\mu$ L) (10%), anemia (hemoglobin <8.0 g/dL) (12%), and thrombocytopenia (platelet count <25, 000 cells/ $\mu$ L) (2%).<sup>158</sup>

In summary, oral valganciclovir offers the obvious advantage of extreme effectiveness against CMV retinitis without the difficulties and inconveniences of intravenous administration. Furthermore, because valganciclovir is converted to ganciclovir in the bloodstream, its pharmacologic safety profile, including side-effects, is no different than that of intravenously administered ganciclovir. Thus oral valganciclovir is an effective and safe alternative to intravenous ganciclovir for the treatment of CMV retinitis. Oral ganciclovir has become unavailable but is now supplanted by valganciclovir.

### **Foscarnet.**

The second drug for the treatment of CMV retinitis in patients with AIDS was licensed by the FDA in 1993. Foscarnet is a pyrophosphate analog with broad antiviral activity via inhibition of viral polymerases, such inhibition not being dependent on activation or phosphorylation by viral or cellular enzymes. Foscarnet inhibits DNA chain elongation by preventing pyrophosphate exchange.<sup>159</sup>

Foscarnet inhibits the DNA polymerase of CMV and other herpesviruses (HSV-1, HSV-2, VZV, and Epstein–Barr virus [EBV]) and the replication of HIV in vitro and in vivo.<sup>160</sup> Both herpesvirus and HIV replication may be inhibited by therapeutically achievable concentrations of foscarnet. Since the drug is not metabolized and is excreted by the kidney, the dosage must be adjusted for renal insufficiency. Foscarnet also has been used successfully to treat HIV-infected patients with acyclovir-resistant HSV and VZV infections, in addition to CMV retinitis. Foscarnet acts directly on the viral polymerase of all herpesviruses and on the reverse transcriptase of HIV-1. Resistance of CMV to foscarnet is associated with mutations in the genes of these polymerases. Cross-resistance to antiviral drugs is likely to be an increasing problem, since

patients with AIDS are living longer as a result of HAART and of the drugs used in the prophylaxis of various opportunistic infections, as well as because of the experience gained in the management of HIV-related problems.

Foscarnet has been shown to be useful against ganciclovir-resistant herpesviruses, such as CMV, because a mutation in a DNA polymerase gene conferring resistance to ganciclovir and acyclovir differs from the region conferring resistance to foscarnet.<sup>161</sup>

Foscarnet also is an effective inhibitor of the HIV reverse transcriptase enzyme and acts in a dose-dependent manner. AZT and foscarnet have synergistic activity in vitro against HIV, and in vivo foscarnet has activity against HIV as measured by surrogate markers.<sup>162</sup>

The use of foscarnet salvage therapy in patients with CMV retinitis who are intolerant of or resistant to ganciclovir was studied in AIDS patients with CMV retinitis who had documented hematologic intolerance or resistance to ganciclovir therapy. This study showed that in patients intolerant of ganciclovir, salvage foscarnet therapy resulted in a longer time to retinitis progression than reported previously in historic controls who terminated ganciclovir therapy. In patients who exhibited clinical resistance to ganciclovir, foscarnet appeared to have efficacy in controlling retinitis. No significant differences in either efficacy or toxicity were observed in the range of foscarnet maintenance doses studied.<sup>163</sup>

A large, randomized, multicenter, blinded clinical trial (the Foscarnet–Ganciclovir Cytomegalovirus Retinitis Trial) compared ganciclovir with foscarnet in the treatment of CMV retinitis in patients with AIDS. No difference was reported between the treatment groups in the rate of progression of retinitis; however, the median survival was 8.5 months in the ganciclovir group and 12.6 months in the foscarnet group. Excess mortality was reported in a subset of patients in the foscarnet group whose renal function was compromised at entry. Differences in mortality could not be explained entirely on the basis of less antiretroviral therapy in the ganciclovir group, which suggests beneficial interactions between foscarnet and antiretroviral nucleosides. These results indicate that, for patients with AIDS and CMV retinitis, treatment with foscarnet initially offers a survival advantage over treatment with

ganciclovir, although foscarnet was not as well tolerated as ganciclovir.<sup>164</sup>

A marginally prolonged survival seen in patients treated with foscarnet compared with those treated with ganciclovir may have been due to a direct effect on HIV replication. Both drugs had a suppressive effect on circulating p24 antigen, which was predictive of improved survival. The inhibitory effect on CMV replication also may have a beneficial effect on limiting HIV replication.<sup>165</sup>

A randomized, controlled, comparative trial of foscarnet and ganciclovir demonstrated that they equally controlled CMV retinitis but that foscarnet was associated with a longer survival. However, foscarnet was less well tolerated than ganciclovir, primarily because of the nature of its side-effects. Since foscarnet and ganciclovir have different side-effects, initial treatment of CMV retinitis should be individualized.<sup>166</sup>

The most frequently reported major adverse effect associated with foscarnet administration is nephrotoxicity, with dose-limiting toxicity occurring frequently and cases of acute renal failure having been observed. Symptomatic hypocalcemia has been reported and may be responsible for arrhythmias and seizures, and the risk is increased by concurrent administration of intravenous pentamidine. Bone-marrow suppression with neutropenia, anemia, and thrombocytopenia can be seen with foscarnet administration. Neutropenia was reported to be less common with foscarnet than with ganciclovir (14% vs. 34%).<sup>164</sup>

Practical guidelines for the use of foscarnet include administration through an infusion pump to avoid the potential consequences of overdose or too rapid infusion, adequate hydration of patients with saline loading<sup>167</sup> to reduce the risk of nephrotoxicity, avoidance of administration of other potentially nephrotoxic agents, and monitoring of renal function two or three times per week during induction therapy and once per week during maintenance therapy, with the dosage being recalculated on the basis of patient weight and serum creatinine. Studies of foscarnet doses have suggested that patients receiving high maintenance doses (120 mg/kg per day) have slower rates of retinitis progression.<sup>168,169</sup>

Foscarnet is active against HIV, and studies have shown that it

raises the CD4 count transiently and decreases viral antigenemia (p24 antigen). Because of its efficacy against CMV and HIV, it would appear to be a potentially effective agent for treating HIV-infected patients; however, it is currently only available for intravenous administration, and its use is associated with substantial toxicity (see above).<sup>162,170</sup>

### **Cidofovir.**

Cidofovir, (S)-1-[3-hydroxy-2-(phosphonylmethoxy)propyl]cytosine, formerly known as HPMPC, was the first antiviral nucleotide analog available for the treatment of CMV retinitis. Cidofovir is active in uninfected cells, may act preemptively, and may retain activity against ganciclovir-resistant strains. Preclinical studies showed the major toxicity of cidofovir to be dose-, schedule-, and species-dependent nephrotoxicity. The concomitant administration of probenecid protects animal models against cidofovir-induced nephrotoxicity. Four treatment modifications are indicated clinically to reduce the incidence of cidofovir-related nephrotoxicity: dose reduction or interruption for changes in renal function; concomitant administration of probenecid; administration of 1 liter of normal saline 1 hour before infusion; and extension of the dosing interval.<sup>171</sup>

The treatment of CMV retinitis with intravenous cidofovir was demonstrated to be effective in slowing the progression of peripheral CMV retinitis in patients with previously untreated CMV retinitis and AIDS. Intravenous cidofovir also has been used for long-term suppression of CMV retinitis. Biweekly therapy (after induction therapy) was reported to have a time to progression of CMV retinitis of 120 days in one randomized, controlled trial<sup>172</sup> and 2.5 months in another randomized, controlled trial.<sup>173,174</sup> Treatment and subsequent maintenance of CMV retinitis with 20 µg of intravitreally injected cidofovir, given at 5- to 6-week intervals, also is safe and highly effective.<sup>175</sup>

Treatment with parenteral cidofovir is complicated by nephrotoxicity, which can be reduced with saline hydration and concomitant administration of probenecid. Despite these additional treatments, the long-term reports from the HPMPC Peripheral Cytomegalovirus Retinitis Trial showed a rate of proteinuria of 1.22

per patient-year and a rate of elevated serum creatinine of 0.41 per patient-year. Thus many patients may have difficulty tolerating cidofovir for a prolonged time. Neutropenia has also been reported with cidofovir.

Unfortunately parenteral cidofovir has also been found to have ocular toxicity, including a high incidence of iritis (up to 50%), including recurrent iritis, and a risk of profound ocular hypotony with vision loss, similar to the iritis and hypotony seen with intravitreal injections of cidofovir.<sup>176-178</sup> It has been estimated in one study that cidofovir-related iritis developed in half of patients within approximately 4 months. The long-term reports from the HPMPC Peripheral Cytomegalovirus Retinitis Trial showed a rate of cidofovir-associated uveitis of 0.20 per person-year and a rate of significant ocular hypotony of 0.16 per patient-year.<sup>174</sup> Thus in the setting of iritis in HIV-infected patients, use of systemic cidofovir or rifabutin should be considered potential causes of iritis, and these drugs may need to be discontinued.

Nephrotoxicity may be cumulative in some patients and appears to be related to toxicity in the proximal tubule. This “secretory toxicity” also may be responsible for the hypotony and iritis that the drug causes when given intravenously or intravitreously. The ciliary body and the proximal tubule of the kidney have many similarities in terms of the mechanism involved in the secretion of fluids across epithelia. Oral administration of probenecid before and after the intravenous infusion appears to help ameliorate the nephrotoxicity of the drug, but the ocular side-effects of iritis and hypotony occur despite concomitant probenecid administration.

### **CMV Resistance.**

Many patients taking chronic maintenance therapy for CMV retinitis develop resistant virus. Development of in vitro resistance of CMV to ganciclovir and foscarnet and disease progression has been shown in several small studies,<sup>179,180</sup> and mechanisms of resistance to ganciclovir have been described.<sup>180</sup> In one prospective, randomized study of 207 patients with newly diagnosed CMV retinitis, drug-resistant CMV occurred in four of nine ganciclovir-treated patients and in none of five foscarnet-treated patients.<sup>126</sup> In patients with CMV retinitis and AIDS treated with either oral or

intravenous ganciclovir, isolates of CMV after a median exposure of 75 and 165 days, respectively, showed increasing resistance *in vitro*.<sup>181</sup> Jabs et al. reported that the cumulative incidence of ganciclovir resistance at 9 months was 27.5%.<sup>180</sup> Similar incidence rates of resistance occur for foscarnet and cidofovir.<sup>182</sup> In addition, the incidence of resistance to valganciclovir appears to be similar to that for ganciclovir.<sup>183</sup>

Resistance to an anti-CMV drug can be described as phenotypic, expressed as an inhibitory concentration 50% greater than a certain threshold (IC<sub>50</sub>). This is determined typically via plaque reduction assays, DNA hybridization assays, or antigen-reduction assays that require large amounts of viable virus, often requiring culturing.<sup>180,184–186</sup> Genotypic resistance is defined by the presence of a mutation in the CMV genome conferring resistance to a particular drug. PCR amplification techniques allow fast detection of resistance-conferring mutations in the viral genome, requiring only small amounts of viral nucleic acids and can use nonviable virus.<sup>187–189</sup> Low-level ganciclovir resistance is typically associated with mutations in the CMV *UL97* gene. *UL97* codes for a phosphotransferase that catalyzes the first step of ganciclovir activation to the triphosphate form. High-level ganciclovir resistance is typically caused by mutations in both the CMV *UL97* and *UL54* genes. *UL54* codes for the cytomegalovirus DNA polymerase.<sup>190</sup> Mutations in the *UL54* gene are also responsible for foscarnet and cidofovir resistance.<sup>190–194</sup> *UL54* mutations responsible for foscarnet resistance are usually distinct from those causing ganciclovir–cidofovir resistance. However, low-grade ganciclovir–foscarnet cross-resistance has been reported, plus Chou et al. reported a DNA polymerase mutation causing resistance to ganciclovir, cidofovir, and foscarnet.<sup>180,188–192</sup>

### **Treatment Strategies in Resistant CMV.**

When clinically resistant retinitis appears, many clinicians employ an alternative antiviral agent systemically; intravenous cidofovir or foscarnet are alternatives. Unfortunately, as mentioned above, there can be cross-resistance between CMV isolates resistant to ganciclovir and resistant to cidofovir and/or foscarnet; this must be borne in mind in such patients. The probability of developing

foscarnet or cidofovir resistance while taking these drugs appears similar to the rates of development of resistance to ganciclovir.<sup>182</sup> For this reason, clinicians often employ intravitreal therapies including the ganciclovir intraocular device when systemic therapy begins to fail. Intravitreal therapies appear to be more effective in such circumstances, largely because they deliver higher doses of anti-CMV medication to the retina.<sup>195</sup> In such circumstances, it is recommended to continue to treat the patient with some form of systemic therapy, often oral valganciclovir, to help prevent systemic CMV infection or infection of the fellow eye. Studies have shown that treatment with the ganciclovir implant alone is associated with a higher risk of contralateral CMV retinitis and extraocular CMV.<sup>196,197</sup>

### **Combination Therapies: Ganciclovir–Foscarnet.**

Several studies have shown that combinations of foscarnet and ganciclovir are more effective in the treatment of recurrent or resistant retinitis than is continued monotherapy.<sup>99,197</sup> Such combination intravenous therapy also has been shown to be safe and effective in children with CMV retinitis.<sup>198</sup> Unfortunately, combination intravenous therapy with these two drugs necessitates multiple intravenous infusions daily and has a marked negative effect on patients' lifestyle. Combination of IV foscarnet and oral valganciclovir has supplanted this combination intravenous therapy.

The combination of foscarnet and ganciclovir in patients with AIDS and CMV retinitis who have relapsed has been shown to be more effective than either agent given alone,<sup>151</sup> however, combination therapy was associated with the greatest negative impact of treatment on quality-of-life measures.

To determine the best therapeutic systemic regimen for treatment of relapsed CMV retinitis, a multicenter randomized controlled clinical trial of 279 patients with AIDS and either persistently active or relapsed CMV retinitis was reported. Patients were randomized to one of three therapeutic regimens: induction with foscarnet sodium at 90 mg/kg intravenously every 12 hours for 2 weeks, followed by maintenance at a dosage of 120 mg/kg per day (foscarnet group); induction with ganciclovir sodium at 5 mg/kg

intravenously every 12 hours for 2 weeks followed by maintenance at 10 mg/kg per day (ganciclovir group); or continuation of previous maintenance therapy plus induction with the other drug (either ganciclovir or foscarnet) for 2 weeks followed by maintenance therapy with both drugs, ganciclovir sodium at 5 mg/kg per day and foscarnet sodium at 90 mg/kg per day (combination therapy group). The mortality rate was similar among the three groups. Median survival times were as follows: foscarnet group, 8.4 months; ganciclovir group, 9.0 months; and combination therapy group, 8.6 months ( $p=.89$ ). Comparison of retinitis progression revealed that combination therapy was the most effective regimen for controlling the retinitis. The median times to retinitis progression were as follows: foscarnet group, 1.3 months; ganciclovir group, 2.0 months; and combination therapy group, 4.3 months ( $p=.001$ ). Although no difference could be detected in visual acuity outcomes, visual field loss and retinal area involvement on fundus photographs both paralleled the progression results, with the most favorable results in the combination therapy group. The rates of visual field loss were as follows: foscarnet group, 28 degrees per month; ganciclovir group, 18 degrees per month; combination therapy group, 16 degrees per month ( $p=.009$ ). The rates of increase of retinal area involved by CMV were as follows: foscarnet group, 2.47% per month; ganciclovir group, 1.40% per month; and combination therapy group, 1.19% per month ( $p=.04$ ). Although side-effects were similar among the three treatment groups, combination therapy was associated with the greatest negative impact of treatment on quality-of-life measures. This study suggests that for patients with AIDS and CMV retinitis whose retinitis has relapsed and who can tolerate both drugs, combination therapy appears to be the most effective therapy for controlling CMV retinitis.<sup>151</sup> Small series suggest that combined intravitreal injections of ganciclovir and foscarnet may be effective in treating CMV retinitis when the infection is clinically resistant to either intravitreal drug alone.<sup>199</sup>

## **Summary of Initial Systemic CMV Retinitis Treatment**

The initial treatment of CMV retinitis is usually oral valganciclovir 900 mg twice a day for induction therapy of approximately 3 weeks

followed by 900 mg daily for maintenance therapy. Intravenous ganciclovir can be used if a patient has a contraindication to oral treatment such as malabsorption. The dose for intravenous ganciclovir is 5 mg/kg twice a day for induction therapy for 2–3 weeks followed by maintenance therapy at 5 mg/kg daily or 6 mg/kg 5 days/week. Induction therapy with intravenous foscarnet is dosed at 90 mg/kg twice a day for approximately 2 weeks followed by maintenance therapy at 120 mg/kg daily. Intravenous cidofovir for induction therapy is dosed at 5 mg/kg weekly for approximately 3 weeks followed by maintenance therapy dosed at 3–5 mg/kg every 2 weeks.

## **Intraocular Therapy of Viral Retinitis**

### **Ganciclovir.**

Because of the difficulties associated with systemic ganciclovir, foscarnet, and cidofovir, interest in local administration has increased. Obviously, intraocular (or periocular) treatment will not affect the systemic CMV infection, but in some patients, especially those with systemic toxicity resulting from the drug, local administration may have certain advantages.

In 40 patients with primary CMV retinitis involving 57 eyes, all had received one 14-day course of intravenous ganciclovir and all were free of other end-organ CMV disease. All affected eyes received weekly intravitreal injections of 400 mg of ganciclovir for maintenance therapy. Median survival of patients was at least 13 months. Fifteen patients had 19 new opportunistic infections during the observation period, but none developed new nonocular CMV disease. Active retinitis recurred in 68.4% of the eyes while receiving maintenance therapy, with a median time to progression of 14.7 weeks. CMV retinitis occurred in 30.4% of the previously uninvolved eyes (follow-up 3.1 years). Bacterial endophthalmitis complicated treatment in one eye, and retinal detachment developed in five eyes. Thus the long-term treatment of CMV retinitis with weekly intraocular injections of ganciclovir was associated with survival and ocular outcomes similar to those reported with systemic ganciclovir.<sup>200</sup>

Intravitreal ganciclovir also was shown to be an effective

alternative to systemic ganciclovir in patients with severe neutropenia and in patients who chose to continue receiving systemic zidovudine or didanosine.<sup>201</sup> Injections of high-dose intravitreal ganciclovir using a 2 mg dose revealed that weekly 2 mg injections appear to offer superior control of retinitis for periods of months or longer.<sup>202</sup> Highly concentrated ganciclovir solution for intravitreal injection also reduced repeated amaurosis and ocular pain and was reported by patients to have improved their comfort and quality of life, thus increasing their compliance to treatment and reducing side-effects, as compared with usual protocols.<sup>203</sup>

### **Foscarnet.**

Intravitreal foscarnet at a dose of 2.4 mg per injection given one or two times weekly also appears to be a safe and effective treatment method for CMV retinitis. Resistance to this treatment regimen may develop, however.<sup>204</sup> High-dose intravitreal foscarnet for CMV retinitis was shown to be a safe, effective, and useful alternative in patients with intolerance to intravenous therapy.<sup>205</sup>

### **Ganciclovir Intraocular Device.**

An intraocular sustained-release ganciclovir delivery implant that releases drug into the vitreous is commercially available.<sup>206</sup> These surgically implanted, time-release implants have been shown to be more effective than intravenous ganciclovir alone in delaying the progression of CMV retinitis.<sup>137,207,208</sup>

Insertion of the device requires a pars plana incision and a partial vitrectomy. The implant is sewn into the pars plana behind the lens.<sup>206</sup> Insertion of the ganciclovir intraocular device (GIOD) requires trimming the strut of the device so that it is nearly flush with the drug pellet. A 5.5-mm incision can be made 4 mm posterior to the limbus with a microvitrectomy blade or similar instrument (Fig. 84.11). A unimanual bipolar intraocular cautery can be used to coagulate bleeding choroid. It is important to ensure that the incision is full-thickness, since the device can be inserted inadvertently under the pars plana. A suture is placed through the preplaced hole (the surgeon must make the hole) in the strut of the device; 8-0 Prolene can be used. The device is anchored in the middle of the wound, and running or interrupted sutures can be

used to close the wound. Astigmatism can result from overzealous wound closure; this is usually transient. This procedure can be performed in an outpatient setting under local anesthesia.

**FIG. 84.11** (A) Insertion of ganciclovir intraocular device. (B) The device can be seen inferotemporally through a dilated pupil.

Despite the relative ease of insertion, it has become clear that the risk of retinal detachment in the first 2 months after insertion is substantially higher than if other methods are used to control retinitis, though in the long term there is no statistical difference in retinal detachment rate.<sup>206,209-211</sup> In addition, the risk of postoperative endophthalmitis appears to be a real one, with incidences on the order of 1% or sometimes higher.<sup>212</sup> The intravitreal levels attained by this drug are over twice those after intravenous administration, and this appears to be associated with a lower incidence of resistance and progression of retinitis. This is particularly true in newly diagnosed cases, but failure can occur in up to 25% of such cases within the first 2 months. In a study of 91 implants in 70 eyes, GIOD was effective as an adjunct to continued systemic therapy in those patients with recurrent CMV retinitis.<sup>208</sup> Intraocular sustained-release implants have been used to treat acute CMV disease and to prevent recurrence. Pathology studies of eyes having undergone implantation with the GIOD have shown no evidence of intraocular toxicity.<sup>204</sup> It is not certain whether implants should be exchanged at the 7-month time period or whether retinitis should be allowed to reactivate before replacing the implant.

### **Intravitreal Cidofovir.**

Another form of intraocular therapy is intravitreal cidofovir (HPMPC), which is injected every 6 weeks. This work was initiated after discovery of long-acting properties of the drug in the eye. The safety and efficacy of intravitreal cidofovir for CMV retinitis in humans were reported in a phase I/II unmasked, consecutive case series in a single-center institutional referral practice. Eligible patients with AIDS had active CMV retinitis in at least one eye, despite adequate intravenous therapy with ganciclovir or foscarnet, were intolerant to intravenous therapy, were noncompliant with intravenous therapy, or refused intravenous therapy. In a preliminary safety study (group 1), 10 eyes of nine patients received 14 injections of cidofovir while being treated concurrently with intravenous ganciclovir. In a dose-escalating efficacy study (group 2), eight eyes of seven patients received 11 injections of cidofovir as sole treatment for CMV retinitis. The primary outcome was time to retinitis progression. In group 1 eyes receiving 20  $\mu\text{g}$  of cidofovir, the median time to retinitis progression was between 49 and 92 days (mean, 78 days). In group 2 eyes treated with 20  $\mu\text{g}$  of cidofovir with probenecid, the median time to retinitis progression was 64 days (mean 63 days). Hypotony occurred in the two eyes treated with a 100  $\mu\text{g}$  dose of cidofovir and in one of three eyes receiving a 40  $\mu\text{g}$  dose. No adverse effects resulted from the remaining 20  $\mu\text{g}$  cidofovir injections. Cidofovir was found to be safe and effective for the local treatment of CMV retinitis, providing a long duration of antiviral effect (Fig. 84.12).<sup>213</sup>

**FIG. 84.12** (A) Active cytomegalovirus (CMV) retinitis with no systemic treatment. The eye was injected with a single injection of cidofovir 20  $\mu\text{g}$  via the pars plana.

(B) The retinitis remains healed 53 days later, with no other therapy.

It was then shown that injections of 20 µg of intravitreal HPMPC resulted in complete suppression of CMV replication with no advancement of retinitis borders when given every 6 weeks.<sup>178,213-217</sup> This medication must be given with oral probenecid. Probenecid 2 g is given orally 2 hours before, and 1 g 2 hours and 8 hours after injection.

Two types of adverse events may occur after intravitreal cidofovir injection: iritis and hypotony. The incidence of these is not dissimilar to what is seen after intravenous administration. The incidence of iritis can be reduced from 70% to 18% if oral probenecid is used, and it is now recommended universally. Iritis can be managed with topical steroids and cycloplegia; however, it may lead to cataract and synechiae in the long term. A mild, asymptomatic 20% reduction in intraocular pressure (IOP) is seen almost universally after cidofovir injection, and this appears to be of no concern. The mechanism of this has been defined by ultrasound biomicroscopy, which has disclosed that severe hypotony after cidofovir injections is associated with ciliary body atrophy.<sup>214</sup> Reduction in aqueous flow has been demonstrated by aqueous fluorophotometry. This effect on secretory epithelia also is probably responsible for the nephrotoxicity of the drug when given intravenously. Indeed, probenecid also is given before and after each intravenous infusion to prevent uptake by the proximal tubule of the kidney and associated nephrotoxicity. Profound hypotony with vision loss occurs in approximately 1% of injections.

A retrospective, cohort study described iritis and hypotony after treatment with intravenous cidofovir for CMV retinitis in association with intraocular inflammation.<sup>176</sup> Eleven cases of iritis (26%) occurred among 43 patients. In six cases the iritis was bilateral. Patients who experienced iritis were more likely to have been previously treated for CMV retinitis ( $p=.03$ ), to be diabetic ( $p=.05$ ), or to be receiving protease inhibitors ( $p=.001$ ). The onset of iritis occurred at a mean ( $\pm$ SD) of  $4.9 \pm 1.8$  days after a cidofovir dose and after a mean ( $\pm$ SD) of  $4.2 \pm 1.6$  doses of cidofovir. Six eyes of four patients had hypotony. Five eyes of five patients had a persistent decrease in visual acuity of at least 2 Snellen lines. Acute

intraocular inflammation may occur with or without hypotony after intravenous cidofovir therapy, similar to the reactions seen after intravitreal administration. Cidofovir therapy can be continued in some patients if medical necessity warrants, but inflammation may recur or permanent hypotony develop.

A lower cidofovir dose (10 µg) has been used to investigate methods of reducing the toxicity of intravitreal cidofovir. This dose is effective in healing retinitis in 75% of patients, but the response in 25% is inadequate. The 10 µg dose, however, is not associated with a significant incidence of iritis or IOP lowering. Cidofovir should be diluted in a sterile manner by a pharmacist. It can be diluted in normal saline and frozen for extended periods in single-dose vials.

The efficacy and safety of HPMPC injections given every 5–6 weeks for the maintenance treatment of CMV retinitis with 20 µg intravitreally injected was shown to be highly effective, with only rare episodes of reactivation and progression.<sup>178</sup>

A correlation between IOP and CD4 T-lymphocyte counts in patients with HIV with and without CMV retinitis has been described.<sup>218</sup> IOP was measured with calibrated Goldmann applanation tonometers in two groups of patients. Group A included 84 HIV patients (120 eyes) with CMV retinitis, and group B included 110 HIV patients (183 eyes) without CMV retinitis; 33 patients without HIV (66 eyes) were included as a control group. Step-wise regression analysis of IOP included correlation with CMV retinitis (presence, extent, and activity), CD4 T-lymphocyte count, age, and gender. The mean IOP was 9.8 mmHg in group A, 12.6 mmHg in group B, and 16.1 mmHg in the control group. All three groups were statistically different from each other when IOP was compared ( $p < .0001$ ). Step-wise regression showed that low CD4 T-lymphocyte count and extent of CMV retinitis both correlated to low IOP. These results demonstrate that IOP is lower than normal in patients with HIV and that decreased CD4 T-lymphocyte count is the major factor associated with low IOP, accounting for 20% of the effect. The extent of CMV retinitis accounts for 8% of the effect.

### **Fomivirsen.**

Fomivirsen, formerly called ISIS 2922, was approved by the FDA in August 1998 for the treatment of CMV retinitis in AIDS patients

intolerant of or who have a contraindication to other CMV regimens or who were insufficiently responsive to previous treatments for CMV retinitis. Fomivirsen is the first of a class of antisense oligonucleotides. This compound possesses potent anti-CMV activity, but does not target the CMV viral DNA polymerase. Fomivirsen is a 21-base synthetic phosphorothioate oligonucleotide designed to be complementary to CMV mRNA that encodes for the major immediate early region (IE2) proteins of CMV. Binding to this location results in specific inhibition of gene expression that is critical to production of essential viral proteins.<sup>219-221</sup>

Following intravitreal administration, the rate of vitreous clearance of fomivirsen is first-order with a half-life of approximately 55 hours in humans. Measurable concentrations of drug are not detected in the systemic circulation after intravitreal injection, making the interaction of fomivirsen with systemic drugs unlikely. Preclinical studies of fomivirsen by Freeman and associates suggested that this type of antiviral antisense compound does inhibit viral replication; however, it did cause changes in the RPE and intraocular inflammation at doses only moderately higher than the dose needed to treat retinitis by the intravitreal route.<sup>222</sup>

The Vitravene Study Group published the data from the clinical trials involving fomivirsen. Two prospective randomized open-label controlled clinical trials (US/Brazilian and EuroCanadian Studies) compared two fomivirsen regimens for the treatment of reactivated CMV retinitis or CMV retinitis that was persistently active despite other anti-CMV treatments. The more intense schedule (regimen A) included 61 patients (67 eyes) and consisted of three weekly 330 µg (0.05 ml) intravitreal injections for induction, then 330 µg every 2 weeks for maintenance therapy. The less intense schedule (regimen B) included 32 patients (39 eyes) and utilized a 330 µg injection for induction on day 1 and day 15, then 330 µg injections every 4 weeks for maintenance therapy. The study endpoint was time to progression based on masked evaluation of serial fundus photos. Eligibility criteria included AIDS patients with active CMV retinitis who had failed prior treatment with ganciclovir, foscarnet, or cidofovir.<sup>223</sup>

In the US/Brazilian study, median time to progression was 106 days (interpolated median 88.6 days) for regimen A and 267 days

(interpolated median 111.3 days) for regimen B ( $p=.2179$  Wilcoxon rank sum test; 0.2950 log rank). In the EuroCanadian study the median time to progression was not determinable for regimen A; only four patients progressed (25th percentile 91 days). The median time to progression for regimen B was 403 days (interpolated median 182 days).<sup>224</sup>

The safety and toxicity of fomivirsen was also reported by the Vitravene study group. The most often reported adverse events were anterior chamber inflammation and increased IOP. Retinal pigment epitheliopathy occurred in 5 : 10 patients in the trial for newly diagnosed CMV retinitis with the 330  $\mu\text{g}$  dose; this prompted a change to the reported 165  $\mu\text{g}$  dose used for the remainder of the study. No episodes of retinal pigment epitheliopathy were reported with the 165  $\mu\text{g}$  dose. No patients developed retinal pigment epitheliopathy in the 330  $\mu\text{g}$  less intense regimen.

Independent of the randomized clinical trials, there have been reports of Vitravene-induced peripheral retinal toxicity and serious inflammation with vision loss. In clinical practice fomivirsen has been used as a fourth-line drug for CMV retinitis resistant to other therapy. The approved dose of fomivirsen is 330  $\mu\text{g}$  intravitreally every 2 weeks for induction therapy for two doses followed by 330  $\mu\text{g}$  intravitreally every month for maintenance therapy. Fomivirsen is no longer available in the United States.<sup>225</sup>

## **Rhegmatogenous Retinal Detachment in CMV Retinitis**

Retinal detachment is a common cause of vision loss in patients with CMV retinitis. In the pre-HAART era, the incidence rate of retinal detachment in patients with CMV retinitis was approximately 33% per eye per year.<sup>145,152,211,226-230</sup> The incidence of retinal detachment in immunosuppressed patients with CMV retinitis was believed to be higher in patients treated with anti-CMV therapies, specifically ganciclovir.<sup>231-232</sup> These retinal detachments were characterized by multiple peripheral breaks in areas of healed atrophic retinitis, and in some patients severe proliferative vitreoretinopathy (PVR) resulted (Fig. 84.13).<sup>233</sup> Detachment occurred from weeks to months after institution of intravenous ganciclovir therapy and was frequently bilateral.

Retinal detachment may also complicate the course of CMV retinitis.

**FIG. 84.13** Retinal breaks (*arrow*) are seen just peripheral to the area of border opacification; the retina is detached.

However, it now appears that rhegmatogenous retinal detachment is associated with healed or active CMV retinitis due to breaks in the necrotic retina.<sup>233</sup> Results of a multicenter, prospective, randomized, controlled clinical trial analyzing incidence and risk factors for rhegmatogenous retinal detachment in a population of patients with newly diagnosed CMV retinitis treated with foscarnet vs. ganciclovir revealed that retinal detachment in patients with CMV retinitis is unrelated to the type of intravenous therapy used or to refractive error. The median time to retinal detachment in an involved eye with CMV retinitis and free of retinal detachment at baseline was 18.2 months.<sup>227</sup>

Studies have confirmed that the risk factors for retinal detachment in eyes with CMV retinitis include the extent of peripheral CMV disease, as well as retinitis activity and involvement of the anterior retina near the vitreous base.<sup>211,231-233</sup> This is logical, considering that in most cases the causative retinal breaks are within or at the border of healed CMV retinitis lesions. A recent report from SOCA investigators has confirmed increased

prevalence and incidence of epiretinal membranes in eyes with inactive extramacular CMV retinitis.<sup>234</sup> In addition, any intervention that violates the vitreous (e.g., vitreous biopsy or insertion of the ganciclovir implant) would be expected to accelerate the development of vitreous detachment or liquefaction, which would increase the risk of retinal detachment.<sup>207,209,211</sup>

With the advent of HAART therapy the incidence of CMV retinitis-related retinal detachment has decreased by 60%. The success of HAART in the reduction of retinal detachment risk may be related to the improved immune control over CMV replication, thus protecting against progression of disease to larger lesion sizes. The altered pattern of inflammation with HAART-mediated immune improvement may also change the course of vitreous detachment, a key step in the development of CMV-related detachments, thus altering the retinal detachment risk.<sup>207,211,235</sup>

Patients with AIDS and CMV retinitis are surviving longer as a result of the use of HAART and improved treatment of opportunistic infections. As a result, though the incidence rate of retinal detachment is lower, the overall prevalence of retinal detachment may become an increasingly common cause of visual morbidity in these patients. In the pre-HAART era, the incidence and outcome of retinal detachment complicating CMV retinitis were studied at two London AIDS centers. Patients with CMV retinitis were identified prospectively and underwent standard treatment. Retinal detachments were diagnosed during regular follow-up. If retinal reattachment surgery was performed, a standard procedure of vitrectomy and internal tamponade with silicone oil was employed. Of 147 patients with CMV retinitis, 41 (28%) developed retinal detachments (47 eyes); 43 detachments were rhegmatogenous and four were exudative. At the last clinic visit, eight eyes (53%) maintained a visual acuity of 6/60 or better. The visual results of surgery are good in selected patients, bearing in mind the progressive nature of the underlying disease and poor life expectancy.<sup>236</sup>

Vitrectomy with silicone oil tamponade also was studied in eyes with retinal detachments related to CMV retinitis or acute retinal necrosis.<sup>237</sup> Anatomic reattachment was achieved in all eyes, and preservation of ambulatory vision was achieved in most eyes.

Visual acuity was limited by concomitant optic nerve disease in some eyes. The authors noted that surgical repair employing silicone oil produces excellent results and that prognosis for vision is strongly related to preoperative visual acuity.

Treatment of retinal detachment consists of vitrectomy, posterior hyaloid removal, and intraocular tamponade with silicone oil or long-acting gas.<sup>237</sup> Retinal reattachment surgery in 29 eyes of 24 patients with AIDS and retinal detachment associated with CMV retinitis was described by Freeman et al.<sup>238</sup> In this study the total retinal reattachment rate was 76%, and the macular attachment rate was 90% after one operation. The mean postoperative visual acuity (best corrected) was 20/60, but in some patients visual acuity decreased because of progressive CMV retinitis. Prophylactic laser photocoagulation of fellow eyes did not appear to prevent retinal detachment (Fig. 84.14).

**FIG. 84.14** (A) Preoperatively the macula has been shallowly detached, associated with a rhegmatogenous cytomegalovirus (CMV)-related retinal detachment. (B) Postoperatively the retina is reattached; silicone oil is in place, and the visual acuity is 20/40. Good visual recovery may be possible even with macula-off detachments because the detachment may be shallow as the vitreous is well formed; the retina may not be completely detached from the macula, and the macular detachments may be shallow.

The repair of retinal detachment in eyes with viral retinitis is complex and is performed using a combination of pars plana vitrectomy, internal tamponade (usually with silicone oil or a long-

acting gas such as perfluoropropane), and endolaser often combined with scleral buckling.<sup>239</sup> Pneumatic retinopexy can cause retinal traction and seldom is useful in these eyes. The most common causes of rhegmatogenous retinal detachment in AIDS patients with viral retinitis are acute retinal necrosis syndrome and previously treated CMV retinitis. In these eyes PVR occasionally is established at the time of detachment or has the potential to occur as a result of multiple retinal breaks and necrosis combined with intraocular inflammation. Scleral buckling alone often is unsuccessful in these cases because of the numerous areas of retinal necrosis and break formation. Retinal breaks are often not apparent until the time of vitrectomy, and the configurations of the retinal detachments are atypical because of peripheral retinal scarring and adhesion to the pigment epithelium and choroid. Thus in these eyes rhegmatogenous retinal detachments may not extend to the ora serrata. In eyes with CMV retinitis, we have favored an approach using complete delamination of the posterior hyaloid combined with endodrainage and permanent tamponade with silicone oil, although we have had good success with intraocular long-acting gases in cases of more limited retinitis and retinal detachment. Patients with AIDS and CMV retinitis appear to be surviving longer, and survival after retinal reattachment surgery has been increased to between 6 months and 2 years.<sup>233</sup>

To determine if scleral buckling is of any benefit in surgical repair of CMV-associated retinal detachment if combined with vitrectomy, silicone oil, and inferior midperipheral endolaser, 22 consecutive eyes with CMV-associated retinal detachments were repaired with vitrectomy and endolaser to all breaks and to the inferior midperipheral retina using silicone oil without scleral buckling. Results were compared with another series of 56 consecutive eyes undergoing vitrectomy, silicone oil injection, endolaser to all breaks, and 360 degrees encircling scleral buckling. Total retinal reattachment rates were 84% for group 1 and 86% for group 2. Rates of macular reattachment were 91% for group 1 and 91% for group 2. Mean best postoperative refracted visual acuity was 20/66 for group 1 and 20/67 for group 2. Median best postoperative refracted visual acuity was 20/74 for group 1 and 20/80 for group 2. These differences between the two groups were not statistically

significant. Patients who underwent surgery with the macula attached had a better postoperative visual outcome. Thus, scleral buckling may not be necessary in CMV-related retinal detachment if repaired with vitrectomy, silicone oil, and inferior midperipheral endolaser.<sup>240</sup> Elimination of scleral buckling may reduce intraoperative time, patient morbidity, and the risk of an accidental needle-stick. Patients with macula-on retinal detachments also should be considered for surgery before macular detachment occurs.<sup>241</sup>

The long-term visual results of CMV retinal detachment surgery are still in question, however, and visual acuity may be limited by factors such as refractive problems resulting from silicone oil and cataract<sup>232,242,243</sup> (Fig. 84.15). In addition, posterior capsule fibrosis is very common if subsequent cataract surgery is performed in the presence of silicone oil. Methods to reduce visual acuity loss from cataract include judicious use of gas tamponade with scleral buckling instead of silicone oil and removal of silicone oil prior to or at the time of cataract surgery. Posterior capsule fibrosis can be treated with Nd : YAG capsulotomy, though success is higher if the silicone oil has been previously removed.<sup>244</sup>

**FIG. 84.15** Postoperatively, inferior retinal redetachment posterior to scleral buckle with use of silicone oil. The detachment has been walled off by laser that was applied intraoperatively. Inferior laser

photocoagulation may obviate the need for encircling scleral buckling in cytomegalovirus (CMV)-related retinal detachments.

The general operative approach to these eyes is by pars plana vitrectomy, and the surgeon should leave the lens intact whenever possible. After the vitreous gel is removed, all epiretinal membranes are segmented and traction is removed, allowing the retina to become mobile. In some cases the peripheral vitreous gel is adherent to the necrotic peripheral retina and cannot be removed without causing further retinal damage. The use of a soft-tipped extrusion needle may allow the surgeon to remove the posterior hyaloid over broad areas of the retina. A posterior retinotomy is made, and, if an endoretinal biopsy is to be performed, it is done at the location of the posterior retinotomy that will be used for internal drainage.<sup>233,239</sup> A pneumohydraulic exchange is made through the retinotomy site, attaching the retina and filling the eye with air using a constant-pressure, sterile, air-delivery pump. Retinopexy is placed around all breaks in eyes to be treated with a long-acting gas. The peripheral retina may be encircled with either a small buckle or a band to relieve vitreous base traction, which may become a problem later in these inflamed eyes. In eyes with widespread retinal necrosis, most surgeons use silicone oil because it permanently tamponades all retinal breaks, including future sites of retinal necrosis and break formation.

In the HAART era, PVR may be seen in CMV detachment. This may be due to immune recovery uveitis causing a propensity to intraocular inflammation.<sup>245-247</sup> The management of CMV-related rhegmatogenous retinal detachments has been reviewed.<sup>248</sup> Certainly, it may be useful in acute retinal necrosis (ARN) because rhegmatogenous retinal detachment develops in a large number of patients with ARN. Similar considerations apply in bilateral healed CMV retinitis. The difficulty in both diseases is that all areas of retinal involvement must be surrounded with three rows of argon laser treatment. It is often impossible to carry out treatment to the ora serrata, however, and fluid may leak anteriorly and cause retinal detachment despite treatment. In addition, subretinal fluid may break through a wall of laser treatment if the mass of detached retina and subretinal fluid is relatively large. For this reason most

surgeons advocate placement of a panretinal type of pattern within the area of healing retinitis as well.<sup>249-251</sup>

## **HIV Disease/CMV Retinitis in the HAART Era**

Since the advent of HAART many patient have had dramatic restoration of immune system function. This also may be associated with a sustained drop in the plasma HIV viral load to low or undetectable levels. This suppression of plasma viremia may be prolonged; however, the HIV genome may still be found.<sup>37,252</sup> As mentioned earlier, with the prevalent use of HAART, the incidence of CMV retinitis has decreased approximately 75%.<sup>253-256</sup> For patients with CMV retinitis on HAART the risk of vision loss is lower,<sup>253</sup> the risk of retinal detachment is approximately 60% less, and long-term survival is much higher.<sup>211,253</sup>

In fact, for patients who have healed CMV retinitis and respond to HAART, discontinuation of maintenance therapy for CMV disease has been shown to be safe in a subset of patients.<sup>253,257-262</sup> We have found that some of these patients may discontinue anti-CMV therapy without reactivation of retinitis (Fig. 84.16). These data suggest that HAART therapy also is permitting at least partial immune reconstitution in some patients. Thus a trial of withdrawal of CMV therapy may be indicated in some patients with good response to HAART therapy and well-healed CMV retinitis. Patients should have a sustained CD4 count elevation of over 100 cells/ $\mu$ L for at least 3–6 months before discontinuing anti-CMV treatment and should be carefully monitored for reactivation. Reactivation of CMV retinitis may occur after successful HAART therapy when the CD4 count diminishes.<sup>263</sup> In addition, some patients may develop CMV retinitis on HAART with CD4 counts above 100/ $\mu$ L, probably because of incomplete restoration of the immune repertoire against CMV.<sup>130</sup>

**FIG. 84.16** (A) Active cytomegalovirus (CMV) retinitis required treatment with systemic ganciclovir. (B) The patient was subsequently treated with highly active antiretroviral therapy, with increase in CD4<sup>+</sup> cell count to over 100 cells/ $\mu$ L. The retinitis had remained healed. (C) The patient's systemic anti-CMV therapy was withdrawn, and the retinitis has remained healed for over 6 months. The CD4<sup>+</sup> cell count remains over 100.

The effects of HAART on the natural history of other AIDS-related opportunistic disorders have been summarized<sup>264,265</sup> and reflect the improvement or resolution of changes in the natural history of these disorders with inflammatory syndromes. The development of CMV retinitis relatively soon after initiation of HAART has been described.<sup>265</sup>

### Immune Recovery Uveitis.

In conjunction with the dramatic improvements in the immune system reported in some patients on HAART therapy, inflammation at sites of opportunistic infections is common, and related to recovery of immunity with effective antiretroviral therapy.<sup>266</sup> The syndrome has been described in the eye as “immune recovery vitritis” or “immune recovery uveitis” (IRU).<sup>267-274</sup>

Immune recovery uveitis appears to occur in eyes with healed CMV lesions in patients with immune reconstitution on HAART. The incidence rate of this phenomenon has varied, with reports from 0.11 to 0.83 per person-year in HAART responders with CMV retinitis.<sup>271,273</sup> Jabs et al. reported the frequency of IRU at 15.5% of 200 prevalent cases of CMV retinitis.<sup>274</sup> Arevalo et al. reported IRU in 37.5% of 32 patients.<sup>275</sup> Eyes in which CMV retinitis lesions involve large surface areas of retina seem to be at higher risk for the development of IRU.<sup>276</sup> Previous treatment with cidofovir may also be a risk factor.<sup>277</sup> Patients with IRU exhibit signs of inflammation

such as iritis, vitritis, macular edema, and epiretinal membrane formation (Fig. 84.17).<sup>278-282</sup> Cataract, vitreomacular traction, PVR, optic disc and retinal neovascularization, panuveitis with hypopyon, and uveitic angle closure glaucoma with posterior synechia have also been reported in IRU.<sup>283-289</sup> Vision loss from these inflammatory sequelae may range from mild to moderate and is usually associated with macular edema and associated macular surface changes or cataract in most cases.

**FIG. 84.17** Macular edema in a patient with immune recovery uveitis.

The pathophysiology of IRU is not well understood. One hypothesis is that once the CMV retinitis is healed and the immune system is reconstituted, the patient can mount an inflammatory response to residual CMV antigens in retinal glial cells in or adjacent to the necrotic CMV lesion. Another hypothesis is that control of CMV retinitis is incomplete in certain individuals with continued subclinical virus or viral protein production that stimulates the immune system. It has been reported that CMV antigens persist in cells of all retinal layers at the borders of clinically healed CMV lesions and in CMV-infected retinal glial cells after treatment with ganciclovir.<sup>288-290</sup>

Periocular steroids may be used successfully to treat this disorder, but ophthalmologists should be aware of CD4 cell counts.

It appears that if the CD4 cell count is elevated above 60/ $\mu$ L, treatment of immune recovery vitritis can be carried out without reactivation of retinitis (Fig. 84.13).<sup>268,283</sup> One case of reactivated CMV retinitis has been reported after treatment of IRU with periocular steroids.<sup>291</sup> Intravitreal triamcinolone is also effective in reducing macular edema; however, caution is needed not to reactivate retinitis.<sup>292</sup>

## Other Complications of CMV Retinitis

Central visual loss in AIDS patients with CMV retinitis occurs in two forms: direct macular tissue destruction and secondary involvement as part of rhegmatogenous retinal detachment. We treated 32 patients (35 eyes) with macular exudation that caused reversible visual loss and initially manifested as neurosensory retinal detachment and lipid exudates. Of 35 eyes, 25 showed papillary or peripapillary active retinitis and 10 showed retinitis 1500–3000  $\mu$ m from the fovea. Of 23 eyes with reduced vision that were followed up until healing of the retinitis and resolution of subretinal fluid and lipid exudates, 22 (96%) showed visual improvement with anti-CMV treatment. Our findings suggest that macular exudation is a reversible cause of visual loss in patients with CMV retinitis.<sup>115</sup>

Cystoid macular edema can occur in the setting of resolving CMV retinitis in patients with immunodeficiency other than AIDS. This entity is distinct from serous macular exudation, which can occur in patients with AIDS with active CMV retinitis involving the posterior pole.<sup>293</sup>

## Herpetic Retinitis

### Acute Retinal Necrosis in HIV Patients

ARN has been reported in AIDS patients.<sup>294</sup> It is a devastating disease characterized by the acute onset of a fulminant panuveitis with confluent, well-demarcated areas of retinitis, plus prominent anterior uveitis, occlusive retinal and choroidal vasculitis, vitritis, and papillitis.<sup>54,117,295,296</sup> In most cases the cause of the clinical syndrome of ARN is VZV but HSV can also cause ARN. The retinitis is characterized by deep retinal whitening, minimal

hemorrhage, and a rapid progression. In some cases, ARN in AIDS patients may be preceded by VZV optic neuropathy.<sup>297</sup> A history of preceding cutaneous zoster infection may be helpful in making the diagnosis in such cases.<sup>298,299</sup> In addition, the CD4 count is usually above 60/ $\mu$ L.<sup>297</sup> The new diagnostic criteria for ARN that do not include immune status of the patient have been published recently.<sup>300</sup>

No evidence of retinal vascular abnormalities may be present either clinically or angiographically early in the course of ARN. Retinal detachment is a common sequela, with multiple retinal breaks evident within areas of retinal necrosis. Retinal atrophy, often accompanied by PVR, is a common end-stage finding, and there may be associated anterior uveitis, scleritis, and ocular hypotension.<sup>117</sup>

Large numbers of herpesvirus particles in retinal tissue affected with ARN have been demonstrated by electron microscopy using endoretinal biopsy techniques. Virus may be detectable only during the acute phase of the disease.<sup>117,301</sup> Necrotic retinal tissue or retina reduced to thin glial remnants may not demonstrate virus. The difficulty in growing virus from these specimens is consistent with the hypothesis of VZV as the causative agent, since VZV is difficult to isolate and grow in vitro. CMV initially was believed to be the presumed infectious agent of ARN, but subsequent studies have not confirmed this.<sup>302</sup>

Studies employing endoretinal biopsy and PCR techniques have enabled definitive identification and culture of the causative virus, which has important diagnostic and therapeutic implications. Recent studies have suggested that combination antiviral therapy given intravenously (usually acyclovir or ganciclovir in combination with foscarnet), if given promptly, can arrest the disease and salvage vision.<sup>197</sup> Retinal detachment in VZV retinitis is common (up to two-thirds of patients) and may be associated with PVR or retinal shortening. Repair with vitrectomy and silicone oil after relief of traction with membrane segmentation and sometimes retinotomy may result in useful vision.<sup>197,303</sup> Prophylactic barrier laser around lesions should be considered to lower the risk of retinal detachment in ARN.

Ganciclovir has good efficacy against all herpesviruses but has a

lower therapeutic index and must be given indefinitely because it acts as a virostatic agent. Determination of a specific viral cause early in the course of the disease when large numbers of viral particles are present is therefore imperative. Both HSV and VZV may be sensitive to acyclovir. However, VZV requires higher serum concentrations than HSV. Treatment for ARN in AIDS patients is usually based on established treatment for non-HIV-infected patients. Acyclovir intravenously 500 mg/m<sup>2</sup> or 10 mg/kg every 8 hours is effective, followed by oral famciclovir 500 mg t.i.d., acyclovir 800 mg five times a day or valacyclovir 1000 mg t.i.d. for maintenance therapy.<sup>93</sup> Duration of maintenance therapy is controversial, with reports of contralateral ARN infection decades later. This may support lifetime maintenance therapy, especially in immunosuppressed AIDS patients. Valacyclovir 1000 mg t.i.d. has been reported effective for initial treatment of ARN in a small series of immunocompetent individuals.<sup>304</sup> Intravenous foscarnet may be used in acyclovir resistant cases.<sup>305</sup> Corticosteroids have been used to decrease vitritis in immunocompetent patients with ARN, but steroids are usually contraindicated in HIV patients with advanced immunosuppression.<sup>93</sup>

## **Progressive Outer Retinal Necrosis**

Progressive outer retinal necrosis (PORN) is another variant of herpetic retinitis in AIDS patients and is nearly always caused by VZV. The incidence of PORN has decreased during the HAART era.<sup>306</sup> It has been described in association with VZV as the onset of retinitis either succeeded by or coincident with an eruption of dermatomal zoster.<sup>307</sup> Most patients with this syndrome have had low CD4 cell counts (i.e., below 50/μL). PORN syndrome is an extremely rapid progressive necrotizing retinitis characterized by early patchy multifocal deep outer retinal lesions (Fig. 84.18) with late diffuse thickening of the retina, absence of vascular inflammation, and minimal to no vitreous inflammation.<sup>308</sup> Severe vision loss develops as a result of a widespread retinal necrosis and from retinal detachment, the latter reported in up to 70% of patients in early studies.<sup>308-313</sup> Perivascular clearing of the retinal opacification is characteristic of PORN syndrome (Fig. 84.19).

**FIG. 84.18** Deep, round retinal lesions seen superior to the optic disc are characteristic of varicella-zoster retinitis in AIDS patients, also termed progressive outer retinal necrosis (PORN) syndrome.

**FIG. 84.19** Varicella-zoster retinitis in an HIV patient shows retinal opacification and perivascular "clearing." The perivascular edema and necrosis is cleared first; the tissue is not spared.

Therapy of PORN often requires immediate high-dose anti-zoster or -HSV therapy. The earliest reports of treatment of PORN with single intravenous antivirals, primarily acyclovir showed poor visual results. Engstrom et al. reported final vision of no light perception (NLP) in 67% of 63 eyes within 4 weeks.<sup>307</sup> Poor outcomes with intravenous acyclovir were possibly due to development of HSV or VZV resistance to acyclovir in patients who developed PORN while on prophylactic anti-HSV therapy with acyclovir. Recent studies have shown improved visual outcomes employing combination intravenous and intravitreal antiviral treatment. Scott et al.<sup>308</sup> reported final vision of 20/80 or better in 5 of 11 eyes (45%) with only two of 11 eyes (18%) progressing to NLP vision utilizing a regimen of intravitreal ganciclovir and foscarnet plus intravenous foscarnet and intravenous ganciclovir or oral valganciclovir. In addition, the authors' data suggested that laser demarcation may be beneficial to decrease the rate of retinal detachment. Combination of antiviral drugs and HAART preserved vision in a report by Kim et al.<sup>314</sup>

## Nonviral Intraocular Infections in AIDS Patients

Nonviral intraocular infections have been reported in AIDS patients. Autopsy studies have documented numerous infections. Many of the opportunistic infections seen in patients with AIDS can be prevented with appropriate prophylactic agents.<sup>315</sup>

### ***Pneumocystis carinii* Choroidopathy**

In 1987 Macher and associates<sup>316</sup> described a patient with AIDS with disseminated pneumocystosis, and choroidal *P. carinii* (now *P. jiroveci*) was found at autopsy; no clinical correlation was reported. In 1989 Rao and colleagues<sup>58</sup> reported the histopathologic findings in an autopsy series of three patients with AIDS who clinically demonstrated yellow choroidal infiltrates while receiving aerosolized pentamidine for *P. carinii* pneumonia (PCP) prophylaxis. In two cases a presumptive diagnosis of disseminated pneumocystosis was made by ophthalmologic examination. Histopathologically, the choroidal infiltrates were eosinophilic,

acellular, vacuolated, and frothy, with the infiltrates within the choroidal vessels and choriocapillaris. Both Gomori's methenamine-silver stain and electron microscopy demonstrated organisms.

In 1989 Freeman et al. described a woman with AIDS with multifocal, slowly enlarging, round-to-oval lesions in the choroid.<sup>317</sup> Fluorescein angiography revealed early hypofluorescence with late staining of the lesions, which appeared deep to the retinal circulation, without evidence of retinal involvement or inflammation (Fig. 84.20). A transscleral choroidal biopsy revealed, by electron microscopy, cystic structures characteristic of *P. carinii* within necrotic choroid.

**FIG. 84.20** (A) Pneumocystis choroiditis. The round lesions are associated with minimal inflammation. Overlying the lesions in the superior portion of the macula is a typical cytomegalovirus (CMV) retinitis lesion. (B) Electron micrograph of *Pneumocystis carinii* organisms seen after choroidal biopsy.

A multicenter study of pneumocystis choroidopathy in 1991 reported 21 patients with AIDS and presumed *P. carinii* choroidopathy.<sup>318</sup> The lesions were characteristically yellow to pale yellow, appeared in the choroid, and were found in the posterior pole. They enlarged slowly before systemic antipneumocystis therapy and eventually resolved. Of 21 patients, 18 were receiving topical therapy with aerosolized pentamidine. There was little evidence of retinal destruction by visual acuity and visual field testing. The choroidal infiltrates were not associated with vitreous inflammation unless another infectious retinitis was present. Resolution of choroiditis took from 6 weeks to 4 months after

systemic therapy. Survival after the diagnosis ranged from 2 to 36 weeks.

The CDC recommends double-strength trimethoprim–sulfamethoxazole (TMP–SMX) daily or three times weekly for primary prophylaxis of PCP when CD4 counts are below 200/ml, with alternatives including dapsone, dapsone plus pyrimethamine and leucovorin, aerosolized pentamidine administered by the Respigard II nebulizer, and atovaquone.<sup>319</sup> PCP is the most common AIDS-defining opportunistic infection. Choroidal *P. carinii* infection appears to have been more common when the prophylactic use of nonsystemically absorbed aerosolized pentamidine for PCP was widespread. The choroidal lesions of *P. carinii* appear as pale, cream- or orange-colored, space-occupying lesions from several hundred to several thousand micrometers in size and they rarely are symptomatic or lead to a decrease in visual acuity. The lesions may be unilateral or bilateral.<sup>58,317–322</sup> *P. carinii* choroidopathy appears to be a marker for disseminated pneumocystosis and should be treated systemically. The need for maintenance systemic therapy for choroidopathy has not been established.

Although the diagnosis of disseminated pneumocystosis may be suggested by the characteristic appearance of *P. carinii* choroidopathy, isolated retinal disease may rarely be the earliest clinical manifestation of disseminated pneumocystosis. The incidence of *P. carinii* choroiditis has decreased, probably because of more widespread use of systemic PCP prophylaxis such as trimethoprim–sulfamethoxazole, immune restoration from HAART, and decreased use of aerosolized pentamidine for prophylaxis and therapy.<sup>319</sup>

## Ocular Toxoplasmosis

Toxoplasmosis is a common CNS opportunistic infection in patients with AIDS. Ocular toxoplasmosis is much less common,<sup>62,323–325</sup> with reported incidence of 3% in HIV-infected patients in France.<sup>326</sup> US incidence is decreased in the HAART era by immune restoration and primary toxoplasmosis prophylaxis with TMP–SMX for those with CD4 counts less than 200/ml.<sup>93</sup> Eight patients with presumed ocular toxoplasmic retinochoroiditis were described in 1988 by

Holland et al.<sup>62</sup> In two cases the diagnosis was confirmed histologically. Lesions were usually bilateral (5/8) and multifocal, with vitreous inflammation noted clinically. Therapy resulted in remission, but reactivation and disease progression followed in two of three patients when therapy was stopped. Three patients had retinal tears or detachment as a result of severe retinal necrosis. The ocular lesions were the first manifestation of toxoplasmosis in four of five patients with disseminated disease, although all patients had preexisting HIV infection, and in four the diagnosis of AIDS had not been made. In four of five patients with no evidence of nonocular infection, evidence of *Toxoplasma* was demonstrated in the CNS (encephalitis or brain abscess). No patient had evidence of preexisting chorioretinal scars, and all had IgG antibodies to *T. gondii* at the time of diagnosis. Ocular disease was believed to be secondary to reactivation of *Toxoplasma* or to newly acquired or newly disseminated disease to the eye from nonocular sites of disease (Fig. 84.21).

**FIG. 84.21** (A) Toxoplasmosis retinitis in an HIV patient who was healed after antitoxoplasmosis therapy with clindamycin. (B) Systemic treatment for toxoplasmosis was withdrawn 6 months later, and the retinitis reactivated.

Retinal toxoplasmosis in HIV infection may present as a focal necrotizing nonhemorrhagic retinitis that does not heal spontaneously and may simulate ARN, CMV, or luetic retinitis.<sup>93,327</sup> Prominent vitreous and anterior chamber reaction, relative absence

of retinal hemorrhage, and thick, densely opaque yellow-white lesions with smooth nongranular borders suggest toxoplasmosis. Endoretinal biopsy or PCR techniques may be useful if diagnosis is difficult.<sup>93,328,329</sup>

Ocular toxoplasmosis often presents differently in AIDS compared to immunocompetent individuals, spreading as a contiguous or multifocal retinitis. AIDS patients more often have extensive areas of retinal necrosis plus multiple areas of active infection.<sup>330,331</sup> Histopathologic studies show absent to scant inflammatory cells in the infected retina of immunocompromised patients. AIDS patients can develop ocular toxoplasmosis in the absence of preexisting chorioretinal scars. This pattern combined with frequent systemic toxoplasmosis at diagnosis suggests that acquired disease is more common than reactivation of congenital disease.<sup>93,332</sup> For immunocompetent individuals, current evidence also suggests that most patients with ocular toxoplasmosis were infected postnatally, even though the risk of ocular toxoplasmosis is higher from congenital infection<sup>333</sup> (Fig. 84.21). Ocular toxoplasmosis in AIDS patients has also been reported to cause miliary disease, optic neuritis, panophthalmitis, and acute unilateral iridocyclitis without retinal lesions.<sup>334,335</sup> Ocular toxoplasmosis is diagnosed clinically and using PCR from a vitreous fluid sample.

Ocular, as well as disseminated, toxoplasmosis in patients with AIDS is treated with standard antitoxoplasma regimens used in immunocompetent patients such as sulfadiazine (4–6 g/day) or clindamycin in sulfa-allergic patients plus pyrimethamine/leucovorin, with apparent response rates of 80%. TMP–SMX was reported in a small (77 patients) randomized trial to be effective and better tolerated than pyrimethamine–sulfadiazine.<sup>336–338</sup> Other treatments for patients unable to tolerate sulfa drugs such as azithromycin or atovaquone have been primarily studied for CNS toxoplasmosis in AIDS patients and ocular toxoplasmosis in immunocompetent patients.<sup>339</sup> Atovaquone was originally synthesized as an antimalarial and has been shown to have activity against both *P. carinii* and *T. gondii*. Ocular toxoplasmosis in patients with AIDS frequently recurs when medical therapy is terminated so maintenance therapy generally is

given. Corticosteroids may be given as adjunctive therapy for intracranial toxoplasmosis to reduce cerebral edema, although this is unproved; systemic corticosteroids are sometimes given to reduce inflammation in ocular disease, although these should be administered cautiously in HIV-infected patients. In addition, resolution of ocular toxoplasmosis in AIDS patients has been seen without corticosteroid therapy.<sup>62</sup>

Toxoplasma retinitis is decreasing because of more widespread use of HAART and of prophylaxis, such as TMP–SMX. Currently the CDC recommends consideration of discontinuing maintenance therapy (sulfadiazine plus pyrimethamine/leucovorin with clindamycin used in sulfa-allergic patients) for toxoplasma encephalitis if a patient maintains a CD4 count above 200/ $\mu$ L for greater than 6 months.

## Fungal Diseases

### Candida albicans

Since HIV can be a consequence of intravenous drug use, which is also associated with candidemia, it is surprising that candida endophthalmitis is not seen more frequently in HIV patients. Focal retinal and chorioretinal lesions and endophthalmitis from *Candida* spp. have been described in patients with AIDS.<sup>55,340</sup> Traditional therapy for candida endophthalmitis has been systemic amphotericin B. However, limited vitreous penetration has resulted in treatment failures, plus adverse effects including nephrotoxicity discourage its use.<sup>341</sup> Trials comparing oral fluconazole to intravenous amphotericin B for systemic candidemia in immunocompetent patients suggested equivalent efficacy with fluconazole being the less toxic.<sup>342</sup> Vitrectomy and intravitreal amphotericin B can be helpful in cases failing systemic therapy.

### Cryptococcus neoformans

Cryptococcal infections may occur in 5–10% of patients with AIDS<sup>343</sup> and are associated with both direct and indirect ocular complications. Cryptococcal infection is a common occurrence in

AIDS, resulting in meningitis and secondary ocular involvement. Chorioretinitis, endophthalmitis, or both, caused by direct intraocular invasion of the organism, have been described in immunosuppressed patients.<sup>344,345</sup> Visual loss caused by cryptococcal infection has been demonstrated to result from invasion of the visual pathways, including the optic nerve, tract, and chiasm.

The treatment of cryptococcal disease in patients with AIDS usually consists of an “induction” phase of about 2 weeks followed by a “consolidation” phase of about 8 weeks. Amphotericin B (>7 mg/kg per day) is most commonly used for induction, if possible combined with 5-flucytosine 100 mg/kg daily in four divided doses. If necessary because of toxicity, amphotericin can be replaced by fluconazole (800–1200 mg/day); a third phase of prolonged maintenance therapy with oral fluconazole (200 mg/day) is continued unless CD4 counts are above 200/ $\mu$ L. Ophthalmologic complications of cryptococcal meningitis were seen infrequently before the description of AIDS.

## Histoplasmosis

Histoplasmosis was initially reported in patients with AIDS in 1982, and in the next eight years more than 100 systemic cases were reported,<sup>346</sup> mostly disseminated disease that presents as fevers without localized symptoms. The treatment of histoplasmosis in patients with AIDS usually consists of an induction phase with amphotericin B followed by a lifelong maintenance phase with either amphotericin B or itraconazole.<sup>347</sup>

Gonzales et al. reported bilateral endogenous endophthalmitis in an HIV-positive patient presenting with severe subretinal exudation, choroidal granulomas, and intraretinal hemorrhage leading to bilateral exudative retinal detachments. Vitreous cultures grew *Histoplasma capsulatum* var. *capsulatum*. Treatment involved systemic and bilateral intravitreal amphotericin B plus vitrectomy/scleral buckle in one eye.<sup>348</sup> Ala-Kauhala et al. reported a case of panuveitis in disseminated histoplasmosis in an HIV patient treated with liposomal amphotericin B, HAART, and topical steroids that ended up with anterior segment scarring.<sup>349</sup>

## Aspergillosis

Endogenous endophthalmitis caused by *Aspergillus fumigatus* rarely has been described in AIDS and can arrive in the eye hematogenously or through extension to the orbit from adjacent sinuses. One case of disseminated, invasive aspergillosis with ocular involvement noted at autopsy was described in 13 patients with pulmonary aspergillosis; no clinical correlation of ocular findings was reported.<sup>350</sup> Whereas four cases of orbital aspergillosis in HIV were reported, ocular aspergillosis is very rare in the HIV population.<sup>351,352</sup>

## Coccidioidomycosis

To our knowledge, no cases of ocular coccidioidomycosis have been described in patients with AIDS. In a retrospective review of 77 patients with HIV infection and coccidioidomycosis, no case of endogenous endophthalmitis secondary to coccidioidomycosis was described, although disseminated disease (including meningitis) was described in a majority of patients.<sup>353</sup> Other unusual mycotic infections causing endophthalmitis, some in association with chorioretinitis, but not necessarily HIV-seropositive patients, are reviewed by McDonnell and Green.<sup>354</sup>

## Paracoccidioidomycosis

Severe CNS plus ocular infection with *Paracoccidioides brasiliensis* that simulated CNS and ocular toxoplasmosis has been reported in a pregnant HIV-positive patient. The infection caused severe iridocyclitis, vitritis, plus a granulomatous chorioretinal lesion also involving the optic nerve that ultimately progressed to retinal detachment, NLP vision, and enucleation despite treatment.<sup>355</sup>

## Advances in Antifungal Therapy

Fungal endophthalmitis traditionally has been treated with intravenous amphotericin B. Limitation of vitreous penetration plus systemic toxicity limit its effectiveness. Flucytosine and fluconazole

have higher vitreous penetration but are limited by lack of broad coverage against many of the organisms typically seen in fungal endophthalmitis. As a result, vitrectomy and intravitreal amphotericin B is usually recommended in serious fungal endophthalmitis or cases unresponsive to systemic therapy.<sup>356</sup>

The triazole antifungal medications fluconazole, itraconazole, voriconazole, posaconazole, and ravuconazole are orally available and are less toxic drugs that can treat a variety of fungal organisms.<sup>357-361</sup>

Older drugs such fluconazole, which treats candidal infection, and cryptococci and itraconazole, which treat histoplasmosis and aspergillosis, remain valuable. Voriconazole has been shown to have mean aqueous and vitreous minimum inhibitory concentrations for 90% of isolates (MIC90) for a wide spectrum of yeast and molds, including *Candida* and *Aspergillus* spp. after oral administration. Voriconazole and posaconazole have also been reported to successfully treat fungal endophthalmitis that was unresponsive to traditional antifungal agents.<sup>362</sup> Voriconazole and posaconazole have been shown to have efficacy against *Candida albicans* isolates from HIV patients.<sup>361</sup>

## Bacterial Retinitis

### Syphilis

Concurrent ocular syphilis appears to be more common in HIV-infected than in uninfected persons. Ophthalmic manifestations of syphilis usually occur during or shortly after the secondary stage. Syphilitic uveitis and chorioretinitis in HIV-infected patients have been described. Nine patients with ocular syphilis and concurrent HIV infection were described by McLeish and colleagues in 1990.<sup>363</sup> They found iridocyclitis in three of 15 eyes, vitritis in one eye, retinitis or neuroretinitis in five eyes, papillitis in two eyes, optic perineuritis in two eyes, and retrobulbar neuritis in two eyes. The three of nine patients with AIDS had the worst initial visual acuities. Six of nine had concomitant neurosyphilis. Benzathine benzylpenicillin, the only treatment in three of the patients, led to relapses in all three. Seven of nine patients treated with high-dose

intravenous penicillin responded dramatically to therapy with no evidence of relapse.

Concurrent ocular syphilis and neurosyphilis reported in two patients with HIV infection, in addition to a review of 13 other HIV-infected patients with ocular syphilis, revealed that 11 of the 13 HIV-infected patients with ocular syphilis had neurosyphilis.<sup>364</sup> The authors stress that neuro-ophthalmic syphilis may be the presenting feature of HIV infection and that ocular syphilis is strongly associated with concurrent neurosyphilis in patients that are HIV-seropositive (Fig. 84.22).

**FIG. 84.22** Papillitis and vitritis from syphilis in an HIV-positive patient. Intravenous penicillin resolved the findings.

Necrotizing retinitis has been reported in a patient with HIV and syphilis. In some cases the appearance of luetic retinitis as a focal expanding white lesion may simulate CMV retinitis, ARN, or toxoplasmic retinitis. Marked inflammation of the vitreous and anterior chamber usually accompanies syphilitic retinal disease with posterior synechiae and keratic precipitates.<sup>365</sup>

Standard treatment of primary and secondary syphilis with 2.4 million units of intramuscular benzathine penicillin in patients with

and without HIV infection produce similar excellent clinical responses. Serologic responses to therapy (reducing nontreponemal antibody to unreactive levels), the primary method for ascertaining adequate treatment, are less certain in HIV patients.<sup>366</sup>

For retinitis, treatment for neurosyphilis with intravenous penicillin should be used and ceftriaxone may be used when penicillin is contraindicated. With regard to diagnosis, false-negative serum rapid plasma reagin (RPR) and Venereal Disease Research Laboratories (VDRL) may occur uncommonly with HIV infection. Thus additional, more specific tests are recommended in this population (i.e., fluorescent treponemal antibody, absorbed [FTA-ABS]).<sup>367</sup>

## Invasive Diagnostic Techniques for Retinal Disease

In difficult cases, biopsy of the vitreous, choroid, or retina may allow for diagnosis of retinal disease. Vitreous biopsy may yield a diagnosis if a moderate to heavy cellular infiltrate is present. Most modern vitrectomy machines use sterile, disposable tubing and cassettes so that vitreous washings obtained are sterile. These washings may be filtered or centrifuged for appropriate stains, cultures, and cytologic study.

An alternative method may be used to obtain undiluted vitreous at the time of pars plana vitrectomy. After the infusion cannula can be visualized within the eye, the cannula is connected to a sterile, constant-air infusion pump, and a vitrectomy is carried out under air. In phakic eyes, a minus-power contact lens is used to visualize the retina under air. In this way the entire volume of the vitreous cavity may be removed in an undiluted form for study.

Appropriate processing of vitreous obtained as part of a diagnosis is mandatory, and the testing performed should reflect the differential diagnosis. Where infection is suspect, plating of undiluted vitreous on appropriate culture media for aerobic bacteria (chocolate and blood agar, brain–heart media), anaerobic bacteria (thioglycolate media and cooked meat broth), media for acid-fast bacilli, and fungal culture media is imperative and should

be done in the operating room. Smears of the undiluted gel should be stained for these etiologic agents, and cytologic smears also should be obtained. In addition, histopathologic stains are useful in ruling out intraocular neoplasms, particularly intraocular lymphoma. Other important diagnostic aids include the use of cytopsin preparations that concentrate the cells in vitreous washings, and the use of cell blocks, should enough cellular material be present in a vitreous specimen. The choice of fixatives should be considered carefully. In general, the use of electron microscopic fixatives such as glutaraldehyde may destroy the antigenicity of proteins, rendering immunostaining impossible. Buffered paraformaldehyde will preserve many antigens, although in some cases, frozen, nonfixed tissue is required. In situ hybridization may work on fixed or fresh tissue and can be valuable in determining the presence of pathogenic DNA.<sup>368</sup>

PCR techniques also may be useful in analyzing aqueous or vitreous specimens in difficult cases. Nonfixed fluids are best; they can be frozen for later evaluation or processed fresh. In cases of active retinitis, the test is very sensitive, although it may be somewhat nonspecific because it may detect CMV in the blood in the absence of retinal infection. Choroidal biopsies may be indicated when infiltrative processes of the choroid are seen clinically. Fungal, bacterial, protozoal, or parasitic disease may cause metastatic focal or diffuse infiltrative lesions in the choroid. Tuberculous disease and neoplastic disorders, including lymphoma, also may produce such lesions. All such diseases respond temporarily, if at all, to steroid therapy, and in many cases the diagnosis cannot be made by study of vitreous cells. Before undertaking this diagnostic procedure, prior arrangements for appropriate histologic examination of all materials obtained must be made, since the amount of material that can be obtained is usually small. Any cultures to be taken should be performed by direct plating of the tissue onto the appropriate media in the operating room, as outlined above.

Thorough preoperative examination of the posterior segment is necessary. The choroidal lesion to be biopsied must be well localized. Echography can be used to gain further information regarding the consistency of the lesion and the presence of

subretinal or suprachoroidal fluid. It can also be useful in determining if an intraocular lesion has extraocular extension. It is best to select a site distant from the macular area; a nasal area of involvement is best.

In the operating room, the conjunctiva is removed from the limbus 360 degrees, and all four rectus muscles are isolated. Tenon's capsule is cleaned from the quadrant to be biopsied, and the margins of the lesion are marked. It is advantageous to choose a site where a serous or exudative retinal detachment is present overlying the lesion in question because this provides an added margin of safety. A half-thickness scleral dissection is performed 5–10 mm<sup>2</sup> and fashioned into a “trap door.” Preplaced 5–0 polyester sutures can be used to allow the trap door to be closed quickly. A smaller area of underlying sclera is closed by diathermy to prevent bleeding, and then an area 3–4 mm on each side is resected. Care is taken to remove choroid and not retina. The trap door is then closed with 5-0 polyester sutures, and the area of resection is examined with the indirect ophthalmoscope. Some sclera should be visible if a full-thickness choroidal biopsy was performed. Retinal incarceration in the biopsy site is a potential source of problems and may have to be addressed using internal pars plana surgical techniques. Vitreous in the biopsy implies retinal incarceration or a retinal break that must be repaired using pars plana vitrectomy techniques. Using this technique, embolic bacterial endophthalmitis, pneumocystis choroidopathy, and other pathologic entities may be diagnosed. Because of the potential to damage the retina or perforate the eye, in some cases it may be preferable to perform a pars plana vitrectomy before choroidal biopsy. This will allow maintenance of intraocular pressure, as well as rapid internal access to the retina should complications arise.

Endoretinal biopsy has been reported to be of value in the diagnosis of viral retinitis. Freeman et al.<sup>117</sup> first reported this technique in 1986. We pursued this technique in patients with CMV retinitis (Fig. 84.23). After healing of retinitis with ganciclovir, rhegmatogenous retinal detachment developed in a large number of these patients as a result of numerous breaks in areas of necrotic and healed retina. We showed in several eyes that persistent infection was present, as viral particles were seen. At this time we

do not recommend endoretinal biopsy for all cases of viral retinitis. Rather, we treat such cases with the appropriate antiviral drug and await a response. Response may not indicate a specific viral cause, however, because some drugs treat multiple viruses. In certain cases it is helpful to obtain an etiologic diagnosis. As new antiviral and immunostimulating drugs become available, viral retinitis may not take on the so-called classic clinical appearance, and aggressive diagnostic techniques may become more important. Currently we obtain endoretinal biopsies at the time of pars plana vitrectomy to repair rhegmatogenous retinal detachments in these patients. During these procedures, undiluted vitreous specimens are taken for viral cultures, and in some cases in situ nucleic acid hybridization studies are done. The retinal biopsy (described below) is divided into three small pieces, and each is placed on a small wedge of sterile paper or on an agar sandwich in the operating room using the operating microscope. Tissue is fixed in glutaraldehyde for electron microscopy, as well as in buffered formalin for light microscopy and some immunologic studies. The third piece of tissue may be frozen for further immunologic studies or cultured for virus. It is important to remember that the choice of fixative and tissue preparation technique is critically important; if an incorrect choice is made, it may not be possible to arrive at a diagnosis. Even when obtaining an endoretinal biopsy, the vitreous should also be examined because vitreous biopsy in cases of infectious retinitis may be positive for the causative organism. One can also perform endoretinal biopsy in nondetached retinas. The preliminary results in animals have been encouraging, and refinement of these techniques in the future may shed light on a variety of retinal disorders.

**FIG. 84.23** Retinal lymphoma in an HIV-positive patient can present as an atypical retinitis. Diagnosis was made by endoretinal biopsy.

In eyes undergoing endoretinal biopsy a pars plana vitrectomy with complete removal of the hyaloid is performed. The biopsy site also is used for internal drainage. To determine the etiologic diagnosis, it is important to make this location at the junction of healed and normal or active retinitis. Vessels are cauterized only posterior to the biopsy site. We prefer to use the pointed 20-gauge intraocular unimanual bipolar cautery. Low power must be used, and major vessels posterior to the biopsy site are cauterized. Using motorized vertical cutting scissors, a rectangular strip of retina is excised, which crosses the site of active retinitis or the leading border. The strip may be 2 mm wide and 3–5 mm long. It is chosen from an area of necrotic or gliotic nonfunctional retina so that no visual loss occurs. Removal of the tissue from the eye through the 20-gauge sclerotomy with a forceps may crush and mutilate the tissue, so, instead, we prefer to guide the tissue toward the sclerotomy with a pick or pick forceps. The tissue is released, and the instrument is then removed from the eye while the infusion bottle is elevated to the high position. In this way the tissue is hydraulically directed into the sclerotomy site and plugs it. The tissue is gently teased out of the sclerotomy with a 0.12 mm forceps and spread over the cornea, removing all folds.

Any ocular tissue, but particularly small endorectal biopsy specimens, must be processed with care. The surgeon must decide in advance on the location of the area to be biopsied and the fixatives and numbers of specimens to be processed. We have developed a mount that allows more facile mounting of retinal biopsy specimens.<sup>368</sup> The agar–albumin sandwich technique allows the small piece of retinal tissue to be floated onto a slab of clear agar and then “glued” to it with liquid agar that has been warmed in a microwave oven. When the tissue is draped on the agar, it can be readily identified and not lost during processing. Multiple sections of the tissue can then be cut for processing and immunostaining. The technique also works well for electron microscopy and other morphologic studies.

## Antiretroviral Therapy

Expert guidelines for use of these drugs are continuously updated.<sup>369,370</sup> Many other antiretroviral agents are undergoing preclinical and clinical studies. Currently available drugs do not eradicate latent HIV infection, which returns when drugs are stopped (Table 84.1). When used in combination, they usually decrease viral replication, improve immunologic status, reduce risk of infectious complications, and prolong life. Drugs active against the patient's HIV strain should always be used in combination for full potency and prevention of resistance.

Drug-Resistant Tuberculosis

## **Introduction**

Ocular mycobacterial infection represents an important form of extrapulmonary infection which encompasses tubercular as well as nontubercular mycobacterial (NTM) diseases in and around the eye. It presents with diverse clinical manifestations because of the

number of factors that are related to the microbe and the host. In spite of recent revolutionary advances in diagnostic technologies, establishing the diagnosis as well as treating the disease are clinical challenges. Mycobacterial diseases have been known to affect humans for more than a century and it still continues to be a global health concern. There are several challenges as far as tuberculosis (TB) is concerned. To list a few, TB stands as the most common opportunistic infection in human immunodeficiency virus (HIV)-positive patients in many developing countries. In 2013, an estimated 1.1 million of the 9 million people (13%) who developed TB were HIV-positive; 1.5 million people died from TB, including 360,000 people with concomitant HIV infection, which equates to about 4100 deaths a day.<sup>1</sup> Yet another global threat is the emergence of multidrug resistant (MDR-TB) and extensively drug-resistant strains of tuberculosis (XDR-TB). In 2013, the World Health Organization has estimated that globally 20.5% of previously treated and 3.5% of new TB patients have had MDR-TB which translates into an estimated 480,000 patients. Of them an estimated 9.0% had extensively drug resistant TB (XDR-TB).<sup>2</sup> Another important concern is the emergence of NTM infections, both in immune competent and immune compromised individuals in previously unrecognized settings and with new clinical manifestations.<sup>3</sup> Clinical manifestations of NTM simulate typical tuberculosis. Lack of better laboratory tools for differentiation, lack of treatment guidelines, and resistance to routine antitubercular treatment challenge the early management of mycobacterial infections. There is also a need to develop a consensus in investigations and treatment guidelines for ocular tuberculosis.<sup>1</sup>

## **Pulmonary and Extrapulmonary Tuberculosis**

Tuberculosis is an infection caused by a rod-shaped, nonspore-forming, aerobic bacterium, *Mycobacteria tuberculosis*. Bacilli spread by small airborne droplets from infected patients. Once the droplet nuclei are inhaled, the bacilli settle in the airways. If the infection is not contained by the immune system, in around 3–8 weeks, local

spread and spread to regional lymph nodes in the lungs occurs. Subsequent spread to other organs results in extrapulmonary tuberculosis (EPTB). EPTB is reported to be increasing over the last several years.<sup>4</sup> Organs affected in EPTB include lymph nodes, pleura, central nervous system, eyes, musculoskeletal system, genitourinary tract, and gastrointestinal tract. Symptoms and clinical presentations of EPTB are variable and depend on the organ involved. Unlike pulmonary TB patients, EPTB patients are less likely to present with cough, dyspnea, hemoptysis, abnormal chest radiograph, night sweats, weight loss, anorexia, or fatigue. They may present with higher rates of abdominal pain, diarrhea, infertility, monoarticular joint pain, headache, meningismus, or lymphadenopathy depending upon the organ involved. Ocular tuberculosis represents an extrapulmonary dissemination of the bacilli primarily from lungs. However, patients with ocular TB may have a normal chest radiograph and negative chest complaints; alternatively they may have evidence of other forms of EPTB such as tubercular lymphadenitis. Ophthalmologists have to include appropriate questions in the history and consider extraocular systems whenever a tubercular etiology is suspected. It is essential to rule out EPTB and involvement of other systems in patients who may appear only to harbor pulmonary tuberculosis.

## Ocular Tuberculosis

Three classic forms of ocular tuberculosis have been described. Direct ocular infection from an exogenous source may involve ocular adnexa, conjunctiva, sclera, or cornea. The second form results from a hypersensitivity reaction to distant foci of infection causing episcleritis, phlyctenulosis, and occlusive retinal vasculitis of the type observed in Eales disease. The third form relates to the hematogenous spread of *M. tuberculosis* from pulmonary or extrapulmonary sites.

Tuberculosis is one of the most common causes of infectious uveitis in tropical countries.<sup>5-7</sup> It is either unilateral or asymmetrically bilateral, characterized by a chronic and insidious course. Anatomically, tubercular uveitis may present as anterior, intermediate, posterior, or pan uveitis; more often a granulomatous

than nongranulomatous uveitis. The manifestations of ocular tuberculosis are numerous (Figs. 85.1–85.5). Clinical signs of ocular tuberculosis based on anatomical location are given in Table 85.1.

**FIG. 85.1** Patient #1. (A) Pretreatment fundus photograph of right eye showing a choroidal tubercle with adjoining exudative detachment. A healed scar is below the active lesion. (B) Post antitubercular treatment fundus photograph of the right eye showing healed scars with resolution of exudative detachment. (C) Multiple tubercular cervical sinuses in the neck of the same patient

**FIG. 85.2** Patient #2. Fundus photograph showing tubercular disc granuloma, vasculitis, and multifocal retinitis in a smear-positive pulmonary tuberculosis patient.

**FIG. 85.3** Patient #3. Fundus photograph showing old healed choroiditis as well as active recurrent lesions with varying chronology of choroidal lesions in the right eye. Mantoux skin test was necrotic and chest radiograph showed calcified lymph nodes.

**FIG. 85.4** Patient #4. (A) Choroidal tubercle with choroidal folds, with shallow serous retinal detachment. (B) Fundus fluorescein angiogram shows vascular staining and perivascular leakage overlying the lesion suggestive of active retinal vasculitis. (C) Fundus fluorescein angiogram shows a well-demarcated choroidal tubercle showing increasing hyperfluorescence with pooling of dye in the area of neurosensory detachment in the late phase extending beyond the tubercle with late disc staining.

**FIG. 85.5** Patient #5. (A) Pretreatment fundus photograph of the left eye showing serpiginous-like choroiditis partly healed in the center with an active peripheral lesion, disc hyperemia with vitreous reaction. Vitreous was positive for real-time polymerase chain reaction for *Mycobacterium tuberculosis*. (B) Fundus fluorescein angiogram of the same patient showing hyperfluorescence in the older central lesion and hypofluorescence in the active peripheral lesion, vessel wall staining, and disc staining.

**TABLE 85.1**

**Clinical Signs: Ocular Mycobacterial Infections**

Primary Site of Inflammation	Clinical Signs
Lids, adnexa, sclera, and cornea	Lupus vulgaris Recurrent episcleritis/scleritis, necrotizing scleritis, posterior scleritis, interstitial keratitis Sclerokerato uveitis
Lacrimal apparatus	Lacrimal gland adenitis, dacryocystitis
Orbit	Tuberculoma, tubercular abscess
Anterior uveitis	Nongranulomatous/granulomatous uveitis Hypopyon Anterior chamber granulomas
Intermediate uveitis	Recurrent, granulomatous
Posterior uveitis	Choroidal tubercles Choroidal tuberculoma Multifocal chorioretinitis Subretinal abscess Serpiginouschoroiditis Perivascular healed chorioretinal scars
Pan uveitis	Endophthalmitis Panophthalmitis Primary vasculitis

	Exudative retinal vasculitis Haemorrhagic vasculitis
Optic nerve	Optic disc granuloma Optic neuritis Neuroretinitis Optic atrophy

Anterior segment inflammation may show granulomatous keratic precipitates, iris granulomas that result in posterior synechiae, and complicated cataract. Posterior segment signs such as multifocal chorioretinitis with pigmented scars and exudative retinal hemorrhagic periphlebitis (Fig. 85.2) with uveitis are highly suggestive of tubercular etiology.<sup>5</sup> Presence of perivascular healed chorioretinal scars in such patients would also suggest a tubercular cause. Serpiginous-like choroiditis (SLC) of presumed tubercular etiology closely mimics classic serpiginous choroidopathy (SC) (Figs. 85.5A–B). However, patients with SLC are more likely to have multifocal scattered highly pigmented lesions with vitreous cells in contrast to classic SC, which is characteristically seen in peripapillary area.<sup>5,6</sup> Intermediate uveitis of tuberculosis and sarcoidosis closely mimic each other. It is granulomatous and recurrent; unlike sarcoidosis, tubercular intermediate uveitis does not respond to steroid and immunosuppressive treatment. In patients with choroidal tubercles, fundus fluorescein angiography may show initial “hypofluorescence” and then a late hyperfluorescence of the tubercles. Vessel wall staining, vascular leakage, disc staining and pooling of dye in the area of exudative detachment are other signs commonly seen in fluorescein angiography (Figs. 85.4B–C).

Thus tubercular uveitis has variable presentation making the clinical diagnosis challenging. To help the clinician, diagnostic criterion has been recommended. Diagnosis is considered as definitive TB only when the bacilli are isolated from the ocular tissues. The criterion for presumed tuberculous uveitis is reported to be presence of any one of the following clinical signs, such as choroidal granuloma, broad-based posterior synechiae, retinal vasculitis with or without choroiditis, or serpiginous-like choroiditis with a positive tuberculin skin test (TST) or QuantiFERONTB Gold test, or any other relevant tests, such as chest radiograph and computed tomography.<sup>5</sup> Good response to antitubercular treatment and absence of recurrence further supports

the diagnosis of presumed ocular tuberculosis.

## Differential Diagnosis

Granulomatous uveitis may also be seen in patients with herpes simplex or varicella zoster infection, phacoantigenic uveitis, sarcoidosis, syphilis, leprosy, Vogt–Koyanagi–Harada disease and sympathetic ophthalmia. Other causes of choroidal granulomas include syphilis, sarcoidosis, and fungal lesions.<sup>5,6</sup>

## Pathogenesis

Tissue damage in ocular tuberculosis is not only a direct consequence of infection but it is also due to nonresolving inflammation that results from a sensitive balance between protective immunity and destructive pathology.<sup>8</sup> Molecular studies and sequencing of the *M. tuberculosis* genome have identified specific and highly immunogenic antigens. These are the so-called 6-kDa early secretory antigenic target (ESAT-6) and the 10-kDa culture filtrate protein (CFP-10). They are capable of eliciting vigorous helper T-cell responses with resultant cytotoxicity in cellular models. They cause cell lysis and may enable the bacteria to invade and spread within the alveolar epithelium. Recent studies indicate ESAT-6 may also stimulate the trafficking of infected macrophages into the granulomas, to utilize the granulomas as foci of macrophage recruitment, infection, and subsequent bacterial dissemination.<sup>8</sup>

Host genetic factors appear to play a role in disease severity. Abnormalities in the genes encoding the IFN-gamma (IFN- $\gamma$ ) receptor chain and genes encoding IL-12 are important in determining the susceptibility to disseminated mycobacterial disease.<sup>9</sup> Pulmonary alveolar macrophages express complement and toll-like receptors and destroy the bacteria when they fuse with lysosomes. However, the mycobacteria can inhibit fusion with lysosomes and may then thrive in the phagosome. Retinal pigment epithelium (RPE) shares several functions with the macrophages, including expression of toll-like receptors and complement and phagocytosis of bacteria. Clinicopathologic study combined with molecular analysis revealed distribution of the mycobacteria in the

RPE in spite of the inflammatory process seen in retina and uvea. The authors suggest a possibility of reactivation of sequestered organisms in cases of recurrent inflammation.<sup>10</sup>

## Nontuberculous Mycobacterial Infections

More recently, nontuberculous mycobacterial (NTM) disease appears to be increasing.<sup>11</sup> The genus *Mycobacterium* contains more than 125 species; these saprophytic mycobacteria are ubiquitous in the environment and may be present in soil, water, and dust particles. Both rapid and slow-growing NTM have been implicated in ocular infection, *M. chelonae* and *M. abscessus* are often reported to result in severe and progressive endophthalmitis. NTM endophthalmitis has been reported after uncomplicated phacoemulsification and intraocular lens implantation, laser in situ keratomileusis, endothelial keratoplasty, scleral buckling, and intravitreal injections.<sup>12</sup> Difficulty in management is mainly due to delay in the diagnosis and varying sensitivity to antibiotics. In many studies, initial cultures took variable periods to demonstrate growth or failed entirely to show the causative organism. Etiologies were often misdiagnosed as *Propionibacterium acnes*, nocardial or fungal endophthalmitis.<sup>12</sup> NTM are resistant to most conventional antimycobacterial drugs but are sensitive to a variety of other antibiotics. Amikacin, moxifloxacin, and to a lesser extent levofloxacin and ciprofloxacin demonstrate significant effectiveness against NTM.<sup>13</sup> Biofilm forming nonpigmented rapidly growing mycobacteria have also been shown to result in endophthalmitis. These organisms show resistance to eradication strategies, resistance to innate host immune responses and to antibiotics.<sup>14</sup> Large gaps still exist in our knowledge on ocular NTM infection. Accurate biomarkers to predict exposure, latency, relapse, and resistant diseases are being investigated and not yet available for clinical use.

## Latent Tuberculosis

Latent tuberculosis infection (LTBI) is diagnosed when there is a positive TST in an asymptomatic person with no clinical or radiographic signs of active tuberculosis. The clinical relevance of

this condition is that 5–15% of persons with latent infection may progress to active tuberculosis during their lifetimes.<sup>15</sup> After entry into the human system, organisms can either begin to proliferate immediately, causing primary TB, or be cleared by the immune system. Alternatively, by slowing their metabolism or becoming dormant, they adapt to stressful conditions generated by the infected host and remain silent to the immune system. When the environmental conditions are favorable, activation may result in clinically apparent disease. Simplified, evidence-based management algorithms are available, and we believe clinicians should consult and follow international and national guidelines to manage the patients with latent tuberculosis.<sup>16</sup>

## Laboratory Evaluation

A complete systemic history and examination are fundamental steps in the evaluation of all patients with ocular tuberculosis and may reveal evidence of pulmonary and other extrapulmonary tuberculosis. Recent advances in diagnostic tools for tuberculous infection, including molecular biology techniques, IFN- $\gamma$  release assays, and radiodiagnostics have improved the specificity of the diagnosis. However, all these investigations have their own strengths and limitations.<sup>17</sup> The suboptimal specificity and sensitivity of existing diagnostic tools delay the diagnosis and treatment of active ocular infection. Clear understanding of their principles and proper test selection are needed to obtain relevant clinical support.

Positive reaction after Mantoux or TST intradermal injection of tuberculin purified protein derivative (PPD) indicate a successful cellular immune response by the patient. The antigen used in TST is a mixture of more than 200 proteins derived from *M. tuberculosis*. They can cross-react with BCG and NTM antigens undermining the specificity of the test. Hence TST has limited specificity; a positive result may not confirm disease. The American Thoracic Society and the United States Centers for Disease Control (CDC) consider reactions of 5 mm or more to be positive in very high-risk individuals (e.g., abnormal chest radiograph, HIV patients), 10 mm or more in high-risk patients (e.g., patients from endemic areas),

and 15 mm or more in patients with no identified risk factors. In addition, a negative test does not rule out TB. In a study on patients with histopathologically proven ocular tuberculosis, 40% had negative TST results.<sup>18</sup>

To study the immune response of patient, novel in vitro tests have been developed using ESAT-6 and CFP-10 proteins (see [Pathogenesis](#)). Commercially available QuantiFERON (QFT) and TSPOT.TB are commonly known as interferon-gamma release assays (IGRA). T cells, collected from the patient, are exposed to these specific tubercular antigens. The assay measures the IFN- $\gamma$  released by sensitized T cells of the patient. The CDC guidelines state that IGRAs can be used in all situations in which the TST is currently used. Canada and United Kingdom national guidelines suggest using IGRAs only to confirm a positive TST.<sup>19</sup> Although these tests were originally designed to screen for latent tuberculosis, they have been tested in active systemic and ocular tuberculosis cohorts as well. A meta-analysis on IGRA concludes that the diagnostic sensitivities of both IGRAs are higher than that of TSTs and the specificities are lower.<sup>20</sup> TST and QFT were found equally predictive of progression to TB disease; QFT was not found superior to TST in a cohort of adolescents in a high systemic TB burden population from South Africa,<sup>21</sup> as well as in uveitis.<sup>22</sup> It is claimed that the QFT result together with the TST may increase the sensitivity.<sup>23</sup> However, positive and negative predictive values of IGRA depend on prevalence of TB in that population. As far as systemic TB is concerned, there is increasing evidence that IGRAs perform differently in high-burden compared to low-burden countries. Because of the low prevalence of TB in the United States, the low pretest probability, and low positive predictive value, IGRAs may not be useful as a standard part of the uveitis work-up.<sup>24</sup> The lack of a gold standard for diagnosis of TB infection prevents an effective and interpretable comparison of the IGRAs and the TST in ocular tuberculosis.<sup>24</sup>

Radiologic examination of the chest may reveal infiltrations, cavitation, hilar lymphadenopathy, pleural effusion, fibrotic, or calcific lesion in some patients. The predominant route of infection to ocular tissues is by hematogenous spread from the lungs, however the pulmonary focus may not be evident clinically or

radiographically in all patients. In a cohort of histopathologically proven ocular TB patients, 57% of patients had negative chest radiograph results.<sup>18</sup> Hence an initial negative workup does not rule out the infection, and repeat workup may be needed. More recently, high resolution computed tomography of the chest was found to be a useful tool in the diagnosis of granulomatous uveitis. Some centers further recommend use of positron emission tomography/CT guided lymph node identification for biopsy to aid the diagnosis of tuberculosis-associated uveitis.<sup>25</sup>

Isolation of *M. tuberculosis* by culture remains the cornerstone for diagnosis; however, isolation from inflamed ocular tissue is not always possible. Whenever it is possible, the specimen is often too small for all the procedures, such as Ziehl–Neelsen staining, inoculation in liquid and solid media, species identification, and drug susceptibility testing. Biopsy specimens may be obtained for histopathologic analysis from either the iris or by retinochoroidal biopsy. The absence of acid-fast bacilli or of caseating necrosis in the biopsy specimen does not rule out tuberculosis. In such circumstances either anterior chamber fluid or vitreous can be subjected to molecular diagnostic testing. Diagnosis based on detection of mycobacterial DNA through PCR and real time PCR are becoming the method of choice because of rapid test results and the ability to test in a very small sample.<sup>18</sup> The sensitivity of the multiplex, multitargeted PCR assay has been reported to be better than single targeted assays.<sup>26,27</sup> The WHO recommends the use of Xpert MTB/RIF, a fully automated real-time nucleic acid amplification technology, for rapid and simultaneous detection of TB and rifampicin resistance. The test provides accurate results in less than 2 hours and has minimal bio-safety requirements, training, and can be housed in nonconventional laboratories.<sup>28</sup> Xpert MTB/RIF is currently used only for sputum samples. Studies are needed to understand its potential role in ocular fluids.

Resistance to anti-TB drugs may be caused by chromosomal mutations in genes encoding drug targets resulting in MDR-TB. Proper management of MDR-TB relies on early recognition of drug resistance. Clinical diagnosis of drug resistance is checked by drug susceptibility testing. It is performed on all positive mycobacterial cultures on Middlebrook 7H10 agar with 1% proportional method

for isoniazid, rifampicin, ethambutol, streptomycin, ciprofloxacin, and kanamycin. Drug susceptibility testing by conventional mycobacterial culture is slow and elaborate, requiring sequential procedures for the diagnosis. Several molecular diagnostic tests such as the Sanger-based DNA sequencing methods are expected to lead to faster identification of MDR and XDR strains.<sup>29</sup>

## Treatment

Antitubercular therapy is highly effective in reducing the recurrences of uveitis in patients with manifest TB. The systemic management of TB is complex and requires the input of infectious disease experts. The WHO recommends new patients with both pulmonary TB and extrapulmonary TB to be treated with a four-drug regimen (isoniazid 5 mg/kg daily, rifampicin 10 mg/kg daily, ethambutol 15 mg/kg daily, and pyrazinamide 20–25 mg/kg daily). Ethambutol and pyrazinamide are stopped after 2 months and isoniazid and rifampicin are continued for 4–6 months.

Corticosteroids seem to have a potential benefit in patients with tubercular pericarditis and meningitis.<sup>30</sup> Similarly, steroids are used in ocular TB as well. More evidence is required on the dose and duration of corticosteroid treatment in ocular infections.

Tuberculosis with HIV coinfection represents a significant challenge, affecting millions of people worldwide. The treating physician has to consider drug interactions, overlapping side-effects, high pill burden, and risk of immune reconstitution inflammatory syndrome. Specific guidelines should be followed with special attention to the CD4 count and drug interactions.<sup>31</sup> In such patients, initiation of concomitant antitubercular and antiretroviral therapy may result in exacerbation of inflammation and clinical deterioration.<sup>32</sup> Either addition of corticosteroids or delaying the administration of HAART treatment is advised.

Hepatotoxic effects are seen with all first-line antituberculosis therapies and usually present as nausea, vomiting, and abdominal pain in the right upper quadrant. In most patients, even if hepatotoxic effects develop, severe liver injury can be avoided and antituberculosis therapy can be completed by following a comprehensive management algorithm.<sup>33</sup> Drug dosage and adverse

reactions are summarized in [Table 85.2](#).

**TABLE 85.2**  
**Five Groups of Antituberculosis Drugs**

Drug	Dose	Adverse Reaction	Additional Information
<b>GROUP 1: FIRST-LINE ORAL ANTITUBERCULOSIS DRUGS</b>			
(Use all possible drugs)			
Isoniazid	4–6 mg/kg (up to 300 mg)	Transient increase in hepatic enzyme Peripheral neuropathy	Use during pregnancy is considered safe Crosses the blood–brain barrier,
Rifampicin	8–12 mg/kg	Hepatotoxicity: Thrombocytopenia	Used during pregnancy
Ethambutol	15–20 mg/kg	Reversible dose-related; retrobulbar neuritis, typically begin 3–6 months after the start of therapy Hepatotoxicity	Does not cross meninges Better ocular penetration Crosses placental barrier, but considered safe in pregnancy
Pyrazinamide	20–25 mg/kg	Pruritus Hepatotoxicity	Safe during pregnancy Crosses the blood–brain barrier
<b>GROUP 2: FLUOROQUINOLONES</b>	<b>GROUP 3: INJECTABLE DRUGS</b>	<b>GROUP 4</b>	<b>GROUP 5</b>
(A fluoroquinolone should always be included in the treatment of MDR or XDR tuberculosis)	(There should always be an injectable drug in the treatment of MDR and XDR tuberculosis)	(Use all the necessary drugs to make up at least four active basic drugs; start with ethionamide, cycloserine; finally aminosalicylic acid)	(Less-effective drugs or drugs on which clinical data are sparse)
Ofloxacin (15 mg/kg)	Streptomycin (15 mg/kg)	Ethionamide/prothionamide (15 mg/kg)	Clofazimine (100 mg)
Levofloxacin (15 mg/kg)	Kanamycin (15 mg/kg)	Cycloserine/terizidone (15 mg/kg)	Amoxicillin with clavulanate (875/125 mg every 12 h)
Moxifloxacin (7.5–10 mg/kg)	Amikacin (15 mg/kg)	P-aminosalicylic acid (acid salt) 150 mg/kg	Linezolid (600 mg)
	Capreomycin (15 mg/kg)		Imipenem (500–1000 mg every 6 h)
			Clarithromycin (500 mg/12 h)

MDR, multidrug-resistant tuberculosis; XDR, extensively drug-resistant tuberculosis.

## Drug-Resistant Tuberculosis

MDR tuberculosis is defined as the disease caused by organisms that are resistant to isoniazid and rifampicin, which are two first-line anti-TB drugs. XDR-TB is defined as tuberculosis that is caused by organisms resistant to isoniazid and rifampicin and to any one of the fluoroquinolones and at least one of the injectable second-line drugs. MDR and XDR tuberculosis are generally thought to have high morbidity and mortality rates, and drug-resistant strains have evolved mainly due to incomplete or improper treatment of TB patients. MDR and XDR-TB are now global threats.<sup>2</sup> In the vast majority of clinical settings in the developing world, culture and drug-susceptibility testing are not available. Most cases likely go undetected due to insufficient laboratory infrastructure for diagnosis.<sup>34,35</sup> At present, MDR-TB is treated by a combination of eight to ten drugs with therapies lasting up to 18–24 months; only four of these drugs were actually developed to treat TB. Such suboptimal therapy leads to almost 30% of MDR-TB patients experiencing treatment failure. The current situation necessitates the immediate identification of new and more potent drugs.<sup>36,37</sup> However, when the drugs are chosen in a stepwise selection process through five groups on the basis of efficacy, safety, and cost, with the right combination and rational use, a better prognosis can be obtained.<sup>38</sup> Drug dosages for MDR and XDR-TB (Group 2–5) are given in [Table 85.2](#). Linezolid is an off-label use for MDR-TB. There are scattered case reports of optic neuropathy secondary to this drug. A baseline ophthalmologic evaluation is recommended before its use.<sup>39</sup>

Detection of drug resistance is possible only in culture isolates, because of challenges in isolating the organisms from the eye; drug susceptibility testing is difficult in ocular TB. This has serious implications specifically in uveitis. When a trial of antitubercular treatment fails in presumed ocular TB, there is a very high possibility for the uveitis specialist to assume a nontubercular

etiology and to start corticosteroids or immunosuppressive treatment to control inflammation.<sup>35</sup> In such situations molecular diagnostic studies may be of help.

According to the WHO 2015 Millennium Development Goal (MDG) of halting and reversing TB, worldwide TB incidence fell at an average rate of about 1.5% per year between 2000 and 2013. Globally, the TB mortality rate fell by an estimated 45% between 1990 and 2013, and TB prevalence rate fell by 41% during the same period.<sup>2</sup> If success is continued and quality care is provided as per the International Standard of TB Care, it is anticipated the incidence of extrapulmonary tuberculosis, including ocular TB, will decline.

## **Summary**

## **Introduction**

Eales disease is an idiopathic, occlusive perivasculitis affecting the peripheral retina, leading to retinal nonperfusion, new vessel formation, and recurrent vitreous hemorrhages. Eales disease was reported from the United Kingdom, United States, and Canada in the latter half of the 19th century and early 20th century.<sup>1,2</sup> The eponym originated from the first description by Henry Eales of a syndrome of recurrent vitreous hemorrhage in young men with epistaxis and constipation.<sup>3</sup> Most cases in the last decade have been reported from the Indian subcontinent, with a few reports from the

Middle East.<sup>4-13</sup> However, the incidence of Eales disease appears to have declined globally, due probably to improved general health and living standards and reduced incidence of tuberculosis (TB),<sup>1,2,10</sup> as well as to improved etiologic diagnosis in a heterogeneous group of allegedly primary vasculitides, previously amalgamated as presumed Eales disease.<sup>14</sup> Most patients are healthy young men, aged 20–40 years; the mean age of onset is generally earlier in Asians than in Caucasians.<sup>2,15-17</sup>

## Clinical Features and Natural History

Three sequential vascular responses that determine the natural course of Eales disease are inflammation, occlusion, and neovascularization.<sup>1,2,10,15</sup> Most patients are asymptomatic at the stages of inflammation and occlusion. The disease starts quietly as multiple, peripheral inflammatory branch retinal vein occlusions: fine, solid white lines representing venous sheathing are the commonest clinical presentation (Fig. 86.1).<sup>1,2</sup> As active vasculitis slowly resolves, the fuzzy vascular sheathing, with indistinct margins, becomes well defined and distinct. Retinal arteries may be involved later, but their involvement is not central to the disease presentation,<sup>1</sup> and is generally suggestive of other conditions like systemic vasculitides.<sup>11,18</sup> Other clinical features that suggest alternative inflammatory etiologies are exudative or focal vasculitis; cotton-wool spots;<sup>11,18</sup> and central retinal involvement including macular and optic disc edema, choroiditis, anterior uveitis, and vitritis.<sup>2,14</sup>

**FIG. 86.1** The most common presentation of Eales disease is solid columns of occlusive sheathing in peripheral veins, as seen here in superior, inferior, and inferotemporal periphery. A few hard exudates inferiorly suggest resolved retinal edema. The posterior pole and visual acuity are unaffected.

As the occlusions are primarily venous, they occur gradually, allowing development of compensatory phenomena like collaterals, microaneurysms, capillary telangiectasia, corkscrew vessels, and venous beading; some of these changes may be observed by careful examination of the apparently uninvolved fellow eye of a patient with unilateral involvement. Prolonged and extensive retinal nonperfusion eventually leads to peripheral neovascularization in up to 80% of eyes; disc neovascularization is rare.<sup>2,4,15</sup> New vessels

bleed into the vitreous, resulting in the classic presentation of Eales disease: a sudden, unilateral blurring of vision or floaters<sup>15,17</sup> (Fig. 86.2). Vision often improves, but recurrences are common. The second eye is ultimately affected in 50–90% of cases, after a gap of 3–10 years.<sup>2,4,14,15</sup> Isolated episodes of vitreous hemorrhage usually settle down without visual deficit; recurrent bleeds lead to progressive contraction of vitreous cortex, resulting in traction retinal detachments, secondary retinal tears, and epimacular membranes.<sup>1</sup> Though anterior segment neovascularization occurs in a small fraction of eyes, the prognosis is better than what is typically associated with iris neovascularization.<sup>4</sup>

**FIG. 86.2** Classic presentation of Eales disease is floaters or blurring of vision due to vitreous hemorrhage from peripheral new vessels. Recurrent bleeds, along with preceding inflammation, lead to epiretinal membrane formation, which is beginning at the posterior pole. Note the linear, extensive sheathing of the peripheral retinal vessels.

Charamis graded the evolution of Eales disease into four stages. Stage I was characterized by mild peripheral perivasculitis; stage II

by extensive inflammation involving larger vessels; neovascularization and vitreous hemorrhage heralded stage III; and tractional complications marked stage IV.<sup>19</sup> A system for grading Eales disease on the basis of the degree and extent of retinal vasculopathy, neovascular proliferations, and vitreous hemorrhage has also been proposed.<sup>20</sup> However, the course of the disease is variable, and a fixed sequence of stages may not be followed consistently.<sup>1,2</sup>

## Pathology and Pathogenesis

The classic histopathologic connotation of the term “vasculitis” is a type III hypersensitivity reaction with deposition of immune complexes in the vessel wall, leading to vessel wall destruction.<sup>21,22</sup> This rheumatologic definition is not applicable to retinal vasculitis in general, and Eales disease in particular, which represents perivascular cuffing with inflammatory cells, graded by clinical appearance rather than vascular caliber or type of immune response.<sup>11,21,22</sup> Most authors have therefore used the terms “vasculitis” and “perivasculitis” interchangeably in the context of Eales disease.

Central to the visually debilitating complications of Eales disease is retinal hypoxia. Inflammation causes hypoxia by an increase in the metabolic demands of cells and a reduction in metabolic substrates caused by inflammatory vascular occlusion. Hypoxia in turn triggers further inflammation, setting up a vicious cycle.<sup>23</sup> This sequence suggest a pathogenetic role for both angiogenic factors and inflammatory cytokines in Eales disease, in a manner similar to noninflammatory vascular diseases like diabetic retinopathy. A simultaneous upregulation of vascular endothelial growth factor (VEGF), and interleukins (IL)-6 and IL-9 has indeed been observed during the proliferative phases of both diabetic retinopathy and Eales disease.<sup>7</sup> Other biochemical analyses have also implicated retinal autoimmunity, angiogenic growth factors, and oxidative stress in causing inflammation and neovascularization in Eales disease.<sup>2</sup> Recent serologic and genetic studies have reinforced the role of cell-mediated immunity in Eales disease, particularly interleukins and tumor necrosis factor-alpha.<sup>9,12</sup> Raised serum

homocysteine has also been proposed to cause both vascular damage and oxidative stress in Eales disease.<sup>24</sup>

The pathogenesis of inflammatory vascular occlusions in Eales disease remains unclear. Systemic association with neurologic, vestibuloauditory, hematologic, and parasitic diseases and infections have been proposed but never proven.<sup>2,15</sup> The most frequently reported association is with systemic TB. While viable organisms have not been demonstrated from the eyes with Eales disease, polymerase chain reaction-based studies have identified mycobacterial DNA in vitreous and epiretinal tissue.<sup>25,26</sup> These findings make the case for hypersensitivity to tuberculo-protein; the case is reinforced by the presence of tuberculin skin test positivity in the majority of patients.<sup>2</sup> This concept continues to be popular among current researchers.<sup>11</sup> Several other studies have, however, disputed this notion by demonstrating Mantoux positivity in healthy controls, as well as Mantoux negativity among Eales patients.<sup>2,15,27</sup>

## Differential Diagnosis

Eales disease is a diagnosis of exclusion (Fig. 86.3). Several ocular and systemic inflammatory and noninflammatory diseases cause retinal vascular sheathing or occlusion, which may closely resemble Eales disease. However, a battery of investigations is not necessary for every patient. A detailed history and a thorough systemic examination rule out most of the mimicking diseases; only a few tailored investigations are required to clinch the diagnosis.

**FIG. 86.3** Differential diagnosis of Eales disease. PDR, proliferative diabetic retinopathy; BRVO, branch retinal vein occlusion; IRV, idiopathic retinal vasculitis; TB, tuberculosis.

Among noninflammatory vascular occlusions, primary branch retinal vein occlusion mimics Eales most closely. The former occurs at an arteriovenous crossing; the crossing artery is frequently sclerosed. The occlusions are not multiple and peripheral like Eales,

and affect older age groups. Proliferative diabetic retinopathy may also exhibit sheathing of vessels during active stage (as part of the appearance labeled “featureless retina”) or at involitional stage. Central retinal vein occlusion in a young adult should be investigated for inflammatory etiology (see [diagnostic workup](#), below) because it represents a rare presentation of Eales.<sup>1</sup> Coats disease, familial exudative vitreoretinopathy (FEVR), and sickle-cell disease also show similar peripheral nonperfusion and should be ruled out. Though Coats disease also occurs in male patients, they are typically younger and have unilateral disease with prominent telangiectasia, more exudation, and less neovascularization or vitreous hemorrhage. FEVR and sickle-cell retinopathy have distinctive clinical and angiographic features, as well as familial and systemic associations respectively, to distinguish them from Eales disease.

Ocular inflammatory conditions like intermediate uveitis, endophthalmitis, multifocal choroiditis, and birdshot retinopathy may have associated retinal vasculitis, but primary lesions are generally prominent and unmistakable. Systemic TB should be ruled out in every case of retinal vasculitis because of its endemic presence, especially in the Southeast Asian region.<sup>28</sup> TB typically causes severe perivasculitis along with granulomatous anterior uveitis, retinal hemorrhages, moderate vitritis and focal choroiditis.<sup>28</sup> Syphilis, like TB, needs to be screened by default because of its recent reemergence with HIV, as well as its varied presentations.<sup>29</sup> Retinal periphlebitis occurs in about half the cases of leptospirosis, the most widespread zoonosis globally. Nongranulomatous uveitis, vitritis, and papillitis help in differentiation.<sup>30</sup> Retinal vasculitis can also occur along with necrotizing retinitis, though arteries are involved more commonly.<sup>11</sup>

Like TB and syphilis, sarcoidosis has no pathognomonic signs and needs to be ruled out in most ocular inflammations. Sarcoid vasculitis is typically segmental and nodular, with snowball vitreous exudates and granulomatous uveitis. Diagnosis is based on key ophthalmic signs and laboratory investigations.<sup>31</sup> Although uncommon, Behçet disease is the classic presentation of occlusive retinal vasculitis along the Silk Route (see below). It involves both arteries and veins, and is accompanied by severe uveitis, vitritis,

and retinal infiltrates; orogenital aphthoses are diagnostic.<sup>32</sup> Systemic vasculitides like systemic lupus erythematosus (SLE) have been erroneously linked with retinal vasculitis in the literature.<sup>22</sup> Their retinal effects are typically mediated through secondary hypertension (e.g., cotton-wool spots, superficial hemorrhages) and manifest as arterial rather than venous occlusions.<sup>33</sup>

## Primary Retinal Vasculitis

Once the diseases causing secondary vasculitis are ruled out, the two main conditions which remain in the picture are Eales disease and idiopathic retinal vasculitis. When (1) the vasculitis is more posterior, sectoral, and exudative; (2) neovascularization, vitreous hemorrhage, and recurrences are uncommon; and (3) presentation is gender-neutral, the term “idiopathic retinal vasculitis” is preferred over “Eales disease.”<sup>2</sup> The differentiation is indeed semantic, and the disease workup remains the same (see below), leading some authorities to suggest that the term “Eales disease” should be discontinued.<sup>34</sup> However, classic Eales disease has the unusual combination of minimal peripheral vascular inflammation but extensive vascular occlusions and neovascularization leading to recurrent vitreous hemorrhages, justifying the eponym.<sup>2,14</sup>

## Diagnostic Workup for Eales Disease

The purpose of the workup is to search for a cause for vasculitis and to rule out infections. This is best done by meticulous history-taking and systemic examination; laboratory investigations should be tailored to the positive findings from history and examination.<sup>35</sup>

After considering the age and sex of the patient, one should elicit information about residence and travel (see below), occupation, and eating habits, all of which may help with the diagnosis of leptospirosis, syphilis, and toxoplasmosis. Similarly, cough, fever, and night sweats (TB or sarcoidosis); joint pain and swelling (SLE, Behçet disease); orogenital ulcerations (Behçet disease, syphilis); recurrent abortions and sexually transmitted disease (syphilis, HIV); skin rashes, nodules, or vesicles (SLE, Behçet disease, sarcoidosis); and neurologic symptoms (sarcoidosis, multiple

sclerosis) reveal underlying diseases that should be investigated further.

A detailed examination for systemic disease, especially for skin and mucosa, joints, and respiratory and central nervous systems, by an internist rules out important systemic associations, some of which may be life-threatening. Only a few basic screening investigations are universally required in retinal vasculitis, which the ophthalmologist should order before referral to the internist: a complete hemogram, peripheral smear, erythrocyte sedimentation rate, tuberculin skin test, chest radiography, rapid plasma reagin (RPR for syphilis), enzyme-linked immunosorbent assay for HIV, and urinalysis are sufficient to screen for most common diseases causing retinal vasculitis; further investigations are required only when history, examination, and/or aforementioned investigations point towards a specific disease.<sup>11,35</sup>

Fluorescein angiography helps mainly to identify peripheral new vessels and the extent of retinal nonperfusion, bordered by compensatory phenomena like collaterals and microaneurysms (Fig. 86.4). Active vasculitis appears as leakage from the stained vessel walls, though it can be detected clinically. B-scan ultrasound is a key presurgical investigation to assess the retinal status, posterior vitreous detachment (PVD), and tractional membranes obscured by vitreous hemorrhage. While assessing PVD, one must beware of vitreoschisis and an anomalous PVD, both common in Eales disease.<sup>36</sup> Recently, ultra-wide-field imaging has expanded the photographic, autofluorescent, and angiographic views of retinal vasculitis, revealing undetected sheathed/blocked vessels, capillary dropouts, and neovascularization.<sup>37,38</sup> The additional information improved disease monitoring in half of the patients and changed the line of management in four-fifths of them.<sup>37</sup> On the other hand, microstructural imaging with adaptive optics technology has also been reported to enhance the early detection of subtle or subclinical retinal vasculitis.<sup>39</sup>

**FIG. 86.4** Midphase angiogram of a patient with Eales disease showing scattered peripheral areas of capillary microaneurysms, telangiectasia, collateral formation, and retinal nonperfusion, most prominent at 3:00 and 9:00 meridians. The posterior pole is largely unaffected. The inflammatory sheathing of inferotemporal retinal vein from the first branching downwards (*arrow*) is not apparent due to resolution of active vasculitis.

## Epidemiologic Spectrum of Retinal Vasculitis

There is considerable geographic variation in the ophthalmologists' perspective on what retinal vasculitis represents, alone or with concurrent uveitis. The default association in the Indian subcontinent is with TB or Eales disease;<sup>1,2,34,40</sup> in the Middle or Far East (including China and Japan) and the Mediterranean region, retinal vasculitis means Behçet disease;<sup>40,41</sup> sarcoidosis is the most common association in the United States, Japan, and The Netherlands;<sup>40,42</sup> and in South America, Europe, Australia, and

Africa, toxoplasmosis is the first intraocular inflammation to rule out.<sup>40,43</sup> The infective etiologies are typically more common in the developing countries, whereas noninfectious vasculitis is the norm in the developed world.<sup>40</sup> The ethnic/cultural subtext in etiologic diagnosis must also be kept in mind (TB or Eales in Indians; sarcoidosis in Scandinavians and African-Americans; Behçet disease in East Asians; and toxoplasmosis in Europeans, native Australians, and South Americans).<sup>40–45</sup> The migration of ethnic groups across the globe has complicated the epidemiologic profile of retinal vasculitis to some extent,<sup>45</sup> but broad causative associations remain relevant. Finally, irrespective of the geographic and ethnic riders, retinal vasculitis as the *predominant* feature of posterior uveitis has only a few key systemic associations: TB, sarcoidosis, and Behçet disease.<sup>28,41,42</sup>

## Management

Patients with resolved vasculitis and clear media should be followed up at 6–12-month intervals. When the vision is good and the macula is healthy, minimal peripheral vasculitis may also be observed, though with close follow-up.<sup>2,34,35</sup>

Once systemic and ocular infections have been ruled out by history, examination, and investigations, corticosteroids are the mainstay of treatment for active vasculitis. Periocular depot corticosteroids like triamcinolone acetonide, 40 mg/mL, are effective in most cases with unilateral disease.<sup>46</sup> When the vasculitis is bilateral or severe, or when there is inadequate response to periocular injections, systemic corticosteroids (typically, oral prednisolone, 1 mg/kg body weight per day) should be considered.<sup>46</sup> In the authors' experience, corticosteroids by these two routes are almost always enough to control the inflammation in Eales disease; immunosuppressive agents are rarely required. A small short-term case series reported successful resolution of active vasculitis in Eales disease with intravitreal injection of triamcinolone acetonide, 4 mg/0.1 mL.<sup>5</sup> The rationale of choosing the intravitreal over the sub-Tenon route and the potential predicament of bilateral treatment were not explained. In the presence of a positive tuberculin test, some investigators

recommend antitubercular therapy.<sup>1,15,28,34</sup> However, its role in the treatment of Eales disease is unproven and controversial, and should be decided by an internist.<sup>2</sup>

Once the proliferative stage is reached, peripheral scatter photocoagulation in the ischemic areas bordering the neovascularization is the treatment of choice.<sup>1,2,4,10,14,15,34</sup> Treatment should be extended posteriorly according to the posterior spread of the retinal nonperfusion and the presence of posterior or disc neovascularization.<sup>2</sup> Scatter photocoagulation is not recommended in the absence of neovascularization for peripheral retinal nonperfusion, which is nearly universal in Eales disease.<sup>20</sup> Photocoagulation is also contraindicated in the presence of active vasculitis, which is likely to flare up and release more angiogenic factors, aggravating neovascularization (Fig. 86.5).<sup>2</sup> Pretreatment with corticosteroids sometimes mitigates the need for subsequent photocoagulation as well.

**FIG. 86.5** This patient underwent peripheral scatter photocoagulation for postinflammatory neovascularization in Eales disease. The picture shows a simultaneous recurrence of neovascularization (*arrow*) and vascular inflammation (*arrowheads*): the inflammation was treated before neovascularization. Note the lack of involvement of the posterior pole.

Persistent vitreous hemorrhage is the most frequent indication for vitrectomy. Early intervention (within 3–6 months) begets better visual outcomes;<sup>47</sup> epimacular membranes or extramacular retinal detachment warrant consideration of early vitrectomy; and macular detachment mandates immediate vitrectomy. Results of vitrectomy

in Eales disease have been reported for about three decades; however, there is marked discrepancy in the reported outcomes due to variability in case selection, mainly PVD status and retinal detachment.<sup>4,8,36,47</sup> With modern surgical instrumentation, good surgical outcomes are possible in spite of incomplete or anomalous PVD and tractional sequelae (Fig. 86.6).<sup>8</sup> Over the past decade, the surgical instrumentation and inclination have irrevocably shifted towards small gauge (23–27G) sutureless vitrectomy for the entire vitreoretinal surgical spectrum, including Eales disease, excellent outcomes and faster recuperation are now common.<sup>48</sup> However, encircling belt-buckle may improve the surgical outcomes in the presence of peripheral tractional membranes.<sup>8</sup> Recently, anti-VEGF drugs like bevacizumab and ranibizumab have been used as adjuvants to scatter photocoagulation and vitrectomy. While bevacizumab probably has merit in treating neovascularization refractory to scatter photocoagulation<sup>6</sup> and as an adjuvant to vitrectomy, it cannot substitute vitrectomy for vitreous hemorrhage in Eales disease, and can precipitate tractional complications.<sup>13,49</sup> The patient should always be cautioned about the need for vitrectomy prior to anti-VEGF injection.

**FIG. 86.6** Postvitrectomy view of an eye with persistent vitreous hemorrhage and membranes due to Eales disease: Note the relatively spared macula in spite of a large nasal residual tractional band with multiple attachments. Peripheral scatter photocoagulation marks are visible all around; indentation of the encircling belt buckle is seen inferonasally (*arrow*). (Reproduced with permission from Shukla D, Kanungo S, Prasad NM, et al. Surgical outcomes for vitrectomy in Eales' disease. *Eye* 2008;22:900–4.)

## Summary

Though numerous ocular and systemic diseases cause retinal vasculitis, isolated retinal vasculitis, as seen in Eales disease, has few systemic associations.<sup>50</sup> A detailed history and clinical examination, and specific investigations as indicated by the positive findings, are cost-effective and sufficient. Once the diagnosis of Eales disease is established, most cases are usually observed;<sup>14</sup> corticosteroids are required when vasculitis is significant. Peripheral scatter photocoagulation is effective in the proliferative disease, but should be delayed in favor of corticosteroids in the presence of active inflammation. Recurrent vitreous hemorrhage and tractional complications require consideration of early vitrectomy. With judicious use of medical and surgical treatment options, visual prognosis is good in most cases. While corticosteroids and scatter photocoagulation remain the standard of care, pharmacotherapy using antiangiogenic molecules, antioxidants, and antibodies against specific inflammatory cytokines may play a larger role in the future treatment of this enigmatic disease.<sup>2,7,9,12,34</sup>

## Introduction

The history of spirochetal infections in the eye extends back to the first reported observations of spirochetes isolated from the nervous system.<sup>1</sup> Today, the most common spirochetal organisms encountered in the tissues of the eye and ocular adnexae are *Treponema pallidum*, the infectious entity causing syphilis; *Borrelia burgdorferi sensu lato* complex, a diverse group of spirochetes that cause Lyme disease (LD); and *Leptospira* species, which upon infection produces a host of local and systemic findings typical of leptospirosis. Diagnosis of spirochetal infections of the eye requires a high degree of clinical suspicion as well as early recognition for more effective treatment.

## Syphilitic Uveitis

Infection with the spirochete *T. pallidum* results in the ocular and systemic findings associated with syphilis. Sexual transmission is the most common means of inoculation, though direct contact with an active lesion or spread via transfusion are also potential routes of infection. Prior to the advent of penicillin, the disease was associated with high morbidity and mortality; however, as the antibiotic became widely available, the incidence of syphilitic disease dropped steeply. In recent years, changing socioeconomic factors and increases in high-risk sexual behavior, infection with human immunodeficiency virus (HIV), and antibiotic resistance have all contributed to resurgence of the disease. Worldwide, there

are an estimated 10 million new cases of syphilis annually, and increases in reported cases are seen most commonly in cases of men who have sex with men (MSM) and those who are coinfecting with HIV.<sup>2,3</sup>

While uncommon, ocular manifestations are typically associated with neurosyphilis, which can occur early or late in the course of infection.<sup>4</sup> Symptoms can be seen roughly 2–6 months after initial infection.<sup>5</sup> The most common ocular finding is uveitis, which can present as anterior, intermediate, posterior or panuveitis.<sup>6</sup>

## Epidemiology and Pathogenesis

The only known reservoir for syphilis is in the human, and historically infection had been limited to populations with poor hygiene, limited access to healthcare, and low socioeconomic status. The most current surveillance data in the United States indicates that the rate of primary and secondary syphilis has more than doubled between the years of 2005 and 2013: from 2.1 cases to 5.3 cases per 100,000 population. Specifically, the greatest percentage increases are seen in young men (149.4% in those ages 20–24 from 2005 to 2009, and 48.4% in ages 25–29 from 2009 to 2013), particularly among MSM.<sup>2,6</sup> Due to such high rates of infection within the younger population and particularly in urban areas in the western United States, recent expansion of syphilis testing in nonclinical settings have been made available to the public via online testing labs as well as social media apps on smartphone platforms.<sup>7,8</sup> This provides an additional avenue for detecting new cases and offers innovative online syphilis prevention information with easily available testing and partner notification tools; however, the impact on public health surveillance has yet to be determined.

The local and systemic response to *T. pallidum* is complex, and is initiated as the bacteria enter the body through intact mucosa. Local invasion of the tissues ensues, and dissemination occurs via blood and the lymphatic system. On the microscopic level, lymphocytic infiltration is seen, either diffuse or focal, surrounding the blood vessels of affected organs. In the eye, this can be found in the iris, ciliary body, and choroid, along with chronic granulomatous inflammation, including epithelioid histiocytes and multinucleated

giant cells. Mononuclear cells, sensitized T lymphocytes, macrophages, and plasma cells can also be seen. This inflammation and the resulting adaptive immune response cause the tissue destruction characteristic of syphilis.

Local antibodies are also produced against the lipid, protein, and lipoprotein components of *T. pallidum*. The majority of bacteria are eradicated by opsonization and engulfed by macrophages. Those organisms that are resistant to phagocytosis may persist locally at the site of inoculation. Dissemination can occur despite the development of the humoral and cellular response, and without treatment, the bacteria can persist in the human host for decades, resulting in continued transmission and end-organ damage.<sup>9</sup>

## Ocular Manifestations

Uveitis is the most common ocular finding, ranging from 0.7% to 16.4% in recent epidemiologic studies, with higher rates of occurrence in patients coinfecting with HIV.<sup>6,10</sup> Findings can include keratic precipitates and iritis in the anterior segment of the eye, manifesting as either granulomatous or nongranulomatous inflammation. Dilated iris capillaries may also be noted (roseola), and these dilated and tortuous vessels may be a result of obliterative endarteritis. Posterior manifestations include vitritis, vasculitis, papillitis, periphlebitis, exudative retinal detachment, uveal effusion, central retinal vein occlusion, subretinal neovascular membrane formation, retinal necrosis, and neuroretinitis.<sup>6,10-12</sup>

Acute syphilitic posterior placoid chorioretinitis can often be seen in the macula or juxtapapillary locations.<sup>13,14</sup> The yellow or gray placoid lesions often have atrophic centers and are flat, with no evidence of fluid or hemorrhage. Fluorescein angiography reveals early hypofluorescence and late stain of the lesion with distinctive “leopard spot” hypofluorescence (Fig. 87.1). In patients with HIV, posterior uveitis is more common, presenting as a dense vitritis or diffuse, creamy retinitis with overlying punctuate retinal precipitates.<sup>6,11,15,16</sup>

**FIG. 87.1** Late fluorescein angiographic image of the left eye in a patient with ocular syphilis with focal hypofluorescence, leakage of the optic disc, and staining of the retinal veins. (Reproduced with permission from Chao

JR, Khurana RN, Fawzi AA, et al. Syphilis: reemergence of an old enemy.

Ophthalmology 2006;113:2074–9.)

Other ocular findings include interstitial keratitis of the cornea; chancre and nonspecific papillary reaction of the conjunctiva; episcleral and scleral inflammation; and inflammation of the optic nerve presenting as optic neuritis. Cataract can also be seen, both in congenital as well as acquired disease. Glaucoma in syphilis is often due to uveitis, though it may occur in either congenital or acquired infection. Lastly, the classic pupillary finding in syphilis (Argyll Robertson pupil) is seen in late syphilis or early neurosyphilis, manifesting with anisocoria and light–near dissociation upon clinical testing.

Findings in neurosyphilis are variable and dependent on the stage of disease. Stroke-like symptoms due to vasculitis and vascular compromise in early neurosyphilis may affect the cranial nerve nuclei as well as the centers for saccadic and smooth pursuit. Focal intracranial gummas may cause visual field deficits and superior orbital fissure syndrome, depending on the location of origination. Horner's syndrome and internuclear ophthalmoplegia may also be observed. Late neurosyphilis may result in general

paresis and tabes dorsalis.

## Diagnosis

A high level of clinical suspicion is required for the appropriate diagnosis of syphilitic uveitis, due to its variable clinical presentation and atypical presentation in HIV-infected individuals. Appropriate laboratory studies can aid in confirming the diagnosis and rule out other disease entities. Visualization of the organism in lesion exudates or tissue via dark-field microscopy with immunofluorescent staining is considered the gold standard and the quickest and most direct approach for establishing the diagnosis; however, the availability of such facilities limits its utility in clinical practice.<sup>17</sup> In addition, these tests are highly specific, but not very sensitive for widespread detection of infection.

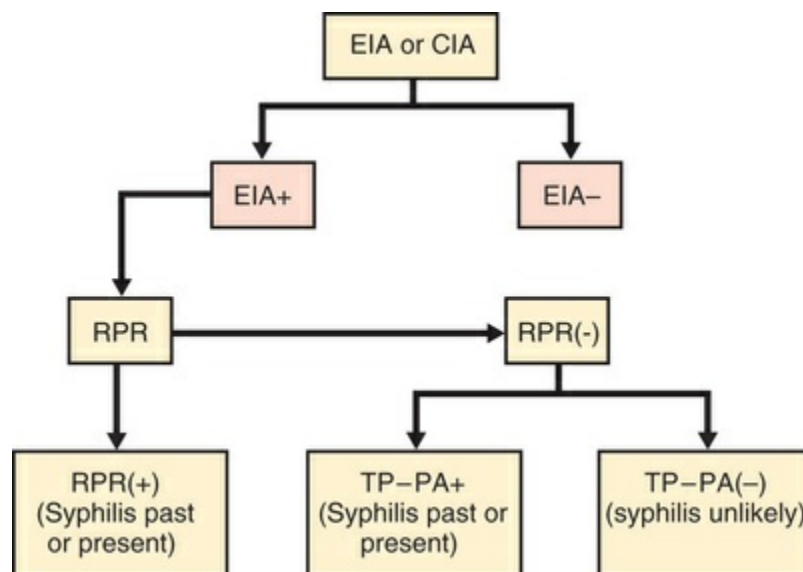

Serologic testing with nontreponemal and treponemal tests is most commonly used in ophthalmic clinical practice.

Nontreponemal tests detect the antibody to cardiolipin cholesterol antigen, and most clinicians are familiar with the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests. These tests are best suited for general screening in a population with a low prevalence of syphilis, as well as for monitoring treatment efficacy as the titers decrease with appropriate therapy.

Treponemal tests, such as the fluorescent treponemal antibody absorption tests (FTA-ABS) and the microhemagglutinin assay for *T. pallidum* (MHA-TP), are more specific than the nontreponemal tests and may be just as sensitive. However, they are more expensive and a proportionate increase in false positives can occur if they are applied to a low-risk population. Thus, they may be used initially in patients who have a high probability of infection. Generally, once these tests are positive, the patient remains positive for life.

Newer treponemal tests, such as enzyme immunoassays (EIA) and chemiluminescence assays (CIA) utilizing specific treponemal antigens, have recently been approved by the Food and Drug Administration (FDA) and are recommended by the Centers for Disease Control and Prevention (CDC) as initial screening tests for syphilis (<http://www.cdc.gov/std/syphilis/Syphilis-Webinar.htm>).

These EIA/CIA tests are qualitative, have specific IgM and IgG antitreponemal antibodies (for detection of early and late syphilis, respectively) and also remain positive for life. The new “reverse sequence” algorithm allows for the capture of those individuals with either very early disease or late findings (e.g., neurosyphilis with ocular complications) who would be positive by treponemal-specific testing but negative by RPR. These discordant results are expected due to the high sensitivity and low specificity of the EIA/CIA tests; thus, a confirmatory treponema particle agglutination test would be submitted (Fig. 87.2). The use of a singular type of serologic test is insufficient for diagnosis, as each has its limitations, specifically the false-positive test results in patients without syphilis. False-positive test results may be associated with certain infections (e.g., Lyme disease, leptospirosis, malaria) and medical conditions (e.g., autoimmune disorders, intravenous drug use, pregnancy).

**FIG. 87.2** Reverse sequencing algorithm for detection of syphilis. The testing protocol begins with an immunoassay for treponemal antibodies. Negative results rule out syphilis, but a positive result is followed by a nontreponemal quantitative test. A positive nontreponemal test is considered diagnostic of syphilis infection, either past or present. Further confirmation can be performed with a sensitive and specific treponemal agglutination test, such as the TP-PA.

Abbreviations: CIA, chemiluminescence immunoassay; EIA, enzyme immunoassay; RPR, rapid plasma regain; TP-PA, treponemal pallidum particle agglutination.

(Adapted from the Centers for Disease Control and Prevention webinar on reverse sequencing syphilis screening, <http://www.cdc.gov/std/syphilis/Syphilis-Webinar.htm>).

Other testing modalities include polymerase chain reaction (PCR) assays and rapid specific treponemal tests. PCR assays, if available, should be conducted on frozen specimens (shipped according to the laboratory specifications), but cannot discern between live or dead organisms. The rapid tests, which may use as little as 10–50  $\mu$ L of sample, are considered to be equivalent to the older specific treponemal antibody tests and have similar limitations in terms of distinguishing active versus inactive infection.<sup>18,19</sup>

For HIV-infected individuals, these serologic tests are often accurate and reliable for diagnosis and following therapeutic response. Atypical results (i.e., unusually high/low/fluctuating titers) without corresponding clinical findings suggestive of early syphilis should prompt further investigation to confirm the diagnosis.<sup>20</sup> False-negative tests may occur due to insufficient production of antibody to the bacterial proteins, or an overall lack of immunoreactivity.

In neurosyphilis, cerebrospinal fluid (CSF) analysis, along with VDRL and FTA-ABS tests, may need to be considered in confirming the diagnosis of neurosyphilis.<sup>4</sup> CSF FTA-ABS is often too sensitive and thus the role of this test is still controversial. CSF VDRL does have the advantage over CSF FTA-ABS in cases requiring differentiation of current active infection from past infection. Leukocytosis and elevated protein concentrations can be seen in the CSF and these findings are often present for more than 1 year in those individuals with neurologic symptoms. This is consistent with neurosyphilis and warrants treatment even if test results are negative.

## Differential Diagnosis

The clinical findings and possible differential diagnoses for syphilitic uveitis are listed in [Table 87.1](#). The most critical diagnosis

to make may be acute syphilitic posterior chorioretinitis, and one must rule out acute posterior multifocal placoid pigment epitheliopathy and atypical serpiginous choroidopathy. In these instances, the use of intravitreal steroid or systemic immunosuppressive therapy for treatment of these conditions may unmask an underlying infection.<sup>14</sup> It is important to emphasize that a high degree of clinical suspicion is vital in order to make the diagnosis, and that serologic confirmation is required.

**TABLE 87.1**  
**Differential Diagnosis of Ocular Syphilis With Laboratory Workup**

Disease/Disorder	Possible Serologic/Laboratory Testing
Toxoplasmosis	IgM-ELISA, IgG-ELISA for antibodies to <i>Treponema gondii</i>
Rubella	IgM-ELISA, IgG-ELISA for rubella; rubella titer
Cytomegalovirus (CMV)	CMV DNA PCR
Human immunodeficiency virus (HIV)	ELISA
Herpes simplex virus (HSV)	Diagnostic viral culture, HSV-1/HSV-2 serologic assays
Varicella-zoster virus (VZV)	Diagnostic viral culture, antibody assays
HLA-B27-related uveitis	HLA-B27 genetic testing
Primary intraocular lymphoma	Cytology on vitreous or aqueous humor; neuroradiologic and CSF studies
Sarcoidosis	Angiotensin-converting enzyme (ACE) level
Tuberculosis	PPD, QuantiFERON gold testing
Idiopathic uveitis	Diagnosis of exclusion after testing for other uveitic entities

CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; HLA, human leukocyte antigen; IgM/IgG, immunoglobulin M/G; PCR, polymerase chain reaction; PPD, purified protein derivative.

## Treatment

The clinician who diagnoses syphilitic infection in a patient has two responsibilities: to report the case to the state Department of Health,<sup>21</sup> and to determine if he or she is comfortable in managing and following the therapeutic regimen for the patient. A survey of infectious disease practitioners conducted in 2008 found variation in the management of syphilis among the experts, particularly in cases where patients were coinfecting with HIV.<sup>17</sup> It is the recommendation of the authors that the ophthalmologist treat the patient in consultation with an infectious disease specialist.

Penicillin G is the preferred treatment for all stages of syphilis

(Table 87.2). The dose, route of administration, and duration of therapy are determined by the stage and clinical findings. Sexual partners of the infected individual also need to be evaluated and treated.<sup>21</sup> For patients with a penicillin allergy, alternative antibiotics may be used; however, as the other medications are not as effective as penicillin, skin testing and desensitization are recommended, especially in those patients who are coinfecting with HIV. As for patients diagnosed with congenital syphilis, treatment with aqueous penicillin G or procaine penicillin G via intravenous administration is recommended. Other antibiotics such as ceftriaxone and ampicillin have been used, but there is no optimal therapy for congenital syphilis noted at this time.

**TABLE 87.2**  
**Recommended Treatment of Syphilis**

Stage of Disease	Preferred Treatment	Alternative Treatment
Primary, secondary, or early latent	Benzathine penicillin G 2.4 million units im, single dose	Doxycycline 100 mg po b.i.d. ×2 weeks or tetracycline 500 mg po q.i.d. ×2 weeks
Late latent, latent syphilis of unknown duration, tertiary stage, or those who fail primary therapy	Benzathine penicillin G 2.4 million units im, administered weekly ×3 weeks	Doxycycline 100 mg po b.i.d. ×4 weeks or tetracycline 500 mg po q.i.d. ×4 weeks
Neurosyphilis	Aqueous penicillin G 3–4 million units iv every 4 hours ×10–14 days	Procaine penicillin 2.4 million units im daily ×10–14 days and probenecid 500 mg po q.i.d. ×10–14 days

Notes: (1) Human immunodeficiency virus-positive patients should be treated with penicillin at all stages of infection, and those allergic to penicillin should be desensitized and then treated with the full regimen. (2) All patients with tertiary syphilis should have a cerebrospinal fluid analysis and be evaluated for neurosyphilis.

(Adapted from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2010. MMWR 2010;59:26–40.)

Syphilitic uveitis or other ocular manifestations associated with neurosyphilis should be treated according to the recommendations for neurosyphilis.<sup>4</sup> A CSF examination is recommended for all patients with syphilitic eye disease to guide therapy. The recommended regimen is aqueous crystalline penicillin G delivered intravenously, as no alternative has been proven scientifically effective. In those patients who have failed primary therapy and

show evidence of tertiary syphilis, asymptomatic neurosyphilis may be present and may warrant evaluation of the CSF.<sup>22</sup> With regard to neurosyphilis in the HIV-positive patient, treatment with intravenous penicillin utilizing the neurosyphilis recommendations results in rapid resolution of findings. It is important to note that therapy must be of a duration and dose sufficient to cure neurosyphilis, regardless of CSF findings.<sup>20</sup>

Success with therapy may be evaluated by improvement in clinical findings and seroconversion or low titers upon nontreponemal testing. The published criteria for treatment of early syphilis describe four- to eightfold decrease in nontreponemal titers that should occur by 3–6 months, respectively. It is important to realize that these criteria cannot be used in monitoring treatment efficacy in HIV-positive patients, and aggressive treatment regimens are recommended in this population.

Once the infection has been appropriately treated, adjunctive therapy with corticosteroids may be applied for any residual ocular inflammation. Topical corticosteroids are beneficial for anterior uveitis and interstitial keratitis, whereas systemic corticosteroid therapy may be required in order to resolve symptoms of residual scleritis, posterior uveitis, or optic neuritis. Corticosteroid regimens should always be administered concurrently with antibiotic therapy.

## Course and Outcome

Outcomes of syphilitic uveitis and systemic disease are dependent on early diagnosis and appropriate antibiotic therapy. These cases often result in full visual recovery and improvement in other systemic findings. Untreated cases of syphilitic uveitis often lead to worsening of intraocular inflammation, development of glaucoma secondary to chronic uveitis, and retinal necrosis. Chronic vitritis and optic atrophy may also occur. Treatment in HIV-positive individuals should be initiated early and aggressively, utilizing the regimen recommended for neurosyphilis.

## Uveitis Associated With Lyme

## Disease

LD is a multisystem disorder found in North America, Europe, and Asia caused by the tick-borne spirochete *Borrelia burgdorferi sensu lato*, a complex of 13 closely related species in the genus *Borrelia*. In the United States the majority of manifestations are caused by infection with *B. burgdorferi sensu stricto* (hereafter known as *B. burgdorferi*), transmitted by the *Ixodes* tick species, whereas in Europe and Asia, the disease is mainly caused by *B. garinii* and *B. afzelii*, respectively.

The disease can be broken down into stages: stage 1, which often begins days to weeks after the tick bite and is denoted by the pathognomonic finding of erythema migrans in conjunction with fever, malaise, and arthralgias; stage 2, which is the phase of dissemination of the spirochete to multiple organs in the days, weeks, or months after infection; and stage 3, which often occurs after a disease-free period lasting months to years.

In all cases, a history of tick bite may be absent in 50% of individuals.<sup>23</sup> The dissemination to multiple organ systems, particularly the skin, heart, joints, and nervous system, along with neurologic manifestations (e.g., cranial and peripheral neuropathies and meningoencephalitis), is the hallmark of stage 2 disease.<sup>24</sup> Chronic arthritis and conduction defects may also develop.<sup>25</sup> The lymphocytoma, another skin lesion, may develop, especially on the earlobe or breast, and the initial erythema migrans fades and reappears.<sup>24</sup> These findings may take days, weeks, or even months to manifest clinically.

The third or late stage of disease often occurs after a disease-free period lasting months to years, and may occur despite adequate antibiotic therapy.<sup>26</sup> Chronic symptoms mark this phase of infection, and common conditions include chronic relapsing arthritis of the knee; acrodermatitis chronica atrophicans, a rash that results in atrophy of the skin and underlying structures; and late neurologic manifestations (e.g., encephalopathy, demyelination, and dementia).<sup>24,26,27</sup>

Ocular disease can manifest at any stage of infection. Though well documented, the majority of cases persist in case reports and case series, with few definitive, large-scale studies in the scientific

literature.

## Epidemiology and Pathogenesis

In the United States, the endemic areas are clustered around three regions: (1) the northeast, down as far south to Virginia, with hyperendemic regions in Connecticut and New York; (2) the Midwest, in the states of Michigan, Wisconsin, and Minnesota; and (3) the west, primarily in northern California. Certain areas of Europe and Asia are also affected, particularly in regions with a temperate climate. It is unclear why there is a preponderance of cases localized to the northeastern United States.<sup>25</sup>

The pathogenesis of the disease is similar to that induced by the spirochete *T. pallidum*, and follows in three distinct stages. The first stage, or early infection, is believed to be due to spirochetemia. After an incubation period of 3–32 days, the spirochete multiplies and induces proinflammatory responses in both the innate and adaptive immune systems. This is clinically observed as the characteristic skin rash, erythema migrans, at the site of the tick bite.<sup>25</sup> Within days to weeks, *B. burgdorferi* can be recovered from many areas of the body. All affected tissues show some infiltration of lymphocytes and plasma cells, along with vascular damage (e.g., mild vasculitis or hypervascular occlusion).

The immunologic response of the host to parasitic invasion is the likely etiology for the manifestations of stage 2 and 3 disease.<sup>28</sup> The specific immunoglobulin M (IgM) response provides for polyclonal B-cell activation and increased levels of circulating immune complexes, while the specific IgG response develops over weeks in response to spirochetal polypeptides and nonprotein antigens. Spirochetal killing is primarily due to bactericidal B-cell responses and utilizes the complement pathway. For the majority of cases, the innate and adaptive response is capable of controlling widespread dissemination of the disease without antibiotic therapy; however, without appropriate therapy, *B. burgdorferi* can survive for several years in particular loci, such as joints, skin, and nervous system.<sup>25</sup> Recent reports seem to support this observation, as *in vitro* studies indicate that these infectious strains are capable of forming cystic bodies and biofilm aggregates, and current antibiotics have varying

effects on these different morphologic forms.<sup>29,30</sup>

## Ocular Manifestations

Ocular findings are less prominent compared to the significant systemic manifestations and can appear at any stage of disease. Conjunctivitis is the most common finding, present in 11% of patients with early-stage Lyme disease.<sup>31</sup> Ophthalmologists are generally not consulted as the nonspecific findings of conjunctival and periorbital inflammation are mild in nature and self-limiting. Neuro-ophthalmic complications are associated with stage 2 disease and commonly manifest as ocular motility problems due to cranial nerve palsies, optic neuritis, papilledema, and pseudotumor cerebri in the setting of meningoencephalitis.<sup>26,32–34</sup> Stromal keratitis, episcleritis, and symblepharon formation have been reported in stage 3 disease.<sup>35</sup>

Intraocular inflammation often presents as chorioretinitis and vitreous inflammation, though there have been a variety of clinical presentations associated with LD.<sup>32,36,37</sup> Vitreous involvement may be nonspecific, with or without associated retinal pathology, such as retinal vasculitis.<sup>37</sup> Clinically, the presence of disc edema in the setting of posterior-segment inflammation may be related to chronic posterior-segment inflammation rather than the neurologic involvement from borreliosis (**Fig. 87.3**). Appropriate neuro-ophthalmic testing should be undertaken to evaluate the potential of other central nervous system complications.

**FIG. 87.3** Fluorescein angiogram depicting disc edema and mild vitritis in a 44-year-old Caucasian male with positive serology for Lyme borreliosis. There is a nonspecific window defect temporal to the fovea.  
(Courtesy of Thomas J. Federici, MD.)

## Diagnosis

The clinical diagnosis of LD is dependent on the following: appearance of the pathognomonic skin rash (erythema migrans) in a patient with a history of tick bite and/or residence in an endemic region; or the appearance of the skin lesion in addition to involvement of two organ systems in those patients without a history of a tick bite or residence in a nonendemic region. The diagnostic criteria for Lyme disease as recommended by the CDC are listed in [Table 87.3](#).<sup>38</sup>

**TABLE 87.3**

### Diagnostic Criteria and Case Classification of Lyme Disease

<b>DEFINITION</b>
Erythema migrans (EM), or at least one advanced manifestation, as defined below, and laboratory confirmation of infection
<b>ADVANCED MANIFESTATIONS</b>
<b>Musculoskeletal System</b>
Recurrent, brief attacks (lasting weeks or months) of objective joint swelling in one or a few joints, sometimes followed by chronic arthritis in one or a few joints; manifestations not considered criteria for diagnosis include chronic progressive arthritis, not preceded by brief

attacks, and chronic symmetrical polyarthritis; arthralgia, myalgia, or fibromyalgia syndromes alone are not criteria for musculoskeletal involvement
<b>Nervous System</b>
Any of the following, alone or in combination: lymphocytic meningitis; cranial neuritis, particularly facial palsy (may be bilateral); radiculoneuropathy; or, rarely, encephalomyelitis (must be confirmed by showing antibody production against <i>Borrelia burgdorferi</i> in the cerebrospinal fluid, demonstrated by a higher titer of antibody in cerebrospinal fluid than in serum); headache, fatigue, paresthesia, or mild stiff neck alone are not criteria for neurologic involvement
<b>Cardiovascular System</b>
Acute-onset, high-grade (2 or 3) atrioventricular conduction defects that resolve in days to weeks and are sometimes associated with myocarditis; palpitations, bradycardia, bundle branch block, or myocarditis are not criteria for cardiovascular involvement
<b>CLASSIFICATION</b>
<b>Suspected</b>
<ul style="list-style-type: none"> <li>• A case of EM where there is no known exposure and no laboratory evidence of infection, <i>or</i></li> <li>• A case with laboratory evidence of infection but no clinical information available (e.g., a laboratory report)</li> </ul>
<b>Probable</b>
Any other case of physician-diagnosed Lyme disease that has laboratory evidence of infection
<b>Confirmed</b>
<ul style="list-style-type: none"> <li>• A case of EM with a known exposure, <i>or</i></li> <li>• A case of EM with laboratory evidence of infection and without a known exposure, <i>or</i></li> <li>• A case with at least one late manifestation (e.g., musculoskeletal, nervous system, or cardiac) that has laboratory evidence of infection.</li> </ul>

Adapted from “Lyme Disease (*Borrelia burgdorferi*) 2011 Case Definition”, available from <http://www.cdc.gov/nndss/conditions/lyme-disease/case-definition/2011/>.

Culture of *B. burgdorferi* from peripheral blood, areas of skin rash, and CSF provides for definitive diagnosis.<sup>39,40</sup> However, positive cultures are often difficult to obtain as they mainly occur early on in the disease process. In these cases, sensitivity is highest in tissue culture, with the positive rates of culture dropping significantly for plasma and CSF.<sup>25</sup> For ocular disease, serologic testing is often more helpful in diagnosis as these manifestations can occur several years after initial inoculation. These results, along with a clinical history suggestive of infection, provide the basis for diagnosis of LD.

The CDC recommends a two-step approach in which serologic samples are tested: first, an enzyme-linked immunosorbent assay (ELISA) is performed to detect the presence of IgG and IgM specific for *B. burgdorferi*. For those individuals suspected of acquiring LD overseas, a specific C6 peptide ELISA is recommended as the other serologic tests may not detect the European and Asian strains.<sup>41</sup> Equivocal results are then tested by Western blotting. According to CDC criteria, the IgM Western blot is considered positive if two of the following three bands are present: 23, 39, and 41 kDa, though the combination of the 23- and 41-kDa bands may still be

considered a false-positive result. The IgG Western blot may be considered to be positive if five of the following 10 bands are present: 18, 23, 28, 30, 39, 41, 45, 58, 66, and 93 kDa.<sup>41</sup> The results still need to be interpreted with care, as a portion of the normal population has IgG reactivity to the 41-kDa flagellar antigen of the spirochete and thus the presence of the band alone cannot be utilized in serologic diagnosis.<sup>25</sup>

As a final note of caution: these tests, though commonly used, can be insensitive during the first few weeks of infection, prior to the development of host antibody response. Actively infected individuals will have a positive IgG response. For those patients with active disease lasting more than 4–8 weeks, an elevated IgM response is likely to be a false positive, and thus an IgM response should not be used to support the diagnosis of an infection after that time period.<sup>25</sup> In instances where the disease course is much more aggressive and severe than initially anticipated, coinfection with *Babesia microti* or *Ehrlichia phagocytophila* (causing human babesiosis and granulocytic anaplasmosis, respectively) should be considered.<sup>42,43</sup>

## Differential Diagnoses

Given the various ocular manifestations of LD, the clinician needs to rule out both infectious and noninfectious etiologies with similar clinical presentations. In terms of other infectious etiologies, findings on the clinical examination as well as appropriate serologic/diagnostic tests should be undertaken to rule out syphilis, tuberculosis, viral meningitis/encephalitis, viral keratitis, infectious arthritis and mononucleosis, and mumps. Examination should also incorporate the following noninfectious etiologies in the differential diagnosis: sarcoidosis, collagen vascular diseases, vasculitis, Vogt–Koyanagi–Harada syndrome, and multiple sclerosis.

## Treatment

Therapy for LD consists of antibiotic treatment for the systemic infection, though preventive measures (i.e., protective clothing, repellents, and acaricides), landscape modifications, and tick checks are often the best defense against infection as they reduce exposure.

Vaccination was once offered to individuals between the ages of 15 and 70 years who may travel to or live in endemic regions;<sup>44</sup> however, the vaccine is no longer available. In addition, a single dose of doxycycline (200 mg) is no longer recommended for prophylaxis after a documented tick bite; rather, appropriate antibiotic therapy for a minimum of 10–20 days is preferred.<sup>45,46</sup>

With regard to management of ocular findings, the most effective treatment strategy remains unclear.<sup>32</sup> Systemic therapy should be initiated in consultation with an infectious disease specialist (Table 87.4). Diplopia secondary to cranial nerve palsies should be addressed according to the severity of patient symptoms. Adjunct corticosteroids have been beneficial in treating the specific ocular manifestations: topical applications for anterior-segment manifestations (e.g., keratitis and episcleritis), and intravitreal injections for macular edema.<sup>35,47–49</sup> Systemic corticosteroids have been utilized in more severe cases of ocular inflammation, such as vision-threatening uveitis, scleritis, or optic neuritis; however, the use may be controversial, as a higher incidence of relapses has been observed. Inadequate treatment in the early stages may lead to relapses and development of late-stage manifestations.<sup>26</sup> Treatment of concomitant infections should also be addressed if the clinical findings persist despite prolonged antibiotic therapy.

---

**TABLE 87.4**  
**Treatment of Lyme Disease**

---

<b>EARLY INFECTION – LOCAL OR DISSEMINATED</b>
<b>Adults</b>
Doxycycline 100 mg orally twice daily for 14–21 days
Amoxicillin 500 mg orally three times a day for 14–21 days
In case of doxycycline/amoxicillin allergy:
Cefuroxime 500 mg orally twice daily for 14–21 days
Erythromycin 250 mg orally four times daily for 14–21 days
<b>Children</b>
Amoxicillin 50 mg/kg body weight per day in three divided doses for 14–21 days
In case of penicillin allergy:
Cefuroxime 30 mg/kg per day in two divided doses for 14–21 days
<b>NEUROLOGIC AND/OR OCULAR ABNORMALITIES (EARLY OR LATE)</b>
<b>Adults</b>
Ceftriaxone 2 g iv once a day for 14–28 days
Cefotaxime 2 g iv every 8 hours for 14–28 days
In case of ceftriaxone or penicillin allergy:
Doxycycline 100 mg orally 3 times a day for 30 days

Children
Ceftriaxone 75–100 mg/kg per day (maximum 2 g) iv once a day for 14–28 days
Cefotaxime 150 mg/kg per day in three to four divided doses (maximum 6 g) for 14–28 days

Notes: (1) Avoid doxycycline in pregnant women. (2) Chronic Lyme disease symptoms seen in late disease may require long-term antibiotic therapy (2 or more months of oral antibiotics, or 1 or more months of iv antibiotics).

Adapted from Steere AC. Lyme disease. *N Engl J Med* 2001;345:115–25.

## Disease Course and Outcome

The majority of patients respond well to systemic antibiotic therapy; however, posterior uveitis, stromal keratitis, and neurotrophic keratitis can be slow to respond to treatment. Untreated disease can have a relapsing course for several years, though the number of patients with chronic symptoms, most notably arthritis, decreases 10–20% each year, with few individuals having symptoms beyond 5 years.<sup>25</sup> In “chronic Lyme disease” or posttreatment Lyme disease syndrome (PTLDS), no consensus has been reached with respect to prolonged antibiotic therapy.<sup>50</sup>

## Ocular Leptospirosis

Leptospirosis is a zoonotic infection with a worldwide distribution, with higher incidence in tropical and subtropical climates. Initially described in 1886, infection causes a severe condition characterized by acute fever, malaise, and uveitis. Most human infection may be asymptomatic, and there is a wide spectrum of disease presentation which ranges from nonspecific febrile illness to multiorgan involvement associated with high mortality rates.

Systemic disease begins with nonspecific symptoms of headache, fevers, myalgias, malaise, and conjunctival chemosis with or without subconjunctival hemorrhage. The fevers may be mild, moderate, or severe. Anicteric disease affects 80–90% of patients, but 10–15% go on to develop severe systemic septicemia or multiorgan failure (icteric leptospirosis, or Weil disease) and mortality ranges from less than 5% to 30%.<sup>51,52</sup> Poor prognostic factors include involvement of the liver, renal failure, rhabdomyolysis, and altered sensorium.<sup>53</sup>

## Epidemiology and Pathogenesis

The genus *Leptospira* consists of two strains: *L. interrogans*, which causes the infectious disease in humans, and *L. biflexa*, which is a saprophytic strain. The natural reservoir for *Leptospira* is wild animals, particularly rodents, but dogs and other domestic livestock may also be affected. The spirochete colonizes the renal tubules of the animal host, and survives excretion in the urine. It also survives as a free-living organism in contaminated soil or water. Individuals at high risk for infection include abattoir workers, farmers, veterinarians, miners, and sewerage workers who contract the disease via direct contact with diseased animals. Indirect contact is more common after exposure to wet soil or water through occupational exposure or recreational exposures (e.g., water sports in either fresh or sea water, ecotourism in endemic regions) as the spirochete has the ability to enter the human body through intact mucosa or abraded epidermis. The appearance of this rural tropical disease in urban centers of developing regions is often secondary to a lack of sanitation in areas of rapid expansion and growth. Sporadic outbreaks have also been reported in developed countries.<sup>54,55</sup>

Hematogenous dissemination allows the organisms to invade the central nervous system and aqueous humor of the eye; transendothelial migration occurs via systemic vasculitis, resulting in a broad spectrum of presentations, including pulmonary hemorrhage, damage to the renal tubule structures, and hepatic cell destruction.<sup>56</sup> It is unclear which mechanism allows for *Leptospira* to cause infection in ocular and systemic infection: innate bacterial virulence factors, direct tissue damage secondary to hemolytic toxins, or innate host immune responses.

## Ocular Manifestations

In the acute phase of infection, the incidence of ocular signs ranges from 2% to 90% of cases, suggesting that the majority of findings may be nonspecific and diagnosed only when there is a high index of suspicion. Conjunctival hyperemia, chemosis, and subconjunctival hemorrhage are most commonly seen in these cases. Changes in the retinal vasculature and the presence of retinal

hemorrhages have been reported, along with disc hyperemia and retinal vasculitis.<sup>54</sup>

After the initial septicemic phase, a period of relative quiescence ranging from 2 days to 4 years precedes the development of ocular symptoms, which can vary from a localized anterior uveitis to diffuse panuveitis. Findings are generally nongranulomatous, though granulomatous reactions may be seen in rare cases.

Anterior-segment findings can include hypopyon (in 12% of cases), a fibrinous reaction, and cataract. In rare cases, spontaneous absorption of the lens opacity has been reported. The symptoms of photophobia, blurred vision, and pain are generally self-limited.<sup>57</sup>

In the posterior segment, vitritis is common, with vitreous strands or veil opacities that attach to the optic disc. There may be other vitreous precipitates in the posterior vitreous, along with snowbanking. Nonocclusive vasculitis, periphlebitis, choroiditis, and papillitis have also been described.<sup>54</sup>

## Diagnosis

Clinical diagnosis of systemic and ocular leptospirosis is difficult given the nonspecific symptoms and variable presentations reported in the literature (Table 87.5). The clinician cannot rely on the examination alone; rather, a high index of suspicion in an endemic region, or in individuals who may have exposure due to socioeconomic or recreational factors, needs to be taken into account, along with laboratory testing for confirmation of clinical suspicion.

---

**TABLE 87.5**

### Differential Diagnosis of Leptospirosis

---

HLA-B27-related uveitis	Sarcoidosis
Behçet disease	Syphilis
Eales disease	Toxoplasmosis
Endophthalmitis	Leprosy
Tuberculosis	

HLA, human leukocyte antigen.

The gold standard for laboratory testing is the microscopic agglutination test (MAT), which is comprised of the agglutination

of live leptospiras by titrated amounts of patient serum. A fourfold change in the titer or seroconversion is considered positive, with a compatible clinical presentation. Of note, false negatives can occur if the infection is due to a serovar not present in the testing panel, and false positives can also occur if there are any residual antibodies to a prior exposure in an endemic area. In chronic cases, a titer of 1 : 100 is considered a positive test. The main difficulty in obtaining MAT testing lies in that large numbers of leptospiral cultures need to be maintained; thus, only large reference laboratories are able to conduct this laboratory test. Other diagnostic procedures, including a *Leptospira* dipstick test, ELISA, and microscopic slide agglutination tests, have replaced the MAT for more routine use. PCR for the detection of leptospiral DNA may be more sensitive in early identification of *Leptospira* outbreaks.<sup>58</sup>

## Treatment

Antibiotic therapy for systemic disease is extremely effective. Supportive care should be initiated for those individuals suffering from multiorgan involvement. Intravenous penicillin G has been effective for severe systemic infection, but for less severe presentations, doxycycline given 100 mg twice daily for 1 week was shown to be effective in eradicating leptospiras from all target organs within 3 days. There does not seem to be any difference between the appropriate use of intravenous penicillin, intravenous cephalosporin, doxycycline, or azithromycin, but they have not been tested to the same extent as intravenous penicillin.<sup>59</sup>

Treatment for leptospiral uveitis includes local administration of corticosteroids, with dose and route of delivery dependent on the location, laterality, and severity of the symptoms. It is unclear if systemic antibiotic therapy during the early phase of infection provides any protective role in the prevention of immunologic sequelae such as uveitis, though a recent study suggests that those treated in the septicemic phase developed only mild disease.<sup>60</sup>

## Disease Course and Outcome

Visual recovery and potential are generally good, with one large series reporting that more than 50% of patients regained 20/20

vision.<sup>57</sup> Most patients have mild disease (anicteric) and recover within 1–2 weeks. For systemic disease, mortality varies from less than 1% to more than 20%, and is dependent on the severity of disease and involvement of multiple organ systems.<sup>52</sup>

Biology, Life Cycle, and Transmission of the Organism

Strains/Clonal Populations – Haplogroups  
Genetics

## **Pathogenesis**

## **Ocular Disease**

## **Laboratory**

## **Outcomes and Complications**

## **Treatment and Prevention**

## **Introduction**

Toxoplasmosis is a common zoonosis caused by the infection with *Toxoplasma gondii*, and one of the most important cause of infectious retinal disease and posterior uveitis. Toxoplasmosis can cause severe, life-threatening disease, especially in newborns and

immunosuppressed patients, but the majority of *T. gondii* infections in immunocompetent patients remain asymptomatic.<sup>1,2</sup>

In the eye toxoplasmosis can cause blindness secondary to the retinitis present in the posterior pole of the eye or vitreoretinal complications in the acute or recurrent form of the disease.<sup>3</sup> Ocular toxoplasmosis (OT) represents 50–85% of the posterior uveitis cases in Brazil and 25% in the United States.<sup>4</sup> The prevalence of OT in the United States is not well determined but ranges from 0.6% to 2% according to published reports, and in Brazil the prevalence ranges from 10% to 17.7%.<sup>5</sup>

OT may occur either in a congenital or a postnatal acquired form and in both the eye may be affected during the acute phase of the infection or more commonly many months to years later<sup>6</sup> (Box 88.1).

## Myths in Ocular Toxoplasmosis

All cases congenital

Must present retinochoroiditis

Vertical transmission (pregnancy) only once

Cats and meat are the only source

Nothing to prevent ocular form

No treatment to avoid recurrences

All patients need antitoxoplasmic drugs for 4–6 weeks

Recurrences are related only to local factors

Beef is probably not important in the transmission of toxoplasmosis, and undercooked lamb, pork, and chicken are the major culprits, as well as food and environment contaminated by the feces of infected cats, organ transplantation, and blood transfusion.<sup>7</sup> Recently, water has been associated with the transmission of OT in different continents.<sup>8</sup>

Fetal toxoplasmosis tends to occur only when the woman acquires the first infection during or months before the pregnancy

and is more severe, and a more frequent cause of abortion, in the first months of pregnancy. In a fetus infected later on, milder infections develop and children are born often with subclinical infections. OT will develop up to decades later, being bilateral in up to 85% of patients.<sup>9</sup> It is known though that rarely even women with IgG serum antibodies against *Toxoplasma* may not be protected against transmitting congenital toxoplasmosis to a fetus.<sup>10</sup>

## Biology, Life Cycle, and Transmission of the Organism

*T. gondii* is an obligate, intracellular protozoan parasite that undergoes a life cycle that includes both sexual and asexual reproduction. The sexual cycle occurs exclusively in felines (definitive hosts), which shed a large number of infectious oocysts in their feces once in their lifetime and usually for a few weeks. Members of the cat family are therefore its definitive hosts, but hundreds of other species, including mammals, birds, and reptiles, may serve as intermediate hosts,<sup>11</sup> The parasite can be found in the host's tissues and body fluids, such as saliva, milk, semen, urine, and peritoneal fluid.<sup>12</sup>

*T. gondii* exists in three infectious forms: the oocyst, the tachyzoite, and the bradyzoite (also called the tissue cyst). Once ingested by the intermediate hosts, the disease causes the production of tachyzoites and under the pressure of the immune response forms tissue cysts, the bradyzoites, that are very resistant and may remain in the retina as well as the central nervous system and many muscles of the organism, such as the tongue, heart etc., for many years.<sup>13</sup> They can remain dormant in the host without tissue damage and, for reasons that are unknown, after many years may rupture, causing reactivation of the ocular acute and recurrent disease.<sup>14</sup>

## Strains/Clonal Populations – Haplogroups Genetics

The ability to identify parasite types may now provide new insights into the pathogenesis of this disease, and, ultimately, become an

important diagnostic and prognostic tool.<sup>15</sup>

The majority of strains identified in Europe and North America are classified into three distinct genotypes (type I, II, and III). Type I strains are very virulent and types II and III are less so. All of them can cause disease in humans. Type I strains are considered to be more often associated with postnatally acquired ocular infections, and type II strains are more associated with congenital infections and toxoplasmic encephalitis.<sup>16</sup> Atypical strains as well as mixed infections have been identified in many parts of the world and seem to be common in Brazil.<sup>17</sup> The make-up of *T. gondii* is more complex than previously recognized and suggests that unique or divergent genotypes may contribute to different clinical outcomes of toxoplasmosis in different localities.<sup>18</sup>

Atypical toxoplasmic retinochoroiditis as well as variations in the clinical presentation and severity of disease has been attributed to several factors, including the genetic heterogeneity of the host and the genotype of the parasite responsible for infection.<sup>19</sup>

## Pathogenesis

Serologic evidence of previous toxoplasma infection is present in 20–70% of individuals in different countries, depending on a variety of factors, including climate, hygiene, and dietary habits, and there is not always a correlation between the prevalence of serum antibodies and the frequency of ocular disease.<sup>20</sup> Different factors such as the pathogenicity of the toxoplasmosis strains may play an important role.<sup>21</sup>

Ocular toxoplasmosis in immunocompetent patients is characterized histologically by foci of granulomatous chorioretinal inflammation and coagulative necrosis of the retina with sharply demarcated borders. Inflammatory changes can be widespread in the eye and involve choroid, iris, and trabecular meshwork. Immunosuppressed patients with ocular toxoplasmosis present both tachyzoites and tissue cysts in areas of retinal necrosis and within retinal pigment epithelial cells.<sup>22</sup> Parasites can occasionally be found in the iris, choroid, vitreous, and optic nerve. The lesions tend to be diffuse and often active in both eyes.<sup>23,24</sup>

## Ocular Disease

The retina is the primary site of *T. gondii* infection in the eye and the hallmark is a necrotizing retinochoroiditis satellite to old hyperpigmented scars and accompanied by vitreous inflammation and anterior uveitis. Retinal vasculitis is also present. OT is characterized by recurrent episodes of necrotizing retinochoroiditis thought to be caused by the proliferation of live organisms that emerge from tissue cysts and or inflammatory reaction triggered by autoimmune mechanisms.<sup>25</sup>

The most common clinical signs of active ocular toxoplasmosis are blurring or loss of vision and floaters. Depending on the location of the lesions and the anterior chamber and vitreous inflammation, patients can be more or less symptomatic.<sup>26</sup>

The diagnosis is clinical and based on the ocular examination, the exclusion of the differential diagnosis and the presence of circulating antibodies for toxoplasmosis. The ocular exam comprises biomicroscopy and indirect ophthalmoscopy. In special cases other procedures such as OCT or fluorescein angiography may be necessary.<sup>27</sup>

Toxoplasmic retinochoroiditis can be associated with severe morbidity if disease extends to structures critical for vision, including the macula and optic nerve, if there is damage to the eye from inflammation, or if there are complications such as retinal detachment or neovascularization.<sup>28</sup> The timing of recurrences varies between individuals and is unpredictable also regarding the site of the recurrence and its clinical presentation.<sup>29</sup>

Toxoplasmic retinochoroiditis lesions have the same characteristics, whether they result from congenital or acquired infections. The acute and new lesions are usually intensely white, focal lesions with overlying vitreous inflammatory haze. Active lesions that are accompanied by a severe vitreous inflammatory reaction will have the classic “headlight in the fog” appearance. Anterior uveitis characterized by inflammatory cells in the aqueous, medium-sized keratic precipitates, and posterior synechiae are present.<sup>30</sup>

Eyes with active toxoplasmic retinochoroiditis will occasionally develop retinal vasculitis with vascular sheathing and hemorrhages

in response to reactions between circulating antibodies and local *T. gondii* antigens.<sup>31</sup> Typically hyperpigmented scars of old and inactive lesions are present and recurrent lesions occur at the border of healed scar as a satellite lesion.<sup>32</sup>

In most cases toxoplasmic retinochoroiditis is a self-limited disease. Untreated lesions generally begin to heal after 1 or 2 months, although the time course is variable, and in some cases active disease may persist for months.<sup>33</sup>

As a lesion heals, its borders become more defined, and after several months may become hyperpigmented. Large scars will have an atrophic center that is devoid of all retinal and choroidal elements; the underlying sclera gives the lesion its white center.<sup>34</sup>

Recent evidence has also suggested that patients with recent acquired infection may present with vitritis or even anterior uveitis in the absence of retinochoroiditis.<sup>35</sup>

The association between Fuchs heterochromic cyclitis and ocular toxoplasmosis has been reported in different countries and the pathologic mechanisms remain unknown.<sup>36</sup>

## Laboratory

Toxoplasmic retinochoroiditis is diagnosed clinically. Parasites are found rarely in intraocular fluids, and invasive diagnostic tests such as retinal biopsy are associated with serious risks that prevent their routine use. Different serologic tests exist and should be used only to confirm past exposure to *T. gondii*; it is inappropriate to base a diagnosis of ocular toxoplasmosis on the presence of antibodies alone. The IgG serum antibodies can persist at high titers for years after an acute infection, and there is a high prevalence of such antibodies in the general population. Because active retinal lesions are usually foci of recurrent disease, serum IgG titers may be low and IgM may be absent. The serologic determination of IgA antibodies may help to determine the time of the primary infection since they last for less time in the serum.<sup>37</sup>

The development of molecular biology techniques has allowed the identification of *T. gondii* DNA in the aqueous humor and the vitreous, as well as ocular tissue sections, of patients with presumed toxoplasmic retinochoroiditis by PCR techniques even

when organisms are not identified on histopathologic examination.<sup>38,39</sup>

The differential diagnoses comprise infectious diseases such as rubeola, cytomegalovirus, syphilis, herpes simplex, tuberculosis, and toxocariasis. Noninfectious conditions like retinal and choroidal coloboma, retinoblastoma, retinopathy of prematurity, gyrate atrophy, retinal vascular membrane, serpiginous choroidopathy among others have to be excluded in some presentations.<sup>40</sup>

## Outcomes and Complications

Toxoplasmic retinochoroiditis can result in permanent loss of vision because of retinal necrosis, uveitis and its complications. Central vision will be lost if lesions affect the fovea, maculopapillary bundle, or optic disc. Other reported complications include macular edema, retinal neovascularization, vascular occlusion, and vitreoretinal lesions such as vitreous hemorrhage and epiretinal membranes. Subretinal neovascular membranes may be a cause of sudden loss of vision. Rhegmatogenous and traction retinal detachments may occur as well as secondary glaucoma and cataracts.<sup>41</sup>

## Treatment and Prevention

There are many questions surrounding the treatment of ocular toxoplasmosis. Available drugs do not eliminate tissue cysts and cannot prevent chronic infection. No treatment has proven to be superior or even more efficient than nothing. It is accepted that steroids decrease the inflammation and therefore can lead to better vision function; they should not be used without antitoxoplasmic drugs in order to avoid the worsening of the infection.<sup>42</sup> But the role of the antitoxoplasmic drugs has never been scientifically proven and it is possible its effect would be limited to the first days of the retinitis. There is no cure for toxoplasmosis since the tissue cysts are resistant to the available drugs and remain viable for many years.<sup>43</sup>

The combination of pyrimethamine, sulfadiazine, and corticosteroids, which is considered “classic” therapy for ocular

toxoplasmosis ([Box 88.2](#)), is the most common drug combination used and considered the best option.<sup>44</sup> Therapy with trimethoprim and sulfamethoxazole probably is equally effective and has fewer side-effects and better patient compliance. It may be considered though as having a higher risk to cause severe allergic reactions because of the long life of sulfamethoxazole.<sup>45</sup> Other drugs, such as [Box 88.2](#) or intraocular clindamycin, have also been used.<sup>46,47</sup>

## Typical Therapy for Ocular Toxoplasmosis

### Pyrimethamine

75 mg to 100 mg loading dose given over 24 hours, followed by 25–50 mg daily for 4–6 weeks depending on clinical response.

### Sulfadiazine

2.0–4.0 g loading dose initially, followed by 1.0 g given 4 times daily for 4–6 weeks, depending on clinical response.

### Prednisone

40–60 mg daily for 2–6 weeks depending on clinical response; taper off before discontinuing trimethoprim–sulfamethoxazole.

### Folinic acid

5.0 mg tablet or 3.0 mg intravenous preparation given orally, 2 to 3 times weekly during pyrimethamine therapy.

The length of treatment depends on the individual clinical picture.

Steroid treatment is often administered systemically and always associated with antitoxoplasmic drugs. Local drops are used when anterior uveitis is present.<sup>48</sup>

Traditional short-term treatments of active toxoplasmic retinochoroiditis lesions do not prevent subsequent recurrences. There is no cure for OT since none of the available drugs penetrates the cyst.<sup>49</sup>

The association of trimethoprim–sulfamethoxazole (TMP–SMX)

given for many months may decrease the number of recurrences and should be considered in higher-risk patients.<sup>50</sup>

A study performed after 10 years, with the objective to evaluate the benefits of the use of the combination of TMP–SMX, showed no difference in the recurrence rate in both groups, suggesting that the prophylactic treatment effect disappears when the treatment is stopped. Thus, long-term intermittent treatment with TMP–SMX can reduce the rate of recurrent toxoplasmic retinochoroiditis only when the patient is being treated.<sup>51</sup>

Long-term therapy may play a role in the management of ocular toxoplasmosis in specific situations. It might be most appropriate for individuals or populations with demonstrated histories of frequent and severe recurrences. It might also be considered for people at greatest risk of vision loss, such as those with retinochoroidal scars adjacent to the fovea, where any reactivation can result in profound vision loss.<sup>51</sup>

Prevention of toxoplasmosis is debatable, and it is unknown if patients with the acquired benign systemic form of the disease should be treated in every case, and specifically in children, to decrease the population of tissue cysts and therefore avoid or decrease the later ocular involvement.<sup>52</sup>

Surgery to cataract secondary to severe inflammation should be performed to restore vision and to allow fundus examination in order to identify new lesions as well as retinal complications secondary to the uveitis. As a rule, patients with cataract secondary to ocular toxoplasmosis should be operated with good results after 3 months of the uveitis being inactive.<sup>53</sup>

Local treatment with intravitreal injections of clindamycin and dexamethasone without concomitant systemic therapy is a treatment option in patients with allergies or inadequate responses to oral medications.<sup>54,55,56</sup>

# Helminthic Disease

Marcos Ávila, David Isaac

## Introduction

### Ocular Toxocariasis

### Diffuse Unilateral Subacute Neuroretinitis

### Onchocerciasis

### Cysticercosis

## Introduction

Helminths have plagued mankind since before the era of our earliest recorded history.<sup>1</sup> It is possible to recognize features of helminthic infections from the ancient writings of Hippocrates, Egyptian medical papyri, and the Bible.<sup>2</sup> Nematode worms or roundworms are a class of one of the most important phylum of the Helminths (Nemathelminthes) and include the major intestinal human worms (e.g., *Ascaris lumbricoides*, *Trichuris trichiura*, *Necator americanus*, *Ancylostoma duodenale*, *Strongyloides stercoralis*), animal worms (e.g., *Toxocara canis*, *Toxocara cati*, *Ancylostoma caninum*, *Baylisascaris procyonis*), and the filarial worms that can cause lymphatic filariasis (e.g., *Wuchereria bancrofti*, *Brugia malayi*) or onchocerciasis (*Onchocerca volvulus*).<sup>1</sup> The other phylum of the Helminths is called Platyhelminths, which is divided into trematodes (e.g., *Schistosoma mansoni*) and cestodes (e.g., *Taenia*

*solium*, *Taenia saginata*). Many kinds of adult worms cannot develop on their own and parasitize human intestine; some in their larval stage can infect humans directly, causing tissue damage that includes the eye.<sup>3</sup> It is estimated that almost 1 billion people worldwide, especially in tropical areas and developing countries, are infected with one or more helminths.<sup>4</sup> This chapter discusses the most common helminthic diseases that affect the posterior segment of the eye: ocular toxocariasis, diffuse unilateral subacute neuroretinitis (DUSN), ocular onchocerciasis, and cysticercosis.

## Ocular Toxocariasis

Toxocariasis is an infection caused by the nematode *T. canis* and less frequently by other roundworms such as *T. cati*.<sup>3,5,6</sup> Systemic effects of *Toxocara* infestation in the human are termed visceral larval migrans (VLM). VLM is usually a self-limited disease and typically affects young children from 6 months to 4 years of age.<sup>5</sup> Findings associated with the disorder range from a mild to moderate eosinophilia in an asymptomatic patient, fever, pallor, anorexia, malaise, hepatomegaly, and transient infiltrates of the lungs in symptomatic VLM to, more infrequently, a fulminating and fatal disease associated with pneumonia, congestive heart failure, or convulsions.<sup>3,5,7</sup> Ocular toxocariasis is unusual in adults but is an important cause of visual impairment during childhood, accounting for approximately 1% of all cases of uveitis among all ages in referral centers in the United States and Japan<sup>8,9</sup> and 3% of panuveitis in Switzerland.<sup>10</sup> Exact correlation between VLM and ocular toxocariasis is not well determined but patients with systemic disease rarely present with ocular involvement. In one study of 245 cases of VLM, only 5% had any indication of ocular disease.<sup>11</sup>

## History

In 1907 Leiper first described the infestation of humans with canine nematodes.<sup>12</sup> Later, Wilder, in 1950, described nematode ocular infection.<sup>13</sup> In her study Wilder reviewed the histopathology of 46 eyes primarily enucleated for suspicion of intraocular malignancy,

and nematode larvae were found in 24 eyes. Two years later Beaver and coworkers identified a *Toxocara* species larva in a liver biopsy from a child with visceral lesions and eosinophilia, identifying the etiological agent with this previously reported syndrome in children.<sup>14</sup> Nichols, in 1956, reported identifying *T. canis* (Toxocaridae family) in specimens originally studied by Wilder who first thought the worm to be part of family Ancylostomidae.<sup>15</sup> These studies demonstrated a common etiology for systemic and ocular diseases. In 1959 Irvine and Irvine<sup>16</sup> described histologic findings in a 4-year-old child presenting with strabismus, decreased vision, and retinal detachment. The eye was enucleated for suspicion of a tumor but an eosinophilic abscess with *Toxocara canis* larva on the pars plana region was demonstrated. This patient differed from cases reported by Wilder<sup>13</sup> since the patient presented with clear media and the retina could be examined. In 1960 Ashton<sup>17</sup> described four histopathologically proven cases of *Toxocara* endophthalmitis that presented with a posterior pole granuloma in a distinct fashion that represented a third classic form of this disorder. Duguid, in 1961,<sup>18</sup> described a case series of ocular toxocariasis and emphasized the difference between the posterior pole granuloma and diffuse chronic endophthalmitis, suggesting that clinical diagnosis could be performed in certain cases. In 1971 Wilkinson and Welch<sup>19</sup> reported 41 cases of proven or presumed ocular toxocariasis. Eyes with chronic endophthalmitis and leukocoria were much more likely to have been enucleated, whereas eyes with the posterior or peripheral isolated and visible granulomas were usually diagnosed clinically, and enucleation was not performed to confirm the diagnosis. Since then, several other relatively unusual forms of ocular *Toxocara* have been described and these are briefly discussed later. Association of *T. canis* and diffuse unilateral subacute neuroretinitis will be discussed separately in this chapter.

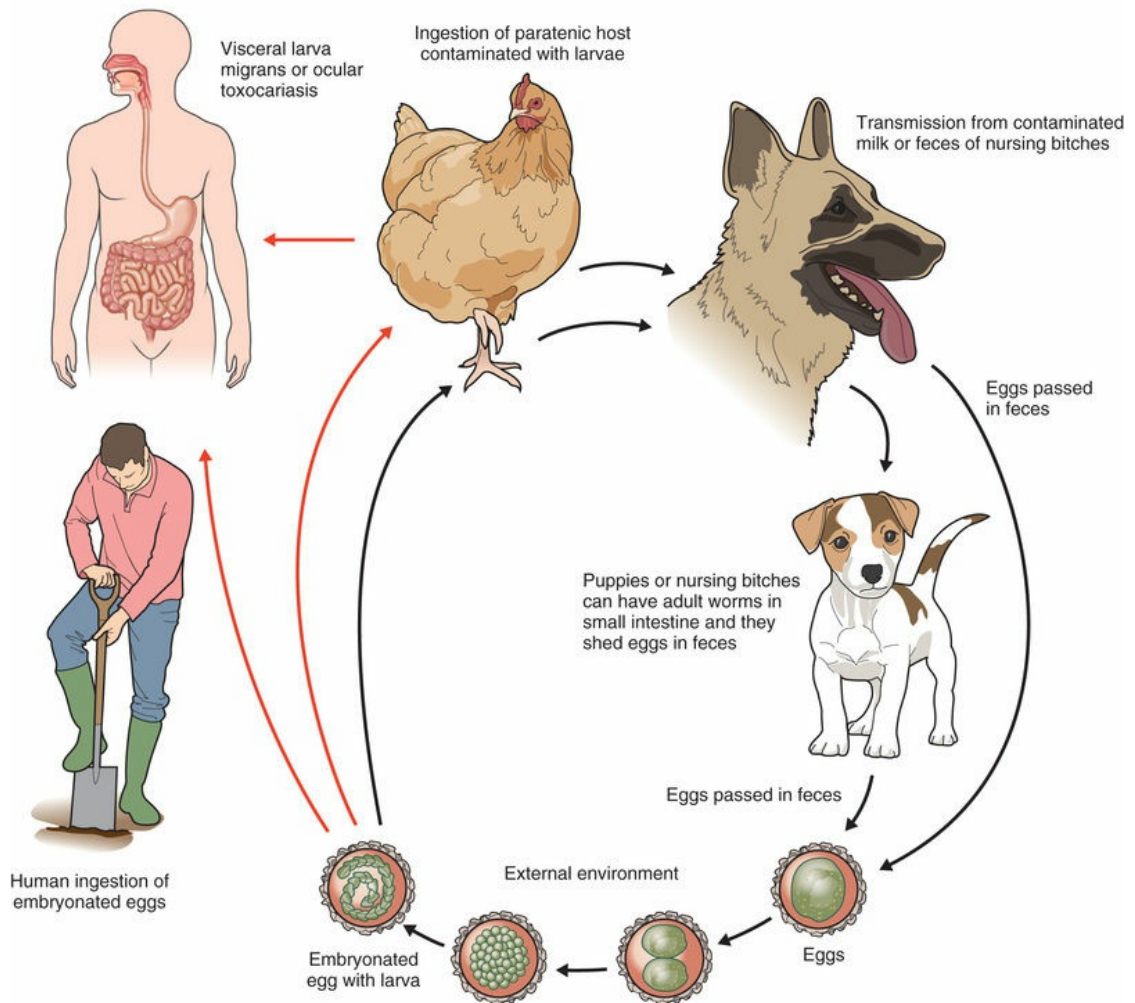

## Parasitology

The *Toxocara* genus comprises 21 species, including *T. canis* which is the most common cause of toxocariasis.<sup>3,5,6,20</sup> *T. canis* is a natural parasite of dogs and occasionally can infest human and other

paratenic hosts such as rodents and rabbits.<sup>21</sup> Adult worms are cylindrical and long, measuring from 75 to 120 mm. Male worms are longer than females and in their development undergo five different stages from larvae to adult parasite.<sup>20</sup> Adult forms are found only on the small intestine of puppies until 6 months of age (definitive host) and pregnant and lactating bitches. In older dogs and humans the cycle is not complete, and because of this only the definitive host where worms reach sexual maturation can shed eggs in feces. To understand the pathogenesis of *T. canis* and the development of VLM and ocular toxocariasis it is necessary to understand the parasite life cycle.

Eggs lacking an embryo are shed in the feces of the definitive host (puppies). The eggs then develop an embryo and become infective in the environment in 2–6 weeks. Following ingestion by dogs or other parasite hosts, the infective eggs hatch and larvae penetrate the intestine wall and are carried by the circulation to a wide variety of tissues (liver, heart, lungs, brain, muscle, eyes). In the human and in adult dogs, this completes the life cycle, and the parasites are usually enclosed by an inflammatory granulomatous response that is primarily eosinophilic, although the larvae may remain viable for years under such conditions.<sup>3,5,22,23</sup> During pregnancy, the host response in the infected bitch is altered, and previously encysted larvae may resume migration,<sup>23</sup> crossing the placenta and affecting the canine fetus. In puppies, larvae reaching the lungs are coughed up and swallowed and, reaching the small intestine, they quickly mature into adult worms that produce infectious ova that are passed in fecal material. Prenatal infection is the primary route of transmission to puppies; however, they can become infected after birth by ingestion of milk or feces from an infected nursing bitch.<sup>6,22</sup> The infection rate in puppies may approach 100%,<sup>24,25</sup> and they start to shed over 200,000 eggs per day in feces from 3 to 6 weeks after initial infestation and may shed eggs until they are about 6 months old when the mature worms die<sup>20</sup> (Fig. 89.1).

**FIG. 89.1** Life cycle of *Toxocara canis*. Parasites mature and complete their cycle of life in puppies and pregnant bitches. Embryonated eggs are shed in feces and they mature in the external environment. Humans become infested by ingestion of embryonated eggs from contaminated soil or larvae from paratenic hosts. Larvae are disseminated to organs originating visceral larva migrans or ocular toxocariasis.

## Pathophysiology

Humans can be infested by ingestion of embryonated eggs or larvae. Eggs can be ingested accidentally after contact with puppies or by geophagia of soil containing embryonated eggs.<sup>26-28</sup> Outdoor parks and playgrounds (sandboxes) can be highly contaminated with embryonated eggs of *Toxocara*, since in this environment people routinely walk their pets.<sup>29-33</sup> Under optimal conditions

embryonated eggs may remain viable for years.<sup>34</sup> Direct contact with untreated puppies is also an important form of transmission. Amaral et al. have shown that perianal hair from stray as well as owned dogs had embryonated eggs in 24% of cases, and 99% of the total number of eggs were found in puppies.<sup>25</sup> A less frequent method of transmission is the ingestion of larvae from contaminated meat. Several studies described infection by eating raw meat or liver from animals such as cows, chicken, and ducks.<sup>35-37</sup>

After ingesting embryonated ova, the parasites mature in the small intestine and transform to second stage larvae which penetrate the intestine wall, enter the lymphatic and portal circulation, and are disseminated to liver and lungs. Then the larvae reach the heart and are disseminated to other organs such as brain, kidney, heart, muscle, and eyes.<sup>20</sup> In human beings the parasites are enclosed by an inflammatory granulomatous reaction and the parasites do not evolve further.<sup>22</sup> The eosinophilic granuloma comprise the larva enveloped by a central core of eosinophils surrounded by mononuclear cells, histiocytes, epithelioid cells, and giant cells. Because of the inability of the parasite to mature into an adult form in humans, a search for *T. canis* ova in human feces is inevitably unrewarding.<sup>38</sup>

*T. canis* can cause either VLM or ocular toxocariasis, and the clinical manifestation depends on factors such as host immunologic condition, inflammatory response, number of eggs/larvae ingested, frequency of ingestion, and localization of the second stage larvae in human tissues.<sup>20</sup> A large amount of ingested embryonated eggs may lead to a rapid increase in eosinophilia and rising antibody levels.<sup>20</sup> One study has shown that the degree of systemic eosinophilia in VLM has been correlated with level of exposure to *Toxocara* larvae.<sup>39</sup> A lower exposure to embryonated eggs may produce lower levels of antibodies and eosinophilia and may permit wider larval migration, reaching the eye.<sup>20</sup> Intraocular involvement by *T. canis* tends to occur in young patients, but in individuals who have developed ocular toxocariasis the age of onset is usually older than patients with VLM.<sup>7,13,22,40</sup> Mean age of presentation for systemic VLM is 2 years<sup>5</sup> versus 7.5 years for ocular toxocariasis.<sup>11</sup>

## Clinical Presentations

Although the average age of presentation is around 8 years for ocular toxocariasis,<sup>5,11</sup> the age at presentation may range from 2 to 30 years,<sup>11,41</sup> and individual cases have been reported in adults with age up to 62 years.<sup>41,42</sup> *Toxocara canis* infection in adults and very young children is rare, probably because of better hygiene habits of adults and less contact with puppies, sandboxes, and geophagia.

The ocular involvement is typically unilateral, and bilateral disease is quite rare.<sup>20,43</sup> Patients usually present with unilateral visual impairment, leukokoria, and/or strabismus in a relatively quiet eye. Careful slit-lamp examination can show cells in the anterior chamber (73%) and vitreous (100%),<sup>44</sup> and vitritis causing decrease in visual acuity was reported in 53% in one series.<sup>9</sup>

Based on ophthalmoscopic findings, ocular toxocariasis can be classified into these categories: peripheral granuloma, posterior pole granuloma, chronic endophthalmitis, or atypical presentations.

The presence of a retinal granuloma is the most common finding in ocular toxocariasis. Wilkinson and Welch,<sup>19</sup> in a study with 41 eyes diagnosed with the disease, reported that a peripheral granulomatous mass with relatively clear media was the most common form of presentation, being seen in 18 of 41 (44%) cases. Stewart et al.,<sup>9</sup> in 2005, described 22 cases of ocular toxocariasis, and in 50% of them peripheral granuloma was diagnosed. However, an isolated posterior pole inflammatory mass was the most common form of presentation in a series of 100 cases reported by Hagler et al.<sup>45</sup> and in 53% of 30 cases published by Oréface and coworkers.<sup>44</sup>

Shields,<sup>7</sup> in a review in 1984, divided ocular toxocariasis into nine different categories, including DUSN.<sup>7</sup> Despite *T. canis* being described as one of the possible nematodes to cause DUSN, other roundworms are also causes of DUSN and therefore the disorder will be discussed separately in this chapter.

### Peripheral Granuloma

The peripheral granuloma, also described as the peripheral inflammatory mass form of *Toxocara* endophthalmitis, is usually seen in a quiet eye with varying levels of decreased vision and strabismus.<sup>19</sup> The vitreous and anterior chamber show mild to

moderate reaction. Intense vitritis can occur; however, at diagnosis the vitreous is generally clear. Peripheral granuloma presents as a dense, white inflammatory mass in the periphery of the retina. Localized traction on the retina may result in the production of a typical retinal fold from the periphery to the optic nerve (Fig. 89.2). This mass may be quite localized, spherical, and similar to those observed in the posterior pole. Fibrocellular bands may be observed running from a peripheral inflammatory mass to the more posterior retina or the optic nerve (Fig. 89.3). The prognosis in eyes with peripheral granulomatous inflammation is usually relatively good and visual acuity can be preserved. By the time this diagnosis is made, active inflammation is usually not progressive.<sup>19</sup> Ultrasound biomicroscopy study of 15 eyes with peripheral toxocariasis has shown alterations such as vitreous membranes in 86.6%, granuloma in 73.3%, pseudocysts in 53.3%, and thickening of ciliary body in 40% of studied eyes.<sup>46</sup> Intraretinal and epiretinal traction bands can lead to production of both traction and rhegmatogenous retinal detachments, macular displacement and distortion, and optic nerve dysfunction.

**FIG. 89.2** Peripheral granuloma. Composite fundus photography showing peripheral granuloma (white mass) and retinal fold towards optic nerve head. There

is hyperpigmentation of surrounding retinal pigmented epithelium and macular displacement inferiorly.

**FIG. 89.3** Fibrocellular bands running from a peripheral granuloma to the optic nerve head (*arrow*).

## Posterior Pole Granuloma

Posterior pole granuloma presents as white or gray spherical intraretinal or subretinal granuloma affecting the posterior pole. Most of the time it is diagnosed in a cicatricial stage when the lesion appears as a well-defined subretinal mass, measuring from 500 to 3000  $\mu\text{m}$ , with no hemorrhage or exudates. Traction bands running from the mass to the surrounding retina may be observed. With cicatricial granulomas, there is very mild or no anterior chamber reaction and a low amount of cells in the vitreous cavity.

Perilesional retina can show hyperpigmentation of retinal pigmented epithelium (RPE) and wrinkling of internal limiting membrane (Fig. 89.4). An optical coherence tomography case report has shown that the granuloma presents as a well-defined subretinal mass above the RPE (Fig. 89.5).<sup>47</sup> Active disease can show different stages of severity from mild anterior chamber and vitreous reaction

to a very intense vitritis, as seen in the chronic endophthalmitis form of the disease. During the active phase the posterior pole granuloma is observed as an ill-defined hazy mass surrounded by retinal exudates or hemorrhages.<sup>19,20</sup> A granuloma is usually seen in the posterior pole temporal to the optic nerve head; however, the occurrence of optic nerve granuloma has been described.<sup>48</sup> Due to posterior pole involvement, patients present with central visual impairment and can have strabismus and leukokoria. Macular lesions may be observed in association with peripheral inflammatory masses, and choroidal neovascularization may occur as a late complication.<sup>45,49,50</sup>

## Chronic Endophthalmitis

Patients with chronic endophthalmitis are typically younger than those with more localized granulomatous forms of the disease. There is usually relatively clear media.<sup>19</sup> Localized granulomatous forms may be a late presentation of an acute form of the disease that had healed without development of retinal detachment or phthisis bulbi. As the vitreous clears it is possible to visualize the retinal lesions.<sup>19</sup> The history is usually negative for trauma, intraocular surgery, or bacterial and fungal endophthalmitis. However, a history of playing in sandboxes in public places and geophagia may be obtained.<sup>19,27,28</sup> External inspection usually reveals a quiet eye, but severe intraocular inflammation can be present. In such cases leukokoria may be seen. Patients present with anterior chamber reaction that can vary from moderate to intense granulomatous reaction and can lead to hypopyon and posterior synechiae. The vitreous shows dense cellular infiltration with hazy media that can clear or develop cyclitic membranes, retinal traction, and detachment that can be diagnosed ultrasonographically.<sup>51</sup> If vitreous clears, a localized granuloma can be seen. The prognosis in this form of endophthalmitis depends primarily on the degree of intravitreal organization and the development of complications such as retrolental membranes, cataract, glaucoma, retinal detachment, and phthisis bulbi.

## Atypical Presentations

Atypical forms of ocular toxocariasis have been reported. Most of

them had a presumed diagnosis. These include optic nerve granuloma and optic neuritis;<sup>48</sup> motile subretinal nematode,<sup>52</sup> which more recently many consider to be an early phase of DUSN; diffuse chorioretinitis;<sup>7</sup> conjunctivitis; keratitis; and lens involvement, including motile intralenticular larva and cataract.<sup>7,22</sup>

## Diagnosis

Definitive diagnosis of ocular toxocariasis is obtained by means of histologic demonstration of the larva or fragments of it in affected tissues. This evaluation is rarely performed, and clinical signs, epidemiology (age, geophagia, contact with puppies, playing in sandboxes), imaging, and serologic tests are sufficient to permit the diagnosis despite the fact they do not confirm the presence of the parasite. Clinical presentation of localized granuloma in the periphery and posterior pole are very typical in many cases and a presumed diagnosis is made. In cases of chronic endophthalmitis when fundus examination is not possible due to media opacification, specific ancillary tests such as ultrasonography or CT scan can help in establishing the differential diagnosis.

The enzyme-linked immunosorbent assay (ELISA) is the current serum test of choice to detect exposure to *T. canis*.<sup>7</sup> Intraocular fluids (aqueous humor, vitreous) can also be used to detect antibodies in a suspected case of ocular toxocariasis with a negative serum ELISA test.<sup>7,41,53</sup> The ELISA test employs antigens secreted by the second-stage larva and recombinant antigens have been produced from them that add even greater specificity to an already-reliable test (approximately 92%). The ELISA has a reasonably high degree of sensitivity as well (approximately 78%), at a titer greater than 1 : 32.<sup>54</sup> The immunodiagnostic tests used for VLM are not as reliable for ocular toxocariasis, and eosinophil count is not usually increased in these patients. Centers for Disease Control and Prevention consider serum ELISA titers less than 1 : 32 to be insignificant in the diagnosis of systemic toxocariasis<sup>55</sup> but others have stated that a serum titer of 1 : 8 is sufficient to support a diagnosis of ocular toxocariasis if the patient has signs and symptoms compatible with that disorder.<sup>45</sup> A positive test may represent a previous contact with the parasite and it does not

necessarily mean that the patient suffers from either VLM or ocular toxocariasis. Ellis and coworkers have shown that 23% of 333 kindergarten children in rural North Carolina without signs of ocular toxocariasis exhibited a serum titer  $\geq 1 : 32$ , and 32% had a titer  $\geq 1 : 16$ .<sup>55</sup> Prestes-Carneiro and coworkers have shown that 14% of 182 randomly studied patients in rural São Paulo, Brazil, presented positive ELISA tests for *T. canis*.<sup>56</sup> Thus a positive serum titer cannot be used to confirm absolutely a diagnosis of ocular toxocariasis, although the absence of any serologic evidence of *Toxocara* infestation does not exclude the diagnosis but may assist in reducing the odds of this organism being the cause of ocular disease. Oréface and coworkers studying 30 cases of presumed ocular toxocariasis found a positive ELISA test in 88% of them.<sup>44</sup> Another study has shown that only 45% of patients with clinically diagnosed ocular toxocariasis had titers higher than 1 : 32.<sup>54</sup>

Cytologic study of aqueous humor or vitrectomy samples may also be helpful in confirming the diagnosis of ocular toxocariasis. The presence of eosinophils in intraocular fluids is consistent with intraocular *Toxocara*. Remnants of *Toxocara* organisms have occasionally been recovered from vitrectomy specimens obtained at surgery.<sup>57</sup>

## Differential Diagnosis

Differential diagnosis of ocular toxocariasis includes retinoblastoma, toxoplasmosis, other causes of endophthalmitis and uveitis, retinopathy of prematurity, Coats disease, persistent hyperplastic primary vitreous, and familial exudative vitreoretinopathy. In localized granulomas with clear media, diagnosis can be determined by clinical evaluation (indirect binocular ophthalmoscope). In eyes with severe vitreous opacification, it may be impossible to make the appropriate diagnosis on the basis of morphologic features alone and considering the differential diagnosis is important.

## Retinoblastoma

Retinoblastoma is the most common intraocular malignancy of childhood and also the most important entity frequently confused

with ocular toxocariasis.<sup>7</sup> The first report of nematode intraocular endophthalmitis by Wilder<sup>13</sup> included enucleated eyes for suspicion of intraocular retinoblastoma. Shields and coworkers<sup>58</sup> reported that among 500 consecutive patients referred to them with leukokoria, 42% had pseudoretinoblastoma and among them 15.6% had a final diagnosis of ocular toxocariasis. Patients with retinoblastoma are usually diagnosed before 2 years of age, being younger than a typical child with ocular toxocariasis. Sporadic retinoblastomas are more frequently confused with ocular toxocariasis since most of them are unilateral, and lack a family history of the malignancy. On ophthalmic evaluation, retinoblastoma usually does not present signs of intraocular inflammation, with clear vitreous and lack of posterior synechiae, cataract or cyclitic membranes, and the tumor presents a growing pattern that does not occur in toxocariasis granulomas.<sup>7</sup> In cases with opaque media the differential diagnosis is harder. Ultrasonography and CT scan may be very valuable in demonstrating an intraocular mass and calcifications of a retinoblastoma or vitreous organization and tractional membranes, which is more frequently observed in ocular toxocariasis. In cases where the differential diagnosis is difficult, evaluation of intraocular fluids by ELISA or cytology may be of particular importance. If retinoblastoma is suspected, however, biopsy should be avoided and consultation with other experts may be a better path to reliable diagnosis. Risks and concerns relating to sampling retinoblastoma tissue are discussed in the oncology section of this book.

## **Toxoplasmosis**

The typical lesion seen with protozoal *Toxoplasma gondii* infection is focal granulomatous and necrotizing retinochoroiditis. It appears as a whitish or yellowish lesion, slightly elevated and with poorly defined limits.<sup>20</sup> During active disease, severe vitritis frequently occurs and in this case a differential diagnosis with chronic endophthalmitis caused by *Toxocara* can be very difficult. Ultrasonographic study can show vitreous membranes and an elevated mass that are more common in toxocariasis. Serologic studies of antibodies to both parasites can be helpful in establishing differential diagnosis.

## Other Forms of Endophthalmitis and Uveitis

Bacterial endophthalmitis is frequently related to a recent history of trauma or intraocular surgery. These acute infections produce much more intraocular inflammation than a typical toxocariasis case.

Endogenous endophthalmitis is rare, but an indolent infection may be nearly impossible to distinguish from nematode endophthalmitis. In such cases, laboratory diagnostic methods may be of value in determining the etiology. Pars planitis or chronic cyclitis is a condition that typically occurs in an older age group than that in which ocular toxocariasis occurs. Hogan and coworkers<sup>59</sup> described a case of pars planitis in which subsequent histologic examination demonstrated that the etiology was *T. canis*.

## Retinopathy of Prematurity

Patients with retinopathy of prematurity (ROP) have a positive history of prematurity and low birth weight, which is not common in ocular toxocariasis. ROP is usually diagnosed soon after birth, and nontreated patients can develop cicatricial signs such as high myopia, temporal macular dragging, peripheral retinal folds, and, in more severe disease, ROP stage V (retrolental fibroplasia). ROP affects both eyes while ocular toxocariasis is almost always unilateral. Morphologic features of ROP may be very similar to those of peripheral cicatricial ocular toxocariasis. In both conditions a peripheral white retinal mass may be associated with a fold of retina extending from the posterior pole to the granuloma.

## Coats Disease

Coats disease is a unilateral condition that affects predominantly young males in the same age group as does toxocariasis.

Ophthalmoscopic and fluorescein angiographic evaluation show classic intraretinal telangiectatic vessels with association with yellow intraretinal and subretinal exudates. In later stages retinal detachment may be present and the differential diagnosis with ocular toxocariasis may be more difficult. In Coats disease vitreous shows no signs of marked inflammation and epiretinal membrane formation is not seen.

## **Persistent Hyperplastic Primary Vitreous**

Persistent hyperplastic primary vitreous (PHPV) is a congenital condition usually diagnosed within the first few weeks of life and presents itself almost always unilaterally. PHPV presents frequently with a retrolental fibrovascular mass that may be confused with toxocariasis. The involved eye is typically microphthalmic, and this feature is not common in ocular toxocariasis.

## **Familial Exudative Vitreoretinopathy**

Familial exudative vitreoretinopathy is an inherited disorder with typically bilateral occurrence. This disorder is associated with peripheral vascular abnormalities, pronounced exudation, vitreoretinal traction, and folds of retina extending from the posterior pole to a peripheral type of mass.

## **Treatment**

Most ocular toxocariasis cases are diagnosed when there is a focal granuloma but no longer vitreous or surrounding active inflammation. In such cases treatment with anthelmintics or corticosteroids is not helpful and surgical treatment is considered when there is clinical cataract, vitreous membranes or opacification, or in cases of retinal detachment.

Medical therapy should be considered in cases of active inflammation. Topical and systemic corticosteroids are useful in managing acute inflammatory reaction and may reduce vitreous opacification and reduce or prevent membrane formation.<sup>7,19,48,60,61</sup> Topical mydriatics may prevent posterior synechia and secondary angle closure secondary to seclusio pupillae.<sup>20</sup> The exact role of anthelmintic therapy in ocular toxocariasis remains unclear and it is not proven that the use of this therapy can kill intraocular larva.<sup>7</sup> Despite this, the use of anthelmintic drugs or combination of them with corticosteroids has been reported with favorable results.<sup>52,62</sup> Anthelmintic drugs such as thiabendazole and diethylcarbamazine have been recommended in selected cases of VLM,<sup>60</sup> and nowadays albendazole is the current drug of choice in the treatment of VLM,<sup>30</sup> showing its superiority over thiabendazole.<sup>63</sup> For the treatment of VLM currently recommended therapy is albendazole 400 mg twice

a day for 5 days.<sup>64</sup> Treatment of ocular disease was described as a dose of 200 mg albendazole twice a day for one month.<sup>20</sup> If a subretinal larva is observed it can be destroyed with photocoagulation.<sup>7</sup> Intravitreal ranibizumab has been described to treat choroidal neovascularization secondary to ocular toxocariasis.<sup>65</sup>

Ocular surgery is indicated mainly in cases of ocular toxocariasis with retinal detachment<sup>43,66,67</sup> and pars plana vitrectomy is the preferred technique, allowing release of membrane traction and retinal reattachment in more than 70% of cases in some series.<sup>45,67,68</sup> Other indications for surgery include management of vitreous opacification, cataract, and glaucoma. Hagler and coworkers<sup>45</sup> reported 17 consecutive cases of retinal detachment secondary to ocular toxocariasis. In this report the retina was successfully reattached in 12 (71%) cases, and vision remained stable or improved in 15 (88%) of the 17 eyes. Small et al.<sup>67</sup> reported 12 cases of retinal detachment with a postoperative reattachment after vitreous surgery in 10 (83%), and visual acuity improved in 7 (70%) of the anatomic successes. Recently Giuliani and coworkers<sup>68</sup> presented 45 cases treated surgically for complicated ocular toxocariasis. Pars plana vitrectomy was the technique of choice in 58% of the cases, 38% had peripheral granuloma, and postoperative visual acuity was equal or better than 20/300 in 60% of the eyes studied.

The most important approach to the management of ocular toxocariasis and VLM is prevention, decreasing the risk of ingestion of *T. canis* embryonated eggs or larvae. Effective measures include anthelmintic treatment of newborn puppies, as well as nursing and lactating bitches after each pregnancy; hygienic disposal of dog feces; avoiding contact of children at risk with potentially contaminated animals; avoiding eating raw meat of possible hosts; stopping children from playing in sandboxes in places where people walk their dogs; and improving hygiene habits in children, among others.

## **Diffuse Unilateral Subacute Neuroretinitis**

DUSN is an ocular disease caused by the presence of a nematode worm in the subretinal space. The disease affects predominantly children and young adults and often causes unilateral severe visual loss. In the acute stage it presents with an appearance of subacute retinitis, optic disc swelling, and mild to moderate vitritis, while in late stages there is retinal and optic disc atrophy, retinal vessel narrowing, and severe visual impairment.

## History and Etiology

In 1978 Gass and Scelfo first described a clinical syndrome in which only one eye of a healthy child or young adult was affected.<sup>69</sup> Features of the syndrome include insidious, usually severe loss of peripheral and central vision; vitritis; diffuse and focal pigment epithelial derangement with relative sparing of the macula; narrowing of the retinal vessels; optic atrophy; increased retinal circulation time; and subnormal electroretinographic findings.<sup>69</sup> Initially the syndrome was termed “unilateral retinal wipeout syndrome.” Later, after recognition of signs of acute stages of the disease, the syndrome was named diffuse unilateral subacute neuroretinitis. The nematodal etiology of the syndrome was not yet clear, but from 36 patients reported, two revealed the presence of a subretinal worm at fundus examination, and both larvae were suspected to be from the *Toxocara* genus.<sup>69,70</sup> Later, in 1983, Gass and Braunstein described two different-sized nematodes causing the disease and postulated that the cause was probably not *T. canis*. The geographic distribution of both was different, and the smaller worm (from 400–1000  $\mu\text{m}$  in length) was proposed to be a larva of *Ancylostoma caninum*, while the larger one (from 1500 to 2000  $\mu\text{m}$  in length) remained uncertain.<sup>71</sup> One year later, Kazacos and coworkers suggested that the larger larva previously described<sup>71</sup> was *Baylisascaris procyonis*, an intestinal nematode of raccoons and squirrels associated with central nervous system infections.<sup>72,73</sup> Association of DUSN and neural larva migrans has been reported, and indirect immunofluorescence assays on serum and cerebrospinal fluid of one patient were positive for *B. procyonis*.<sup>74</sup> Other case reports of DUSN with confirmed serologic evidence of *B. procyonis* infestation were reported and support its etiology as the

larger nematode to cause DUSN.<sup>75,76</sup>

The exact etiology of the smaller larva remains unclear. Despite the first impression of the larvae being *Toxocara*,<sup>70</sup> later Gass and Braunstein<sup>71</sup> opined that *T. canis* might not be the cause of DUSN due to lack of consistent serologic evidence, the length of second-stage larva of *T. canis* being smaller than the small worm described, the clinical features being different than other forms of ocular toxocariasis, and the worldwide prevalence of *T. canis* not fitting with the limited distribution of DUSN. Gass theorized that *A. caninum*, a common parasite of dogs, could be the causative agent because it is a frequent cause of cutaneous larval migrans in the southeastern United States, its infective third-stage larva measures approximately 650  $\mu\text{m}$ , it can survive in host tissues for months to years without changing size or shape, and cutaneous larval migrans had immediately preceded the onset of DUSN in some patients.<sup>77</sup> Casella and coworkers<sup>78</sup> also described cases of DUSN and cutaneous larva migrans, reinforcing that *A. caninum* could be a probable cause of the disease in Brazil. Cunha de Souza and Nakashima<sup>79</sup> successfully extracted a subretinal worm in a 9-year-old Brazilian boy through a retinotomy after pars plana vitrectomy. This larva was morphologically similar to third-stage *T. canis* based on length of body and esophagus, tapered tail, and mouth shape. *Toxocara canis* causes visceral larva migrans and *A. caninum* causes cutaneous larva migrans, and there is evidence that both can be related to DUSN; thus confirmation of one as causative agent does not necessarily exclude the other as a possible cause. Cases of DUSN caused by non-nematode worm were reported by McDonald and coworkers. In such cases the larva related to DUSN was *Alaria mesocercaria*, a trematode worm.<sup>80</sup> Despite this report, nematodes are described as the main etiologic factors in DUSN. Among them, some filariae, such as *Dirofilaria*,<sup>81-83</sup> have been proposed to cause the disease, but *B. procyonis* as the large worm and *A. caninum* and/or *T. canis* as the small worms are the most probable etiologic factors.

## Epidemiology

DUSN is an endemic disease in the southeastern United States

where the smaller worm (400–1000  $\mu\text{m}$ ) is most often seen and in the northern-midwestern part of the country where the larger worm (1500–2000  $\mu\text{m}$ ) is mostly related to the disease.<sup>71,77</sup> Its occurrence has been described also in the Caribbean,<sup>9</sup> Canada,<sup>84</sup> Germany,<sup>85</sup> Spain,<sup>86</sup> China,<sup>87</sup> and India.<sup>82,83,88</sup> It is endemic in South America, with most cases described in Brazil<sup>78,89–92</sup> and Venezuela.<sup>93</sup> In South America, DUSN is caused by a smaller worm, although in one case report a larger worm was found as the etiologic factor (Fig. 89.6).<sup>94</sup>

**FIG. 89.6** Subretinal large nematode (A). Retinal aspect after photocoagulation of the nematode (B).

DUSN typically affects healthy patients in the second and third decades of life,<sup>69,71</sup> with a higher incidence in the male gender. In the typical disease only one eye is affected and a single motile subretinal nematode can be identified. Cases of nematodes infesting both eyes<sup>91</sup> or two nematodes infesting the same eye<sup>85</sup> are less frequently reported.

## Pathophysiology

The complete pathophysiology of DUSN is not clearly determined, but it is presumed that DUSN develops as a local reaction of outer

retina to toxic products released by subretinal worm.<sup>69</sup> These products would also produce a toxic reaction to inner retina. Through the years there is a progressive loss of ganglion cells, secondary arterial narrowing, and optic atrophy.<sup>78</sup> Gass and Scelfo<sup>70</sup> reported histopathologic findings from one eye of a patient with clinical evidence of DUSN. Histopathologic analysis has shown a nongranulomatous vitritis, retinitis, and retinal and optic nerve perivasculitis. An extensive degeneration of the peripheral retina, mild degeneration of the posterior retina, retinal pigmented epithelium (RPE), choroiditis, and mild optic nerve atrophy were also observed. There was no eosinophilic reaction as usually seen in the typical granuloma of ocular toxocariasis. Histopathologic data were not sufficient to explain severe visual loss in this case (light perception), which contributed to speculation about the role of functional mechanisms in causing visual damage such as an inflammatory and/or toxic aggression towards retinal bipolar cells.<sup>95</sup> Recently Gomes and coworkers<sup>96</sup> and Casella and coworkers<sup>97</sup> described two case series of patients with DUSN studied by means of time domain optical coherence tomography (OCT). In both series the OCT main finding was diffuse atrophy of the retinal nerve fiber layer. Berbel et al. described normal choroidal thickness despite retinal atrophy measured by spectral domain OCT with enhanced depth imaging.<sup>98</sup> The variability of the inflammatory signs and tissue damage seen in patients with the disease may reflect differences in host immune response to the organism or the characteristics of the nematode itself.<sup>99</sup>

## Clinical Presentation

Clinical features of DUSN can be divided into early and late stages.

### Early Stage

Most patients with DUSN are asymptomatic or have mild symptoms in this stage of the disease.<sup>91</sup> Main symptoms include central or paracentral scotoma, floaters, mild to moderate visual loss, and ocular discomfort.<sup>70</sup> Signs include afferent pupillary defect; mild to moderate vitritis; optic disc swelling; vasculitis; and/or narrowing of retinal vessels. Less frequently, posterior

segment signs include retinal and subretinal hemorrhages, serous exudation, and choroidal neovascularization.<sup>70</sup> The anterior segment is typically calm, although occasionally anterior uveitis may be present. The most characteristic retinal finding is the presence of recurrent crops of evanescent, multifocal, gray-white or yellow lesions at the level of the outer retina (Fig. 89.7). These active lesions are typically clustered in posterior pole, and the larva may be found in the surrounding area.<sup>77</sup> These lesions disappear in 1–2 weeks as the worm moves to other retinal area. Less than 1% of the lesions can lead to a focal chorioretinal scar that simulates that seen in the presumed ocular histoplasmosis syndrome.

**FIG. 89.7** Early stage presumed DUSN. Fundus photographs showing typical retinal finding: crops of multifocal, gray-white, or yellow lesions at the level of the outer retina. (Courtesy of Fernando Oréface, MD and Editora Cultura Médica.)

## Late Stage

Frequently in children, visual loss is insidious, and the patient comes to medical attention during the late stages of the disease.<sup>99</sup> If the nematode is not recognized and the condition is not treated, the disease evolves to its late stage. Main symptoms include a dense central or paracentral scotoma and severe permanent visual loss, while signs include an afferent pupillary defect in the affected eye, progressive optic atrophy, narrowing of the retinal arteries, and marked focal and/or diffuse degenerative changes in the RPE. The nematode may survive for 4 years or longer and may be found in

the subretinal space even after the development of retinal and optic disc changes<sup>99</sup> (Fig. 89.8).

**FIG. 89.8** (A) Arrow indicates the location of a subretinal nematode in the macular region. This case represents a late stage of DUSN with optic disc pallor, retinal pigmented epithelium changes, and vascular narrowing. (B) Same eye after photocoagulation of the nematode. (Courtesy of Arnaldo Cialdini, MD.)

## Diagnosis

Definitive diagnosis of DUSN is based on identification of subretinal nematode after observation of clinical aspects that raise suspicion of the disease. Indirect ophthalmoscopy is important in making the correct diagnosis and in locating the cluster of active gray-white outer retinal lesions. These lesions are typically found in acute stages of the disease and, if they are present, the nematode will usually be found biomicroscopically in their vicinity.<sup>99</sup> If these lesions are absent, a detailed search of the entire fundus using a contact lens may locate the worm (Fig. 89.9). The rates of nematode identification in previous studies has varied from 33% to 52%.<sup>93,96,100</sup> A case report has shown that scanning laser ophthalmoscopy enhances contrast between the nematode and the ocular fundus and improves visualization and location of a moving worm.<sup>101</sup> In cases in which nematode is not located on fundus examination, a presumed diagnosis is established based on clinical findings, epidemiology, and ancillary exams.

**FIG. 89.9** Red-free retinography showing subretinal nematode (*arrow*) located on nasal-inferior retina.

Fluorescein angiography (FA) findings are different in acute and late stages of DUSN. During the early stages of the disease FA shows leakage of dye from the optic nerve head and perivenous phlebitis.<sup>70</sup> The active gray-white lesions exhibit early hypofluorescence and hyperfluorescence with staining in late phases of the angiogram. The aspect of the lesions on FA is very similar to the fluorescein pattern found in other white dot syndromes; however, in multiple evanescent white dot syndrome (MEWDS) the lesions are hyperfluorescent on early angiogram. In early stages of the disease there are also minimal changes in RPE and cystoid macular edema may occur. In late stages of DUSN, FA shows diffuse hyperfluorescence from RPE window defects and delay in retinal perfusion (Fig. 89.10). Indocyanine green angiography (ICGA) shows multiple small round hypofluorescent lesions that persist during all angiograms. Their aspect is similar to lesions found in birdshot chorioretinopathy.<sup>102</sup>

**FIG. 89.10** Fluorescein angiography performed in a late stage of DUSN, showing diffuse hyperfluorescence from retinal pigmented epithelium window defects and delay in retinal perfusion.

The electroretinogram (ERG) may be normal in the very early stage of the disease, however it typically varies from subnormal to severely decreased as the retinopathy progresses. During all stages of the disease the b-wave is more affected than the a-wave, possibly due to a toxic effect of the nematode and its products to retinal bipolar cells.<sup>95</sup> Rarely the ERG is extinguished<sup>70,71</sup> and the unaffected eye presents normal ERG. Eradication of the nematode in one case resulted in improvement in multifocal ERG amplitudes.<sup>103</sup>

OCT shows diffuse retinal thinning and diffuse retinal nerve layer atrophy.<sup>96,97</sup> Casella and coworkers also described focal retinal edema in areas affected by the worm and have shown the topography of subretinal worm by means of OCT<sup>97</sup> (Fig. 89.11). Gomes et al., studying 38 patients with DUSN, described statistical significance between retinal nerve fiber thickness and worse visual acuity.<sup>96</sup>

**FIG. 89.11** (A) Color fundus photograph showing subretinal nematode (*arrow*). (B) Optical coherence

tomography showing retinal atrophy and nematode in subretinal space (*arrow*). (Images courtesy of Antônio Marcelo

Casella, MD.)

Serologic studies, stool examinations, and peripheral blood smears are of little value in making the diagnosis of DUSN.<sup>70</sup> Toxocaral and *B. procyonis* antibody titers have been suggested as diagnostic tools to try to characterize which nematode is producing the disease.<sup>72</sup> Recent study showed that ELISA cross-reactivity between them may be present and suggests a Western blot analysis to complete serologic differentiation between *Toxocara* and *Baylisascaris* as cause of larva migrans.<sup>104</sup> ELISA test has been also used for serologic characterization of cutaneous larva migrans caused by *A. caninum*.<sup>105</sup>

## Differential Diagnosis

DUSN can mimic several other chorioretinal diseases.<sup>77</sup> The disease presents differently in early and late stages and the differential diagnosis will be described separately for better comprehension.

In the early stages of DUSN, the typically seen gray-white lesions can mimic many other infectious and inflammatory conditions (Fig. 89.7). In DUSN, typical lesions occur in outer retina and after healing they normally present few or no RPE scars. In other infections such as toxoplasmosis, cytomegalovirus, and bacterial or fungal retinitis generally the inner retina is affected and there is prominent chorioretinal scarring left in the area of the retinitis. DUSN may also mimic white dot syndromes such as acute posterior multifocal placoid pigment epitheliopathy (APMPPE), serpiginous choroiditis, MEWDS, multifocal choroiditis with panuveitis (MFC), and birdshot chorioretinopathy.<sup>102</sup> These entities are discussed in other chapters in more detail. Briefly, unlike DUSN, the active lesions in APMPPE and serpiginous choroiditis are accompanied by loss of visual acuity only when the lesions involve the center of the fovea, and they always cause permanent visible alterations in the pigment epithelium. APMPPE and serpiginous choroiditis occur in adults and are generally bilateral. In APMPPE, the electro-oculogram may be abnormal but the ERG is normal, and visual prognosis is good. Serpiginous choroiditis has a

worse prognosis than APMPPE and electrophysiologic tests are normal. MEWDS occurs in young adults; it is more frequent in women and may be distinguished from DUSN by a frequent history of an antecedent flu-like illness and photopsia, widely scattered gray-white outer retinal lesions, an enlarged blind spot, hyperfluorescent dots seen from the early phases of fluorescein angiography (in DUSN lesions are initially hypofluorescent), a decrease in the ERG a-wave that normalizes as symptoms fade, and return of the fundus and visual function to normal in most patients within several months.<sup>99</sup> Birdshot chorioretinopathy often occurs in middle-aged women, is bilateral, and is frequently associated with positive HLA-A29. Fundus changes include moderate vitritis and multiple scattered yellowish rounded lesions that may resemble DUSN lesions. Fluorescein angiography shows hypofluorescent lesions and may demonstrate active retinovascular leakage along the large retinal vessels, small vessel leakage, and cystoid or diffuse macular edema. Circulation times are often delayed and the vessels empty much more rapidly than in a normal eye.<sup>101</sup> Other uveitis can mimic DUSN. In Behçet disease, the white lesions involve the inner retina and the patient usually has other systemic manifestations of the disorder, including oral and/or genital ulcers, arthritis, and erythema nodosum. Patients with DUSN occasionally may demonstrate perivenous candle-wax-dripping exudate or subretinal exudate similar to that seen in patients with sarcoidosis.<sup>77</sup>

In late stage of the disease after fading of gray-white lesions and development of scattered focal chorioretinal scars, the fundus of patients with DUSN may be mistaken for the presumed ocular histoplasmosis syndrome (POHS). POHS is frequently bilateral, shows normal RPE between the focal scars, presents clear vitreous without inflammatory cells, and there is a lack of optic atrophy and retinal vessel narrowing. Retinitis pigmentosa (RP) is another important differential diagnostic entity. The presence of bone-spicule RPE hyperpigmentation, bilaterality, and posterior subcapsular cataract are common in RP but rare in DUSN.<sup>99</sup> Other causes of optic atrophy may mimic DUSN, such as trauma, retrobulbar or intracranial tumors, and sustained occlusion of ophthalmic artery.

## Treatment

Prompt identification of the early signs of the disease allows treatment that can prevent late manifestations and encourage visual recovery/preservation. Treatment of DUSN can be performed with either photocoagulation of the nematode when it is identified during fundus examination (careful searching often with a contact lens is needed) or systemic anthelmintic drugs when the diagnosis is presumed. Photocoagulation of the subretinal worm is the current treatment of choice (see [Figs. 89.6](#) and [89.8](#)). It causes minimal or no posttreatment exacerbation of inflammation and is successful in causing prompt and permanent inactivation of the disease. Visual acuity improvement depends on the stage of the diagnosis.

Initially the use of oral anthelmintic was considered ineffective,<sup>71</sup> but further studies have shown that thiabendazole is effective in the treatment of patients with a moderate degree of vitritis associated with a breakdown in the blood–retinal barrier.<sup>106–108</sup> Subsequently, ivermectin has been tried as a less toxic alternative to thiabendazole.<sup>109</sup> However, Casella and coworkers reported that ivermectin failed to kill a nematode that was subsequently identified and destroyed with laser photocoagulation.<sup>110</sup> Two studies report case series of successful treatment of DUSN with albendazole<sup>100,111</sup> ([Fig. 89.12](#)). Cunha de Souza and coworkers<sup>100</sup> and Malaguido and coworkers<sup>111</sup> report the use of albendazole 400 mg/daily for 30 days with fading of active lesions and visual recovery. In patients with late-stage DUSN some degree of improvement of vision was observed. No adverse side-effects were observed in both studies, and this therapy has been advocated in cases of presumed DUSN where the nematode is not located.<sup>91,112</sup>

**FIG. 89.12** (A) Color fundus photograph of a 9-year-old boy with unilateral multifocal retinitis diagnosed as presumed early stage of DUSN. (B) Appearance after 45 days. The patient was treated with albendazole 400 mg/day twice a day for 30 days. Visual acuity improved from 20/200 (A) to 20/70 (B).

## Onchocerciasis

Onchocerciasis (river blindness) is caused by the microfilarial stage of the nematode *Onchocerca volvulus*. More than 99% of infected people live in 31 sub-Saharan African countries, but the disease also exists in some regions in Latin America (Brazil, Guatemala, Mexico, and Venezuela) and Yemen.<sup>92,113,114</sup> According to the World Health Organization, onchocerciasis is the world's second leading cause of preventable blindness and its prevalence is estimated at 37 million individuals worldwide.<sup>114,115</sup> The filariae cause dermatitis, subcutaneous nodules due to encapsulation of parasites in fibrous tissue, and eye disease. The disease is transmitted by an insect of the genus *Simulium* (Blackflies) which breed in fast-flowing rivers and streams, lending the name “river blindness.” The vector ingests microfilariae during a blood-meal from a sick human. Then the parasites develop into infectious stages and are transmitted to other persons on subsequent bites. Humans are the only definitive known host.<sup>113</sup>

## Clinical Presentation

Ocular onchocerciasis can involve any part of the eye and disease manifestations are characterized either as posterior or anterior eye disease.<sup>116</sup>

Anterior eye disease prevalence has been described ranging from 43 to 48% of affected individuals in studied populations. The most frequently diagnosed anterior eye disease is the presence of microfilariae in the anterior chamber associated or not with iridocyclitis, followed by punctate epithelial keratitis, corneal microfilariae, sclerosing keratitis, and neovascularization leading to visual impairment and blindness in one or both eyes in 2–4% of patients.<sup>117,118</sup>

Posterior eye disease prevalence ranges from 34% to 75% of affected patients.<sup>117,118</sup> Posterior segment lesions include atrophy of RPE and choroid mainly in the posterior pole, hyperpigmentation clumping of RPE, white and shiny intraretinal deposits, retinitis, subretinal fibrosis, neuritis, and optic nerve atrophy.<sup>117-120</sup> Patients may present with visual field loss and poor night vision, and in patients with hyperpigmentation of RPE a differential diagnosis with retinitis pigmentosa is important. Another important differential diagnostic consideration is hypovitaminosis A, which can cause also night blindness and intraretinal white spots.

## Treatment and Prevention

Through the years the prevalence of ocular onchocerciasis is falling in endemic areas. This fact is due to several task forces of the World Health Organization in Africa and the Americas to reduce vector breeding and also to the treatment of patients with the disease, preventing blindness in affected and contamination of healthy individuals.

Ivermectin is a safe and effective microfilaricidal drug which has been donated by Merck and Company since 1987 to be delivered through mass drug administration programs to control onchocerciasis. Ivermectin rapidly kills the microfilariae and reduces the lifespan of adult worms. This therapeutic scheme is administered twice each year, and the goal of these programs was to treat at least 85% of the population at risk and completely eliminate transmission of the parasite in Africa and America by the

year 2012.<sup>113</sup> By the end of 2011, transmission was interrupted in 10 of 13 active locations throughout Latin America. In 2013 and 2014, respectively Colombia and Ecuador were declared free of river blindness by the World Health Organization<sup>114</sup>. In 2012, approximately 99 million treatments for onchocerciasis were administered in Africa, and the World Health Organization leads a consortium the main purpose of which is complete elimination of onchocerciasis by 2025.<sup>121</sup>

## Cysticercosis

Cysticercosis is the infestation of human tissues by *Cysticercus cellulosae*, the larval form of *Taenia solium*, a common pork parasite that can cause taeniasis in man. The ingestion of contaminated and uncooked meat containing cysticerci leads to development of taeniasis, the infestation of human small intestine by the adult tapeworm of *T. solium* (definitive host). Cysticercosis occurs when the intermediate host (e.g., pork, man) ingests eggs of *T. solium* from contaminated food or water, or by autoinfection of the definitive host when there is accidental ingestion of eggs shed in the host feces.<sup>122,123</sup> The ingested eggs develop into larvae, which penetrate the small intestine wall, reaching lymphatics and vascular system. The larvae then spread to highly vascularized organs such as brain, heart, muscles, and eyes, where they become a cystic structure containing the scolex named cysticercus (metacestode).<sup>124</sup> Cysticerci may remain viable in the ocular and central nervous system for years, and ocular manifestations can be devastating as the cysticercus increases in size or dies releasing toxic products leading to a profound inflammatory reaction, causing blindness in 3–5 years.<sup>125</sup>

## Clinical Presentation

The central nervous system is the most affected system and neurocysticercosis is the most commonly diagnosed form of cysticercosis.<sup>126</sup> Neurocysticercosis is the main cause of acquired seizures worldwide. The disease can also lead to encephalopathy, meningeal signs, obstructive hydrocephalus, and other neurologic

abnormalities.<sup>127</sup> Cysticerci appear as cystic lesions on computed tomography (CT) or magnetic resonance imaging (MRI), and when calcified appear as hyperdense spots on radiographs.

Eyes and adnexal tissues are affected in 13–46% of infected individuals.<sup>122</sup> Cysticerci may be present in virtually all ocular and adnexal structures such as in the eyelids, orbit, extraocular muscles, subconjunctival space, anterior chamber, vitreous and subretinal space.<sup>123,126,128–130</sup> Vitreous and subretinal locations are the most often diagnosed locations of ocular cysticercosis, ranging from 68 to 74% of studied cases, and 41% occurred either subretinally or intraretinally in one series.<sup>122,126</sup> The parasite reaches the eye through posterior ciliary arteries to the subretinal space. A subretinal cysticercus is seen ophthalmoscopically as a cyst in subretinal space containing one scolex that usually presents as a white spot inside the cyst (Fig. 89.13). Associated findings may be observed, such as retinal pigmented epithelium hyperpigmentation, serous retinal detachment, retinal edema and/or hemorrhages, and severe uveitis in later stages (Fig. 89.14). Intravitreous cysticercus presents as a well-defined translucent floating cyst that can produce undulating movement, especially when stimulated by light. Epiretinal membranes or RPE changes in the spot where the parasites traverse the retina may be observed (Fig. 89.15).<sup>124,128,131,132</sup> Ultrasonography may be used to confirm the cystic nature of the parasite, and MRI has been suggested to confirm ultrasonographic findings as well as determine the presence of possible other cysts in orbit or brain.<sup>130</sup>

**FIG. 89.13** Subretinal cysticercus in the posterior pole surrounded by hemorrhage.

**FIG. 89.14** Subretinal cysticercus located in the inferior

retina.

**FIG. 89.15** Intravitreal cysticercus. It is possible to see an epiretinal membrane and pigmented epithelium changes inferiorly. This is the possible site from where the parasite passed from the subretinal space to the vitreous cavity. During vitrectomy it was possible to detect cyst movements as the light pipe was directed to it.

## Treatment

Intraocular cysticercosis is treated with surgical removal.<sup>131-133</sup> Treatment with systemic drugs has not been successful<sup>134</sup> and killing the cyst without removing it might produce severe uveitis. An intravitreal cysticercus can be removed by pars plana vitrectomy, and the subretinal cyst removal can be performed by either vitrectomy or transcleral removal.<sup>131</sup> The cysticercus should be removed unharmed, avoiding its rupture and release of intracystic material in the vitreous cavity; however, there are reports of successful suction of the cyst during vitrectomy with the vitreous cutter,<sup>131,132</sup> and rupture of intravitreal or partial removal of the subretinal cyst during vitrectomy followed by administration of intravitreal and systemic corticosteroids without postoperative significant inflammation.<sup>124,133</sup>

# Endogenous Endophthalmitis

---

## Bacterial and Fungal

*Ajay E. Kuriyan, Stephen G. Schwartz, Janet L. Davis, Harry W. Flynn Jr.*

**Epidemiology and Risk Factors**  
**Clinical Assessment of the Patient**  
**Medical Evaluation of the Patient**  
**Endogenous Bacterial Endophthalmitis**  
**Endogenous Fungal Endophthalmitis**  
**Treatment Strategies**  
    Systemic Pharmacotherapies  
    Intravitreal Pharmacotherapies  
    Surgical Treatments  
**Suggested Management**

## **Epidemiology and Risk Factors**

Endogenous endophthalmitis remains an uncommon but serious

cause of intraocular inflammation.<sup>1</sup> The incidence may be increasing, due to several factors. An increasing number of immunocompromised patients are receiving antineoplastic agents, immunomodulating agents, and newer broad-spectrum antimicrobial agents, all of which may reduce normal flora.<sup>1,2</sup> Low-birthweight premature infants and patients with a history of intravenous substance abuse are at increased risk for endogenous endophthalmitis.<sup>3-5</sup> Other reported risk factors include long-term intravenous line placement, peripheral hyperalimentation, systemic corticosteroids, abdominal surgery, hemodialysis, human immunodeficiency virus (HIV) infection, systemic malignancy, diabetes mellitus, pregnancy or postpartum state, massive systemic trauma, alcoholism, hepatic insufficiency, and genitourinary manipulation.<sup>1,6-9</sup>

A series of 64 cases over 10 years reported a culture positivity rate of 64%. Of culture-positive cases, fungi (predominantly *Candida* spp.) were isolated in 66%, Gram-negative bacteria in 19%, and Gram-positive bacteria in 15%.<sup>10</sup> Fungal cases were generally associated with better visual outcomes.<sup>10</sup> Another study found that among endogenous fungal endophthalmitis cases, better visual outcomes were associated with yeast species (e.g., *Candida* spp.) compared to mold species (e.g., *Aspergillus* spp.).<sup>11</sup>

## Clinical Assessment of the Patient

Infectious endophthalmitis may be categorized by the cause of the infection and by the characteristic timing of clinical signs/symptoms.<sup>12</sup> One proposed categorization scheme is presented in [Box 90.1](#).<sup>13</sup> In general, endogenous endophthalmitis is suspected in a patient without risk factors for exogenous endophthalmitis, such as prior surgery, intravitreal injection, trauma, or keratitis. Patients with endogenous endophthalmitis may present with varying degrees of pain, inflammation, and visual loss. In the anterior chamber, cell and flare, fibrin, posterior synechiae, and hypopyon may occur. In the posterior segment, findings may include vitreous opacification and chorioretinitis, including hemorrhage, cotton-wool spots, retinal opacification, and vasculitis. An insidious onset, focal vitreous opacities, and

chorioretinal infiltrates suggest fungal etiology. Relatively more rapid progression and more severe intraocular inflammation suggest bacterial etiology.

## **Classification of Endophthalmitis and Common Causative Organisms**

Acute-onset postoperative endophthalmitis

Coagulase-negative staphylococci

*Staphylococcus aureus*

*Streptococcus* spp.

Chronic (delayed-onset) postoperative endophthalmitis

*Propionibacterium acnes*

*Candida parapsilosis*

Coagulase-negative staphylococci

Filtering bleb-associated endophthalmitis

*Streptococcus* spp.

*Staphylococcus* spp.

*Haemophilus influenza*

Posttraumatic endophthalmitis

*Staphylococcus* spp.

*Bacillus cereus*

Endogenous endophthalmitis

*Candida albicans*

*Aspergillus* spp.

*Staphylococcus aureus*

Gram-negative organisms

Endophthalmitis associated with microbial keratitis

Gram-negative organisms

*Staphylococcus aureus*

*Fusarium* spp.

Endophthalmitis associated with intravitreal injection

Coagulase-negative staphylococci

*Streptococcus* spp.

---

Adapted from Schwartz SG, Flynn HW Jr, Scott IU. Endophthalmitis: classification and current management. *Expert Rev Ophthalmol* 2007;2:385–96.

Endogenous endophthalmitis may present as a relatively mild and nonspecific anterior uveitis.<sup>14</sup> Early in the clinical course, the clinical features may be subtle, making the diagnosis difficult. The rate of initial misdiagnosis has been reported as high as 63% in one large series.<sup>15</sup> A differential diagnosis of endogenous

**Box 90.2** Endophthalmitis is presented in [Box 90.2](#).

## Differential Diagnosis of Endogenous Endophthalmitis

---

Uveitis

Anterior/intermediate

Pars planitis

Posterior

Vogt–Koyanagi–Harada disease

Posterior scleritis

Sarcoidosis

Syphilis

Tuberculosis

Sympathetic ophthalmia

Intraocular lymphoma

Lyme disease

Tumor necrosis with inflammation

Retinoblastoma

Disseminated toxoplasmosis

Disseminated viral retinitis

Vitreous metastases

Occlusive diseases of the choriocapillaris

Disseminated intravascular coagulation

Thrombotic thrombocytopenic purpura

Asteroid hyalosis

Cases may be classified according to several criteria. One published classification scheme for endogenous bacterial endophthalmitis used zones of anatomic involvement ([Box 90.3](#)).<sup>16</sup> Another scheme, designed for endogenous fungal endophthalmitis, also used anatomic criteria ([Box 90.4](#)); in this series, the stage at initial diagnosis was statistically correlated to the final visual

### **Box 90.3**

## **Anatomic Classification of Endogenous Bacterial Endophthalmitis**

Focal: One or a few discrete foci in the iris, ciliary body, retina, or choroid

Anterior diffuse: Severe generalized signs of inflammation in the anterior segment

Posterior diffuse: Intense inflammatory reaction in vitreous, obscuring the fundus

Panophthalmitis: Severe involvement of anterior segment, posterior segment, and orbital structures

Adapted from Greenwald MJ, Wohl LG, Sell CH. Metastatic bacterial endophthalmitis: a contemporary reappraisal. *Surv Ophthalmol* 1986;31:81–101.

### **Box 90.4**

## **Classification of Endogenous Fungal**

## Endophthalmitis

Stage I: Chorioretinal changes without extension into the vitreous cavity

Stage II: Fungal mass penetrating through the internal limiting membrane and budding into the vitreous cavity

Stage III: Vitreous opacity resulting in a blurred fundus

Stage IV: Vitreous opacity plus retinal detachment

Adapted from Takebayashi H, Mizota A, Tanaka M. Relation between stage of endogenous fungal endophthalmitis and prognosis. *Graefes Arch Clin Exp Ophthalmol* 2006;244:816–20.

## Medical Evaluation of the Patient

In contrast to patients with other categories of endophthalmitis, nearly all patients with endogenous endophthalmitis have an identifiable systemic infection and require at least some degree of systemic evaluation. Generally, the medical evaluation is performed in consultation with an infectious disease specialist or other medical specialist. A high index of suspicion should be maintained because both the ophthalmic and systemic symptoms are quite variable. In one series, 43% of patients with endogenous endophthalmitis had no nonocular symptoms.<sup>18</sup> Endogenous endophthalmitis may present prior to the onset of systemic symptoms<sup>19</sup> or may occur in patients later found to have no other systemic infection.<sup>20</sup> In one series, the rate of negative systemic workup was over 40%.<sup>21</sup> In a patient not known to have systemic infection, intraocular cultures (aqueous and/or vitreous) may be necessary to confirm the diagnosis. Intraocular cultures are also important in patients who progress despite treatment with empiric antimicrobial therapy.

Obtaining cultures from multiple sites may be necessary to make a specific diagnosis. In one series of patients with endogenous bacterial endophthalmitis, the rate of diagnostic cultures was 74% for vitreous, 72% for blood, and 96% overall.<sup>22</sup> The rates of positive cultures are lower in patients with endogenous fungal

endophthalmitis. Rates of positive cultures have been reported in the range of 44–70%,<sup>23</sup> and as low as 18% in one series.<sup>24</sup> One study reported the highest rate of diluted vitrectomy cassette vitreous specimens culture positivity using a combination of both a membrane filter system and blood culture bottle.<sup>25</sup> Although polymerase chain reaction-based identification of organisms is not routinely performed, it may provide higher rates of organism identification than routine culture techniques.<sup>26,27</sup>

## Endogenous Bacterial Endophthalmitis

Endogenous bacterial endophthalmitis is reported to comprise between 2% and 8% of all cases of infectious endophthalmitis (Fig. 90.1).<sup>22</sup> Many bacteria have been reported to cause endogenous endophthalmitis.<sup>28</sup> Gram-positive agents associated with bacterial endogenous endophthalmitis include *Staphylococcus aureus*,<sup>29</sup> group B *Streptococcus*,<sup>30</sup> *Streptococcus pneumoniae*,<sup>31,32</sup> *Streptococcus bovis*,<sup>33</sup> *Enterococcus faecalis*,<sup>34,35</sup> *Propionibacterium acnes*,<sup>36</sup> *Listeria monocytogenes*,<sup>37</sup> *Bacillus* spp.,<sup>38</sup> *Nocardia* spp.,<sup>39,40</sup> and others. Gram-negative agents associated with bacterial endogenous endophthalmitis include *Klebsiella pneumoniae*,<sup>41–44</sup> *Pseudomonas aeruginosa*,<sup>45,46</sup> *Escherichia coli*,<sup>47</sup> *Neisseria meningitidis*,<sup>48</sup> *Proteus* spp.,<sup>49</sup> *Salmonella* serotype B,<sup>50</sup> *Serratia marcescens*,<sup>51</sup> and others.

**FIG. 90.1** Endogenous *Klebsiella pneumoniae* endophthalmitis. (A) Note anterior chamber cell and flare. (B) Note hypopyon. (C) Note vitreous opacification overlying macular chorioretinitis and associated hemorrhage. (Case courtesy of Lisa C. Olmos, MD, MBA.)

## Endogenous Fungal Endophthalmitis

Over 50,000 species of fungi have been reported, yet fewer than 200 of these are associated with clinical disease in humans and even fewer have been reported to cause endogenous endophthalmitis (Box 90.5). Fungi may be differentiated using several criteria, but are commonly divided between unicellular yeasts and multicellular molds. Molds contain tubular structures (hyphae). Some fungi may grow with both yeast-like and mold-like morphology in tissues or culture. Fungi may also be classified by pigmentation (moniliaceous versus dematiaceous), virulence (pathogenic versus opportunistic), **Box 90.5** presentation (cutaneous, subcutaneous, or systemic).

### Fungal Isolates

Yeasts and yeast-like isolates

*Candida* species

*C. albicans*

*C. parapsilosis*

*C. tropicalis*

*C. glabrata*

*Cryptococcus neoformans*

*Trichosporon beigeli*

*Sporobolomyces salmonicolor*

Hyaline molds – septate (colorless hyphae)

*Aspergillus* spp.

*A. fumigatus*

*A. niger*

*A. glaucus*

*A. flavus*

*Pseudoallescheria boydii*

*Fusarium* spp.

*F. solani*

*F. oxysporum*

*Bipolaris hawaiiensis*

*Paecilomyces* spp.

*Penicillium* spp.

Hyaline molds – aseptate (colorless hyphae)

*Mucor* spp.

*Absidia* spp.

*Rhizopus* spp.

Dematiaceous molds (colored hyphae)

*Scedosporium* spp.

*S. apiopsermum*

*S. prolificans*

*Cladophialophora bantiana*

*Phialemonium curvatum*

Dimorphic molds

*Blastomyces dermatitidis*

*Histoplasma capsulatum*

*Sporothrix schenckii*

*Coccidioides immitis*

*Candida albicans* is the most common yeast isolate and the most common overall fungal isolate in patients with endogenous fungal endophthalmitis.<sup>52,53</sup> *C. albicans* may be found as a commensal organism in the gastrointestinal tract and mucous membranes of healthy individuals.<sup>54</sup> Although the organism is of low virulence to healthy individuals, candidemia is associated with relatively high rates of morbidity and mortality.<sup>55</sup> In one series, the mortality rate among patients with candidemia and endogenous *Candida* endophthalmitis was 77%.<sup>56</sup> *Candida* endophthalmitis is strongly associated with intravenous drug abuse.<sup>57</sup> Other *Candida* species reported to cause endophthalmitis include *C. tropicalis*, *C. parapsilosis*, *C. glabrata*, *C. guilliermondii*, *C. krusei*, and *C. dubliniensis*. Among patients with diagnosed candidemia, reported rates of endogenous endophthalmitis range from less than 3%<sup>58</sup> to 44%.<sup>59</sup> The prevalence of *Candida* endophthalmitis may be decreasing, as systemic antifungals are now more commonly prescribed for

patients with positive blood cultures.<sup>60</sup> The most characteristic clinical sign of *Candida* endophthalmitis is one or more creamy white, well-circumscribed chorioretinal lesions, less than 1 mm in diameter, most commonly in the posterior pole, with an overlying haze of vitreous inflammatory cells (Figs. 90.2 and 90.3). Yellow or fluffy-white vitreous opacities, sometimes connected by strands of inflammatory material (“string of pearls” configuration), may be noted.<sup>61</sup> A subretinal abscess has been reported in a patient with endogenous *C. albicans* endophthalmitis.<sup>62</sup> The initial misdiagnosis rate may be high; one series reported this rate to approach 50%.<sup>3</sup>

**FIG. 90.2** Endogenous *Candida* endophthalmitis. Note creamy white chorioretinal lesion, with associated retinal hemorrhage and evidence of vasculitis.

**FIG. 90.3** Macular chorioretinitis, clinically suspected endogenous *Candida* endophthalmitis. This patient was an intravenous drug abuser and improved with empiric oral fluconazole. (Case courtesy of Jeffrey K. Moore, MD.)

*Aspergillus* is the most common mold isolate and the second most common overall fungal isolate in patients with endogenous fungal endophthalmitis.<sup>52</sup> Reported risk factors include chronic pulmonary disease, liver transplantation,<sup>63</sup> and treatment with systemic corticosteroids, but rare cases are reported in apparently immunocompetent individuals.<sup>64</sup> Endogenous *Aspergillus* endophthalmitis is associated with a characteristic central macular chorioretinal inflammatory lesion.<sup>65</sup> A gravitational layering (pseudohypopyon) of inflammatory exudates in either the preretinal (subhyaloid) or subretinal space may be noted with the macular lesion. Additionally, *Aspergillus* endophthalmitis may be associated with retinal vascular occlusion, choroidal vascular occlusion, exudative retinal detachment, and/or diffuse hemorrhagic retinal necrosis.<sup>66,67</sup>

*Cryptococcus neoformans* is associated with meningitis and visual loss through a variety of mechanisms, including cryptococcomas in the visual pathway, optic neuritis, and elevated intracranial pressure.<sup>68</sup> *C. neoformans* may cause endophthalmitis, which is typically characterized by nonspecific intraocular inflammation,

making initial misdiagnosis relatively common. The most common presentation is a multifocal chorioretinitis.<sup>69</sup> Successful outcomes have been reported with a combination of systemic amphotericin B and fluconazole with intravitreal amphotericin B.<sup>70</sup> *Coccidioides immitis* endophthalmitis is associated with chronic pulmonary or disseminated coccidioidomycosis.<sup>71</sup> Endogenous endophthalmitis is infrequently reported.<sup>72</sup> Asymptomatic patients with systemic coccidioidomycosis may have inactive chorioretinal scars, suggesting prior intraocular involvement.<sup>73</sup> Alternatively, a case of ocular coccidiomycosis has been reported 22 years following treatment of systemic disease.<sup>74</sup> Rare causes of endogenous fungal endophthalmitis include *Histoplasma capsulatum*,<sup>75</sup> *Sporothrix schenckii*,<sup>76</sup> *Fusarium solani*,<sup>77,78</sup> and others.

The Infectious Disease Society of America recommends ophthalmic evaluation for all patients with fungemia. These recommendations are mainly based on older studies, which found rates of ocular involvement in fungemic patients as high as 37%.<sup>79–81</sup> More recent studies have found rates of ocular involvement in fungemic patients ranging from 1 to 16%.<sup>82–85</sup> The lower rates of ocular involvement are attributed to increased use of intravenous triazoles which have higher intraocular bioavailability than intravenous amphotericin B.<sup>86</sup> Routine ocular screening of verbal asymptomatic fungemic patients is controversial. Although a very small number of verbal patients with fungal endophthalmitis were asymptomatic, the screening results may not change the patient management and may not be cost-effective.<sup>82–85</sup>

## Treatment Strategies

Although successful treatment of chorioretinitis in a patient with systemic candidiasis has been reported after simply removing an infected catheter,<sup>87</sup> most patients with endogenous endophthalmitis require treatment with systemic antimicrobial agents. The choroid and retina are highly vascular structures, which suggests that systemic pharmacotherapy may be sufficient to treat infections confined to these structures, while severe intravitreal involvement may require intravitreal agents.<sup>86</sup> In patients not responding to systemic therapy, intravitreal therapy should be considered. There

is no current consensus regarding the precise role of surgical techniques, such as pars plana vitrectomy (PPV). The Endophthalmitis Vitrectomy Study (EVS) did not enroll patients with endogenous endophthalmitis, and therefore its results are not directly applicable to these patients.<sup>88</sup> However, PPV and intravitreal injection of antifungals are an important treatment option in patients who fail to respond to initial intravitreal and systemic antifungal treatments.

## Systemic Pharmacotherapies

Although the EVS reported no additional benefit using systemic amikacin and ceftazidime, patients with endogenous bacterial endophthalmitis are generally treated with systemic antimicrobials in order to manage systemic infections. The selection of systemic pharmacotherapies is frequently made in consultation with an infectious disease or other medical specialist. The management is typically individualized based on the severity of the ocular and systemic infections.

Systemic antimicrobials are associated with variable intravitreal penetration. For example, in a prospective study, intravenous teicoplanin was reported to have poor intravitreal penetration.<sup>89</sup> A more recent series of patients with postoperative endophthalmitis reported that systemic meropenem and linezolid offered no additional benefits.<sup>90</sup>

Alternatively, both systemic gatifloxacin<sup>91</sup> and moxifloxacin<sup>92</sup> have been reported to reach potentially therapeutic intraocular drug levels in the noninflamed eye, but their specific benefit in the treatment of endogenous bacterial endophthalmitis remains unproven. Systemic gatifloxacin is no longer commercially available, due to an associated dysglycemia in some patients.<sup>93</sup> Additionally, systemic fluoroquinolones are associated with other serious adverse events, including tendinopathy, especially in the elderly and in patients taking systemic corticosteroids.<sup>94</sup>

A case report demonstrated that after a single dose of intravenous daptomycin, intravitreal concentrations of daptomycin were approximately 28% of the serum concentration, suggesting a potential role for this drug in the treatment of endogenous bacterial

endophthalmitis.<sup>95</sup>

Systemic antibiotics may not prevent the onset of endogenous bacterial endophthalmitis. One case report documented that *P. aeruginosa* endophthalmitis involved the second eye despite initiation of intravenous ceftazidime.<sup>96</sup>

**Box 90.6** Only used systemic antifungals are reviewed in [Box 90.6](#).

## Systemic Antifungal Agents

Amphotericin B 0.6–1 mg/kg per day IV

Azole compounds

Fluconazole 400–1600 mg/day oral or IV

Itraconazole 400–800 mg/day oral or IV

Voriconazole 6 mg/kg/day oral or IV

Posaconazole 400–800 mg/day oral or IV

Echinocandins

Caspofungin 70 mg loading dose, then 50 mg/day IV

Micafungin 50–150 mg/day IV

Anidulafungin 50–100 mg/day

IV, intravenous.

Amphotericin B has been widely used in the treatment of various fungal infections. An alternative liposomal formulation is also available,<sup>97</sup> but experience with this formulation in the treatment of endogenous fungal endophthalmitis is limited at this time.<sup>98,99</sup>

Amphotericin B is administered intravenously and is generally effective in the treatment of infections due to *Candida*,<sup>100</sup>

*Aspergillus*,<sup>101</sup> *Blastomyces*,<sup>102</sup> *Coccidioides*,<sup>72</sup> and other fungi. The use of amphotericin B is limited by multiple toxic effects, including renal failure, chills, fever, vomiting, nausea, diarrhea, dyspnea, malaise, anemia, arrhythmia, hypokalemia, and hearing loss.<sup>103</sup> The intravitreal penetration of systemic amphotericin B is relatively poor, and although successful treatment of *Candida* endophthalmitis has been reported using systemic amphotericin B alone,<sup>104</sup> this approach has a high rate of treatment failure.<sup>105</sup> Either a systemic agent with better intraocular penetration, or combined systemic and intravitreal treatment, is generally selected.

Azoles collectively represent an alternative antifungal drug class. The imidazoles (miconazole and ketoconazole) were used historically, but largely have been replaced by the newer triazoles (fluconazole, itraconazole, voriconazole, and posaconazole), although a case report documented a good outcome in endogenous *Aspergillus terreus* endophthalmitis using intravitreal amphotericin B, oral ketoconazole, and topical natamycin.<sup>106</sup>

Fluconazole has excellent gastrointestinal absorption and may be used orally or intravenously.<sup>107</sup> Intraocular penetration from the systemic circulation is generally excellent.<sup>108</sup> A case report documented good outcomes in a patient with bilateral endogenous *C. albicans* endophthalmitis using intravenous fluconazole and PPV in one eye only.<sup>109</sup> Fluconazole (with or without PPV) has also been reported to successfully treat endophthalmitis caused by *C. tropicalis*,<sup>110</sup> *Coccidioides immitis*,<sup>111</sup> and *Cryptococcus neoformans*.<sup>112</sup> Fluconazole is generally well tolerated, with gastrointestinal disturbance as the major reported toxicity.<sup>113</sup> Oral fluconazole may be an appropriate antifungal choice in patients with chorioretinitis outside the posterior pole,<sup>114</sup> in patients who have been initially treated with intravenous amphotericin B,<sup>115</sup> and in patients at risk for toxicity.

Itraconazole may also be prescribed orally but is used infrequently in the treatment of endogenous endophthalmitis.<sup>116</sup> It has relatively more effectiveness against *Aspergillus* than the other azoles,<sup>113</sup> but intraocular penetration is relatively poor.

Voriconazole is a synthetic second-generation azole derived from fluconazole. It may be used orally or intravenously. Voriconazole is generally effective against most *Candida* species (including those

resistant to fluconazole, such as *C. krusei* and *C. glabrata*),<sup>117</sup> as well as *Aspergillus* and *Cryptococcus*.<sup>118</sup> Voriconazole has excellent intravitreal penetration from the systemic circulation.<sup>119</sup> Oral voriconazole alone has been reported to successfully manage a patient with presumed endogenous *Candida* endophthalmitis.<sup>120</sup>

Posaconazole is a newer azole with efficacy against *Candida*, *Aspergillus*, and *Zygomycetes*.<sup>121</sup> Relatively little is known about its intraocular penetration. Successful treatment of refractory *Fusarium* deep keratitis or endophthalmitis has been reported with oral (or oral plus topical) posaconazole.<sup>122,123</sup>

Commonly used echinocandins include caspofungin, micafungin, and anidulafungin. These are newer agents and, compared with amphotericin B and the azoles, relatively little has been reported about their use in endogenous endophthalmitis. Caspofungin may be effective against *C. albicans* resistant to azoles.<sup>124</sup> One case report documented successful treatment of *C. glabrata* endophthalmitis using only systemic caspofungin.<sup>125</sup> A second report documented treatment of *A. fumigatus* endophthalmitis resistant to intravitreal amphotericin and systemic voriconazole with systemic caspofungin.<sup>126</sup> Another study found that eight eyes with endogenous fungal endophthalmitis in patients treated with intravenous micafungin had intravitreal levels of micafungin (measured from vitrectomy sample) above the minimal inhibitory concentration.<sup>127</sup>

## Intravitreal Pharmacotherapies

In endogenous endophthalmitis, intravitreal pharmacotherapies may be used as adjunctive therapies to systemic medications.

The EVS did not enroll patients with endogenous endophthalmitis, and its results are not directly applicable,<sup>88</sup> although many principles are relevant. The EVS used intravitreal vancomycin and amikacin, which achieved broad-spectrum coverage of both gram-positive and gram-negative organisms. In a patient with bacteremia due to a known organism, targeted pharmacotherapy may be considered in patients with suspected ocular involvement. To reduce the risk of aminoglycoside toxicity, ceftazidime or ceftriaxone may be considered as an alternative to

amikacin. Ceftazidime may precipitate when mixed with vancomycin, but this does not appear to affect its clinical efficacy.<sup>128</sup> Injecting antibiotics through separate syringes is generally recommended. Intravitreal daptomycin has been reported to be safe and effective in treating one case of bilateral endogenous endophthalmitis secondary to vancomycin resistant *S. aureus*.<sup>129</sup>

Intravitreal antifungals are listed in [Box 90.7](#). Animal studies have suggested that intravitreal amphotericin B, 5–10 µg, is generally nontoxic.<sup>130</sup> A case series of patients inadvertently treated with very high doses reported severe noninfectious panophthalmitis, but ultimately good visual outcomes, following treatment with doses as high as 500 µg.<sup>131</sup> Intravitreal amphotericin B alone, without systemic therapy, has been reported to successfully treat endogenous *Candida* endophthalmitis.<sup>132</sup> A case report documented good outcomes using PPV, intravitreal liposomal amphotericin B, and systemic fluconazole in a patient with bilateral endogenous *C. albicans* endophthalmitis.<sup>133</sup>

## Intravitreal Antifungal Agents

Amphotericin B 0.005–0.01 mg/0.1 ml

Voriconazole 0.1 mg/0.2 ml

Caspofungin 0.1 mg/0.1 ml

Fluconazole (experimental)

Flucytosine (experimental)

Intravitreal fluconazole has been tested in animal models,<sup>134,135</sup> but does not appear to be any more effective than intravitreal amphotericin B and is thus rarely used clinically.<sup>112</sup> Intravitreal ketoconazole has been reported safe in a rabbit model,<sup>136</sup> but its use has not been reported in humans.

Based on animal models, intravitreal voriconazole appears to be nontoxic up to doses of 100 µg and may be less toxic to the retina than intravitreal amphotericin B.<sup>137</sup> Intravitreal voriconazole, with or without PPV, has been reported to successfully treat patients

with endogenous fungal endophthalmitis,<sup>138</sup> including in a patient resistant to PPV with repeated injections of intravitreal amphotericin B and systemic voriconazole.<sup>139</sup> The combination of intravitreal amphotericin B and voriconazole has been shown to be effective in a series of patients with exogenous filamentous fungal endophthalmitis.<sup>140</sup> One study found of exogenous fungal endophthalmitis isolates found 100% sensitivity to intravitreal voriconazole, compared to 69% sensitivity to intravitreal amphotericin B.<sup>141</sup>

Intravitreal corticosteroids (e.g., dexamethasone 400 µg) may be a helpful adjunct in some patients with bacterial or fungal endophthalmitis, by reducing inflammation.<sup>142</sup> Generally, corticosteroids should be withheld until proper antimicrobials have been initiated, especially in patients with suspected fungal disease.

## Surgical Treatments

Although there is no general agreement on exactly which patients will benefit from PPV,<sup>104</sup> surgical treatments are typically reserved for patients with established vitreous involvement.<sup>143</sup> PPV offers the advantages of removing infectious organisms from the vitreous cavity and providing ample material for cultures. Disadvantages of PPV include surgical risks, such as retinal detachment, choroidal detachment, or sclerotomy site leakage. One large series reported improved outcomes in patients treated with PPV.<sup>15</sup> In patients with endogenous fungal endophthalmitis treated with PPV and systemic antifungals, adjunctive intravitreal antifungals were not used in one series of *Candida* cases.<sup>110</sup> In phakic patients with an uninvolved crystalline lens, lensectomy is not required at the time of vitreous surgery.<sup>144,145</sup>

Vitreous needle tap may be useful in hospitalized patients who are poor surgical candidates or in facilities where access to PPV instrumentation and support staff is limited (Fig. 90.4). Patients who fail to respond to tap and inject should be considered for PPV during subsequent follow-up.

**FIG. 90.4** (A) Endogenous methicillin-resistant *Staphylococcus aureus* endophthalmitis. Note white subretinal lesion with overlying vitritis. (B) Four months after treatment with intravitreal vancomycin and ceftazidime, as well as systemic vancomycin, the patient improved. Note clear vitreous and subretinal scar.

## Suggested Management

In patients with clinically suspected endogenous endophthalmitis, the history, physical findings, and blood cultures may be useful to determine an etiology. Because of the relative infrequency of these cases (especially bacterial cases), there are no generally established treatment guidelines.<sup>15</sup>

An insidious onset, diffuse vitreous opacities, and chorioretinal infiltrates suggest fungal etiology. Rapid progression and more severe intraocular inflammation suggest bacterial etiology. Other causes of vitreous cellular inflammation should be considered, including toxoplasmosis, sarcoidosis, syphilis, neoplastic etiologies, pars planitis, and dehemoglobinized vitreous hemorrhage.

In patients with clinically suspected endogenous endophthalmitis, consultation with an infectious disease or other medical specialist should be considered to search for evidence of bacteremia/fungemia or other organ involvement. Patients with chorioretinal infiltrates with no or mild vitreous cells may be initially managed with systemic antimicrobials and close observation. Patients with moderate or severe vitreous

inflammation, or patients with milder disease who progress despite systemic therapy, may be treated with systemic antimicrobials, as well as PPV with intravitreal antimicrobials.

Using a high index of suspicion and these treatment suggestions, many patients will achieve good anatomic and visual outcomes. Unfortunately, some patients with endogenous endophthalmitis will lose vision despite prompt and appropriate therapy.

# Acute Retinal Necrosis Syndrome

---

*G. Atma Vemulakonda, Jay S. Pepose, Russell N. Van Gelder*

## Definition

## Patient Population

## Etiology

## Pathologic Features

## Differential Diagnosis

## Treatment and Prognosis

## Definition

In 1971 Urayama and coworkers<sup>1</sup> reported six cases of an apparently new syndrome characterized by acute necrotizing retinitis, vitritis, retinal arteritis, choroiditis, and late-onset rhegmatogenous retinal detachment. Young and Bird<sup>2</sup> described two similar cases in 1978 and gave the syndrome the acronym BARN (bilateral acute necrosis syndrome). With the subsequent recognition of unilateral and asynchronous bilateral cases, the disease has been termed simply *acute retinal necrosis syndrome*, or ARN syndrome. ARN syndrome is characterized by the initial onset of episcleritis or scleritis, periorbital pain, and anterior uveitis,

which may be granulomatous or stellate in appearance. This is followed by decreased vision resulting from vitreous opacification, necrotizing retinitis, and, in some cases, optic neuritis or neuropathy. The retinitis appears as deep, multifocal, yellow–white patches, typically beginning in the peripheral fundus (Figs. 91.1 and 91.2) and then becoming concentrically confluent and spreading toward the posterior pole (Figs. 91.3–91.5); the macula frequently is spared. An active vasculitis is present, with perivascular hemorrhages, sheathing, and terminal obliteration of arterioles by thrombi. The phase of active retinitis usually lasts 4–6 weeks, during which time an exudative retinal detachment may occur.<sup>3–8</sup>

**FIG. 91.1** Typical fundus appearance of early acute retinal necrosis syndrome demonstrating necrotizing peripheral retinitis, intraretinal hemorrhage, and vitritis.

**FIG. 91.2** White patches of retinal necrosis are seen in the periphery with isolated areas of necrosis more posterior early in the course of acute retinal necrosis.

**FIG. 91.3** Marked vitritis associated with acute retinal necrosis syndrome. Episcleritis and keratic precipitates are also often seen early in the syndrome.

**FIG. 91.4** Fundus appearance in early acute retinal necrosis syndrome, with areas of peripheral retinal whitening and arterial vasculitis. Disease at this stage is often accompanied by marked vitritis and intraretinal hemorrhage.

**FIG. 91.5** The peripheral retinitis becomes confluent for 360 degrees and is accompanied by an obliterative vasculitis and papillitis.

With resolution, pigmentation of the peripheral lesions begins at their posterior margins, leaving a scalloped appearance (Fig. 91.6), frequently accompanied by retinal breaks at the junction of normal and necrotic retina. Giant retinal pigment epithelial tears may develop.<sup>9</sup> A rhegmatogenous retinal detachment has been observed in approximately 75% of untreated eyes, generally within 1–2 months after the onset of the disease, although earlier detachments have been noted, particularly in cases associated with herpes simplex virus (HSV).<sup>3,6,8,10</sup> Vitreous inflammation may lead to organization and proliferative vitreoretinopathy,<sup>11</sup> adding a traction component to the retinal detachment (Fig. 91.7). Vision may also decrease as a result of anterior ischemic optic neuropathy.

**FIG. 91.6** During the resolution of active retinitis, the lesions become pigmented starting at their posterior margins, leaving a scalloped border between necrotic and normal-appearing retina.

**FIG. 91.7** Retinal breaks and the onset of proliferative vitreoretinopathy can lead to a combined traction–rhegmatogenous retinal detachment 1–2 months after the onset of the acute retinal necrosis syndrome. (From Clarkson JG, Blumenkranz MS, Culbertson WW, et al. *Ophthalmology* 91:1665-1668, 1984.)

Computed tomography<sup>12-14</sup> and ultrasonography<sup>14</sup> have revealed enlargement of the optic nerve sheath in ARN cases associated with prominent optic disc edema. ARN patients can develop meningoencephalitis and must be closely evaluated for this.<sup>15</sup> Even in ARN patients who are not immunocompromised and who have no clinical evidence of encephalitis, magnetic resonance imaging of selected cases has shown lesions of the lateral geniculate, optic tracts, and chiasm,<sup>16</sup> suggesting viral spread through the central nervous system by axoplasmic transport from retinal ganglion cells. An explanation for this has been shown in mouse models, where there is evidence to show that HSV1 infection may progress through the optic chiasm from one eye to the other and along the visual pathways leading to meningoencephalitis.<sup>17</sup>

The contralateral eye is involved in approximately 36% of untreated ARN cases, usually within 6 weeks of the onset of disease

in the first eye.<sup>9,18</sup> However, the second eye can be affected as late as 46 years after involvement of the first eye, and the fellow eye has become involved even after acyclovir treatment for ARN in the first eye.<sup>19</sup> Mild forms of ARN syndrome, characterized by patchy, peripheral retinal opacification, have been reported. These mild cases did not become rapidly confluent or lead to detachment.<sup>20</sup> It is unclear whether this atypical presentation is a result of intense acyclovir and corticosteroid therapy or a reflection of a wide range of disease severity. In addition, less involved forms of ARN have been reported after primary varicella.<sup>21</sup>

## Patient Population

The British Ophthalmological Surveillance Unit reported an incidence for ARN syndrome of 0.63 cases per million population per year, with age range from 10 to 94 and nearly equal incidence in men and women.<sup>22</sup> ARN syndrome occurs most commonly in otherwise healthy patients. However, ARN patients may demonstrate subclinical immune dysfunction. In one review of 216 patients with ARN, impaired cellular immunity was noted in 16%.<sup>23</sup> Skin testing of patients with ARN revealed anergy in five of seven tested cases and abnormal lymphocyte proliferative indices in one-third.<sup>24</sup> The significance of cutaneous anergy is unclear, however, since patients with zoster infections frequently demonstrate anergy.<sup>25</sup> Specific HLA haplotypes may increase the relative risk of developing ARN syndrome, such as the HLA-DQw7 antigen and phenotype Bw62 and DR4 in white patients in the United States<sup>26</sup> and HLA-Aw33, B44, and DRw6 in Japanese patients.<sup>27</sup> Pleocytosis of the cerebrospinal fluid frequently accompanies the syndrome,<sup>9,13,28</sup> and intrathecal production of antibodies against herpesviruses has been demonstrated in selected cases.<sup>4</sup> Some patients present with ARN before, after, or at the same time as they show skin manifestations of varicella-zoster infection<sup>29,30</sup> (e.g., primary varicella, herpes zoster ophthalmicus, or Ramsay Hunt syndrome). Unilateral ARN also has been noted after herpes simplex keratitis.<sup>31</sup> Diffuse cerebral atrophy and labyrinthine deafness have been reported following ARN,<sup>32</sup> and some investigators have suggested that ARN be considered as one of the

uveomeningeal syndromes.<sup>14</sup>

Acute necrotizing retinitis that is clinically identical to ARN or shares many features with ARN has been reported in immunocompromised patients. ARN was first described in immunocompromised patients in 1985;<sup>33</sup> the largest case series described 26 cases of ARN in AIDS patients, noting a generally fulminant course.<sup>34</sup> The cause of the retinitis in these immunocompromised patients may be particularly diverse or multifactorial. For example, an AIDS patient died after an ARN-like syndrome with concurrent encephalitis, and herpes simplex viral antigens were localized in the central nervous system at postmortem examination.<sup>35</sup> In contrast, several immunocompromised patients have presented with ARN in association with skin manifestations of zoster.<sup>36</sup> Although ARN syndrome initially was defined as manifesting in otherwise healthy patients, many authorities have broadened the diagnostic criteria to include immunocompromised hosts.<sup>36-39</sup> It is the evolution of clinical signs and symptoms, and not the specific pathogen or immune status of the patient, that serves as the sole basis by which ARN syndrome has been defined (see [Differential Diagnosis](#), below).

Several systemic medications and conditions appear to increase risk of ARN syndrome. There are several reports of ARN following natalizumab therapy for multiple sclerosis.<sup>40,41</sup> There have also been several reports of ARN syndrome following immunizations for varicella zoster<sup>42,43</sup> and influenza,<sup>44</sup> although these cases appear very rarely. HSV viral encephalitis has also been recognized as a risk factor for subsequent ARN syndrome.<sup>45-48</sup>

Numerous reports have documented ARN syndrome following intraocular or periocular steroid injections.<sup>49-51</sup> ARN syndrome has also been reported following intravitreal dexamethasone implant (Ozurdex®)<sup>52</sup> and intravitreal fluocinolone acetonide implant (Retisert®).<sup>53</sup> However, in a review of cases of postinjection viral retinitis, 23 of 30 reported cases were cytomegalovirus (CMV) retinitis, with only six reported cases of HSV or varicella-zoster virus (VZV) ARN.<sup>54</sup> The incidence of ARN syndrome following intravitreal or periocular steroid injection is presently unknown but appears rare.

## Etiology

Considerable evidence points to multiple members of the herpesvirus family in the etiology of ARN syndrome. In numerous studies, VZV has been the most frequent virus isolated,<sup>55</sup> up to 66.7%.<sup>56</sup> VZV was isolated in tissue culture from the vitreous of a blind eye enucleated early in the course of the disease, and specific varicella-zoster antigens were identified in retinal tissue by immunocytologic staining<sup>57</sup> (Fig. 91.8). VZV was identified by electron microscopy in necrotic retinal tissue (Fig. 91.9) in two other cases of ARN.<sup>58</sup> Varicella-zoster DNA in intraocular fluids of ARN cases has been confirmed by polymerase chain reaction (PCR),<sup>59</sup> and Witmer quotients of paired serum to intraocular fluid antibody levels have been diagnostic of varicella-zoster in numerous cases.<sup>60,61</sup> Varicella-zoster antigens have been demonstrated in vitreous aspirates of patients with ARN syndrome.<sup>62</sup>

**FIG. 91.8** Varicella-zoster antigens (brown) are seen in cells scattered in all layers of a necrotic retina.

**FIG. 91.9** Ultrastructural studies of necrotic retina reveal multiple 100-nm nucleocapsids (*double arrows*) and enveloped virions typical of a herpes-type virus.

(Courtesy MS Blumenkranz.)

Restriction endonuclease patterns of the ARN virus isolate were similar to those of typical varicella-zoster strains and showed similar sensitivities to a panel of antiviral drugs.<sup>63</sup> Although strain heterogeneity has been observed in the varicella-zoster viruses associated with ARN syndrome,<sup>64</sup> the data thus do not support the notion that the ARN virus represents a mutant strain of VZV with significant alterations in either the viral thymidine kinase or DNA polymerase genes. It therefore remains enigmatic why an “old virus” should give rise to a “new” syndrome.

Numerous reports have suggested that other members of the herpesvirus family may cause ARN.<sup>56</sup> A number of studies have implicated HSV because of concurrent herpes simplex skin lesions,<sup>65</sup> the detection of herpes simplex antigens on vitreous cells,<sup>7</sup> the presence of immune complexes containing herpes simplex antigens in aqueous or serum,<sup>66</sup> the documentation of intraocular antibody synthesis directed against HSV,<sup>61</sup> diagnostic changes in serum antibody levels to herpes simplex, PCR detection of herpes simplex,<sup>67</sup> or the culture of herpes simplex from vitreous humor.<sup>3,8,57</sup> Several cases have been described of ARN caused by reactivation of HSV type 2.<sup>59,67,68</sup> Interestingly, patients with herpes simplex type 2 appear to be much younger (mean 21 years) than those with either herpes simplex type 1 or varicella zoster (mean age 40 years).<sup>61,69,70</sup>

The proportion of ARN syndrome patients with disease caused by HSV-2 may be higher in Japan than in the United States, perhaps coincident with changing epidemiologic distributions of HSV-1 vs HSV-2 in this population.<sup>71,72</sup> Patients with ARN syndrome caused by herpes simplex type 1 appear to have a higher risk of encephalitis or meningitis than those with disease caused by varicella-zoster.<sup>45–48,69,73</sup>

In one study,<sup>74</sup> CMV was cultured and CMV antigens were demonstrated in retinal tissue from a case of ARN, but megaly cells or electron-dense cytoplasmic inclusions were not identified. In another case the PCR yielded positive results for CMV in one immunocompetent individual whose vitreous was negative for varicella-zoster and HSV types 1 and 2.<sup>75</sup> Epstein–Barr virus has also been postulated in some cases of ARN syndrome,<sup>76,77</sup> with one reported case showing histopathologic confirmation.<sup>78</sup> However, caution should be applied in making this diagnosis as EBV has been found in 20% of normal cadaveric eyes.<sup>79</sup> While one study found EBV by PCR in 16.7% of ARN cases, each case was also positive for VZV by PCR.<sup>56</sup> Human herpes virus 6 (HHV-6) is a more recently discovered HHV and has also been rarely associated with an ARN-like presentation.<sup>80,81</sup>

## Pathologic Features

Studies of blind eyes enucleated early in the course of ARN have demonstrated retinal necrosis, hemorrhage, and considerable vitreous debris. The retinal necrosis is full thickness, and an underlying choroiditis is present that may be granulomatous (Fig. 91.10). Varicella-zoster virus DNA and antigens have been identified in lymphoid cells within choroidal infiltrates in an eye enucleated in the late stage of disease.<sup>82</sup> Eosinophilic intranuclear inclusions within cells of all layers of retina and retinal pigment epithelium were the first clues suggesting a possible viral etiology by a member of the herpes group.<sup>58</sup> There is histologic evidence of retinal arteritis (Fig. 91.11), although no virus particles have been detected in vascular endothelium. Deposits of immune complexes containing varicella-zoster viral antigens have been demonstrated in retinal vessel walls by immunocytologic methods and may play a

role in the vasculitis seen during active stages. The perivasculitis is not restricted to retinal vessels alone and can involve the extraocular muscles (Fig. 91.12). Immune complexes with herpes simplex also have been identified in intraocular fluids in ARN cases.

**FIG. 91.10** Photomicrograph of a case of acute retinal necrosis shows full-thickness retinal necrosis with an underlying granulomatous choroiditis. (Courtesy Robert Y Foos.)

**FIG. 91.11** Histologic evidence of retinal vasculitis

(arrows) in acute retinal necrosis. (Courtesy Robert Y Foos.)

**FIG. 91.12** Foci of perivascular inflammation (*arrows*) are seen in the inferior oblique muscle in a case of acute retinal necrosis. (Courtesy Robert Y Foos.)

Ultrastructural studies of retinal tissue have revealed 180 nm virions containing icosahedral capsids, consistent with particles of the herpes group<sup>58</sup> (see Fig. 91.8). The optic nerve may be largely necrotic and heavily infiltrated with plasma cells, but no virus particles or antigens have been seen in the optic nerve. It is possible that the absence of viral antigens or particles reflects more the time point in the course of the disease when enucleation was performed in these rare cases than conclusive evidence regarding acute optic nerve infection. The multifocal, deep retinitis observed early in the course of ARN is compatible with either bloodborne spread of virus or transmission to the eye through a bilateral nerve pathway. An animal model of ARN using herpes simplex virus suggests that spread to the contralateral eye occurs by retrograde axonal

transport between the suprachiasmatic nucleus of the hypothalamus and the contralateral retina.<sup>83</sup>

Retinal necrosis in ARN probably is the result of multiple factors, including a direct lytic viral infection of retina, immune complex disease mediating an obliterative arteritis, choroidal inflammation and occlusion, T-cell mediated inflammation, and vitreous inflammation. All these elements contribute and lead to a combined traction-rhegmatogenous retinal detachment.

## Differential Diagnosis

The American Uveitis Society released its criteria for diagnosis of acute retinal necrosis syndrome in 1994.<sup>39</sup> Under this definition, diagnosis of ARN syndrome is dependent solely on the observed clinical findings and their progression. Neither the identification of an etiologic agent nor knowledge of the patient's immune status is required to render a diagnosis of ARN syndrome. The diagnostic criteria are divided into mandatory and supporting categories and are summarized in [Table 91.1](#). By this definition, retinal lesions presumptively caused by herpesviruses (but not part of other well-recognized syndromes such as CMV retinitis or progressive outer retinal necrosis [see below]) are covered under the umbrella term *necrotizing herpetic retinopathy*. A similar set of disease criteria has been suggested by the Japanese ARN study group.<sup>84</sup>

**TABLE 91.1**

### American Uveitis Society Criteria for Diagnosis of Acute Retinal Necrosis Syndrome

Required Clinical Criteria	Supporting Clinical Criteria
One or more foci of retinal necrosis with discrete borders, located in peripheral retina	Optic neuropathy/atrophy
Rapid progression of disease in the absence of therapy	Scleritis
Circumferential spread of disease	Pain
Evidence of occlusive vasculopathy and arteriolar involvement	
A prominent inflammatory reaction in the vitreous and anterior chamber	

The differential diagnosis of ARN includes CMV retinopathy, syphilitic retinitis, toxoplasmosis (particularly in

immunocompromised hosts), large cell lymphoma, and acute multifocal hemorrhagic retinal vasculitis. A more extensive differential diagnosis includes toxocariasis, fungal or bacterial retinitis, pars planitis, Behçet disease, sarcoidosis, commotio retinae, central retinal artery or ophthalmic artery occlusion, ischemic ocular syndrome, collagen-vascular disease, intraocular leukemia/lymphoma (including T-cell-mediated<sup>85</sup>) and retinoblastoma.

ARN syndrome is distinguished from a separate form of varicella-zoster retinitis reported in human immunodeficiency virus (HIV)-infected patients, sometimes referred to as “progressive outer retinal necrosis syndrome” or PORN.<sup>66,86</sup> This latter entity shares an etiologic agent with some cases of ARN but is otherwise distinct. It is characterized by multifocal, patchy choroidal, and deep posterior retinal opacification that initially may be parafoveal. Additional features differentiating this syndrome from ARN include the absence of vitreous or anterior chamber inflammation or signs of active vasculitis. PORN progresses rapidly from the posterior pole to involve the entire retina, resulting in widespread retinal necrosis and atrophy. Despite a common etiologic agent, varicella-zoster retinitis should not be referred to as ARN syndrome. Indeed, the two diseases may even affect different eyes of the same patient.<sup>87</sup>

Although ARN syndrome is a clinical diagnosis established on the basis of a constellation of evolving signs and symptoms, which may be pathognomonic in many cases, in atypical or difficult diagnostic cases ancillary clinical history or laboratory tests can support the diagnosis. It is important to assess the patient's level of immunocompetence, since knowledge of seropositivity to HIV and syphilis may help to establish the appropriate specific diagnosis. Diagnostic vitrectomy is appropriate in cases of uncertain diagnosis. The most sensitive and specific method for the detection of herpes viruses in vitreous specimens is the polymerase chain reaction (PCR). PCR assays are capable of detecting a single varicella zoster virion from vitreous biopsy.<sup>88</sup> Simultaneous PCR for multiple herpes viruses has been used to screen for an etiologic agent in atypical cases of ARN and has implicated both CMV<sup>88</sup> and HSV<sup>59</sup> as potentially causative. PCR can be performed in multiplex for VZV, HSV, CMV, and toxoplasmosis.<sup>89</sup> Sensitivity for each, even

in multiplex testing, is at least 10 genomes per microliter. With application of quantitative PCR (qPCR), accurate estimates of pathogen load can be achieved.<sup>90,91</sup> Quantitative PCR may be used to follow disease response to antiviral agents.<sup>92</sup> The great sensitivity of PCR can be problematic, however; assays that yield false positive results, likely through amplification of latent virus in host tissue, have been reported.<sup>88</sup> False-negative results can also occur. Consensus has not yet been reached regarding the negative predictive value of a negative PCR test for viral DNA. PCR requires meticulous technical performance to avoid specificity problems and is best performed by a laboratory with considerable experience with this method. In most cases, aqueous and/or vitreous sampling for PCR has become the diagnostic test of choice when faced with viral retinitis.<sup>56,93,94</sup>

In cases in which PCR is negative but clinical suspicion is high, endoretinal biopsy may be appropriate. Taking the biopsy from the transition zone between normal and necrotic retina during the acute phase of the disease greatly increases its diagnostic yield. Obtaining paired serum and intraocular fluid specimens and calculation of a modified Goldmann–Witmer coefficient (GWC) may be calculated to confirm diagnosis. With the increased use of PCR, GWC testing is used less frequently, and is not widely available clinically.<sup>56,93,94</sup> However, GWC testing may be more valuable in late stages of disease, as viral DNA disappears but immunologic responses increase.<sup>60,95</sup>

## Treatment and Prognosis

Treatment of ARN syndrome is complex and must be individualized in response to the many pathogenic and temporal facets of the disorder, as well as to the specific vitreoretinal pathologic findings at hand. Cases of ARN associated with mild or minimal inflammation have been reported in which ARN did not progress to extensive retinal necrosis, traction, or detachment.<sup>20,21</sup> Controlled, randomized, prospective treatment studies on ARN have not been conducted given the relative rarity of this disease, so current recommendations are based solely on anecdotal data and case series. Early studies indicated that the natural history of classic

ARN syndrome carries a generally poor prognosis in untreated eyes,<sup>9</sup> with only 28% of affected eyes obtaining a final vision better than 20/200 because of rhegmatogenous retinal detachment (75% of affected eyes), optic nerve dysfunction, or macular abnormality. The advent of antiviral therapy and vitrectomy techniques<sup>96</sup> has decreased this level of vision loss to less than one-third of cases in recent years.<sup>12</sup> In one series of cases that were detected early and treated aggressively with acyclovir and laser photocoagulation, outcome for 13 eyes of 12 patients showed 20/40 or better vision in 46% of eyes and 20/400 or better in 92%,<sup>97</sup> (although it should be noted that the use of prophylactic laser photocoagulation has become more controversial than it was in the past,<sup>98,99</sup> see below). Another recent outcome study of 62 eyes of 53 patients showed less favorable results, with surgical intervention required in 51% of patients and good functional outcome seen in 45%.<sup>100</sup> Outcome seems to be dependent on virus type. In one retrospective study of 81 eyes of 74 patients, VZV was associated with significantly worse visual acuity outcomes and a 2.5-fold higher risk of retinal detachment than in HSV-affected eyes.<sup>101</sup> Meghpara et al.<sup>99</sup> reviewed 25 eyes of 25 patients with at least 1 year of follow-up, of whom half had received intravitreal antivirals and all patients had received systemic treatment. They noted 5 of 25 eyes developed retinal detachment, with greater extent of retinitis at presentation being the major risk factor for poor outcome.

Acyclovir has been used in an effort to limit the direct cytopathic effect of virus on retinal tissue. Based on the dose required for a 50% reduction of virus plaques in tissue culture ( $ED_{50}$ ), oral administration of acyclovir results in subtherapeutic serum levels; in contrast, intravenous acyclovir (13 mg/kg every 8 hours) results in an intravitreal acyclovir level<sup>4</sup> over three times the ARN  $ED_{50}$ . After intravenous administration of acyclovir to ARN patients (1500 mg/m<sup>2</sup> per day in three divided doses), retinal lesions were first noted to regress 3.9 days after the beginning of therapy, new lesions did not develop, and existing lesions did not progress.<sup>19</sup> Historically, intravenous therapy for 5–10 days was followed by oral acyclovir at the zoster dosage (800 mg orally five times daily, assuming normal renal function) for up to 6 weeks after the onset of infection, and longer in immunocompromised patients.

Valacyclovir (1 g orally three times daily) or famciclovir<sup>102,103</sup> (500 mg orally three times daily) may also be used following intravenous acyclovir administration. Side-effects of acyclovir include decreased renal function, gastrointestinal irritation, phlebitis, central nervous system dysfunction, and hypersensitivity reactions. Acyclovir has potent antiviral action against varicella-zoster virus, HSV types 1 and 2 (both of which have been implicated in ARN), and Epstein–Barr virus, but it has low activity against CMV. Valganciclovir is active against VZV, HSV, and CMV, but is FDA-approved at present only for CMV retinitis.

In recent years, many clinicians have moved to outpatient use of oral antivirals for treatment induction of ARN.<sup>104–106</sup> Prodrugs such as valacyclovir and famciclovir have high systemic absorption, are active against VZV and HSV, and may be used for prophylaxis against involvement of the second eye.<sup>3,107</sup> Valganciclovir, another prodrug, has been used in other cases.<sup>108</sup> Treatment algorithms have used oral valacyclovir 1 g 3 times daily, oral famciclovir 500 mg 3 times daily, or valganciclovir 450–900 mg 2 times daily until complete resolution of retinitis was observed. Some clinicians have used higher doses of valacyclovir, 2 g 3–4 times daily, to achieve resolution,<sup>109</sup> although there is some risk of renal impairment or mental status changes at this higher dose.<sup>110</sup> These medications are then generally slowly tapered over 1.5 to 75.7 months.<sup>98,111</sup> Recent studies have not found a significant superiority of intravenous over oral treatment induction, but these studies have been retrospective and limited by the relative rarity of this disease. Given the risk of encephalitis particularly in patients with HSV-1-associated disease, close monitoring of patient mental status is warranted.

Recent studies have suggested an adjunctive role for intravitreal antiviral medication in the treatment of ARN syndrome. Ganciclovir (typically 2–4 mg/0.1 mL) and foscarnet (2.4 mg/0.1 mL) have been utilized, with injections typically repeated at 48–72 hours depending in clinical response. Early administration of intravitreal antivirals also provides an opportunity for vitreous sampling (akin to the “tap and inject” for endophthalmitis), allowing for PCR-based identification of causative virus. In one small series, three patients treated with intravitreal ganciclovir as well as intravenous foscarnet, ganciclovir, or acyclovir led to excellent outcomes,<sup>112</sup>

while in another series three patients responded to intravitreal antiviral treatment despite progression on intravenous acyclovir.<sup>113</sup> A similar approach has been employed for progressive outer retinal necrosis.<sup>114,115</sup> In one series of 81 eyes with ARN syndrome, intravitreal foscarnet was associated with a 40% lower rate of retinal detachment than eyes treated solely with systemic therapy.<sup>101</sup> Yeh et al.<sup>116,117</sup> compared 12 patients receiving intravitreal and systemic antivirals to 12 patients receiving only systemic therapy. This group found that patients receiving combination therapy were more likely to gain visual acuity and less likely to develop detachment, with progression to severe vision loss at 0.13 per patient year in the combination group compared with 0.54 per patient year in the systemic-only group. However, Tibbetts et al.<sup>118</sup> studied a cohort of 58 ARN patients of whom 36 were treated with acyclovir only and 22 were treated with either newer agents and/or intravitreal antivirals, and found equivalent outcomes for the groups, with 24% of each group achieving 20/200 or worse vision.

Acute decreases in vision in ARN patients can result from ischemic optic neuropathy and have led to trials of anticoagulants such as aspirin, along with high-dose oral steroids early after initiation of antiviral therapy. Systemic corticosteroids also may limit intraocular inflammation and the vitreous reaction, but are generally begun only after 24–48 hours of intravenous acyclovir. Virus particles or antigens have not been observed in the optic nerve in ARN, and it appears that the optic nerve dysfunction is caused by ischemia from swollen vascular endothelial cells, thrombotic arteriolar occlusion, and infiltration of the optic nerve by inflammatory cells. Hyperaggregation of platelets has been reported in six of seven patients with bilateral ARN studied, as determined by adenosine 5-diphosphate aggregation testing and partial prothrombin times.<sup>119</sup> Optic nerve dysfunction has been reported in ARN patients despite anticoagulation therapy or antiplatelet therapy. Studies have employed optic nerve sheath fenestration in conjunction with acyclovir therapy in a small group of ARN patients with optic neuropathy and disc edema, with reported improvement in final vision in six of eight eyes.<sup>14</sup> Better results were obtained in the subgroup that underwent

decompression within 12 days of the onset of the optic neuropathy.

In early studies prior to current antiviral management techniques, the second eye became involved in 36% of ARN patients, usually within 6 weeks of the first eye's involvement.<sup>19</sup> More recent studies have suggested a fellow-eye involvement rate of ~3% with appropriate antiviral treatment.<sup>118</sup> The duration of systemic treatment to prevent fellow-eye involvement is not well established but generally risk is felt to be decreased in 6–12 weeks, although one report suggested significantly reduced fellow-eye involvement when systemic treatment was carried out greater than 14 weeks.<sup>120</sup> However, bilateral ARN has been reported up to 46 years after the first eye was affected,<sup>121,122</sup> raising a question as to utility of very long-term or life-long prophylaxis in patients who have lost vision in one eye from ARN syndrome. Risk of second-eye involvement may also be dependent on the etiologic agent causing disease. Additionally, rare cases of reactivation in the originally affected eye have been reported.<sup>123</sup>

Retinal tears at the junction of normal and necrotic retina, as well as subsequent proliferative retinopathy creating a complicated combined traction–rhegmatogenous retinal detachment, pose a difficult problem in the management of ARN. Whereas Peyman et al.<sup>7,18</sup> obtained good results in selected patients with intravenous and intravitreal acyclovir in conjunction with prophylactic vitrectomy and scleral buckles in an uncontrolled study of active ARN cases that had not yet developed detachment, others have not been able to prevent retinal detachment by similar management,<sup>124</sup> while still others have found decreased incidence of secondary detachment, but no improvement in final mean visual acuity.<sup>125</sup> In a study of 13 eyes of 12 ARN patients, the incidence of retinal detachment despite intravenous acyclovir therapy was 84%, suggesting that antiviral therapy alone does not effectively preclude retinal detachment.

The use of prophylactic laser has been an issue of great debate in recent years. Several studies have demonstrated the benefit of prophylactic laser photocoagulation posterior to areas of active retinitis,<sup>28,58,97,126</sup> while others have found no decrease in the risk of retinal detachment.<sup>98,127</sup> One reason for this variability may be the small sample sizes used in these studies. Investigators have also

postulated that generally the eyes receiving prophylactic photocoagulation have less vitritis, which allows for treatment. It is thought that vitritis over necrotic retina increases the risk of retinal detachment. They further reason that the eyes unable to receive prophylactic photocoagulation because of media opacity are at higher risk for retinal detachment than those with less vitritis and subsequently clearer media.<sup>98</sup> Without prospective randomized controlled studies, this question may not be definitively answered.

One study found that retinal detachments appear to occur anywhere from 9 to 148 days from the onset of symptoms, so these eyes should be carefully examined at each office visit.<sup>56</sup> With the use of modern microsurgical techniques, including intravitreal silicone oil, air–fluid exchange, demarcating laser photocoagulation, and a long-acting gas tamponade, a high percentage of retinas can be anatomically reattached. In one recent study of 12 eyes of 10 patients with follow-up of mean 4.4 years undergoing retinal detachment surgery, there were no cases of redetachment or of hypotony.<sup>128</sup> However, patients must be carefully selected, and it must be kept in mind that patients with known optic atrophy or minimal vision because of macular pucker or dysfunction before detachment are unlikely to obtain improved visual function despite anatomically successful retinal reattachment. Several studies have looked at whether prophylactic vitrectomy might improve outcomes.<sup>129–131</sup> However, the largest study of 48 eyes treated with prophylactic vitrectomy versus 56 eyes treated conventionally<sup>132</sup> found no improvement in outcome in the group treated prophylactically.

ARN syndrome remains a relatively recently described, potentially visually devastating disorder with multifactorial pathogenesis. Its successful management appears to depend on further advances in antiviral chemotherapy, control of the ischemic vasculopathy, and prevention of proliferative vitreoretinopathy.

## **Introduction**

**Disruption of the Retina and Retinal Pigment Epithelium**

**Vascular Damage and/or Occlusion**

**Cystoid Macular Edema**

**Retinal Folds**

**Crystalline Retinopathy**

**Uveitis**

**Miscellaneous**

**Summary**

## **Introduction**

A variety of systemic (and select topical and intravitreal) medications are associated with retinal abnormalities and/or toxicity. Fortunately, in the majority of cases the loss of visual function is minimal or even at times reversible, following discontinuation of the inciting drug. Nevertheless, permanent or progressive visual loss may occur in some instances. We present

those medications known to produce a well-described anomaly and have omitted others that have not been definitively proven to cause retinal abnormalities. The medications are grouped according to the type of retinal toxicity they produce, and they are summarized in

### **Box 92.1**

## **Patterns of Retinal Toxicity**

### **Disruption of the retina and retinal pigment epithelium**

Chloroquine derivatives

Chloroquine

Hydroxychloroquine

Phenothiazines

Thioridazine

Chlorpromazine

Quinine sulfate

Clofazimine

Deferoxamine

Corticosteroid preparations

Cisplatin and BCNU (carmustine)

#### **Vascular damage**

Quinine sulfate

Cisplatin and BCN

Talc

Oral contraceptives

Aminoglycoside antibiotics

Vancomycin

Interferon (carmustine)

Ergot alkaloids

Phenylpropanolamine

**Cystoid macular edema**

Epinephrine

Latanoprost

Nicotinic acid

Paclitaxel/docetaxel

Fingolimod

**Retinal folds**

Acetazolamide

Chlorthalidone

Ethoxzolamide

Hydrochlorothiazide

Metronidazole

Sulfa antibiotics

Triamterene

Topiramate

**Crystalline retinopathy**

Tamoxifen

Canthaxanthin

Methoxyflurane

Talc

Nitrofurantoin

### **Uveitis**

Rifabutin

Cidofovir

### **Miscellaneous**

Digoxin

Methanol

MEK inhibitors

## **Disruption of the Retina and Retinal Pigment Epithelium**

### **Chloroquine Derivatives**

#### **Chloroquine**

Chloroquine was first used as an antimalarial drug in World War II. Currently it is prescribed for treatment of amebiasis, rheumatoid arthritis, systemic lupus erythematosus, and in countries primarily outside the United States, for prophylaxis against malaria. Retinal toxicity with degeneration of the RPE and neurosensory retina as a result of long-term daily use of chloroquine has been well described.<sup>1-7</sup> However, most cases of retinopathy have developed when a higher than currently recommended dose (3 mg/kg/day using lean body weight) was used.<sup>8</sup> A daily dose exceeding 250 mg

with a total cumulative dose between 100 and 300 g is customarily needed to develop features of toxicity.<sup>9</sup> One study showed a 19% incidence of chloroquine retinopathy in patients taking a mean daily dose of 329 mg.<sup>10</sup> Conversely, with strict adherence to a low dose per diem, the incidence of retinal abnormalities is minimal even when cumulative doses reach over 1000 g.<sup>11</sup>

A paracentral scotoma may be the earliest manifestation of retinal toxicity and can precede the development of any ophthalmoscopic or ERG abnormality.<sup>12</sup> Subtle macular pigment stippling with a loss of the foveal light reflex (Fig. 92.1) usually appears on fundus examination before the development of a classic bull's-eye maculopathy, in which a ring of depigmentation surrounded by an area of hyperpigmentation is seen centered on the fovea (Fig. 92.2). Visual acuity decreases when the RPE abnormalities involve the center of the fovea. The peripheral retina can display pigment mottling, which may, in severe cases, develop into the appearance of primary tapetoretinal degeneration with narrowed retinal vessels, optic disc pallor, and eventual blindness (Fig. 92.3).

**FIG. 92.1** Early chloroquine toxicity. Photograph (A) and fluorescein angiogram (B) show early perifoveal pigmentary changes. (Reproduced with permission from Mieler WF.

Focal points. American Academy of Ophthalmology, December 1997.)

**FIG. 92.2** Advanced chloroquine toxicity. Later photograph (A) and fluorescein angiogram (B) from the patient in Fig. 92.1 show marked progression with advanced widespread pigmentary changes. (Reproduced with permission from Mieler WF. Focal points. American Academy of Ophthalmology, December 1997.)

**FIG. 92.3** Chloroquine retinopathy. Photograph shows bone-spicule pigmentary changes that can develop in advanced cases. The appearance is similar to endstage retinitis pigmentosa.

After the cessation of chloroquine treatment, early subtle macular changes may possibly revert back to normal. Although far advanced cases may progress despite discontinuation of the drug, most patients remain stable with long-term follow-up.<sup>13,14</sup> Chloroquine, however, is very slowly excreted from the body. It has been detected in the plasma, red blood cells, and urine of patients 5

years after their last known ingestion.<sup>15</sup> This prolonged presence may account for the rare cases of delayed onset of chloroquine retinopathy seen up to 7 years or longer after discontinuation.<sup>16,17</sup>

Fluorescein angiography (FA) may be helpful in the early demonstration of pigment abnormalities in the macula (see [Figs. 92.1](#) and [92.2](#)). There is minimal evidence of damage to the choriocapillaris on FA in the areas of pigment disturbance. The electroretinogram (ERG) and electro-oculogram (EOG) may be abnormal early, although the EOG is sometimes supernormal initially and is not as helpful diagnostically.<sup>18</sup> Histopathologic sections demonstrate loss of retinal pigment epithelium (RPE) pigmentation with an accumulation of pigment-laden cells in the outer retinal layers with damage and reduction of photoreceptors.<sup>19</sup> Electron microscopic studies reveal more widespread damage to the retina, especially the ganglion cell layer.<sup>20</sup> The retinal nerve fiber layer thickness has been shown to be significantly decreased compared to normal in patients on chloroquine therapy and is correlated to the daily dose taken.<sup>21</sup> Fundus autofluorescence (FAF) and optical coherence tomography (OCT) findings suggest that the ganglion cell layer is affected by toxicity initially, especially surrounding the retinal vasculature.<sup>22</sup>

Like the phenothiazines (to be discussed later in this section), chloroquine is bound by melanin and concentrated in the RPE and uveal tissues.<sup>23</sup> It appears that chloroquine toxicity may be mediated by disruption of lysosomal function in the RPE and neural retina and by inhibition of critical enzymes and interference with their metabolic function.<sup>16,24,25</sup>

With the availability of hydroxychloroquine, a less toxic though quite similar medication, use of chloroquine has steadily waned. Screening for toxicity has been more fully evaluated recently for hydroxychloroquine (see below), and similar testing is likely appropriate for chloroquine as well. Color vision can be abnormal in early toxicity and use of the Standard Pseudoisochromatic Plates Part 2 (SPP-2) or the American Optical Hardy Rand Rittler (AO-HRR) color vision plates provides adequate sensitivity and specificity for detection of abnormalities.<sup>26,27</sup> Multifocal ERG testing may be abnormal in early toxicity even when other tests such as visual field and full-field ERG are normal.<sup>28,29</sup>

## Hydroxychloroquine

Given the incidence of toxicity with chloroquine, most rheumatologists prefer hydroxychloroquine for the treatment of rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). Although it can produce a retinopathy identical to chloroquine, its occurrence is much less common.<sup>30-33</sup> Toxicity involving decreased visual acuity, paracentral scotoma, and a bull's-eye maculopathy has been documented (Figs. 92.4 and 92.5).<sup>34-39</sup> Many of these patients received above the recommended daily dosage of 6.5 mg/kg per day, but the classic fundus findings have been reported at lower doses as well.<sup>34,36,39-41</sup> Screening for toxicity becomes more important the longer the patient has been taking the drug as toxicity approaches 1% after 5-7 years of therapy and/or a cumulative dose of 1000 g.<sup>42-44</sup>

**FIG. 92.4** Hydroxychloroquine toxicity. Photograph displays nonspecific pigmentary changes in the central macula.

**FIG. 92.5** Hydroxychloroquine toxicity. Photograph (A) and fluorescein angiogram (B) show a marked bull's-eye maculopathy, virtually identical to what has been described in association with chloroquine maculopathy. The patient was of short stature.

Several authors have questioned the utility of screening given the low yield, high cost, and the difficulty in diagnosing the condition early enough to prevent damage.<sup>45-48</sup> Nevertheless, if retinal and functional changes are detected early, severe visual impairment can be averted.<sup>41,49</sup>

The revised American Academy of Ophthalmology guidelines for screening include a baseline examination performed at the commencement of therapy.<sup>50</sup> Screening examinations during the first 5 years of therapy can be performed during routine ophthalmic examination (interval to be determined by the age of the patient and the presence or absence of retinal or macular disease). Earlier recommendations emphasized dosing by weight. As most patients are given 400 mg/day of hydroxychloroquine, this dose is acceptable for all except for those with short stature (generally 5 feet 2 inches or less in height). These patients should be given a dose based on their ideal body weight, otherwise overdose may occur.<sup>51</sup> Furthermore, the dosage may need to be altered if the patient has renal or liver dysfunction.

After 5 years of therapy, screening should be performed at least annually.<sup>43</sup> Current guidelines are centered around tests found to detect early toxicity often prior to any appreciable fundus findings. Patients should have a Humphrey 10-2 automated visual field test (HVF 10-2) with a white test object and in addition should have one of three objective tests at each screening: multifocal

electroretinogram (mf-ERG),<sup>42,52-56</sup> spectral domain OCT (SD-OCT),<sup>57-59</sup> and/or FAF<sup>60</sup> (Fig. 92.6). Any abnormalities of the pattern deviation on the HVF 10-2 need to be taken seriously and the test repeated to confirm its reproducibility. In most situations, SD-OCT should also be obtained, particularly since SD-OCT testing is so readily available. While abnormalities on FAF are generally associated with concerns for active disease, the test has not yet been shown to be reliably predictable as a screening tool for future toxicity.

**FIG. 92.6** Screening tests for hydroxychloroquine toxicity. Color photograph (A) showing mild macular pigment mottling in a patient on hydroxychloroquine. Fluorescein angiogram (B) demonstrates hyperfluorescence in the area of the perifoveal pigmentary changes. Fundus autofluorescence (C) shows a perifoveal hypoautofluorescence with a border of hyperautofluorescence. Spectral domain optical coherence tomography (D) shows atrophy of the outer nuclear layer and disruption of the ellipsoid segment. Multifocal electroretinogram (E) shows diminished paracentral waveforms. (Courtesy of David Sarraf, MD, Los Angeles, CA.)

Adjunctive testing now allows for earlier detection of hydroxychloroquine toxicity. FAF has become a widely employed imaging tool with a fairly high sensitivity for recognition of early toxicity. Mild retinopathy may show a paracentral ring of increased FAF, while more advanced stages may present as pericentral mottled loss of FAF with increased FAF in the adjacent retina. Late stages may demonstrate a complete loss of pericentral FAF.<sup>60</sup> Many regard mf-ERG as the most definitive test of toxicity. An analysis of mf-ERG findings in long-term hydroxychloroquine users revealed multiple patterns of abnormalities – paracentral loss, foveal loss, peripheral loss, and generalized loss.<sup>52</sup> The SD-OCT abnormalities associated with hydroxychloroquine toxicity include discontinuity of the ellipsoid zone, thinning of the outer nuclear layer and hyperscattering of the outer segment level (Fig. 92.7).<sup>57</sup> However, perifoveal thinning of the inner plexiform and ganglion cell layers on OCT may precede structural changes to the photoreceptors.<sup>59</sup>

**FIG. 92.7** Hydroxychloroquine toxicity: optical coherence tomography image of (A) the right and (B) the left eye, demonstrating perifoveal atrophy of the outer retinal layers and attenuation of the ellipsoid segment in a patient taking hydroxychloroquine for nine years.

As noted in the preceding paragraph, it is imperative to discuss the risk of toxicity with patients and the rationale for screening (to detect, but not necessarily prevent visual loss). If ocular toxicity occurs,<sup>35,37,38,61</sup> and is recognized at an early stage, efforts should be made to communicate this directly to the prescribing physician so that alternative treatment options can be discussed with the patient. In almost all cases, cessation of the drug should be suggested.

In early 2016, the American Academy of Ophthalmology task force on screening recommendations for hydroxychloroquine retinopathy published new updated guidelines in the journal *Ophthalmology*.<sup>62</sup> The 2016 guidelines have lowered the recommended safe dosage to <5.0 mg/kg per day of real body weight. Additionally, it is important to recognize that patients of Asian descent tend to have perifoveal retinopathy, rather than central macular involvement. Annual screening, especially after 5 years of hydroxychloroquine usage, should be performed with Humphrey VF 10–2 and SD-OCT. Finally, one needs to be aware that coexisting renal disease and/or concurrent usage of tamoxifen may increase or hasten development of hydroxychloroquine retinopathy.

## Phenothiazines

### Thioridazine

Blurred vision, dyschromatopsia (reddish or brownish discoloration of vision), and nyctalopia characterize acute toxicity with thioridazine.<sup>63</sup> In the earliest stages the fundus appearance may be normal or display only mild granular pigment stippling (Fig. 92.8). An intermediate stage is characterized by circumscribed nummular areas of RPE loss from the posterior pole to the midperiphery<sup>64</sup> (Fig. 92.9A). FA reveals disruption of the choriocapillaris in these zones of pigment rarefaction (Fig. 92.9B). In late stages of thioridazine toxicity, widespread areas of depigmentation alternating with hyperpigmented plaques, vascular attenuation, and optic atrophy are seen<sup>65</sup> (Fig. 92.10).

**FIG. 92.8** Early thioridazine toxicity. Photograph shows mild granular pigment stippling temporal to the macular region.

**FIG. 92.9** Intermediate thioridazine toxicity. Fundus photograph (A) and fluorescein angiogram (B) show central and peripheral nummular pigmentary changes with corresponding atrophy of the choriocapillaris.

(Courtesy of David Sarraf, MD, Los Angeles, CA.)

**FIG. 92.10** Endstage thioridazine toxicity. Photograph (A) and fluorescein angiogram (B) show diffuse pigmentary and choriocapillaris atrophy, optic atrophy, and vascular attenuation. This severe endstage disease resembles choroideremia. (C) Optical coherence tomography demonstrates outer retinal atrophy with mild cystic changes. (Courtesy of Daniel Kiernan, MD, New York, NY.)

Retinal toxicity from thioridazine is dependent more on the total daily dose than on the cumulative amount of drug received.<sup>66</sup> With higher daily doses, toxicity can occur rapidly, even within the first two weeks of therapy.<sup>67</sup> Toxicity is rare at dosages less than 800 mg/day. Nonetheless, a few cases have been reported with lower

doses given over several years.<sup>68-72</sup> As a result, many now suggest that any patient taking thioridazine, regardless of the daily dose, should be monitored for the development of visual symptoms or fundus changes.

In the initial stages of toxicity, visual field testing can reveal mild constriction, paracentral scotomas, or ring scotomas. ERG is either normal or shows decreased oscillatory potentials. In the later stages, both the rod and cone functions of the ERG, as well as EOG, are markedly abnormal.<sup>73</sup> If the drug is stopped early, ERG testing often improves over the first year.<sup>74</sup> Histologic studies demonstrate that atrophy and disorganization of photoreceptor outer segments occurs primarily, with a secondary loss of the RPE and choriocapillaris.<sup>65</sup>

The early fundus changes associated with thioridazine often progress despite discontinuation of therapy.<sup>64</sup> It is unclear whether this degeneration represents continued toxicity of the drug or a delayed expansion of chorioretinal scarring to areas of subclinical, preexisting damage.<sup>74</sup> Visual function, in contrast to fundus appearance, usually improves over the first year after a toxic reaction, but there has been one report of severe progressive decline in vision after cessation of the drug.<sup>75</sup>

The mechanism of thioridazine-mediated toxicity remains unknown. Many phenothiazines bind melanin granules of the RPE and uveal tissue, but not all commonly instigate retinal toxicity.<sup>76-78</sup> The compound NP-207 (piperidyl-chlorophenothiazine hydrochloride) has a remarkably similar chemical structure to thioridazine, including the same piperidyl side chain. NP-207 was never marketed because of the pronounced pigmentary retinopathy that developed during early clinical trials.<sup>79</sup> This piperidyl side chain is not present in other phenothiazines such as chlorpromazine, which exhibit much less retinal toxicity. Experimental studies demonstrate that phenothiazines both alter enzyme kinetics and inhibit oxidative phosphorylation with subsequent abnormalities in rhodopsin synthesis.<sup>80-82</sup> Other studies postulate that phenothiazine toxicity is due to the drug's effect on the dopamine receptors in the retina.<sup>83</sup> Further study is necessary to determine whether these observed effects are involved in the pathogenesis of thioridazine toxicity.

A review of the daily and cumulative drug dosage is essential in patients taking thioridazine. Baseline fundus photography and possibly ERG testing may be helpful if future toxicity develops. Given the many antipsychotic medications available today, consideration of alternative agents may be discussed with the patient's psychiatrist. At the earliest sign of toxicity, thioridazine should be discontinued.

## Chlorpromazine

Chlorpromazine is a piperazine similar to thioridazine but lacks the piperidyl side chain as mentioned above. The compound binds strongly to melanin and can cause hyperpigmentation in the skin, conjunctiva, cornea, lens, and retina<sup>84-90</sup> (Fig. 92.11). Other ocular effects include oculogyric crisis, miosis, and blurred vision caused by paralysis of accommodation. Usual doses range from 40 to 75 mg/day, but dosages up to 800 mg/day are not uncommon.

**FIG. 92.11** Typical chlorpromazine-induced anterior stellate lens opacities. These findings are generally not felt to be of visual significance.

Retinal toxicity from chlorpromazine is rare. When massive doses are given (e.g., 2400 mg/day for 12 months), pigmentary changes may occur in the retina with attenuation of retinal vessels and optic nerve pallor<sup>87</sup> (Fig. 92.12). Similar to thioridazine, the development and extent of toxicity are more closely related to daily dosage than total amount of drug taken.

**FIG. 92.12** Chlorpromazine toxicity. Photograph (A) and fluorescein angiogram (B) show granular pigmentary changes, though less severe than those generally seen with thioridazine.

## MEK Inhibitors

A new class of chemotherapy agents selectively inhibiting the mitogen-activated protein kinase/extracellular signal-regulated kinase (MAPK/ERK) kinase, also referred to as the MEK enzyme, has shown promising results for systemic malignancies. To date, trametinib is the only FDA-approved medication in this class, although binimetinib, selumetinib, and cobimetinib are actively being researched. These drugs have demonstrated particular efficacy for select metastatic cutaneous and uveal melanoma. However, frequent retinal toxicity has recently been recognized. The typical ocular side-effect described is multifocal serous retinal detachment. Pigment epithelial detachment, optic neuropathy, retinal vein occlusion, retinal hemorrhage, cystoid macular edema, and anterior chamber inflammation have also been reported.<sup>91-97</sup> Retinopathy has been described in patients undergoing treatment for metastatic melanoma, metastatic cholangiocarcinoma, and metastatic rectal cancer.

A large proportion of patients with objective signs of retinal toxicity remain asymptomatic. A detailed study of 35 patients on binimetinib therapy for melanoma demonstrated subretinal fluid visible on OCT in approximately three-quarters of patients, affecting the subfoveal region in 85% of these patients. The

subretinal fluid can be quite shallow and extend laterally for large distances. FA and SD-OCT imaging did not exhibit areas of choroidal abnormality or focal RPE defect. Additionally, EOG was abnormal in over 90% of tested patients. Thus, the authors concluded that the retinal toxicity was secondary to a panretinal dysfunction of the RPE. While visual acuity returned to the pretreatment baseline in nearly all patients, EOG findings remained subnormal beyond resolution of the subretinal fluid. In some patients, full-field ERG showed a decreased B-wave, while multifocal ERG showed a diminished response. Furthermore, an array of antiretinal and anti-RPE antibodies were positive in a subset of patients.<sup>91</sup> There have been reports of retinal vein occlusion while on MEK inhibitor therapy. However, given the potentially hypercoagulable state of patients with metastatic malignancy, a causative relationship has not yet been established.<sup>97</sup> A small number of uveitis cases possibly related to MEK inhibitor treatment have been described. Both iritis<sup>93</sup> and panuveitis<sup>98</sup> have been published. However, the panuveitis patient was receiving both trametinib and the B-raf inhibitor dabrafenib, so the underlying etiology of the condition is uncertain.<sup>98</sup>

Subretinal fluid typically reverses with 2–6 weeks of ongoing therapy or discontinuation of treatment (Fig. 92.13).<sup>92</sup> Some pigment epithelial detachments have resolved spontaneously. Macular edema may be responsive to topical steroid or nonsteroidal antiinflammatory agents.<sup>94</sup> Inflammatory episodes have resolved with steroid treatment and stopping therapy. Discontinuation or decreased dosing may be considered for sight-threatening toxicity.<sup>94</sup> Given the relatively minor visual changes and reversibility of ocular toxicity, full ophthalmologic work-up of all patients on these agents has not been advocated at this time.<sup>92</sup>

**FIG. 92.13** MEK inhibitor toxicity. (A) Optical coherence tomography demonstrating multifocal neurosensory retinal detachments, which were seen bilaterally, 2 weeks after starting pimasetib. Resolution of subretinal fluid was seen 1 week after discontinuation. (B) Fluid accumulation was again seen 2 weeks after rechallenge at half dose, which resolved after being at the lower dose for 1 month (C). (Courtesy of Michael Chilov, MD, Sydney, Australia.)

## Quinine Sulfate

Quinine sulfate was first used for the treatment of malaria in World War II, but it currently is prescribed for the management of nocturnal muscle cramps or “restless leg syndrome.” The recommended daily dose is less than 2 g. Signs of systemic toxicity occur with doses greater than 4 g, and the fatal oral dose is 8 g. Ocular toxicity with quinine develops after an overdose, either by accidental ingestion or by attempted abortion or suicide. Rarely, chronic ingestion at low levels can result in ocular toxicity as well.<sup>91</sup>

With an overdose, a syndrome known as *cinchonism* is rapidly produced, consisting of nausea, vomiting, headache, tremor, and sometimes hypotension and loss of consciousness. When patients awake they often are completely blind and have dilated, unreactive pupils.<sup>92</sup> In the acute stages of toxicity, fundus examination reveals mild venous dilation with minimal retinal edema and normal arterial caliber. The FA displays minimal abnormalities. ERG testing shows an acute slowing of the a-wave with increased depth, loss of oscillatory potentials, and a decreased b-wave.<sup>93</sup> EOG and visual-evoked potential (VEP) testing are also abnormal.

Over the next few days visual acuity returns, but the patient is left with a small central island of vision. There is a progressive attenuation of the retinal arterioles with the development of optic disc pallor over the next few weeks to months and iris depigmentation can occur<sup>94</sup> (Fig. 92.14). Early investigators believed the mechanism of quinine toxicity to be vascular in origin. This was based primarily on the fundus appearance several weeks after ingestion, which showed marked arteriolar attenuation and optic disc pallor.<sup>92,95</sup> More recent experimental and clinical studies have demonstrated minimal involvement of the retinal vasculature in the early stages of quinine toxicity.<sup>92,95,96</sup> Furthermore, ERG and histologic studies show that the site of toxicity is likely the retinal ganglion, bipolar, and photoreceptor cells.<sup>92,96</sup> Findings on SD-OCT demonstrate inner retinal atrophy.<sup>97</sup> The exact mechanism of quinine toxicity is unidentified, but some have suggested that it may act as an acetylcholine antagonist and disrupt cholinergic transmission in the retina.<sup>98</sup>

**FIG. 92.14** Quinine toxicity. Photograph illustrates the characteristic optic nerve head pallor with diffuse arteriolar attenuation approximately 2 months after an intentional overdose of the medication.

## Clofazimine

Clofazimine is a red phenazine dye that has been used to treat dapsone-resistant leprosy, psoriasis, pyoderma gangrenosum, discoid lupus, and more recently, *Mycobacterium avium*-complex infections in AIDS patients. With treatment over several months, clofazimine crystals may accumulate in the cornea. Two cases of bull's-eye maculopathy with pigmentary retinopathy (Fig. 92.15) have been reported in AIDS patients with doses of 200–300 mg/day (total dose, 40–48 g).<sup>99,100</sup> Visual acuity was mildly affected, with reduced scotopic, photopic, and flicker ERG amplitudes. Cessation of treatment may result in the clearance of the corneal deposits but does not appear to affect the retinopathy.

**FIG. 92.15** Clofazimine toxicity. Photograph (A) and fluorescein angiogram (B) show moderate macular pigmentary changes in a bull's-eye pattern.

## Dideoxyinosine (DDI)

A midperipheral pigmentary retinopathy was initially reported in

three children with AIDS receiving high-dose therapy with the antiviral 2', 3'-dideoxyinosine.<sup>101</sup> The cases were associated with ERG and EOG changes. More recently, similar phenotypes have been observed in adults, with chorioretinal atrophy anterior to the vascular arcades with corresponding hypoautofluorescence or mottled hyperautofluorescence and hypoautofluorescence (Fig. 92.16). SD-OCT confirms severe chorioretinal atrophy in these regions.<sup>102</sup> The retinal toxicity typically stabilizes after discontinuation of the medication, yet some degree of continued pigment degradation may occur years later

**FIG. 92.16** Dideoxyinosine (DDI) toxicity. Fundus photograph (A) showing severe midperipheral retinal pigmentary mottling in an adult having been exposed to DDI in the past. Fluorescein angiogram (B) highlights the retinal pigment epithelium (RPE) changes. Fundus autofluorescence (C) demonstrates patches of peripheral hypoautofluorescence. Optical coherence tomography (D) shows outer retinal and RPE atrophy. (Courtesy of David Sarraf, MD, Los Angeles, CA.)

## Deferoxamine

Intravenous and subcutaneous administration of deferoxamine has been used to treat patients who require repeated blood transfusions and subsequently develop complications of iron overload. High-dose intravenous and subcutaneous therapy has produced visual loss, nyctalopia, peripheral and central field loss, and reduced ERG amplitudes and EOG ratios.<sup>103,104</sup> The fundus examination can be normal initially, or there may be a faint graying of the macula.<sup>105</sup> Pigmentary changes in the macula and periphery develop within a few weeks and are particularly highlighted by FA (Fig. 92.17).<sup>106</sup> In some instances, toxicity may present as vitelliform macular lesions.<sup>107</sup> Accumulated material has been shown to deposit within the outer retina or in Bruch's membrane-RPE complex on OCT.<sup>108</sup> Return of visual function occurs with cessation of therapy. Deferoxamine chelates many metals other than iron, and it is possible that the mechanism of toxicity may involve the removal of copper from the RPE.<sup>103</sup> Histopathologic changes occur primarily in the RPE and include loss of microvilli from the apical surface, patchy depigmentation, vacuolation of the cytoplasm, swelling and calcification of mitochondria, and disorganization of the plasma membrane.<sup>109</sup>

**FIG. 92.17** Deferoxamine toxicity. Photograph (A) and fluorescein angiogram (B) show a diffuse pigmentary retinopathy with macular and retinal edema.

## Corticosteroid Preparations

The vehicles of several common corticosteroid preparations have been shown to cause retinal necrosis when inadvertently injected into the eye<sup>110,111</sup> (Fig. 92.18). The corticosteroids themselves probably have a minimal toxic effect on the retina.<sup>112</sup> Celestone Soluspan, with its vehicle benzalkonium chloride, and Depo-Medrol, with myristyl gamma-picolinium chloride, caused the most extensive retinal damage in an experimental study comparing several depot steroids.<sup>102</sup> If one of these agents is inadvertently injected, immediate surgical removal should be instituted.

**FIG. 92.18** Inadvertent intraocular corticosteroid injection. Photograph shows endstage retinopathy, with sclerotic vessels and diffuse pigmentary changes, after an inadvertent intraocular injection of corticosteroid.

## Cisplatin and BCNU (Carmustine)

Cisplatin and BCNU are used for the treatment of malignant gliomas and metastatic breast cancer. Three different types of retinal toxicity have been reported with these agents. One type of change consists of a pigmentary retinopathy of the macula with markedly decreased visual acuity and frequently abnormal electrophysiologic testing. This pigmentary change has been reported after administration of combined intraarterial cisplatin and BCNU and with cisplatin alone for malignant glioma.<sup>113,114</sup> These findings probably are the result of platinum toxicity of the retina. Severe bilateral visual loss was reported after intravenous

cisplatin in a patient that received four times the intended dose for treatment of lymphoma.<sup>115</sup> Later histology showed a splitting of the outer plexiform layer.

A second type of retinopathy has been described and consists of cotton-wool spots, intraretinal hemorrhages, macular exudate, and optic neuropathy with disc swelling. This was reported in the setting of high-dose chemotherapy with cisplatin, cyclophosphamide, carmustine, and autologous bone-marrow transplantation for metastatic breast cancer.<sup>116</sup> The third type of change involves a vascular retinopathy or optic neuropathy, which can include arterial occlusion, vasculitis, and papillitis. This has been seen in approximately 65% of patients receiving intraarterial BCNU alone or combined with cisplatin for malignant glioma.<sup>114</sup> These fundus changes are associated with a profound visual loss that begins about 6 weeks after the start of therapy. Other ocular effects may include orbital pain, chemosis, secondary glaucoma, internal ophthalmoplegia, and cavernous sinus syndrome. Injection of medication above the ophthalmic artery can still result in toxicity.<sup>107</sup> The visual loss usually is progressive, and no treatment is known.

## Miscellaneous Agents

Overdose of potassium iodate, an iodized salt used for iodine supplementation in areas endemic for goiter, has been shown to cause profound visual loss and extensive fundus pigmentary abnormalities.<sup>108</sup> FA reveals RPE window defects and ERG and VEP testing show marked impairment of retinal function. Visual acuity may improve slowly over several months. There have been two cases of pigmentary retinopathy with diminished ERG amplitudes reported after administration of denileukin diftitox.<sup>117</sup>

## Vascular Damage and/or Occlusion

### Quinine Sulfate

See above, in the section [Disruption of the retina and retinal pigment epithelium](#).

## Cisplatin and BCNU (Carmustine)

See above, in the section [Disruption of the retina and retinal pigment epithelium](#).

## Talc

A characteristic retinopathy consisting of small, white, glistening crystals concentrated in the end arterioles of the posterior pole has been described in intravenous drug abusers<sup>118-120</sup> (Fig. 92.19). These addicts crush oral medications such as methylphenidate hydrochloride (Ritalin) or methadone HCl and then create an aqueous suspension by adding water and heating the mixture. The solution is subsequently drawn up into a syringe, with occasional attempts at filtering the mixture with cotton fibers, gauze, or cigarette filters. These oral medications contain talc (hydrous magnesium silicate) as inert filler material; after intravenous administration, talc particles embolize to the pulmonary vasculature, where the larger particles are trapped. After repeated injections over months to years, collateral vasculature develops, allowing the particles to enter the systemic circulation and embolize to other organs, including the eye. Even before shunt development, particles smaller than 7  $\mu\text{m}$  can traverse the pulmonary capillary bed and enter the retinal circulation.<sup>121</sup>

**FIG. 92.19** Talc retinopathy. Characteristic perifoveal

yellow-white glistening crystals.

Once a large number of talc particles lodge in the small arterioles of the retinal vasculature, a characteristic picture of an ischemic retinopathy begins to develop. Capillary nonperfusion, microaneurysm formation, cotton-wool spots, and venous loops can all be seen. In severe cases optic disc and peripheral neovascularization and vitreous hemorrhage can develop<sup>122-124</sup> (Fig. 92.20). An experimental model of talc retinopathy in monkeys has demonstrated with light and electron microscopic techniques that the vascular abnormalities induced are very similar to other ischemic retinopathies seen in humans, such as sickle cell and hypertensive retinopathy.<sup>125-127</sup>

**FIG. 92.20** Ischemic talc retinopathy. Photograph (A) and fluorescein angiogram (B) show widespread capillary dropout, neovascularization, and preretinal hemorrhage.

Once talc retinopathy is diagnosed, an attempt at educating the patient as to the cause of the disorder is indicated. Treatment of neovascularization and vitreous hemorrhage should be undertaken using laser photocoagulation and pars plana vitrectomy if necessary in a manner similar to that used for sickle cell or proliferative diabetic retinopathy.

## Oral Contraceptives

Oral contraceptives have been implicated in some cases of central retinal vein occlusion (CRVO), retinal and cilioretinal artery

obstruction, and retinal edema occurring in young women.<sup>128-134</sup> The synthetic estrogen and progesterone contained in contraceptive pills are thought to adversely affect coagulation factors and induce a hypercoagulable state leading to thromboembolic complications. Most of the studies reporting ocular complications are from the 1960s and 1970s, when the estrogen concentrations used in “the pill” were much higher (Fig. 92.21). Some recent prospective studies have failed to show an increased incidence of ocular complications with the drug, though one large study showed an increase in “retinal vascular findings”.<sup>135-137</sup>

**FIG. 92.21** Nonischemic central retinal vein occlusion (CRVO) in a 40-year-old hypertensive female on oral contraceptives. Upon stopping the oral contraceptives, the CRVO resolved without treatment.

## Aminoglycoside Antibiotics (Intraocular)

Retinal toxicity from aminoglycoside antibiotics has been reported after inadvertent intraocular injection of massive doses, intravitreal injection for bacterial endophthalmitis, prophylactic intravitreal injection after pars plana vitrectomy, prophylactic subconjunctival injections after routine ocular surgery, and with the use of small amounts in the infusion fluid during cataract extraction.<sup>138-141</sup> Gentamicin is the most toxic antibiotic in the aminoglycoside

family, followed by tobramycin and amikacin.<sup>142</sup> Massive doses result in early superficial and intraretinal hemorrhages, retinal edema, cotton-wool patches, arteriolar narrowing, and venous beading<sup>141</sup> (Fig. 92.22). Fluorescein angiography reveals severe vascular nonperfusion in the acute stages. Visual loss is profound, and late rubeosis iridis, neovascular glaucoma, pigmentary retinopathy, and optic atrophy are common. Intravitreal injection of smaller doses thought to be safe for the eye (100–400 µg) can still cause toxicity with less severe fundus changes.<sup>139–141</sup> The major preservatives found in injectable gentamicin (methylparaben, propylparaben, sodium bisulfite, and edetate disodium) likely play an additive role in its ocular toxicity, along with a quite acidic formulation.

**FIG. 92.22** Intraocular gentamicin injection. Photograph (A) and fluorescein angiogram (B) show acute macular necrosis, with virtually complete cessation of blood flow where presumably the medication came in contact with the retina while the patient was in a supine position during the early postoperative timeframe.

A number of factors appear to affect the extent of toxicity observed with similar doses of these medications. Peyman found that retinal toxicity could be enhanced with an intravitreal injection directed at the posterior pole with the bevel of the needle pointed toward the retina, and Zachary and Forster demonstrated that an increased rate of injection during intraocular administration could

also increase the retinal toxicity observed.<sup>143,144</sup> One investigator stated that eyes that have undergone a previous pars plana vitrectomy are at greater risk for gentamicin toxicity, but an experimental model has shown no difference between eyes that had cataract extraction alone compared with those that underwent lensectomy and vitrectomy.<sup>145,146</sup> Finally, increased ocular pigmentation protects the rabbit retina from aminoglycoside toxicity and may explain some of the wide variability seen with intraocular exposure in humans.<sup>147,148</sup>

Although clinical aminoglycoside toxicity appears to affect the retinal vasculature primarily, pathologic studies have revealed that gentamicin in small doses causes the formation of abnormal lamellar lysosomal inclusions in the RPE, and larger doses cause increasing amounts of retinal necrosis, first of the outer then inner segments.<sup>107,142,149,150</sup> Histologically, vessel closure appears to result from granulocytic plugging.

Prevention of aminoglycoside toxicity can be accomplished by abandoning the use of these medications as routine prophylaxis following intraocular surgery, eliminating them from intraocular infusion fluids used in vitrectomy and cataract surgery, and using alternative medications for the treatment of bacterial endophthalmitis. Animal studies have demonstrated that thinned sclera alone without perforation can result in markedly elevated intraocular gentamicin levels after subconjunctival injection.<sup>151</sup> If inadvertent intraocular injection does occur, immediate pars plana vitrectomy with posterior segment lavage should be performed.<sup>152,153</sup> Since there is some evidence that gravity plays a role in the predilection of gentamicin-induced toxicity for the macula, the patient should be placed upright as soon as possible after surgery.<sup>154</sup>

## Vancomycin (Intracameral)

Intracameral vancomycin injection has increased in popularity for endophthalmitis prophylaxis following cataract extraction.<sup>155,156</sup> To date, several case series of severe hemorrhagic occlusive vasculitis have been published (Fig. 92.23).<sup>157-159</sup> The toxicity appears to be immune-mediated and manifests a week or so following the

cataract surgery. With the delay in development of the occlusive vasculitis, several bilateral cases have been described, especially when the two eyes are operated on in close time proximity. Despite aggressive treatment including high dose corticosteroids, antiviral medication, and pars plana vitrectomy, visual outcomes are often very poor.<sup>158</sup> Clinicians must also monitor closely for neovascular glaucoma and treat as necessary. Additionally, some authors have suggested a potentially increased incidence of cystoid macular edema has been found in the setting of intracameral vancomycin administration.<sup>160</sup>

**FIG. 92.23** Vancomycin toxicity. Fundus photograph of the left (A) and right (B) eye demonstrating a severe bilateral hemorrhagic occlusive retinal vasculitis following cataract extraction with intracameral injection of vancomycin. Fluorescein angiogram (C) exhibits extensive nonperfusion. (Courtesy of Stephen Russell, MD, Iowa City, IA.)

## Interferon

Interferon- $\alpha$  is used to treat Kaposi sarcoma, hemangiomas of

infancy, chronic hepatitis C, melanoma, renal cell carcinoma and in chemotherapy protocols for leukemia, lymphoma, and hemangiomas. Interferon therapy has been associated with the development of multiple cotton-wool spots associated with retinal hemorrhages<sup>161-163</sup> (Fig. 92.24). Optic disc edema, branch arterial and venous occlusion, central retinal venous obstruction, anterior ischemic optic neuropathy, and cystoid macular edema have been reported with the more severe findings observed in patients receiving high-dose therapy.<sup>164-168</sup> Visual acuity usually is not affected if the fundus findings are limited to cotton-wool spots and intraretinal hemorrhage. Changes are noted within the first 4–8 weeks of therapy and are seen more frequently in diabetic and hypertensive patients<sup>169</sup> (Fig. 92.25).

**FIG. 92.24** Interferon retinopathy, consisting primarily of multiple cotton-wool spots dispersed throughout the posterior pole. The findings resolved following cessation of therapy.

**FIG. 92.25** Interferon microangiopathy. Photograph (A) and fluorescein angiogram (B) showing multiple cotton-wool spots and microangiopathy in a patient being treated for hepatitis C. Spectral domain optical coherence tomography (SD-OCT) (C) documents mild cystoid macular edema. Once the interferon was discontinued, photograph (D), taken one month later, documents significant resolution of the cotton-wool spots. SD-OCT (E) shows resolution of the cystoid macular edema. (Courtesy of Joseph Maguire, MD, Philadelphia, PA.)

Intravitreal injection of interferon- $\alpha$ -2b is well tolerated in the rabbit eye up to dosages of 1 million units; 2 million units causes a vitreous haze, and intraretinal hemorrhages.<sup>170</sup> Interferon toxicity may be caused by an increase in immune complex deposition and activated complement C5a with leukocyte infiltration. EOG testing may become abnormal in early toxicity.<sup>171</sup>

## Miscellaneous Agents

Ergot alkaloids in higher than recommended doses have been reported to cause retinal vasoconstriction,<sup>172,173</sup> and over-the-counter phenylpropanolamine used in appetite suppressants and decongestants has been implicated in one case of central retinal vein occlusion.<sup>174</sup>

Gemcitabine is a chemotherapeutic agent used for non-small-cell lung carcinoma, breast, ovarian, and pancreatic cancers. It has been associated with one case of Purtscher-like retinopathy with vascular nonperfusion<sup>175</sup> (Fig. 92.26).

**FIG. 92.26** Gemcitabine toxicity. Photograph (A) documents multiple cotton-wool spots, while the fluorescein angiogram (B) shows extensive capillary nonperfusion in a patient being treated for lung carcinoma.

## Cystoid Macular Edema

### Epinephrine (Topical)

The use of epinephrine compounds in glaucoma has decreased with the advent of newer, more efficacious agents. Topical epinephrine can cause macular edema in aphakic eyes, indistinguishable clinically and angiographically from postoperative aphakic cystoid macular edema (CME). In the largest controlled study, 28% of aphakic eyes treated with epinephrine and 13% of untreated aphakic eyes had macular edema, a difference that was statistically significant.<sup>176</sup> Most cases of CME resolve with cessation of epinephrine usage. This medication should be avoided in the treatment of the glaucomatous aphakic and pseudophakic eyes.

### Nicotinic Acid

High doses of niacin have been used to reduce serum lipid and cholesterol levels. Better-tolerated HMG-CoA reductase inhibitor agents have curtailed their utilization, though there has been a recent resurgence in their use in both monotherapy and combination therapy with statins. At doses greater than 1.5 g/day, a minority of patients will report blurred central vision, sometimes

associated with a paracentral scotoma or metamorphopsia.<sup>177</sup> FA fails to demonstrate vascular leakage despite the typical clinical appearance of CME<sup>178,179</sup> (Fig. 92.27). This has led to speculation of a direct toxic effect on Müller cells, resulting in intracellular edema.<sup>180</sup> OCT reveals cystoid spaces in the inner nuclear and outer plexiform layers.<sup>181,182</sup> With cessation of treatment, the CME resolves, and vision generally returns to normal. Given the rarity of this condition, only patients who are taking high-dose niacin and who have visual symptoms should be evaluated.

**FIG. 92.27** Nicotinic acid maculopathy. Red-free photograph (A) shows blunted foveal reflex, while the fluorescein angiogram (B) shows minimal late leakage. A time domain optical coherence tomography (OCT) (C) shows mild macular edema. The nicotinic acid was

discontinued, and two weeks later, the OCT (D) returned to normal. The findings were bilateral. (Courtesy of Lawrence A Yannuzzi, MD, New York City, NY.)

## Latanoprost (Topical)

Latanoprost is a prostaglandin analogue that is used for the control of a variety of forms of glaucoma. Although initial human and animal studies did not show an association between latanoprost and CME, recent case reports and studies have documented that approximately 2–5% of susceptible patients with glaucoma may develop CME and anterior uveitis, which resolves after discontinuation of the drug<sup>183–190</sup> (Fig. 92.28). This may be caused by the preservative used in the drug formulation.<sup>191</sup> Patients with CME who are taking latanoprost should undergo a trial off the medication before initiating further therapy for the edema. High-risk CME patients, such as those with a history of recent surgery or uveitis, should be managed with other agents.

**FIG. 92.28** Latanoprost-associated cystoid macular edema. Angiogram shows characteristic fluorescein filling of the cystic spaces.

## Paclitaxel/Docetaxel

Paclitaxel and docetaxel are similar antimicrotubule agents that are used for treatment of breast, lung, and prostate cancer. They have both been associated with angiographically negative CME (Fig. 92.29). The edema appears to respond on occasion to cessation of the taxel agent, or to treatment with topical or systemic acetazolamide, and/or intravitreal anti-VEGF therapy.<sup>192,193</sup>

**FIG. 92.29** Paclitaxel maculopathy. Photograph (A) showing a blunted foveal reflex in a patient on paclitaxel for treatment of metastatic breast carcinoma. The fluorescein angiogram (B) shows minimal late leakage of dye, though spectral domain optical

coherence tomography (SD-OCT) (C) shows intraretinal cystic spaces. Upon treatment with topical carbonic anhydrase inhibitors, the cystic spaces on SD-OCT (D) gradually resolved. The findings were bilateral.

## Fingolimod

Fingolimod (Gilenya) is an immunomodulatory agent targeting the sphingosine-1-phosphate receptor for the treatment of multiple sclerosis. This medication has been implicated in the development of cystoid macular edema, usually within 4 months of treatment initiation. The incidence of macular edema ranged from 0.3% to 1.2%, depending on the dosage. OCT localizes the cysts to the inner nuclear layer, and to a lesser extent, the outer nuclear layer. There may be associated perifoveal leakage on FA. Most cases resolve with discontinuation of the drug and administration of topical antiinflammatory agents.<sup>194</sup>

## Retinal Folds

### **Sulfa Antibiotics, Acetazolamide, Chlorthalidone, Disothiazide, Ethoxzolamide, Hydrochlorothiazide, Metronidazole, Sulfonamide, Topiramate, Triamterene**

Several medications, most with a structure similar to sulfanilamide, as those listed above, can cause a syndrome of transient acute myopia, retinal folds, and anterior chamber shallowing. This is thought to occur as a result of ciliary body swelling, choroidal effusion, or both, or with swelling of the lens itself with subsequent forward rotation of the lens–iris diaphragm.<sup>195–204</sup> Retinal folds in the macula are typically seen in young patients with this syndrome, but an FA does not reveal retinal leakage (Figs. 92.30 and 92.31). The folds presumably develop as a result of vitreous traction on the macula that is caused by the forward shift of the lens and iris

diaphragm. The folds typically resolve following discontinuation of the offending medication. It should be noted, however, that on occasion, topiramate may lead to development of angle closure glaucoma.

**FIG. 92.30** Chlordalidone-induced retinal folds. Photograph (A) shows perifoveal retinal folds associated with chlordalidone therapy, which resolve within 2 weeks following discontinuation of the drug (B).

**FIG. 92.31** Topiramate-induced retinal folds. Fundus photograph demonstrating macular and extramacular

striae in a patient on topiramate.

## Crystalline Retinopathy

### Tamoxifen

Tamoxifen is an antiestrogen agent used in the treatment of estrogen-receptor-positive tumors such as advanced breast carcinoma (and in some estrogen-receptor-negative tumors such as hepatocellular carcinoma) and as adjuvant therapy after surgical resection of early disease. Retinal toxicity consisting of decreased visual acuity and color vision with white intraretinal crystalline deposits, macular edema, and punctate retinal pigmentary changes can occur.<sup>205</sup> The intraretinal deposits appear to reside in the inner retina and are most numerous in paramacular areas (Fig. 92.32). Early reports involved patients who had received high doses (60–100 mg/day, total dosage >100 g) of the drug over 1 year.<sup>206</sup> More recent studies have demonstrated that chronic low-dose administration (10–20 mg/day) with as little as 7.7 g total, also can cause ocular toxicity.<sup>207–210</sup> Even asymptomatic patients may exhibit intraretinal crystalline formation.<sup>211</sup> Visual function and edema improve after discontinuation of the drug, but the refractile deposits remain.

**FIG. 92.32** Tamoxifen crystalline retinopathy. Characteristic yellow–white macular crystals are seen in a perifoveal distribution. The crystals were not felt to

be of visual significance.

There has been a recent upturn in cases of tamoxifen-induced retinal crystals, as patients with aggressive glioblastoma are now being treated with 100–200 mg of tamoxifen on a daily basis ([Fig. 92.33](#)). Concurrent CME may be treated with intravitreal anti-VEGF therapy.

**FIG. 92.33** Tamoxifen crystalline retinopathy in a patient with advanced glioblastoma being treated with high-dose tamoxifen. Photograph (A) shows perifoveal crystals, while the fluorescein angiogram (B) shows

diffuse cystoid macular edema (CME). Time domain optical coherence tomography (OCT) (C) confirms the findings of diffuse CME. A follow-up OCT (D) several months later, following administration of intravitreal bevacizumab, shows resolution of the CME. The findings were bilateral. (Courtesy of David Sarraf, MD, Los Angeles, CA.)

FA demonstrates late focal staining in the macula consistent with CME. Decreased photopic and scotopic a- and b-wave amplitude is noted on ERG testing.<sup>212</sup> Light microscopy reveals lesions confined to the nerve fiber and inner plexiform layers, which stain positive for glycosaminoglycans. Small (3–10  $\mu\text{m}$ ) intracellular and large (30–35  $\mu\text{m}$ ) extracellular lesions within axons are noted on electron microscopy.<sup>206</sup> The lesions appear to represent products of axonal degeneration similar to corpora amylacea. Experimentally, tamoxifen inhibits glutamate uptake by RPE cells.<sup>213</sup> OCT findings in lower-dose therapy interestingly do not show an increase in macular edema, but rather a foveal cyst with disruption of the photoreceptor line, while high-dose therapy can show CME.<sup>214–216</sup>

Decreased vision with bilateral optic disc swelling and retinal hemorrhages has been reported in a patient just 3 weeks after commencement of therapy with tamoxifen. These findings resolved completely after the drug was stopped.<sup>217</sup> It is unclear whether the findings in this patient were related to the more commonly seen toxic effects. Optic neuropathy with tamoxifen has been reported as well.<sup>218</sup> With current low-dose therapy (10–20 mg/day), retinal lesions are rare, and routine examination of asymptomatic patients is not indicated.<sup>211,219</sup> If a patient taking tamoxifen is noted to have intraretinal crystals, FA should be performed, primarily to rule out juxtafoveal telangiectasis, which can have similar-appearing lesions.<sup>220</sup> With confirmed evidence of toxicity causing a visual disturbance, the medication should be stopped. In asymptomatic patients who truly need the medication for treatment of their systemic cancer, continuation of the medication is reasonable with close monitoring of the ocular findings. For persistent macular edema, which has been noted after prolonged high-dose therapy seen following cessation of the drug, anti-vascular endothelial growth factor (anti-VEGF) injection may be beneficial.<sup>221</sup>

## Canthaxanthin

Canthaxanthin is a naturally occurring carotenoid. It is used as a food-coloring agent, for skin pigmentation in the treatment of vitiligo, and for the treatment of photosensitivity disorders such as erythropoietic protoporphyria, psoriasis, and photosensitive eczema. It also has been used over-the-counter in high doses as an oral tanning agent. Many reports have described a characteristic ring-shaped deposition of yellow-orange crystals in the superficial retina with high doses (usually a total dose greater than 19 g over 2 years)<sup>222-224</sup> (Fig. 92.34). The crystals appear more prominently in eyes with preexisting retinal disease and with concurrent use of beta-carotene.<sup>222,225</sup>

**FIG. 92.34** Canthaxanthin retinopathy. Prominent perifoveal punctate yellow deposits in a doughnut-shaped ring surrounding the macula.

Patients usually are asymptomatic, and FA usually is normal. There have been published reports of both normal and abnormal ERG, EOG, dark adaptation, and static threshold perimetry.<sup>226-229</sup> Although only clinically evident in the macula, the lipid-soluble crystals are found pathologically in the entire inner retina and ciliary body.<sup>230</sup> The crystals are, as would be expected, larger and more numerous surrounding the fovea. Canthaxanthin crystals are localized to the spongy degeneration of the inner neuropil and are associated with atrophy of the Müller cells. Interestingly, a single case report showed OCT localization of crystals to the outer

plexiform layer.<sup>231</sup> An experimental model of canthaxanthin-induced retinopathy also has demonstrated RPE cell vacuolization and disruption of phagolysosomes.<sup>232</sup>

With discontinuation of treatment, deposits may slowly clear over many years.<sup>233,234</sup> This slow reversal correlates with the detection of high plasma levels of canthaxanthin many months after discontinuation of the drug. Rarely, a fundus picture identical to canthaxanthin maculopathy can be seen in patients who have no known history of extradietary canthaxanthin.<sup>235</sup> A high dietary intake concurrent with preexisting retinal disease is thought to partially explain this phenomenon.

## Methoxyflurane

Methoxyflurane is an inhalational anesthetic, which, if used for extended periods, especially in patients with renal insufficiency, causes irreversible renal failure as a result of deposition of calcium oxalate crystals in the kidney. These crystals are also deposited elsewhere throughout the body. Fundus examination of these patients reveals numerous yellow-white punctate lesions in the posterior pole and periarterially<sup>236,237</sup> (Fig. 92.35). The deposits are located histologically in both the RPE and inner retina.<sup>238,239</sup>

**FIG. 92.35** Methoxyflurane crystals. (A,B) Photographs document intraretinal crystals dispersed throughout the posterior pole in a patient subjected to methoxyflurane anesthesia who developed postoperative renal failure.

## Talc

See above section [Vascular damage and/or occlusion](#).

## Miscellaneous Agents

A single case of crystalline retinopathy following 19 years of nitrofurantoin (Macrochantin) use has been reported.<sup>240</sup> Three cases of rapid visual loss with fludarabine phosphate, a nucleoside analog, during treatment for SLE or metastatic melanoma were reported, with two of the cases exhibiting deep yellow retinal flecks.<sup>241</sup> Three patients receiving long-term ritonavir therapy as part of a highly active antiretroviral therapy regimen were reported to have a retinal pigment epitheliopathy, parafoveal telangiectasis, and intraretinal crystal deposits.<sup>242</sup>

## Uveitis

### Rifabutin

Rifabutin is a semisynthetic rifamycin antibiotic that is used for the treatment and prevention of disseminated *Mycobacterium avium*-complex (MAC) infection in patients with and without AIDS.<sup>243-251</sup>

A small percentage of patients treated with higher doses of rifabutin (>450 mg/day) for systemic MAC infection, or lower doses (300 mg/day) for prophylaxis against MAC, can develop uveitis.<sup>252</sup>

The uveitis usually is bilateral and can be severe enough to cause a hypopyon that simulates infectious endophthalmitis.<sup>253</sup> It can occur from 2 weeks to 14 months after initiation of the drug.<sup>251</sup>

Concomitant use of clarithromycin and/or fluconazole (or itraconazole), especially when lower doses of rifabutin are used, greatly increases the chance of a uveitic episode.<sup>254</sup> Both systemic fluconazole and clarithromycin elevate rifabutin levels by inhibiting metabolism of the drug via the hepatic microsomal cytochrome P-450.<sup>249</sup> Although most cases have reported mainly an anterior uveitis and corneal endothelial deposits, posterior vitritis and retinal vasculitis have been described as well.<sup>243,255</sup>

Rifabutin-associated uveitis can be treated successfully with

topical corticosteroids or by decreasing or discontinuing the medication. Long-term use may result in ERG abnormalities.<sup>256</sup> Patients without systemic MAC infection who are taking rifabutin for prophylaxis and also are taking fluconazole or clarithromycin should be warned about the potential for uveitis and counseled as to its signs and symptoms.

## Cidofovir

Cidofovir, also known as HPMPC, is a nucleotide analogue that inhibits viral DNA polymerase and is used for the treatment of cytomegalovirus (CMV) retinitis.<sup>257-266</sup> Cidofovir therapy, with both intravenous and intravitreal (20 µg) routes of administration, has been associated with an anterior uveitis, hypotony, and visual loss.<sup>267</sup> These complications can be treated and sometimes prevented with the use of topical corticosteroids, cycloplegics, and oral probenecid. Cidofovir has been shown experimentally and clinically to cause a direct toxic effect to the ciliary body, with a resulting iritis and intraocular pressure decrease.<sup>257,265</sup> Although a 10-µg intravitreal dose had fewer side effects, it is also much less effective against CMV retinitis.<sup>266</sup> Investigations continue to try to determine the optimal dose and route of administration of cidofovir.

## Latanoprost

See the drugs listed under the section [Cystoid macular edema](#).

## Miscellaneous

### Cardiac Glycosides

Cardiac glycosides such as digoxin are used in the treatment of chronic heart failure and as antiarrhythmic agents. Although these drugs do not cause a characteristic fundus abnormality, ocular symptoms including blurred vision, scintillating scotomas, and xanthopsia (yellowing of vision) are common.<sup>268,269</sup> These changes probably are caused by direct toxicity to the photoreceptors. The visual symptoms are reversible with discontinuation of the drug.

## Methanol

Methanol occasionally is ingested by alcoholics. Visual blurring and field deficits are seen within 18 hours. Early fundus findings include optic nerve hyperemia and retinal edema, and late findings include optic atrophy<sup>270-277</sup> (Fig. 92.36). OCT findings have shown the optic nerve head swelling with adjacent edema of the retinal nerve fiber layer.<sup>278</sup> Optic nerve toxicity is mediated by formic acid, a breakdown product of methanol, which directly affects the inner retina and optic nerve. The degree of systemic acidosis correlates well with the extent of visual dysfunction. Early hemodialysis is effective in removing methanol from the body, but if visual recovery is not evident by 6 days, it often remains permanently decreased.

**FIG. 92.36** Methanol poisoning. Acute changes revealing peripapillary retinal whitening and edema.

## Vigabatrin

Vigabatrin is used for treatment of epilepsy and has been associated

with optic atrophy and visual field defects.<sup>279,280</sup>

## Sildenafil, Tadalafil, Vardenafil

Sildenafil, tadalafil, and vardenafil are a class of drugs that are potent inhibitors of phosphodiesterase-5 (PDE-5) and are used for the treatment of erectile dysfunction. Sildenafil also blocks PDE-6, though with only about one-tenth of its effect on PDE-5. PDE-6 is a key enzyme in the phototransduction cascade, and sildenafil modifies this cascade in photoreceptor outer segments causing a rise in cyclic guanosine monophosphate (cGMP). Commonly, patients notice a bluish dyschromatopsia (dose dependent) 1–2 hours after ingestion and this has been associated with a significant transient depression in the ERG in at least one study, though others have shown minimal to no effect on the ERG.<sup>281–290</sup> There appears to be no appreciable effect to slight increase in choroidal circulation with use of sildenafil on the ocular circulation and no adverse effects on those with early age-related macular degeneration.<sup>291–296</sup> There have been reported cases of nonarteritic ischemic optic neuropathy, central serous retinopathy, and cilioretinal artery obstruction with use of sildenafil and tadalafil.<sup>297–309</sup> The true incidence of nonarteritic ischemic optic neuropathy in comparison to age-matched controls is not known.

## Summary

Although there are thousands of systemic medications, only a small number of these agents produce retinal abnormalities and/or toxicity. Retinal toxicity can occur when agents are used at standard therapeutic levels, and also when they are used in excess or for nonapproved indications. The mechanism by which toxicity develops is unknown in many cases. With numerous new medications reaching the market annually, ophthalmologists need to maintain a high index of suspicion that patients' symptoms and/or clinical findings may be related to one or more of their medications.

### **Safety Standards**

Practical Considerations

### **Conclusion**

Photic retinal injuries are uncommon. Managing them effectively requires knowledge of how intense light interacts with the retina and choroid. Recent advances in retinal imaging have improved our understanding of these interactions.

Photic injuries occur when light is absorbed by tissue chromophores. Melanin and hemoglobin are the most effective retinal light absorbers.<sup>1-3</sup> Light is also absorbed by lipofuscin, macular pigment and photopigments for visual and nonvisual photoreception.<sup>4,5</sup> Absorption spectra describe how light absorption varies by wavelength. Melanin and lipofuscin absorption increase steadily with decreasing wavelength. Other absorption spectra peak at specific wavelengths.<sup>1,2,4,5</sup>

Optical radiation includes 400–700 nm visible light and shorter wavelength ultraviolet (UV) radiation (UV-C, 100–280 nm; UV-B, 280–320 nm; UV-A, 320–400 nm). The cornea shields the retina from UV radiation below 300 nm.<sup>6</sup> The crystalline lens protects the retina from most UV-B and UV-A radiation, but crystalline lenses under 30 years of age may transmit a small amount of potentially harmful UV-B radiation.<sup>6-8</sup> Other ocular defense mechanisms against UV radiation and intense visible light include eyebrow shadowing, corneal reflection of light not incident perpendicular to its surface

(Fresnel law), and the pupillary, aversion, squint and blink responses.<sup>9-11</sup>

Retinal light exposure is specified using parameters including optical energy (joule), exposure (joule/cm<sup>2</sup>), power (watt) and irradiance (watt/cm<sup>2</sup>).<sup>3</sup> Optical power is high when energy is delivered quickly in brief exposures. Exposure and irradiance are high when optical energy and power are confined to small areas, respectively.

Light can produce beneficial or harmful photomechanical, photothermal, and/or photochemical retinal effects.<sup>12-16</sup>

## Photomechanical Effects

The most common signs of acute photomechanical retinal trauma are retinal hemorrhages and/or holes.

## Photomechanical Mechanisms

Surgical photomechanical effects include photodisruption, photofragmentation, and photovaporization.<sup>16</sup> Photodisruption occurs in Nd : YAG laser capsulotomy and lamellar keratectomy when infrared laser energy ionizes target tissue molecules, producing plasma and a rapidly expanding shock wave that dissects target tissue.<sup>17</sup> Photofragmentation occurs in excimer laser photorefractive keratectomy when UV laser energy breaks bonds in corneal surface molecules and residual energy volatilizes molecular fragments. Photovaporization occurs in holmium laser sclerostomy and erbium laser phacolysis when rapid water vapor expansion excavates target tissues.

Most accidental photomechanical retinal injuries are caused by very brief laser exposures ranging in duration from a hundred femtoseconds ( $10^{-15}$  sec) to microseconds ( $10^{-6}$  sec).<sup>18-22</sup> Their very high retinal irradiances (power densities) produce tissue heating and expansion that cause immediate thermomechanical chorioretinal distortion and bleeding. Photovaporization may occur, but retinal irradiances are generally far too low for other photomechanical effects. Most victims experience a brilliant light flash followed by immediate monocular vision loss. An audible

sound (pop) and/or momentary pain occur infrequently at the time of the laser accident.

## Photomechanical Retinal Injuries

A few photomechanical laser accidents occur each year.<sup>19-22</sup> Most are caused by laboratory research lasers and military rangefinders or target designators.<sup>20-27</sup> Iatrogenic injuries have also been reported.<sup>28-30</sup> Injuries can be prevented by effective laser safety training and proper protective eyewear. Surgical Q-switched and femtosecond laser systems have numerous safeguards that limit high optical irradiances to small, restricted spatial volumes.

Initial vision loss depends on a laser injury's retinal location and associated chorioretinal disruption and bleeding.<sup>21,23,24,31</sup> Blood can spread laterally in subhyaloid, subretinal or sub-retinal pigment epithelium (RPE) spaces. Chorioretinal scars form and evolve. Vision may improve over days to months. Prognosis is excellent for less severe injuries that do not involve the fovea. Patients should be followed for macular holes and choroidal neovascularization (CNV) that can develop in the months following an injury (Fig. 93.1).<sup>25,30,32-37</sup>

**FIG. 93.1** The most common signs of acute photomechanical retinal trauma are retinal hemorrhages and/or holes. Exposure to very high retinal irradiance laser radiation produces tissue heating and expansion that causes immediate chorioretinal distortion and bleeding. Symptoms depend on the extent and retinal location of injuries. In this case, an 11-year-old boy was injured by blue-light from a powerful handheld consumer laser. One week later, his visual acuity was 20/300 and a small full-thickness macular hole was present in his right eye (A). The hole enlarged markedly over the next 2 months (B) and vitrectomy with internal limiting membrane peeling was performed. The hole was closed (C) and visual acuity improved to 20/160 post-operatively. (Ophthalmology 2014;121:566-572. © 2014 American Academy of Ophthalmology. Published by Elsevier Inc. All rights reserved.)

## Treatment

Optical coherence tomography (OCT) and fluorescein angiography

are valuable for evaluating, managing, and documenting real and alleged injuries. Anti-inflammatory and neuroprotective drugs for reducing laser damage have been studied experimentally,<sup>38,39</sup> but clinical trials of their efficacy have been impractical because injuries are uncommon. Macular holes may close and CNV may resolve spontaneously but conventional macular hole surgery and anti-VEGF therapy are potentially useful when needed.<sup>23,26,30,32-36</sup>

## Diagnosis of Real Laser Injuries

In actual laser accidents, (1) the light source is usually known, (2) typical chorioretinal damage occurs, (3) there is an unambiguous temporal relationship between the laser incident and serious visual symptoms, (4) the severity of visual symptoms is commensurate with the extent of retinal damage demonstrable with retinal imaging and examination, and (5) typical chorioretinal remodeling occurs after the injury.<sup>40</sup>

Most laser injuries and noninjurious laser exposures are painless.<sup>40</sup> Eye rubbing after a laser incident can cause painful self-inflicted corneal abrasions sometimes falsely attributed to the laser exposure.<sup>40-42</sup> Real retinal laser injuries do not cause chronic headache or other somatic complaints, including head, neck or jaw pain.<sup>40</sup>

The ease of laser injury diagnosis is directly proportional to the severity of the laser injury.<sup>40</sup> In ambiguous cases, subtle retinal findings have an excellent visual prognosis. When a retinal laser injury is alleged and objective findings are absent or within normal limits, diagnosis of laser injury should be deferred pending a rigorous review of the patient's retinal findings, ophthalmic and systemic tests, clinical course, and past medical history. A guideline has been published for this type of analysis.<sup>40</sup>

Pressure from patients or attorneys to reach quick conclusions in alleged but inapparent laser injuries should be resisted.<sup>40,43</sup> Organic retinal laser injuries do not cause chronic pain, and if a significant visual abnormality is present, it should be reproducible and consistent with a significant chorioretinal abnormality.<sup>40</sup>

## Photothermal Effects

The most common signs of acute photothermal retinal trauma are ophthalmoscopically visible photocoagulation burns without hemorrhage or holes.

## Photothermal Mechanisms

Photocoagulation occurs when intense light is absorbed mostly by melanin in the RPE and choroid. Light energy is converted into heat, increasing the temperature of directly exposed pigmented tissues.<sup>2,3,44</sup> Heat conduction spreads temperature elevation to adjacent sites. Overlying neural retina damaged by heat conduction loses its transparency and becomes visible as a focal white lesion (“burn”) because it scatters white fundus illumination light back at an observer. Retinal burns increase in size over time due to post-exposure scarring and collateral chorioretinal damage that is not apparent immediately after the exposure.<sup>2</sup>

Standard clinical photocoagulation produces immediately visible burns with increases in retinal temperature exceeding 20 °C.<sup>1</sup> Photomechanical effects occur at roughly three times the laser exposure needed for a visible lesion. Invisible lesions that are apparent only with fluorescein angiography or autofluorescence imaging occur at half to a fourth of the exposure needed to produce ophthalmoscopically visible lesions. In clinical parlance, “subthreshold” means ophthalmoscopically invisible or “subvisible”.<sup>3</sup> Subthreshold photocoagulation can produce beneficial therapeutic effects with low temperature rises that produce minimal or no apparent retinal damage.<sup>45</sup>

Most accidental photothermal retinal injuries are caused by pulsed laser exposures ranging in duration from a microsecond to a few seconds. Retinal irradiance is high enough for photocoagulation but too low for photomechanical effects. The magnitude and duration of chorioretinal temperature elevation determine the severity of a retinal burn, along with lesion size, fundus pigmentation and chorioretinal sequelae.<sup>3,21</sup> Photothermal and photomechanical retinal injuries are managed similarly. Injuries should be followed for retinal holes and CNV that can

develop within a few months of the injury.<sup>34,46-51</sup>

## Photothermal Retinal Injuries

Industrial and military photothermal laser accidents are less common than photomechanical ones because they require a narrow range of lower retinal irradiances.

### Operating Room or Medical Office Injuries

Most medical laser accidents go unreported for legal reasons.<sup>40</sup> Indirect ophthalmoscope photocoagulator beams and their reflections are potentially hazardous for many meters. Bystanders should put on protective eyewear before these systems are switched from standby to treatment mode. Protective operating microscope filters should be in place and the laser delivery probe inside a patient's eye before an endoscopic photocoagulator is switched to treatment mode.<sup>52</sup>

### Slit-Lamp Photocoagulators

Slit-lamp photocoagulator operators are protected from backscattered laser light by optical filters.<sup>53</sup> Laser beam reflections are theoretically hazardous for bystanders up to 2 meters from a flat-surfaced contact lens,<sup>54</sup> so they should wear laser safety glasses or goggles effective for the laser treatment wavelength. No injury of this type has ever been reported.

### Laser Pointers and Other Consumer Laser Devices

Laser pointers marketed in the United States are regulated by the Food and Drug Administration (FDA).<sup>41,42,55</sup> They are supposed to produce less than 5 mW (milliWatt) of power (Class 3A) and have warning labels cautioning users not to stare into the laser beam. Brief accidental or inadvertent laser pointer exposures do not cause retinal damage because they are terminated typically in less than 0.25 seconds by normal aversion responses to uncomfortable, dazzling light.<sup>41,55</sup>

Staring deliberately into a laser pointer beam for more than 10 seconds is hazardous and has caused retinal injuries.<sup>41,42,56-58</sup> A laser

pointer injury occurred in an 11-year-old girl who stared into a red laser pointer beam for more than 10 seconds because her classmates wanted to see if her pupil would constrict.<sup>56</sup> Prominent foveolar pigment mottling occurred in her affected eye, along with an initial decrease in visual acuity to 20/60. Pigment mottling faded and visual acuity normalized over several months.

Powerful “handheld laser systems” with dangerous output powers ranging from 20 to 1000 mW (Class 3B or 4) can appear identical to laser pointers and be purchased over the Internet. Low cost has made them available to children, adults who may not observe warning labels, and rioters. These devices are photocoagulators, not laser pointers. They have already caused serious photothermal and photomechanical retinal injuries and represent an increasing public health concern.<sup>47,49,57,59–61</sup> A powerful 100 mW consumer handheld laser resembling a laser pointer caused an injury in a 12-year-old boy who stared for several seconds into its beam reflected by a mirror (Fig. 93.2).<sup>62</sup> Visual acuity reduced to 20/60 and foveolar pigment mottling occurred. Spectral domain OCT of this case and many similar cases demonstrated focal loss of the ellipsoid zone and an area of hyperreflectivity adjacent to the RPE.<sup>48,50,51,62–69</sup> Fundus autofluorescence may show heterogeneous hyperautofluorescence in injured retinal areas.<sup>51,65,70</sup>

**FIG. 93.2** Acute photothermal injury causes photocoagulation burns or pigment changes without hemorrhage or holes. Retinal injury occurred in a 12-year-old boy who deliberately stared for several seconds into a green handheld laser beam reflected by a mirror. Visual acuity reduced to 20/60 and foveolar pigment mottling occurred. Spectral domain optical coherence tomography demonstrated focal loss of the ellipsoid zone and an area of hyperreflectivity adjacent to the retinal pigment epithelium. Visual acuity normalized over several months. (Reproduced with permission from Weng CY, Bauml CR, Albin TA, et al. Self-induced laser maculopathy in an adolescent boy utilizing a mirror. *Ophthalmic Surg Lasers Imaging Retina* 2015;46(4): 485-488.)

Lasers have been inappropriately marketed as toys for young children.<sup>48,61,66,68,71</sup> Lasers in recreational lightshows have also caused serious photothermal retinal injuries in bystanders.<sup>72,73</sup>

## Photochemical Effects

The most common signs of acute photochemical retinal trauma are yellow–white small foveolar lesions in solar and welding arc maculopathy, and larger often extrafoveal lesions in operating microscope and endoilluminator injuries.

## Photochemical Mechanisms

Accidental photochemical retinal injuries (known as photic retinopathy or retinal phototoxicity) are caused by prolonged intense light exposures that probably would be well tolerated if experienced only momentarily.<sup>5</sup> They occur at chorioretinal temperature elevations too low for photothermal damage, at illuminances far exceeding normal environmental levels, in exposures lasting from seconds to minutes. Optical radiation produces highly reactive oxygen radicals that can damage retinal cell membranes, proteins, carbohydrates, and nucleic acids. The extent of a photochemical retinal injury depends on individual defense mechanisms, the location and area of exposed retina, and the duration, intensity, and spectrum of the light exposure.<sup>5,10,12,74–76</sup>

Photic retinopathy does not occur unless acute cellular damage is so excessive that it acutely overwhelms retinal repair mechanisms.<sup>5,52</sup> Patients safely undergo bright but much lower irradiances in ophthalmic imaging studies and light therapy for seasonal affective disorder.<sup>12,52,77</sup>

Action spectra characterize how effectively different wavelengths cause a photochemical effect.<sup>78</sup> Photic retinopathy can be divided into photosensitizer- and photopigment-mediated phototoxicities which have different action spectra.<sup>4,5,79</sup>

The hazardousness of photosensitizer-mediated retinal phototoxicity increases rapidly with decreasing wavelength.<sup>5,74</sup> This is similar to the absorption spectrum of lipofuscin in the RPE, which is its primary mediator.<sup>80,81</sup> Thus, UV radiation is much more hazardous than visible light. In an aphakic eye, UV radiation, violet light (400–440 nm) and blue light (440–500 nm) account for 67%, 18%, and 14% of potential retinal phototoxicity, respectively.<sup>82,83</sup> Photosensitizer-mediated phototoxicity is the basis for the

international consensus aphakic standard  $A\lambda$  phototoxicity function used to estimate industrial acute retinal phototoxicity risks.<sup>84</sup>

In an adult phakic eye, the retina has the additional shielding of crystalline lens attenuation of UV radiation and shorter wavelength visible light. That is why the international consensus phakic standard  $B\lambda$  phototoxicity function peaks at 440 nm in the blue part of the spectrum. The  $B\lambda$  function is often termed a “blue light hazard” function, even though blue light has far less retinal phototoxicity than violet light or UV radiation.<sup>4,5,84</sup>

The hazardousness of photopigment-mediated retinal phototoxicity peaks around 500 nm (blue–green), similar to the luminous sensitivity of scotopic vision because the photopigment rhodopsin mediates both processes.<sup>5,85,86</sup> This type of photic retinopathy requires only 1% of the retinal irradiance needed for photosensitizer-mediated phototoxicity,<sup>10,79,87,88</sup> but experimental studies were performed with highly light-sensitive nocturnal rodents whose primary photopigment is rhodopsin.<sup>5,85,88</sup>

Clinical findings are similar in solar or welding arc maculopathies, and operating microscope and endoilluminator injuries.<sup>5,52</sup>

## Photochemical Retinal Injuries

### Solar and Welder's Maculopathy

Fig. 93.3 shows a typical yellow–white solar maculopathy lesion.<sup>89,90</sup> In the acute setting, OCT imaging demonstrates a full-thickness hyperreflective lesion.<sup>91–94</sup> Central retinal dysfunction has also been shown on multifocal electroretinography.<sup>95</sup> Lesions fade over several weeks, resolving completely or leaving foveolar distortion, pigment mottling, or even a macular hole.<sup>89</sup> Welding arc injuries produce similar clinical abnormalities.<sup>5,96,97</sup> Welder's maculopathy is extremely rare but it may be underreported because its transient clinical symptoms may be masked by those of associated photokeratitis.<sup>5,8,98</sup>

**FIG. 93.3** Acute solar maculopathy typically produces a small yellow–white foveolar lesion, as seen in this patient who presented with visual acuity of 20/40 after gazing directly at the sun. Optical coherence tomography in the acute setting demonstrated full-thickness foveal hyperreflexion. The lesions faded and visual acuity returned to 20/30 in the 3 months following the injury. (Reproduced with permission from Levy S, Sheck L, Guest S. OCT appearances in acute solar retinopathy. *Arch Ophthalmol* 2012;130:1540.)

Common visual complaints after acute solar or welding arc injury are blurred vision, central scotoma, and erythropsia. Post-injury visual acuity may be normal or decreased to the 20/40 to 20/200 range. Visual acuity usually returns to 20/20 to 20/40 over 6 months.<sup>5,89</sup> Fluorescein angiography may be normal or may show foveal RPE defects in more severe injuries.<sup>89,93,99–103</sup> Fundus autofluorescence may be normal or demonstrate focal hypoautofluorescence.<sup>93,94,100</sup> The characteristic OCT finding months to years after injury is a well-defined outer retinal hyporeflexive gap in the ellipsoid and interdigitation zones, as shown in [Fig. 93.4](#)

for a welding arc injury.<sup>5,92,93,97,100,102-112</sup>

**FIG. 93.4** Optical coherence tomography (OCT) images taken months to years after solar or welding arc injuries usually reveal a well-defined foveolar outer retinal hyporeflective space.<sup>5,97,104,108</sup> This 34-year-old male had been welding since 11 years of age and complained of vision loss for 5 months prior to the OCT study. A horizontal scan through his fovea shows largely normal retinal pigment epithelium and external limiting membrane hyperreflective bands but interruption of ellipsoid and interdigitation zone hyperreflective bands. These OCT findings are consistent with chronic damage to photoreceptor inner and outer segment segments.<sup>89</sup> (Courtesy of Suman Pilli, MD, Muralidhar Ogoti, MD, and Vishwanath Kalluri, MD.)

The histopathology of solar retinopathy has been studied in volunteers who stared at the sun monocularly for 10 to 60 minutes before enucleation for choroidal melanoma.<sup>90,113</sup> Photoreceptor damage included vesiculation and fragmentation of photoreceptor outer segment lamellae, mitochondrial swelling, and nuclear pyknosis.<sup>90,113</sup> Cones appeared to be more damage-resistant than rods, possibly accounting for good visual outcomes after some injuries.<sup>113</sup> RPE damage was variable.<sup>90,113</sup> Imaging and histopathologic data to date do not permit determination of

whether solar and welding arc injuries are primarily of RPE and/or photoreceptor origin.

Foveomacular retinitis is a term used to describe foveal abnormalities resembling photic retinopathy. It occurs after blunt ocular trauma and whiplash injury<sup>114-116</sup> and in people with no history of mechanical or photic trauma.<sup>117,118</sup> Outbreaks were reported in military personnel during World War II and again from 1966 to 1973,<sup>119-122</sup> which were ascribed to solar exposure.<sup>121,123</sup> This is consistent with reports of solar maculopathy in young people who have been sunbathing but not sungazing,<sup>124,125</sup> possibly due to Henle layer fiberoptic channeling of short-wavelength photons from perifoveal regions to the center of the fovea (Fig. 93.5).<sup>126</sup>

**FIG. 93.5** Acute solar maculopathy typically causes a small yellow–white foveolar lesion with full-thickness optical coherence tomography hyperreflectivity. This patient had a localized, less severe injury when he gazed at an eclipse at low solar inclination. These findings may be consistent with Henle layer fiberoptic channeling of photons to the central fovea. (Image courtesy of Daniel Chiu, FRANZCO.)

Momentary solar observation is safe or it would be dangerous to look upwards on a bright sunny day. Even at noontime on a clear

day, direct solar observation with a 3-mm pupil diameter causes only a 4 °C retinal temperature rise, far too low for photocoagulation.<sup>127</sup> Thus, typical solar maculopathy is photochemical not photothermal damage. Conversely, solar observation with a dilated 7-mm pupil produces a 22 °C retinal temperature increase, well above the 10 °C threshold for retinal photocoagulation.<sup>44,127</sup> Telescope-assisted solar observation produces even higher retinal temperature increases.<sup>127,128</sup>

Solar eclipse observation is particularly hazardous because pupillary dilation can occur and increase retinal irradiance.<sup>128</sup> There are many indirect methods for safely viewing solar eclipses.<sup>128,129</sup> Sungazing injuries have been reported to occur during hypoglycemia, drug abuse, psychosis, and religious rituals.<sup>5,103</sup> Sunglasses are not safe for sungazing and pupillary dilation potentially associated with their use may increase the risk of solar injury.<sup>9,12,129</sup> Prolonged solar observation causes the most damage, especially with pharmacologically dilated pupils.

Photokeratitis is a common welding arc accident, but welder's maculopathy is an unusual event. When welders fail to use appropriate eye protection filters, younger workers are at greater risk for retinal injury because of their clear ocular media. The UV-B window in the crystalline lens discussed previously closes by roughly 30 years of age.<sup>6-8</sup> At younger ages, some highly phototoxic UV-B welding arc radiation may be transmitted to the retina, possibly accounting for welding arc maculopathy and welders' reportedly increased risk of uveal melanoma.<sup>6,8</sup> Photic injuries have also been caused by UV-B radiation and/or short wavelength visible light from a femtosecond laser plasma<sup>130</sup> and a short-circuiting high-tension electric circuit.<sup>131</sup>

Experimental photic retinopathy is enhanced by elevated body temperature,<sup>85,132,133</sup> so increased body temperature from a hot day, exercise, or fever could increase the risk of retinal phototoxicity, perhaps accounting for the age-old admonishment to protect children with fevers from bright sunlight.<sup>5</sup> Darker chorioretinal pigmentation could increase local chorioretinal temperature rise associated with solar observation, perhaps further increasing the risk of damage. The fovea is at greatest risk for solar damage in direct sungazing, but foveal injuries in young adults who have been

sunbathing but not sungazing may occur because of crystalline lens UV-B transmission and/or Henle fiberoptic transmission of short wavelength photons toward the fovea.<sup>126</sup>

## Operating Microscope and Endoilluminator Injuries

Typical operating microscope injuries are oval lesions measuring 0.5–2 disc diameters in size.<sup>134,135</sup> Damage sites are often inferior to the fovea due to microscope tilt and illumination positioning.<sup>136,137</sup>

Fiberoptic endoilluminators can cause comparable lesions elsewhere,<sup>138</sup> as shown in Fig. 93.6. Injuries have occurred in corneal, cataract, glaucoma, and retinal surgery.<sup>134,135,139–141</sup>

Photochemical retinal damage is localized primarily to photoreceptors and the RPE as in solar and welder's maculopathies.<sup>142–144</sup>

**FIG. 93.6** An operating microscope injury in a 67-year-old male with diabetes who had undergone an intraocular lens exchange operation 1 year earlier. The oval-shaped area of retinal pigment epithelial degeneration inferior to the fovea was not prominent ophthalmoscopically, as shown in the fundus photograph (A), but the lesion was quite apparent in the fluorescein angiogram taken on the same day (B).

Lesion size, location, and severity determine vision loss from an operating microscope injury. Lesions initially have a yellow–white appearance sometimes accompanied by a shallow serous neural retinal detachment. This finding resolves rapidly, followed by local

RPE atrophy and pigment mottling. Chronic lesions are usually much less apparent ophthalmoscopically than angiographically, as shown in Figs. 93.6A–B, respectively. Lesions may also appear as localized areas of hyperautofluorescence.<sup>145</sup> Fig. 93.7A is the OCT image of a 70-year-old female with an operating microscope injury temporal to her fovea and also central cystoid macular edema (CME) shortly after complicated cataract surgery. The OCT image in Fig. 93.7B taken years after the resolution of the CME shows persistent chorioretinal scarring at the site of operating microscope injury,<sup>145</sup> consistent with histopathologic findings in human and animal studies.<sup>142–144</sup> Imaging and histopathologic data to date do not permit determination of whether operating microscope and endoilluminator injuries arise primarily in the RPE or photoreceptors or a combination of both.

**FIG. 93.7** An operating microscope injury in a 70-year-old female who had recently undergone complicated cataract surgery for a partially subluxated crystalline lens due to a tennis ball injury. Initial foveal cystoid macular edema and a serous neural retinal detachment associated with the operating microscope lesion (A) gradually resolved. Prominent chorioretinal scarring (B) is present in the region of the operating microscope lesion 3 years later, long after resolution of the cystoid macular edema. (Image courtesy of Richard B. Rosen, MD)

The risk of operating microscope injury is potentially increased

by higher body temperature,<sup>132</sup> increased chorioretinal pigmentation (theoretically increasing local light absorption and thermal enhancement of retinal phototoxicity),<sup>5</sup> oxygen administration during surgery (hypothetically increasing retinal free radical production),<sup>146</sup> and photosensitizing medications such as hydroxychloroquine, hydrochlorothiazide, furosemide, allopurinol, and the benzodiazepines.<sup>147-149</sup> Diabetes mellitus and hypertension may also increase retinal phototoxicity risks.<sup>150</sup>

Faster cataract surgery reduces the risk of operating microscope injury,<sup>151</sup> as does minimizing operating microscope intensity and discontinuing photosensitizing medications preoperatively when possible.<sup>5,149</sup> Other potentially useful techniques include maintaining patients' eyes in downgaze, using corneal occluders, and avoiding supplemental oxygen use and/or elevated patient core body temperatures.<sup>5,152,153</sup> Operating microscopes produce minimal UV radiation,<sup>154-156</sup> so UV-blocking filters are of little value. One study reported that UV-blocking intraocular lenses reduce postoperative CME,<sup>157</sup> but three subsequent studies refuted that conclusion.<sup>158-160</sup> Reducing operating microscope violet and blue light illumination hypothetically decreases acute retinal phototoxicity risks, but blue light is important for tissue visualization.<sup>5</sup>

Indocyanine green (ICG) is useful for retinal angiography and staining the inner limiting membrane (ILM) during macular hole surgery. ICG fluorescence can persist for months after ICG-assisted vitreoretinal surgery.<sup>161</sup> Visual field defects have occurred after these procedures and may be multifactorial in origin.<sup>162</sup> RPE damage possibly of phototoxic origin has been reported,<sup>163</sup> however alternate mechanisms such as physical trauma to the retinal nerve fiber layer should also be considered. The potential risks and benefits of ILM staining with ICG and alternative vital dyes continue to be evaluated.<sup>164</sup>

## **Ophthalmoscope and Fundus Camera Exposure**

Indirect ophthalmoscopes and fundus cameras produce dazzling exposures and transient afterimages, but there is no evidence that they cause photochemical or thermal retinal injury in routine clinical use.<sup>12,165-168</sup> A 15-minute indirect ophthalmoscope exposure

focused on a single retinal area can cause a localized phototoxic injury in an anesthetized rhesus monkey,<sup>132</sup> but that certainly is not a clinical light exposure. No immediate or long-term retinal abnormalities could be detected after similar exposures were attempted in human volunteers with blind eyes or those requiring enucleation.<sup>169</sup> These results are consistent with instrumentation data showing that fundus camera, indirect ophthalmoscope, and scanning laser ophthalmoscope retinal irradiances are lower than experimentally determined damage thresholds.<sup>12,165,166,168,170</sup> Anterior segment slit-lamp photography has been reported to cause photic retinopathy under unusual circumstances.<sup>171</sup>

Sixty-second stabilized retinal exposures accelerated local retinal degeneration in dogs with rhodopsin gene mutations, prompting recommendation that retinal photography and clinical light exposure be minimized in patients with retinitis pigmentosa.<sup>172</sup> Human and canine retinas differ significantly,<sup>172</sup> and the experimental exposures were 10,000 times longer than 2-msec clinical fundus camera flashes.<sup>168</sup> Light exposure has never been proven to adversely affect the clinical course of retinitis pigmentosa and even light deprivation does not prevent its progression.<sup>173</sup> No current scientific evidence suggests the need for retinal disease-specific light exposure safety standards.<sup>168</sup> Nonetheless, regardless of a patient's condition, clinical retinal imaging should be performed only when necessary and patient comfort dictates that clinical procedures always be carried out at the lowest clinically effective retinal illumination levels.<sup>12,168</sup>

## Safety Standards

Safety standards that affect laser users include the voluntary American National Standard Institute (ANSI) Standards “Safe Use of Lasers” (ANSI Z136.1-2007)<sup>174,175</sup> and “Safe Use of Lasers in Health Care Facilities” (ANSI Z136.3-2005).<sup>176</sup> The ANSI Z136.1 Standard is similar to the International Standard IEC 60825-1. ANSI standards are technically “voluntary,” but regulatory groups use them to assess medical laser facility safety and litigants use them to scrutinize purported injuries.<sup>177,178</sup>

Safety standards that affect laser manufacturers include the FDA

regulatory “Laser Performance Standard” (21 CFR1040). This standard requires manufacturers to equip laser devices with features such as emission indicators and keyed switches. There are also specific standards for ophthalmic devices such as slit lamps and endoilluminators.

ANSI standards define four laser classes.<sup>174,178</sup> Class 1 lasers are considered incapable of causing damaging ocular exposures and do not require control measures. Their maximum power output in the visible spectrum ranges from 0.0004 mW or less for blue or green light to 0.024 mW or less for red light. Class 2, 3a, and 3b lasers produce laser power that is less than 1 mW, between 1 and 5 mW, and between 5 and 500 mW, respectively. Laser pointers are Class 3a devices. Some dangerous Class 3b handheld laser devices are identical in appearance to laser pointers. Class 4 lasers include potentially hazardous industrial, military or medical lasers that generate more than 500 mW of laser power. Safety standards assign control measures to each laser class.<sup>174,176</sup>

## Practical Considerations

Control measures are designed to decrease the risk of laser accidents.<sup>128,177,178</sup> “Engineering” controls are protective measures built into laser systems such as housings, labels, and interlocks. “Administrative” and “procedural” controls are designed to assure the proper use of potentially hazardous laser systems. They include written protocols for (1) operating, maintaining, and servicing laser systems; (2) assuring proper personnel education and training; and (3) using appropriate protective eyewear.

For an ophthalmic laser facility, the ANSI Z136.3-2005 standard recommends that (1) a “Laser Safety Officer” be given local safety oversight responsibility, (2) a warning sign with the signal word “danger” be displayed on the outside of the closed treatment room door during any laser procedure, (3) personnel wear laser eye protection in the nominal hazard zone where diffuse reflections and stray beams could be hazardous, and (4) operators be trained in the safe use of their laser equipment.<sup>176,177</sup> From a practical perspective, the nominal hazard zone is the treatment or operating room in which a surgical laser is located. The laser safety office is

responsible for assuring that (1) protective eyewear is available and used appropriately, (2) personnel using lasers are trained properly, and (3) laser safety measures are audited regularly.

## Conclusion

Light can cause photomechanical (thermomechanical), photothermal (photocoagulation), or photochemical (photic retinopathy) retinal damage. Accidental laser injuries are preventable with protective eyewear. Clinical retinal photocoagulation does not cause chronic pain and neither do accidental retinal laser injuries. Visual abnormalities from an alleged laser injury should be correlated with chorioretinal abnormalities. Powerful handheld laser devices that appear identical to laser pointers can be retinal photocoagulators. The only common clinical photochemical injuries are solar and welding arc maculopathies and operating microscope and endoilluminator injuries. Solar maculopathy can occur with or without sungazing. People under 30 years of age are at greatest risk to photic retinopathy because of the UV-B window in their crystalline lenses.

Terson Syndrome

Valsalva Retinopathy

Shaken Baby Syndrome

**Conclusion**

## Introduction

Ocular trauma consists of closed globe injuries and open globe injuries. A closed globe is defined as the absence of a full-thickness defect of the cornea and/or sclera. Nonpenetrating posterior segment ocular trauma includes blunt trauma applied directly to the eye in the setting of a closed globe and trauma to other parts of the body that indirectly affects the eye. The ophthalmologist must be familiar with the wide variety of posterior segment manifestations of nonpenetrating trauma to perform appropriate evaluation and treatment. The prevention of ocular trauma is of equal importance. The ophthalmologist should encourage the use of protective eyewear in the industrial workplace and during athletic events, and the use of polycarbonate spectacle lenses in the trauma patient with an intact fellow eye cannot be overemphasized.

Blunt trauma accounts for 51–66% of ocular injuries,<sup>1-3</sup> and posterior segment involvement includes commotio retinae, choroidal rupture, sclopetaria, macular holes, and conditions associated with traumatic retinal detachment such as vitreous base avulsion, retinal dialysis, retinal tears, and giant retinal tears; remote systemic trauma with indirect ocular involvement consists of Purtscher retinopathy, Terson syndrome, Valsalva retinopathy, and shaken baby syndrome.

The pathogenesis of posterior segment involvement from blunt ocular trauma includes coup injury, contrecoup injury, and direct ocular compression.<sup>4</sup> A coup injury is damage at the site of impact, as seen with sclopetaria. In a contrecoup injury, damage occurs at tissue interfaces opposite the site of impact. This occurs with commotio retinae, posterior choroidal rupture, and traumatic

macular hole. Anteroposterior ocular compression results in equatorial stretching because the eye has a fixed volume, and vitreous base avulsion and retinal dialysis occur via that mechanism.<sup>5</sup> The pathogenesis of ocular manifestations from remote trauma is varied and is discussed with each clinical entity.

## Direct Ocular Injury

### Commotio Retinae

In 1873, Berlin<sup>6</sup> described retinal whitening following blunt trauma to the globe. The condition, now known as commotio retinae, is characterized by transient opacification of the deep retina opposite the site of impact (a contrecoup injury) (Fig. 94.1). The findings may vary from a small area of subtle retinal whitening to widespread marked retinal opacification. If the posterior pole is involved, the fovea is often spared, resulting in a pseudo cherry-red spot. Vision may be affected if the macula is involved, but it usually returns to normal in several days when the opacification resolves.<sup>7,8</sup> With more severe injury, visual loss may persist, and the opacification may be replaced by mottling of the retinal pigment epithelium<sup>7,9</sup> or intraretinal pigment deposition.<sup>10,11</sup>

**FIG. 94.1** Commotio retinae in a 23-year-old man who

was struck in the eye with a finger while playing football. (Courtesy of Lucia Sobrin, Massachusetts Eye and Ear.)

The blood–retinal barrier has been studied extensively in both animals and humans with commotio retinae. Francois and De Laey<sup>12</sup> and Hart et al.<sup>7</sup> found no leakage on fluorescein angiography (FA) performed on patients immediately after trauma. Gregor and Ryan<sup>13</sup> performed fluorescein angiography on pigs immediately after trauma and found no leakage from retinal blood vessels but detected staining of the retinal pigment epithelium that resolved within 24 hours. Blood–retinal barrier disruption at the level of the retinal pigment epithelium was demonstrated in morphologic studies using the horseradish peroxidase tracer technique. Kohno et al.<sup>14</sup> noted no leakage on fluorescein angiography in Rhesus monkeys with commotio retinae, and no disruption of the blood–retinal barrier was found using horseradish peroxidase. Pulido and Blair<sup>15</sup> performed fluorescein angiography and vitreous fluorophotometry on 10 patients with unilateral macular commotio retinae an average of 16 hours after trauma. Fluorescein angiography showed no leakage and vitreous fluorophotometry yielded no difference in the vitreous penetration in the traumatized versus untraumatized eyes of the same patient. The authors concluded that, because vitreous fluorophotometry is highly sensitive in detecting low levels of leakage, breakdown of the blood–retinal barrier is not a major pathophysiologic factor in producing commotio retinae. Mansour et al.<sup>16</sup> reported the histopathologic findings obtained within 24 hours after injury in a human eye with commotio retinae. They noted that only a minimal amount of albumin was detected immunohistochemically around retinal vessels and presented this as additional evidence that the blood–retinal barrier is relatively intact and therefore does not play a major role in the pathogenesis of commotio retinae.

The pathogenesis of commotio retinae, based on histopathologic studies, has included extracellular edema, intracellular edema (of glial cells), and photoreceptor outer segment disruption. Berlin<sup>6</sup> postulated that extracellular edema resulted in the loss of retinal transparency, and the condition became known as “Berlin's edema.” Subsequent histopathologic studies in animals revealed a

different pathogenesis. In an experimental model in pigs, Hart et al.<sup>7,9</sup> and Blight and Hart<sup>17</sup> demonstrated intracellular edema of retinal glial elements. Blight and Hart,<sup>18</sup> in the same model, also found photoreceptor outer segment fragmentation and intracellular edema of the retinal pigment epithelium. Sipperley et al.<sup>19</sup> detected disruption of only the photoreceptor outer segment in an owl monkey model. Using Rhesus monkeys, Kohno et al.<sup>14</sup> demonstrated disruption of photoreceptor outer segments in addition to intracellular edema in Müller cells, retinal pigment epithelial cells, nerve fibers, and the outer plexiform layer axons of photoreceptor cells. Mansour et al.<sup>16</sup> found disruption of the photoreceptor outer segment and damage to the adjacent retinal pigment epithelium in a histopathologic report of a human eye. The authors attributed the susceptibility of the outer segments to the architecture of the retina, particularly the Müller cell skeletal system, because Müller cells occupy the retina from the internal limiting membrane to the photoreceptor inner segments and support all cellular layers except the photoreceptor outer segments.

Souza-Santos et al.<sup>20</sup> described the morphologic characteristics in 11 eyes with commotio retinae using spectral domain optical coherence tomography (OCT) and also evaluated its utility in prognosis and follow-up. Cases with severe trauma had acute disruption of the ellipsoid zone and hyperreflectivity of the overlying retina and were regularly associated with retinal atrophy, pigment disturbance, and poor visual prognosis. Ahn et al.<sup>21</sup> described the OCT features of macular commotio and its association with anatomic and visual outcomes. They also proposed a grading system based on the morphology of the OCT: increased ellipsoid zone reflectivity with disappearance of the thin hyporeflective optical space (grade 1), cone outer segment tips (COST) defect only (grade 2), COST and ellipsoid zone defects (grade 3), and COST, ellipsoid zone, and external limiting membrane defects (grade 4). Eyes with higher grades at baseline had worse visual and anatomic outcomes.

In summary, trauma may induce a mechanical distortion of the retinal elements via deformation of the vitreous, resulting in transient deep retinal opacification, termed “commotio retinae.” The blood–retinal barrier appears to be intact, and the fundus

changes are probably caused by disruption of the photoreceptor outer segments. The condition typically resolves, but persistent visual loss and retinal pigment changes may occur in severe cases.

## Choroidal Rupture

In 1854, Von Graefe<sup>22</sup> described crescent-shaped lesions of the posterior pole resulting from trauma to the globe. These usually are single lesions located temporal to the disc in a concentric fashion. Known as choroidal ruptures, these lesions, in fact, are tears of the choroid, Bruch's membrane, and retinal pigment epithelium.

There are both direct and indirect choroidal ruptures. Direct ruptures are located anteriorly at the site of impact (coup injury) and are oriented parallel to the ora. Direct choroidal ruptures are relatively rare and are thought to be caused by compression necrosis.<sup>23</sup> Indirect choroidal ruptures occur opposite the site of impact (contrecoup injury) and appear as the typical curvilinear shaped lesion of the posterior pole (Fig. 94.2), oriented concentric with the disc margin. Trauma induces compressive forces that rupture the relatively inelastic Bruch's membrane and its adherent choriocapillaris (resulting in acute subretinal hemorrhage), as well as the retinal pigment epithelium (resulting in late pigment changes). The retina and sclera do not rupture because the retina is relatively elastic, whereas the sclera has strength sufficient to resist these forces.<sup>24</sup> Patients with pseudoxanthoma elasticum have been shown to have a relatively brittle Bruch's membrane, and these patients are particularly susceptible to choroidal rupture following relatively minor ocular trauma.

**FIG. 94.2** (A) Choroidal rupture in the macula with associated subretinal hemorrhage in an 11-year-old boy who sustained blunt trauma to his right eye with a baseball cap. Visual acuity is 20/100. (B) Optical coherence tomography (OCT) scan showing the area of the choroidal rupture as a discontinuity in Bruch's membrane. There is subretinal hyperreflective material consistent with the subretinal hemorrhage. (C) Five weeks later most of the blood has resolved except there is a small amount of dehemoglobinized subretinal blood at the fovea. There is also subretinal fluid at the superior edge of the choroidal rupture consistent with the development of a choroidal neovascular membrane. Visual acuity is 20/100. (D) OCT scan showing subretinal hyperreflective material in the area of the choroidal rupture and subfoveal hyperreflective material in the area of the dehemoglobinized hemorrhage. (Courtesy of Shizuo Mukai,

Massachusetts Eye and Ear.)

Since the initial injury often involves subretinal hemorrhage, the crescent-shaped lesion may not become visible ophthalmoscopically until the overlying hemorrhage resolves. If the macula is involved by the rupture or the accompanying subretinal hemorrhage (or if there is other evidence of macular injury, such as commotio retinae or macular hole), visual acuity usually is reduced. In a report by Hart et al.,<sup>25</sup> initial visual acuity was 20/200 or worse

in all 10 patients with posterior pole choroidal ruptures; six of these patients ultimately improved to 20/30 or better. The choroidal rupture typically develops a gliotic scar within a few weeks, and hyperpigmentation develops at the margins of the healed lesions (Fig. 94.2). The lesions should be followed closely because choroidal neovascularization from the margins may develop at any time. Patients should be instructed to report any changes in central vision (e.g., reduced visual acuity, metamorphopsia), and the examination should focus on the presence of subretinal fluid, hemorrhage, and lipid. Several authors<sup>26,27</sup> have described late hemorrhagic detachment of the pigment epithelium secondary to subretinal pigment epithelial neovascularization, and others have reported serous detachment of the macula from subretinal neovascularization.<sup>8,24,28,29</sup> Many of these patients suffered visual loss months to years following the initial injury and, in some cases, laser photocoagulation resulted in resolution of the choroidal neovascular membrane.<sup>24,28,29</sup> An additional potential complication of choroidal rupture is chorioretinal vascular anastomosis.<sup>30</sup>

FA is useful in evaluating acute choroidal ruptures and cases of suspected choroidal neovascularization. In the acute setting, FA may aid in the detection and localization of small choroidal ruptures and suspected ruptures beneath subretinal hemorrhage. Fluorescein initially may leak from the ruptured choroidal vessels into the outer retina, but this resolves within a few days.<sup>25</sup> Healed choroidal ruptures typically demonstrate early hypofluorescence within the rupture because of the damaged choriocapillaris (the large choroidal vessels usually are intact) and late hyperfluorescence from diffusion from the surrounding intact choriocapillaris. In cases with choroidal neovascularization, FA demonstrates early lacy subretinal vessels with late leakage into the subretinal space.<sup>31</sup>

In choroidal ruptures, fundus autofluorescence typically reveals hypoautofluorescence within the rupture due to loss of pigment epithelium. There is an associated hyperautofluorescence of the rupture rim, likely due to pigment epithelial hyperplasia at the margins of the rupture,<sup>32</sup> which has been well documented clinically and histologically.<sup>33,34</sup> In cases with associated subretinal hemorrhage, there is blocked autofluorescence from the blood.

In a histopathologic report of cases by Aguilar and Green,<sup>35</sup> most ruptures initially were associated with hemorrhage, usually in the subretinal space and occasionally involving the choroid and vitreous. Fibroblastic activity usually was present by 1–2 weeks and a well-developed scar was present by 1 month after injury. In some cases, the retina overlying the choroidal rupture exhibited atrophy and thinning due to the loss of outer layers. Retinal pigment epithelial hyperplasia at the margins of the lesion was common. In three eyes with healed choroidal ruptures, foci of chronic inflammation (lymphocytes) were present in the inner choroid and subretinal space. Choroidal neovascularization from the margin of the choroidal rupture, extending under the retinal pigment epithelium, was present in one eye, and choroidal neovascularization extending into the subretinal space was found in two eyes. The authors concluded that new choroidal blood vessels are common in the healing process and that these vessels usually regress as the scarring process evolves.

Nair et al.<sup>36</sup> described the morphological patterns of indirect choroidal rupture based on spectral domain OCT. Two types of choroidal rupture were seen. The first type seen (type 1) was a forward protrusion of the retinal pigment epithelium (RPE)–choriocapillaris layer with an acutely angled pyramid or dome shape. This was associated with either a small loss of continuity of the retinal pigment epithelial layer or elevated RPE–choriocapillaris projection accompanied by a significant quantity of subretinal hemorrhage. The second type (type 2) was a larger area of disruption of the RPE–choriocapillaris layer, photoreceptor ellipsoid zone, and external limiting membrane, with a posteriorly directed concave contour depression and downward sliding of tissues into the defect. The study included 18 eyes of 18 patients. At presentation, 10 eyes were observed to have type 1 and eight to have type 2. Of the 18 eyes, one with type 1 and two with type 2 developed choroidal neovascularization (16.6%).

In a study of all cases of choroidal rupture diagnosed at Massachusetts Eye and Ear Infirmary between 1993 and 2001,<sup>37</sup> 111 cases were identified. Sixty-eight percent of ruptures occurred in the macula, with 37% being foveal and 31% extrafoveal. Thirty-two percent were peripheral. A majority (61%) of patients had one

rupture, while 21% had two ruptures, 11% had three ruptures, and 7% had four or more ruptures. Two patients (10%) developed choroidal neovascularization between 1 and 18 months after the initial trauma. Longer ruptures also exhibited an increased risk of choroidal neovascularization (0% in ruptures <1.10 mm in length, 11% in ruptures 1.10–2.35 mm, and 50% in ruptures >2.35 mm;  $p=.03$ ). Ruptures within the arcades and older age also increased the risk of choroidal neovascularization.

Multiple treatment modalities have been reported for choroidal neovascularization secondary to choroidal rupture. These include thermal laser photocoagulation,<sup>38</sup> photodynamic therapy,<sup>39,40</sup> surgical excision,<sup>38,41,42</sup> and more recently intravitreal injection of anti-vascular endothelial growth factor (VEGF) agents. There are several case reports of intravitreal injection of the monoclonal antibody to VEGF, bevacizumab, producing an improvement in visual acuity and resolution of leakage in subfoveal,<sup>43,44</sup> juxtafoveal,<sup>45</sup> and extrafoveal choroidal neovascularization.<sup>46</sup> These studies report stability 9 months,<sup>44</sup> 3 months,<sup>45</sup> and 1 month<sup>46</sup> after treatment of subfoveal, juxtafoveal, and extrafoveal CNV, respectively. Although there are no reports of longer follow-up, the limited data suggest that anti-VEGF agents may produce a more durable response than laser or photodynamic therapy.

In summary, trauma-induced indirect choroidal ruptures occur as crescent-shaped lesions of the posterior pole. These lesions initially can be associated with subretinal hemorrhage and later may develop hyperpigmentation at the margins. Vision initially is affected if the lesion involves the fovea, but late visual loss also may occur if choroidal neovascularization develops. A variety of treatment options are available for patients who develop choroidal neovascularization.

## Sclopetaria (Traumatic Chorioretinal Rupture)

Rupture of the choroid and retina (known as sclopetaria or chorioretinal rupture) may occur after nonpenetrating ocular trauma in which a high-velocity projectile strikes or passes tangential to the globe. The condition is rare and has been described

by numerous terms, including chorioretinitis proliferans,<sup>47</sup> traumatic proliferating choroidoretinitis,<sup>48</sup> retinitis proliferans,<sup>49</sup> and acute retinal necrosis.<sup>50</sup> Goldzieher<sup>51</sup> described the first case in 1901, caused by a gunshot wound, and used the term “chorioretinitis sclopetaria.” Because the pathogenesis is not inflammatory, the terms sclopetaria and chorioretinal rupture currently are accepted.

The appearance of the fundus is characterized by an area of absent retina, retinal pigment epithelium, Bruch's membrane, and choroid in the same quadrant as the projectile injury (Fig. 94.3). The lesion often extends posteriorly to involve the macula. Bare sclera is visible ophthalmoscopically, but may not be apparent acutely because there may be overlying vitreous hemorrhage and adjacent intraretinal and subretinal hemorrhage. With resolution of the hemorrhage, the lesion ultimately develops irregular, scarred, pigmented borders, and the posterior hyaloid usually remains attached.

**FIG. 94.3** Sclopetaria. Inferotemporal area of bare sclera, pigment, and hemorrhage in a 19-year-old man after a shotgun injury. Pellets passed tangential to the globe and lodged in the orbit. Ocular findings also included commotion retinae, choroidal rupture, and macular hole. (Courtesy of Daniel F. Martin, Cole Eye Institute, reproduced with permission from Elliott D, Avery R. Nonpenetrating posterior segment trauma. *Ophthalmology Clinics of North America*, Volume 8, Number 4, December 1995.)

Sclopetaria typically is seen following a high-velocity projectile injury to the orbit, usually caused by a shotgun or BB pellet. The missile directly strikes or passes tangential to the globe and often remains in the orbit. Sclopetaria is an example of a coup injury because damage occurs at the site of impact. High velocity projectiles cause rapid deformation of the globe and a sudden increase in the tensile stresses in the ocular tissues. These stresses may exceed the tensile strength of the retina and choroid, but not the relatively elastic posterior hyaloid or the relatively strong sclera. Rupture of the retina and choroid is followed by retraction of these tissues to expose the sclera.<sup>52</sup>

Martin et al.<sup>52</sup> reported eight eyes of seven patients with sclopetaria. A shotgun or BB pellet was the projectile in five of these patients. Seven of eight eyes were managed initially by observation only. One eye was treated with a prophylactic scleral buckle. The retina remained attached in all cases for at least 6 months. Late complications included vitreous hemorrhage in two eyes and retinal detachment in two eyes. The vitreous hemorrhages occurred in the setting of posterior vitreous detachment and one of these eyes required vitrectomy. The retinal detachments were due to breaks at a site distant from the original chorioretinal rupture. The authors concluded that the risk of retinal detachment is low, and they attributed this to an intact posterior hyaloid, which prevents access of liquid vitreous into the subretinal space, and to the adhesion of the retina to the choroid, because these tissues retract as a single unit and prevent access of fluid to the subretinal space.

Ahmadabadi et al.<sup>53</sup> reported the largest series with 13 eyes of 13 patients. The mean follow-up was 37 months. Vitrectomy was performed in two patients with dense vitreous hemorrhage, and one of these patients had retinal detachment, which was treated with silicone oil tamponade. Final visual acuity ranged from 20/1200 to no light perception. The retina remained attached in all eyes during follow-up.

A more recent report<sup>54</sup> described three consecutive patients with traumatic chorioretinal rupture who developed retinal detachment at 1, 2, and 3 weeks after the trauma. In the first case, the underlying retinal breaks were likely created by severe traction from the chorioretinal rupture site. In the second case, the retinal

defect was a small hole at the edge of the superior sclopetaria lesion, associated with early PVR. In the third case, there were multiple breaks in severely atrophic retina at the posterior edge of the lesion. In both cases 1 and 3, proliferative vitreoretinopathy resulted in redetachments that required further intervention.

In summary, sclopetaria or chorioretinal rupture is a rare manifestation of high-velocity projectile injuries to the globe that can lead to rupture of the retina, retinal pigment epithelium, Bruch's membrane, and choroid and leads to retraction of these tissues to expose bare sclera. Regular follow-up is necessary because complications include retinal detachment and vitreous hemorrhage.

## Traumatic Macular Hole

While the vast majority of macular holes are idiopathic, they may also develop after blunt ocular trauma. Knapp, in 1869, and Noyes, in 1875 were the first to describe full-thickness macular holes occurring in that setting.<sup>4</sup> Fuchs, in 1901,<sup>55</sup> reported a posttraumatic inner lamellar macular hole. Macular holes have been seen in association with commotio retinae, subretinal hemorrhage, choroidal rupture, and whiplash injury.<sup>4,5</sup> Cox et al.<sup>56</sup> reported that macular holes occur in 6.3% of eyes after blunt trauma, and a subsequent study by Giovinazzo et al.<sup>57</sup> reported the presence of macular cysts or holes in 4% of boxers. Macular holes also have been associated with nontraumatic retinal conditions such as epiretinal membrane, central retinal vein occlusion, and myopia. In addition, they may occur after surgery for rhegmatogenous retinal detachment,<sup>58,59</sup> and they may be idiopathic.<sup>60</sup>

The clinical features and FA appearance are similar for all full-thickness macular holes, regardless of the cause. Visual acuity typically is 20/40 to 20/400, and symptoms include metamorphopsia and central scotoma. The lesion appears as a full-thickness, round, sharply defined hole in the center of the macula with a surrounding cuff of subretinal fluid and intraretinal cystic changes. The size is variable, but most idiopathic holes measure 200–500  $\mu\text{m}$  in diameter (one-third disc diameter or smaller). Frangieh et al.<sup>61</sup> studied 44 eyes and found that the largest macular holes (up to 1.5

mm in diameter) were associated with blunt trauma (0.86 mm average diameter versus 0.66 mm for nontraumatic macular holes; Fig. 94.4). FA in eyes with macular holes characteristically demonstrates a retinal pigment epithelial window defect in the center of the macula in the early transit phase. In the mid-phase, a surrounding halo of lighter fluorescence may be present. In the late phase, the fluorescence gradually fades.<sup>31</sup>

**FIG. 94.4** Large traumatic macular hole with a cuff of subretinal fluid.

Huang et al.<sup>62</sup> described the morphologic features of traumatic macular holes based on OCT. Seventy-three consecutive patients with traumatic macular holes were included in the study. Traumatic macular holes were classified into five morphologic types with varying average retinal thicknesses, apical areas, and basal areas. Patients who presented >90 days after injury had greater average retinal thickness ( $p=.03$ ) and apex areas ( $p=.002$ )

compared with those who presented within 90 days. Older patients developed more circular holes, i.e., less eccentricity of the apex ( $p=.04$ ) and base ( $p=.01$ ). None of the morphologic parameters investigated in the current study correlated with visual acuity. Patients who presented later in the clinical course or who had greater average retinal thicknesses tended to have better vision ( $p=.11$  and  $p=.07$ , respectively).

Mechanisms of macular hole formation following blunt ocular trauma include postcontusion necrosis with cystoid degeneration and anteroposterior vitreofoveal traction.<sup>27</sup> Severe ocular contusion may result in cystoid macular edema. Rupture of the inner retinal layer occasionally occurs, resulting in a lamellar hole; rupture of both the inner and outer retinal layers results in a full-thickness macular hole. The sequence of cystoid degeneration, cyst coalescence, and full-thickness macular hole formation may take months to years.<sup>61</sup> Vitreofoveal traction may produce a macular hole because the vitreous adheres tightly to the retina at the fovea.<sup>30,60</sup> A sudden separation of the posterior hyaloid from the retina at the macula may produce a dehiscence of retinal tissue at the fovea. However, most traumatic macular holes have an attached hyaloid.

Macular holes usually are stable lesions, but progression to retinal detachment occurs rarely.<sup>63</sup> Margherio and Schepens<sup>64</sup> reported that macular holes were present in 10 of 758 eyes (1.3%) with traumatic retinal detachment. Because macular holes rarely are an isolated cause of rhegmatogenous retinal detachment, a thorough examination of the peripheral retina is essential. Prophylactic photocoagulation to the edge of traumatic macular holes is not necessary but, in cases with resultant retinal detachment, vitrectomy with fluid–gas exchange and endophotocoagulation has been performed.

Several studies have reported the use of vitrectomy for traumatic macular hole with an overall single operation success rate of 83%.<sup>65–72</sup> Intraocular gas tamponade is a key component of any surgical attempt to repair macular holes. It is thought that the surface tension of gas at the site of the hole provides a seal that prevents reaccumulation of the intraretinal fluid as the hole closes with time.

Other vitreous substitutes such as silicone oil have been tried for macular hole closure. Ghoraba and Ellakwa<sup>69</sup> published a study involving 22 patients who underwent vitrectomy with silicone oil or intraocular gas for traumatic macular hole. Silicone oil was used in children, in patients with large holes, and in those unable to comply with strict positioning. Despite a selection bias for the use of silicone oil in children, the difference in average age of the two groups was <1 year. With a single surgery, traumatic macular hole closure was achieved in 67% with silicone oil and 92% with perfluoropropane gas.

Miller et al.<sup>68</sup> reported the long-term outcome of traumatic macular holes. Twenty-eight patients were identified with a mean initial visual acuity of logMAR 1.3 (20/400) and a mean follow-up of 2.2 years. Eleven holes (39.3%) closed spontaneously in median 5.7 weeks. Eleven underwent vitrectomy with a median time to intervention of 35.1 weeks. Vision improved in closed holes ( $p<.01$ ), whether spontaneously ( $p<.01$ ) or via vitrectomy ( $p=.04$ ), but it did not improve in holes that did not close ( $p=.22$ ). There was no relation between initial OCT dimensions and final hole closure status, although there was a trend toward small dimensions for those that closed spontaneously.

## Traumatic Retinal Detachment and Associated Conditions

### Retinal Detachment

Approximately 10–20% of patients with rhegmatogenous retinal detachment (Fig. 94.5) report a history of blunt ocular trauma,<sup>73–76</sup> and in children, the majority of retinal detachments occur in the setting of trauma. When the vitreous suddenly is deformed and shifted, retinal tearing may occur in areas with firm vitreoretinal adhesion, such as the vitreous base, the fovea, areas of lattice degeneration, and chorioretinal scars. The vitreous base is the most significant of these locations, and retinal damage at the vitreous base may result in retinal dialysis, peripheral retinal tears, and giant retinal tears. Indeed, Goffstein and Burton<sup>74</sup> reported that retinal dialyses account for 53% of traumatic retinal detachments; giant retinal tears, 16%; retinal flap tears with adherent vitreous

(horseshoe tears), 11%; and tears at the edge of lattice degeneration, 8%. (In nontraumatic retinal detachment, retinal dialyses account for 5%; giant retinal tears, 2%; retinal flap tears, 45%; and lattice degeneration, 38%.) In this same report,<sup>74</sup> the mean age of patients with traumatic retinal detachment was 28 years (vs. 53 years for nontraumatic retinal detachment) and 78% of patients were male (vs. 50% for nontraumatic retinal detachment). An earlier study by Cox et al.<sup>56</sup> described similar age and sex distributions.

**FIG. 94.5** Traumatic retinal detachment involving the macula.

Many patients with retinal detachment report a history of trauma but it often is difficult to establish a direct causal relationship. According to Goffstein and Burton,<sup>74</sup> factors suggesting trauma-induced retinal detachment include unilateral vitreoretinal pathology, retinal dialysis or giant retinal tear, age younger than 40 years, interval from trauma to diagnosis of retinal detachment less than 2 years, and objective evidence of trauma.

### **Vitreous Base Avulsion**

The vitreous base normally is strongly adherent to the pars plana and peripheral retina. With blunt ocular trauma, the vitreous base may be avulsed from these structures, and this may be an isolated finding or associated with retinal dialysis or a giant retinal tear. Cox

et al.<sup>56</sup> reported this finding in 26% of patients with traumatic retinal detachment.

In the absence of retinal detachment, patients may be asymptomatic or may complain of floaters. Examination of the fundus reveals an arcuate band elevated from the peripheral retina. When the superior vitreous base is avulsed, it may appear draped over the superior peripheral retina (Fig. 94.6). Occasionally, fragments of pars plana epithelium remain adherent to the disinserted vitreous base. Avulsion of the vitreous base is pathognomonic of ocular trauma, and its presence should prompt a careful examination for associated ocular injury. Cryopexy to the edges of the avulsed vitreous base may prevent retinal breaks and retinal detachment.

**FIG. 94.6** Superior mid-peripheral fundus demonstrating draped ribbon-like opacity (avulsed vitreous base). Cryopexy was performed to the peripheral retina in the region of the vitreous base avulsion. This 40-year-old woman was a victim of domestic violence; the fellow eye had a giant retinal tear with retinal detachment and underwent scleral buckling surgery. Visual acuity remained 20/20 in both eyes. (Reproduced with permission from Elliott D, Avery R. Nonpenetrating posterior segment trauma. *Ophthalmology Clinics of North America*, Volume 8, Number 4, December 1995.)

## Retinal Dialysis

The retina normally is adherent to the pars plana epithelium at the ora serrata. Retinal dialysis is a discontinuity or separation of the retina from the pars plana at the ora, and it may result in retinal detachment. Retinal dialysis occurs in the inferotemporal quadrant in 66% of cases, followed by the superonasal quadrant in 14%, the superotemporal quadrant in 10%, the inferonasal quadrant in 4%, and more than one quadrant in 6%.<sup>77</sup> Most dialyses are traumatic,<sup>78</sup> but developmental<sup>77</sup> and genetic<sup>31</sup> causes also have been proposed. All patients with a history of blunt ocular trauma should undergo scleral depression to assess for retinal dialysis (after an open globe is ruled out).

Patients with retinal dialysis may be asymptomatic or may complain of floaters. If retinal detachment also is present, patients may note loss of peripheral visual field if the detachment extends posterior to the equator or loss of visual acuity if the macula is involved. The vitreous is typically attached in eyes with retinal dialysis, and there may be pigment clumps in the inferior vitreous in cases with associated chronic retinal detachment. Indirect ophthalmoscopy reveals a slit at the ora that opens with scleral depression, and serrations within the dialysis are less prominent than normal (Fig. 94.7). If retinal detachment is present, it often is localized and elevated minimally, especially if the dialysis is small or located inferiorly. Trauma occurs most commonly in young patients with a formed vitreous, which often limits the extent of the detachment. In these patients, the retinal detachment may remain stable or progress slowly. Indeed, Ross<sup>78</sup> noted that one or more demarcation lines were present in 46% of patients with retinal dialysis. With posterior vitreous detachment or avulsion of the vitreous base, the retinal detachment is more likely to extend posteriorly or become highly elevated. Retinal dialysis is treated with photocoagulation or cryopexy as prophylaxis for retinal detachment. The treatment of retinal dialysis with retinal detachment is scleral buckling surgery. The success rate of scleral buckling surgery is approximately 90%<sup>78,79</sup> and visual acuity of 20/100 or better ultimately is achieved in two-thirds of patients.<sup>78</sup>

**FIG. 94.7** Inferotemporal retinal dialysis in a 65-year-old woman who suffered blunt ocular trauma 2 years prior in a motor vehicle accident. Visual acuity is 20/30. The patient underwent scleral buckling surgery.

(Reproduced with permission from Elliott D, Avery R. Nonpenetrating posterior segment trauma. *Ophthalmology Clinics of North America*, Volume 8, Number 4, December 1995.)

## Retinal Tears

Areas of strong vitreoretinal adhesion are particularly susceptible to traumatic damage. Horseshoe-shaped retinal tears and operculated retinal holes may result from trauma-induced vitreoretinal traction. These lesions may be found anywhere in the peripheral retina, but often are located at areas of lattice degeneration or at the edges of chorioretinal scars. Formed vitreous is attached to the elevated flap of a horseshoe tear and to the operculum in an operculated hole. In either case, liquid vitreous may pass through the retinal break, and traumatic retinal tears therefore are more likely than retinal dialyses to result in retinal detachment. This is especially true for horseshoe tears because vitreous traction on the retinal flap holds the tear open.

Patients may be asymptomatic or may complain of floaters or photopsia. Floaters may be particularly severe if vitreous hemorrhage results from a torn retinal vessel within the retinal tear. If retinal detachment also is present, patients may complain of loss of peripheral visual field or reduction in visual acuity, depending

on the extent of the detachment. Traumatic retinal tears are treated with photocoagulation or cryopexy as prophylaxis for retinal detachment. Scleral buckling surgery may be performed for retinal detachment associated with traumatic retinal tears, and the success rate exceeds 80%.<sup>56</sup> Vitrectomy is also a common procedure for traumatic retinal detachment.

## Giant Retinal Tears

Giant retinal tears (GRTs) are retinal breaks extending circumferentially more than 3 clock-hours (equal to or greater than 90°), and they occur in the presence of a posterior vitreous detachment. They are oriented circumferentially, and there may be a radial extension posteriorly at one or both ends. GRTs occur at the posterior edge of the vitreous base. They differ from dialyses in that the anterior edge of a GRT is a strip of attached retina under the vitreous base. In addition, the state of the vitreous is critical in making this distinction. In eyes with GRTs the posterior hyaloid is detached while in eyes with retinal dialysis the vitreous remains attached. It is important to differentiate GRTs from retinal dialysis, as the latter carries a different natural history and is managed in a different manner. In GRTs, retinal detachment often develops because liquid vitreous easily enters the subretinal space. In some cases, the posterior edge of the tear is folded over the posterior pole (inverted posterior retinal flap), making it difficult to determine the status of the macula (Fig. 94.8).

**FIG. 94.8** Temporal giant retinal tear and associated retinal detachment. There is also a nasal retinal

**detachment.** (Courtesy of Yoshi Yonekawa and George Williams,  
Associated Retina Consultants, William Beaumont Hospital.)

The treatment of GRTs without retinal detachment is usually scleral buckling surgery. Some giant tears can be treated with cryopexy or photocoagulation, but there is a risk of developing a retinal detachment prior to the formation of an adequate chorioretinal adhesion.

Retinal detachments associated with GRTs are challenging cases and success rates were historically poor. Prior to the introduction of vitrectomy, GRTs were managed with scleral buckling combined with intraocular tamponade with either air or silicone oil, and the success rates were 51–65%.<sup>80,81</sup> These cases were technically and physically challenging for the retinal surgeon, as they required the use of specially designed operating tables with the surgeon operating in a supine “car-mechanic” fashion.

For GRTs associated with retinal detachment, the treatment depends on several factors, including the size of the tear, the location of the edges of the tear, the presence of an inverted posterior retinal flap, and the presence of proliferative vitreoretinopathy. Some GRTs fewer than 4 clock-hours in size without an inverted flap and without evidence of proliferative vitreoretinopathy may be treated successfully with scleral buckling surgery. The remainder of GRTs with retinal detachment usually are managed by vitrectomy with fluid–gas exchange with or without a scleral buckle. Some surgeons prefer the additional presence of a buckle if the edges of the GRT are located in the inferior clock-hours. Lensectomy may be performed in some cases, especially in cases with proliferative vitreoretinopathy, to facilitate removal of anterior vitreous.

The introduction of vitrectomy revolutionized the treatment of GRTs and the introduction of heavy liquids was associated with increased retinal reattachment rates. Perfluorocarbon liquid is an essential adjunct in GRTs with an inverted posterior retinal flap. Kreiger<sup>82</sup> proposed meticulous vitreous base shaving and showed that retinal reattachment can sometimes be achieved without the use of adjunctive scleral buckling. Primary retinal reattachment rates with vitrectomy alone range between 77% and 94%<sup>82–87</sup> and

between 68% and 96% when vitrectomy is combined with a scleral buckle.<sup>83,88-95</sup> Based on the current literature, it is difficult to determine the impact of adjunctive scleral buckling to vitrectomy in GRTs. Visual acuity improved postoperatively in at least half of the patients in most studies, and vision deteriorated in up to 40% when compared with the presenting visual acuity. Factors associated with higher redetachment rates were age below 30 years, female gender, prior vitrectomy, GRT extent greater than 180°, and the presence of preoperative proliferative vitreoretinopathy.<sup>92</sup> The rate of proliferative vitreoretinopathy is higher for GRTs than for detachments due to smaller tears, in part because retinal pigment epithelial cells are dispersed easily within the vitreous cavity as a result of the large size of the tear.

## Optic Nerve Avulsion

Optic nerve avulsion is a catastrophic event that occurs after nonpenetrating or penetrating ocular trauma, when an object enters between the globe and the orbital wall and displaces the eye.<sup>96,97</sup> Patients experience an acute loss of vision, and often the vision is very poor to the level of no light perception. Optic nerve avulsions can be complete or partial. Complete avulsion is characterized by complete separation of the retina from the optic nerve, and the lamina cribrosa is retracted from the scleral rim. Funduscopic findings in complete optic nerve avulsion include extensive hemorrhages around the optic nerve, vitreous hemorrhage, excavation of the optic nerve and hemorrhage within the optic nerve and central retinal artery occlusion (Fig. 94.9). Possible pathophysiologic mechanisms include sudden extreme rotation of the globe or sudden rise in the intraocular pressure that forces the nerve out of the scleral wall. Unfortunately, there is no treatment for this devastating condition and final visual acuity is usually very poor.<sup>98</sup>

**FIG. 94.9** Avulsed optic nerve in a 15-year-old boy who presented with immediate vision loss after he fell onto a rock, striking his left eye. There were no signs of globe rupture or laceration. The area of the optic nerve head was excavated and filled with hemorrhage (*arrows*) with blood emanating into the vitreous. There was also a ring of peripapillary hemorrhage and central retinal artery occlusion. (Reproduced with permission from Modjtahedi et al. Optic nerve head avulsion: Clinical, radiographic and sonographic correlations. *Ophthalmology*, 2015, volume 122, issue 12, page 2442.)

## Indirect Ocular Injury

### Purtscher Retinopathy

In 1910, Purtscher<sup>99</sup> described multiple patches of superficial retinal whitening, intraretinal hemorrhages, and papillitis in five patients following severe head trauma. He postulated that the whitening was caused by lymphatic extravasations caused by a sudden increase in intracranial pressure.<sup>99,100</sup> The pathognomonic *Purtscher flecken* appear in about 50% of the patients. These are polygonal areas of retinal whitening in the inner retina, between retinal arterioles and venules and have a characteristic zone of normal appearing retina extending for an average of 50  $\mu\text{m}$  on either side of the vessels. The findings typically are bilateral, but unilateral cases have been described.<sup>101,102</sup> In apparent unilateral cases, the fellow eye may demonstrate very subtle findings.<sup>103</sup>

Although Purtscher's patients experienced visual loss, presenting visual acuity may range from 20/20 to counting fingers. An afferent pupillary defect and central or paracentral scotomas may be present. The fundus changes may be seen immediately and may

progress for 1–2 days following trauma (Fig. 94.10). The fluorescein angiographic findings are variable and include normal choroidal filling, focal areas of retinal arteriolar obstruction, patches of capillary nonperfusion, venous staining, and disc leakage.<sup>101–104</sup>

**FIG. 94.10** Purtscher retinopathy. (A) Right eye demonstrating patches of superficial retinal whitening throughout the posterior pole in a 30-year-old man 2 days after he was assaulted and suffered head trauma. Visual acuity is 20/100 in both eyes. (B) Left eye shows symmetric involvement. (Reproduced with permission from Elliott D, Avery R. Nonpenetrating posterior segment trauma. *Ophthalmology Clinics of North America*, Volume 8, Number 4, December 1995.)

Agrawal et al.<sup>100</sup> reviewed clinical data from 24 eyes of 15 patients with Purtscher retinopathy. Without treatment, 50% of eyes improved at least 2 lines and 23% improved at least 4 lines at last follow-up. Only 1 of the 24 eyes had worse vision than at presentation. The course is unpredictable because some patients experience resolution of visual loss and fundus changes (over a several-month period), whereas others develop permanent visual loss associated with macular pigmentary disturbance, nerve fiber layer dropout, and optic atrophy.<sup>101,104</sup> Isolated case reports may suggest that treatment of Purtscher retinopathy with high-dose, intravenous steroids may be beneficial.

The typical setting for Purtscher retinopathy is severe head trauma in the absence of direct trauma to the globe, but a similar appearance of the fundus may develop in a variety of traumatic

injuries and diseases. These include acute pancreatitis,<sup>101,105–107</sup> as well as chronic pancreatitis,<sup>108</sup> long bone fracture,<sup>109</sup> chest compression injuries,<sup>103,110</sup> air embolization,<sup>101</sup> amniotic fluid embolization,<sup>111</sup> childbirth,<sup>112</sup> hydrostatic pressure syndrome,<sup>113</sup> and connective tissue diseases such as lupus, scleroderma, dermatomyositis,<sup>27</sup> and thrombotic thrombocytopenic purpura.

The pathogenesis of retinal findings for all of the aforementioned conditions is uncertain, but acute pancreatitis and long bone fracture can lead to fat embolization.<sup>105,107,114</sup> Fat embolization syndrome occurs in up to 5% of patients with long bone fractures and may be fatal. Signs appear within 24 hours after injury and include tachycardia, tachypnea, pyrexia, mental status changes, seizures, focal neurologic signs, petechial hemorrhages, and lipuria.<sup>114–116</sup> Retinal findings are present in 50–60% of patients with fat embolization syndrome and include cotton-wool spots, blot hemorrhages, intravenous fat, and central retinal artery occlusion.<sup>109,115,117–119</sup>

Additional pathogenic mechanisms have been proposed, including arteriolar occlusion from air or amniotic fluid embolization,<sup>101</sup> arteriolar or venous damage resulting from elevated intravascular pressure,<sup>120</sup> and complement-induced granulocyte aggregation.<sup>106,121</sup> Severe trauma can activate the clotting and complement systems, and acute pancreatitis has been shown to activate complement. Complement C5A levels are elevated in patients with Purtscher retinopathy from acute pancreatitis.<sup>121,122</sup> Complement C5A causes intravascular leucoaggregates measuring 60–80  $\mu\text{m}$  in diameter. In an animal model, similar retinal lesions have been observed after infusion of glass beads measuring 15–75  $\mu\text{m}$  into the carotid artery.<sup>123</sup> Blodi et al.<sup>112</sup> suggested the retinal arteriolar embolization theory, most likely secondary to granulocyte aggregates or “leukoemboli,” formed in response to complement activation. Features of Purtscher retinopathy that support this concept include sudden onset, multifocal lesions, otherwise healthy retinal vessels, and the characteristic distribution of ischemic patches.<sup>112</sup>

## Terson Syndrome

In 1881, Litten<sup>124</sup> reported intraocular hemorrhage in association with subarachnoid hemorrhage, and, in 1900, Terson<sup>125</sup> described vitreous hemorrhage in association with any form of intracranial hemorrhage. Subsequently known as Terson syndrome, the retinal and vitreous hemorrhage most commonly occurs after subarachnoid hemorrhage, the majority resulting from spontaneous rupture of an intracranial aneurysm.<sup>126</sup> Approximately 20% of patients with subarachnoid hemorrhage may develop the condition.<sup>113</sup> Terson syndrome also may occur after subdural hemorrhage, the majority resulting from trauma.<sup>126</sup> Stienen et al.<sup>127</sup> studied the incidence of Terson syndrome in patients with aneurysmal subarachnoid hemorrhage in 60 patients admitted to the hospital. Eleven (18.3%) were noted to have Terson syndrome within 24 hours after aneurysm rupture. Compared with the non-Terson syndrome group, patients with Terson syndrome had worse outcomes, including a significantly higher mortality (36.4 vs. 10.2%;  $p=.028$ ).

Kuhn et al.<sup>128</sup> studied prospectively the incidence of Terson syndrome with vitreous hemorrhage in patients with subarachnoid hemorrhage. Any type of intraocular hemorrhage was found in 17% of eyes in patients with subarachnoid hemorrhage; vitreous hemorrhage was present in 8%. All patients with vitreous hemorrhage and 89% of the patients with other types of intraocular hemorrhage had a history of coma compared with 46% of those without intraocular hemorrhage ( $p=.0003$ ).

The vitreous hemorrhage often results in limited visualization of the posterior pole, and multiple preretinal, intraretinal, and subretinal hemorrhages are often present in the peripapillary region (Fig. 94.11). In some cases, a dome-shaped accumulation of blood spans the temporal arcades. Schultz et al.<sup>126</sup> reported the long-term visual outcome in 30 eyes with Terson syndrome. The mean age was 36 years and 11 of 19 patients had bilateral involvement. Presenting visual acuity ranged from 20/20 to light perception. Sixty-three percent of eyes developed a clinically apparent epiretinal membrane; this resulted in significant visual loss in two eyes. With a mean follow-up of 48 months, 83% of eyes achieved visual acuity of 20/50 or better. Half of these eyes had undergone vitrectomy while half were managed conservatively.<sup>126</sup>

**FIG. 94.11** Terson syndrome with hemorrhages in multiple layers. There is a large sub-internal limiting membrane hemorrhage, multiple intraretinal white-centered hemorrhages, and a large area of subretinal hemorrhage.

The pathogenesis of Terson syndrome remains controversial. An early report postulates that hemorrhage in the subarachnoid space can dissect within the optic nerve sheath to enter the eye.<sup>129</sup> This hypothesis cannot explain the presence of preretinal hemorrhage, as there is no direct communication between the subarachnoid space and the vitreous cavity.<sup>119</sup> The mechanism cited most frequently proposes that intracranial hemorrhage produces an acute elevation of intracranial pressure that is transmitted within the optic nerve sheath to obstruct the venous drainage from the eye. This acute rise in venous pressure causes distension and rupture of the fine papillary and retinal capillaries, often resulting in significant hemorrhage.<sup>130-133</sup> The hemorrhage may spread to the subretinal space, within the retina, the subinternal limiting membrane space, the subhyaloid space, or the vitreous cavity.

Vanderlinden and Chisholm<sup>134</sup> first described blood between the retina and the internal limiting membrane in Terson syndrome.

Keithahn et al.<sup>135</sup> reported two adults with perimacular folds spanned by a glistening membrane. In one of these patients, this membrane was shown by electron microscopy to be internal limiting membrane.<sup>135</sup>

The typical clinical course consists of gradual resolution of the vitreous hemorrhage, but vitrectomy may produce good results as well.<sup>126,133,136-138</sup> Indications for vitrectomy include visually immature eyes, in which early rehabilitation may prevent amblyopia, and bilateral Terson syndrome.<sup>126</sup> Indications for conservative management include rapidly clearing vitreous hemorrhage, unilateral involvement with a normal fellow eye, associated ocular damage that precludes good vision, and poor health.<sup>126</sup> In the report by Schultz et al.,<sup>126</sup> ultimate visual outcome was independent of presenting visual acuity, the location of peripapillary hemorrhage, the presence of a dome-shaped lesion, the location of intracranial hemorrhage, and the method of treatment (vitrectomy versus observation). Although there was no difference in the final vision in eyes that underwent vitrectomy compared with eyes managed conservatively, visual recovery was significantly faster in eyes managed with vitrectomy. Sharma et al.<sup>139</sup> reported 15 eyes of 11 patients with Terson syndrome that underwent vitrectomy. Visual acuity of 20/40 or better was achieved in 14 eyes (93.3%). The mean follow-up time was 18 months. Ritland et al.<sup>140</sup> reported 22 eyes with Terson syndrome managed with vitrectomy. Twelve cases underwent unilateral vitrectomy and five had bilateral surgery. The interval between intracranial hemorrhage and vitrectomy was 1–10 months (mean 5.9 months). During a mean follow-up of 23 months (range 1–69 months) visual acuity improved in 21 of 22 eyes. Preoperative visual acuity was  $\leq 0.1$  in 20 of 22 eyes, while postoperative visual acuity was  $\geq 0.5$  in 16 of 21 eyes. One eye experienced vision loss due to subtotal retinal detachment with massive epiretinal membrane formation and proliferative vitreoretinopathy. Poor visual outcomes were mainly caused by retinal detachment (seven eyes, in which three were associated with proliferative vitreoretinopathy), epiretinal membrane (seven eyes), and optic atrophy (one eye).

Skevas et al.<sup>141</sup> analyzed the need for surgical intervention in Terson syndrome and the rate of Terson syndrome, as well as the

effect of vitrectomy with or without internal limiting membrane peeling. The rate of Terson syndrome was 19.6% (20/102). Eight (9 eyes) of the 20 patients with Terson syndrome (40% of the patients with Terson syndrome) underwent a vitrectomy for nonclearing vitreous hemorrhage. In four patients (4 eyes; 20% of patients with Terson syndrome), internal limiting membrane peeling was considered necessary because of subinternal limiting membrane blood. The mean interval between subarachnoid hemorrhage and vitrectomy was 4.4 months (range, 3–5 months). Postoperative follow-up was 6.4 months. Visual acuity improved in all patients.

## Valsalva Retinopathy

The Valsalva maneuver is defined as a sudden elevation in intrathoracic or intraabdominal pressure against a closed glottis. In 1972, Duane<sup>142</sup> described “Valsalva hemorrhagic retinopathy” resulting from rupture of superficial retinal capillaries associated with sudden elevation of ocular venous pressure. Incompetent or absent valves in the venous system of the head and neck allow transmission of thoracic or abdominal pressure into the eye.<sup>142,143</sup> Typical activities producing Valsalva retinopathy include heavy lifting, coughing, vomiting, and straining during bowel movement. Gass<sup>27</sup> described the classic dumbbell-shaped red elevation beneath the internal limiting membrane in or near the central macula; larger round or oval hemorrhages also may be seen (Fig. 94.12). Occasionally, the subinternal limiting membrane hemorrhage breaks through to the subhyaloid space or vitreous cavity.<sup>142</sup> In almost all cases the hemorrhages eventually resolve and vision returns to normal.

**FIG. 94.12** (A) Valsalva retinopathy associated with coughing after waking from general anesthesia in a 41-year-old woman. There is a sub-internal limiting membrane (ILM) hemorrhage in the macula. (B) Vertical optical coherence tomography scan showing the sub-ILM hemorrhage.

## Shaken Baby Syndrome

Approximately 30–40% of physically abused children develop ophthalmic manifestations.<sup>144,145</sup> The most common findings include retinal hemorrhages (Fig. 94.13), cotton-wool spots, perimacular retinal folds and vitreous hemorrhage,<sup>27,144</sup> but retinal detachment, retinal folds,<sup>146</sup> retinoschisis,<sup>147</sup> and peripheral chorioretinal atrophy<sup>148</sup> also have been described. Caffey<sup>149</sup> was the first to demonstrate the association between manual shaking of an infant with whiplash-induced intraocular and intracranial hemorrhage. The head accounts for approximately 10% of the weight of an

infant. Because newborns have poorly developed neck muscles, the shaking maneuver causes rapid acceleration–deceleration of the infant's head and may result in whiplash-induced retinal hemorrhages. Hypoxic ischemic brain injury has been shown to account for the cerebral pathology in shaken baby syndrome.<sup>150</sup> Caputo et al.<sup>151</sup> reported three babies with nonaccidental head trauma that presented with traction retinal detachment and retinal ischemia. Bielory et al.<sup>152</sup> also reported three cases of shaken baby syndrome with bilateral peripheral nonperfusion.

**FIG. 94.13** Presumed shaken baby syndrome. Multiple white-centered intraretinal hemorrhages in an 8-month old boy who was found unresponsive with multiple fractures. He was admitted to the intensive care unit for suspected child abuse. (Reproduced with permission from Elliott D, Avery R. Nonpenetrating posterior segment trauma. *Ophthalmology Clinics of North America*, Volume 8, Number 4, December 1995.)

Muni et al.<sup>153</sup> reported the optical coherence tomography (OCT) findings in three babies with nonaccidental head trauma. Handheld spectral domain OCT documented focal posterior vitreous

separation in four of the six eyes, multilayered retinoschisis in one eye, disruption of the foveal architecture and foveolar detachment in one eye, and disinsertion of the internal limiting membrane or inner retinoschisis in one eye. Handheld spectral domain OCT documented preretinal hemorrhages in all six eyes.

The presence of retinal hemorrhages should arouse suspicion of possible child abuse, especially in infants with additional injuries. Because ocular findings are the presenting signs of child abuse in approximately 5% of cases, the ophthalmologist may play a critical role in the recognition of this serious situation.

## Conclusion

It is essential that the ophthalmologist is familiar with the wide variety of posterior segment manifestations of nonpenetrating trauma. A timely and thorough evaluation is critical for accurate diagnosis and appropriate treatment, and awareness of potential late complications is important in the long-term management of the trauma patient. The ophthalmologist also must play a role in the prevention of eye trauma by stressing the use of protective eyewear, especially for the trauma patient with an intact fellow eye.<sup>154</sup>

## Retinal and Choroidal Disorders in Pregnancy

### Preeclampsia, Eclampsia, and “HELLP” (“Hemolysis, Elevated Liver Enzymes, and Low Platelets”) Syndrome

Preeclampsia typically develops in the second half of pregnancy and is characterized by hypertension, edema, and proteinuria. In healthy women, preeclampsia is generally seen in first pregnancies, with an incidence estimated at 5%.<sup>1</sup> Risk factors for preeclampsia include very young or advanced maternal age, multifetal pregnancy, hemolytic disease of the newborn, diabetes mellitus, chronic systemic hypertension, and renal disease. Eclampsia is preeclampsia with seizures that usually occur late in pregnancy. The HELLP Syndrome consists of hemolysis, elevated liver enzymes, and low platelets. Its incidence ranges from 0.5 to 0.9% of all pregnancies, and 10–20% of those with severe preeclampsia or eclampsia.<sup>2</sup>

Preeclampsia and eclampsia place the fetus at risk due to placental vascular insufficiency. In the early 1900s, severe retinal arteriolar narrowing was believed to reflect placental vascular insufficiency and to be an indication for pregnancy termination and much attention was paid to retinal findings. With improved medical and obstetrical management of hypertension and other aspects of preeclampsia, retinal findings are no longer used to assess this disease.

Early reports gave impressive rates of visual disturbances. Scotomas, diplopia, dimness of vision, and photopsias were noted in 25% of patients with severe preeclampsia and up to 50% of patients with eclampsia.<sup>3</sup> Recent studies, discussed below, suggest

that the rate of visual disturbances has markedly decreased with improved medical management of preeclampsia. Nevertheless, comprehensive ophthalmic examination should be performed, at least for symptomatic patients. Although photic stimuli may predispose to seizures in susceptible patients, the benefits of an ophthalmic examination outweigh the small risk of seizure when an examination is indicated.<sup>4</sup>

Preeclampsia and eclampsia have been associated with hypertensive-like retinopathy; serous retinal detachments; yellow, opaque retinal pigment epithelium (RPE) lesions; arterial and venous occlusive disease; and cortical blindness. HELLP syndrome has been associated specifically with serous retinal detachments. Early studies of retinal disorders in preeclampsia have been discussed in previous works,<sup>5</sup> and an updated review is presented below.

## Retinopathy in Preeclampsia and Eclampsia

Retinal arteriolar constriction is the most common funduscopy change seen in preeclampsia; edema, exudates, hemorrhages, and cotton-wool spots are uncommon. The cause of retinal arteriolar narrowing seems to be central retinal artery vasospasm as suggested by increased central retinal artery blood flow velocity.<sup>6</sup> The retinal arteriolar attenuation generally resolves after delivery, presumably due to normalization of central retinal artery blood flow. Pathologically attenuated retinal microvasculature can be seen early in pregnancy, before the onset of preeclampsia, and can be predictive of later development of the disease. Lupton followed normotensive pregnant women with retinal vessel analysis and blood pressure measurements throughout gestation, and he found that those who later developed preeclampsia had significant attenuation early in gestation.<sup>7</sup>

Early twentieth-century studies reported rates of arteriolar attenuation in preeclamptic patients as high as 40–100%.<sup>8</sup> By the end of the twentieth century, studies were showing much lower rates of these arterial changes. A retrospective study of fluorescein angiograms in preeclamptic patients by Schreyer identified normal retinal vessel caliber in 16 of 16 patients, while 4 of 14 patients with

preexisting chronic systemic hypertension had mild retinopathy.<sup>9</sup> Jaffe prospectively demonstrated a statistically significant difference in reduced arteriolar caliber and arteriovenous ratio between those with severe preeclampsia when compared to healthy controls, but there was no difference between those with mild preeclampsia and controls.<sup>10</sup> Neudorfer found that only 14.8% of preeclamptic women had pathologic findings, specifically those with severe preeclampsia and higher systolic blood pressure. Also, all of the visually symptomatic women had findings, while only 1 asymptomatic woman had findings.<sup>11</sup> The difference in the reported prevalence of retinopathy between the early and recent literature is probably related to better medical management of preeclampsia and its complications. Further, these studies suggest that arteriolar narrowing may be more common in those with severe preeclampsia, those with visual symptoms, and those with chronic preexisting hypertension than those with mild preeclampsia.

Li found that in pregnant women every 10-mmHg increase in mean arterial blood pressure was associated with a 1.9- $\mu$ m reduction in retinal arteriolar caliber. Of note, retinal venous caliber and vascular tortuosity were *not* associated with blood pressure measures.<sup>12</sup> Li found that narrower maternal retinal arteriolar caliber was significantly associated with decreased infant head circumference and birthweight at delivery, reflecting the relative uteroplacental insufficiency.<sup>13</sup> Similarly, Gupta correlated the severity of retinopathy in preeclampsia to the level of placental insufficiency and intrauterine fetal growth retardation. In this study though, the severity of retinopathy did not correlate with the degree of systolic or diastolic hypertension. Interestingly, serum uric acid levels also had a statistically significant positive correlation with retinopathy in this group, but the meaning of this finding is unknown.<sup>14</sup>

It should be briefly mentioned that in the past few years, with improved imaging modalities, retinochoroidal thickening has been shown to occur not only in those with preeclampsia but additionally in those with a normal pregnancy.<sup>15</sup>

## Choroidopathy in Preeclampsia, Eclampsia,

## and HELLP Syndrome

Choroidal dysfunction is a common ocular complication of preeclampsia and eclampsia, seen clinically as serous retinal detachments or yellow RPE lesions. Fig. 95.1 shows bilateral serous retinal detachments in a 28-year-old female with severe preeclampsia one day after delivery.<sup>16</sup> The serous retinal detachments usually are bilateral and bullous but occasionally are cystic.<sup>4,15</sup> Vigil-De Gracia reviewed 28 cases of serous retinal detachments in patients with severe preeclampsia, eclampsia, or HELLP syndrome. Of these, 89% had bilateral retinal detachments, 69% were diagnosed postpartum, and all patients had complete recovery of vision with clinical management within 2–12 weeks.<sup>17</sup>

**FIG. 95.1** Color fundus photograph depicting bilateral serous retinal detachments in a 28-year-old female with severe preeclampsia one day after delivery.

(Reproduced with permission from Chen KH, Chen LR. Bilateral retinal detachment with subsequent blindness in a pregnant woman with severe preeclampsia. *Taiwan J Obstet Gynecol.* 2013;52(1):142-4).

In the early twentieth century, serous retinal detachments were seen in 1% of severely preeclamptic patients and about 10% of eclamptic patients.<sup>18,19</sup> More recently, Saito retrospectively evaluated women with severe preeclampsia or eclampsia and found that 65% had serous retinal detachments and 58% had RPE lesions. RPE lesions were usually located in the macular or peripapillary regions: 92% were solitary or grouped, and 8% were large and diffuse. After delivery, all serous retinal detachments and RPE lesions resolved, but three eyes with geographic RPE lesions developed significant chorioretinal atrophy.<sup>20</sup> The apparent

historical increase in the incidence of serous detachments and RPE lesions is almost certainly due to improved examination instrumentation and diagnostic testing.

The etiology of choroidal dysfunction is thought to be ischemic based on fluorescein angiography, limited histopathologic study, and the presence of Elschnig spots on resolution<sup>21</sup> and indocyanine green angiography.<sup>22</sup> Posterior ciliary artery vasospasm, hypoalbuminemia, and microangiopathic anemia during HELLP syndrome also contribute to the incidence of serous retinal detachments.

Although serous retinal detachment and RPE dysfunction can cause marked loss of visual acuity, these changes fully resolve postpartum and most patients return to normal vision within a few weeks (unless atrophy develops). Some patients have residual RPE changes in the macula. Years later, these changes can mimic a macular dystrophy or tapetoretinal degeneration.<sup>23</sup> Rare patients may develop optic atrophy if chorioretinal atrophy is extensive.<sup>18</sup>

Saito has suggested that serous detachments are more specific to preeclampsia and eclampsia, whereas retinopathy is seen more often in preeclampsia superimposed on preexisting hypertension.<sup>24</sup> Retinopathy is associated with higher levels of blood pressure than is serous detachment.<sup>25</sup> Although retinopathy was believed to be a reflection of possible placental insufficiency and possible adverse neonatal outcome, serous retinal detachment is not an additional risk factor.<sup>21</sup>

Postpartum serous detachments have been reported in preeclamptic patients,<sup>26-28</sup> and there are rare reports of exudative detachments in patients *without* preeclampsia.<sup>29,30</sup> While these serous retinal detachments may be mechanistically distinct, they also resolve over several weeks.

## Other Ocular Changes Seen in Preeclampsia, Eclampsia, and HELLP Syndrome

Cortical blindness that appears late in pregnancy or postpartum is an uncommon complication of severe preeclampsia and eclampsia. The etiology of vision loss may be occipital ischemia in watershed areas from vasospasm,<sup>31-34</sup> possibly related to extracellular

hypercalcemia,<sup>35</sup> ischemia from antiphospholipid antibody-related vascular occlusion,<sup>36</sup> vasogenic edema,<sup>37-44</sup> petechial<sup>43</sup> or larger hemorrhages,<sup>44,45</sup> hypertensive encephalopathy,<sup>46,47</sup> ischemia from hypotension during delivery,<sup>48</sup> or as part of a postictal state.<sup>49</sup> Most patients recover normal vision over several weeks. A prospective study by Cunningham showed that 15/15 women with cortical blindness experienced complete recovery over 4 hours to 8 days. CT scanning was obtained in 13/15 and MRI scanning in 5/15, revealing edema and petechial hemorrhages in the occipital cortex.<sup>43</sup>

The presence of large intracranial hemorrhages may portend a worse prognosis in terms of both mortality and visual recovery. Akan evaluated CT scans from 22 patients with neurologic complications from eclampsia and found that 2 of the 3 patients who died had massive intracranial hemorrhages.<sup>44</sup> Drislane found that among 4 patients with severe preeclampsia and multifocal cerebral hemorrhages, 1 died and the 3 others developed prolonged cognitive deficits.<sup>45</sup>

Cortical vision loss has been reported in eight patients with HELLP syndrome.<sup>49-54</sup> Other ocular disorders reported associated with HELLP syndrome include vitreous hemorrhage<sup>55</sup> and bilateral anterior ischemic optic neuropathy that resolved within months.<sup>56</sup>

Other ocular disorders reported associated with preeclampsia and eclampsia include ischemic optic neuropathy<sup>57</sup> and optic neuritis,<sup>58,59</sup> ischemic papillophlebitis,<sup>60</sup> peripheral retinal neovascularization,<sup>61</sup> choroidal neovascularization,<sup>62</sup> macular edema,<sup>63</sup> macular ischemia,<sup>64</sup> a tear of the retinal pigment epithelium,<sup>65</sup> and bilateral Purtscher's retinopathy.<sup>66</sup> Retinal arterial and venous occlusions, potential causes of irreversible visual loss, have been reported in patients with preeclampsia and will be discussed below.

## Central Serous Chorioretinopathy

Central serous chorioretinopathy (CSC) is caused by localized RPE dysfunction resulting in the accumulation of subretinal fluid. People between the ages of 20 and 50 years are typically affected, and there is an 8 : 1 male predominance.<sup>67</sup> Pregnancy may predispose some women to CSC. The limited amount of

information available concerning CSC in pregnancy makes it difficult to determine whether CSC during pregnancy is typical CSC coincident with pregnancy, or if it is a separate disorder possibly related to the hormonal hypercoagulability or hemodynamic changes of pregnancy.

Only a few dozen cases of CSC associated with pregnancy are reported in the medical literature.<sup>68-79</sup> Unlike the serous retinal detachments observed in preeclampsia and eclampsia, CSC is generally unilateral. The women were all previously healthy, and no cases were associated with preeclampsia or eclampsia. No patients had antecedent eye disease other than refractive error. Primiparas and multiparas were both represented. Most of the cases developed in the third trimester, and all resolved spontaneously within a few months after delivery. There were no cases of significant visual sequelae.

Pregnancy-associated CSC may recur in the context of, or outside of, subsequent pregnancies. CSC recurred in at least two women, always in the same eye, in subsequent pregnancies. One patient had four successive pregnancies with CSC,<sup>69</sup> and one had two successive pregnancies complicated by CSC.<sup>75</sup> One woman developed CSC one month postpartum in two successive pregnancies,<sup>76</sup> and one patient experienced a recurrence of CSC outside the context of pregnancy.<sup>71</sup>

There is an increased incidence of subretinal white exudates (presumably fibrin) in pregnancy-associated CSC (~90%) compared to CSC in males and nonpregnant women (~10%). Sunness reported that 3 of 4 patients with pregnancy-related CSC had subretinal exudates.<sup>71</sup> Gass found that 6/6 cases of pregnancy related CSC had subretinal exudates compared to only 6/50 of nonpregnancy related cases.<sup>72</sup> However, a report of 3 pregnant women with CSC had no exudates,<sup>80</sup> and a large analysis of 17,000 pregnant women found a prevalence of CSC to be 0.008%, with 50% having exudates.<sup>78</sup> The cause of this higher prevalence of subretinal exudates in pregnant women is unknown.

## Occlusive Vascular Disorders

An increase in the level of clotting factors and clotting activity

occurs during pregnancy.<sup>81</sup> Several pathologic sources of thrombosis and embolic events can also occur. One review of ischemic cerebrovascular disease suggested that pregnancy is associated with a 13-fold increase in the risk of cerebral infarctions compared to nonpregnant women.<sup>82</sup> This increased risk of vaso-occlusive disease may also manifest as retinal or choroidal vascular occlusions.

## Retinal Artery Occlusion

Two cases of unilateral central retinal artery occlusion (CRAO),<sup>83,84</sup> one case of bilateral CRAO,<sup>85</sup> five cases of unilateral branch retinal artery occlusion (BRAO),<sup>86,87</sup> and 3 cases of bilateral multiple BRAO<sup>82</sup> have been reported in association with pregnancy and in the absence of additional risk factors. Two cases of cilioretinal artery occlusion have been reported.<sup>88,89</sup> Several cases of arteriolar occlusion were associated with preeclampsia,<sup>85,90</sup> and one was associated with disc edema.<sup>87</sup> Five of the thirteen cases (38.5%) occurred within 24 hours of delivery, suggesting that this is a particularly susceptible period. Two of the patients with unilateral BRAO also were found to have mild transient protein S deficiency upon further systemic workup.<sup>91</sup>

In addition to the aforementioned cases, Blodi reported that multiple retinal arteriolar occlusions were seen within 24 hours after childbirth in four women. Two patients were preeclamptic and required cesarean section. One of the two also had evidence of cerebral infarctions. The third patient had hypertension, pancreatitis, and premature labor. The fourth was a previously healthy 16-year-old who had an oxytocin-induced labor and had a generalized seizure 2 hours after delivery. The patients reported decreased vision, and all had fundus findings characterized by retinal patches characteristic of ischemia and intraretinal hemorrhages that were similar to Purtscher's retinopathy. After resolution, patients were left with focal arteriolar narrowing and optic disc pallor. The visual acuities ranged from 20/20 to 4/200 with visual field defects corresponding to the areas of occlusion. The authors suggest that complement-induced leukoemboli could have caused the retinal arteriolar occlusions.<sup>90</sup>

At least eight additional cases of pregnancy-associated BRAO have been reported in the literature.<sup>92-98</sup> However, all of these cases had significant additional risk factors for vascular occlusion. Since pregnancy is a common condition, it is difficult to know whether these cases represent true pregnancy associations. One case was associated with intramuscular progesterone therapy for a threatened abortion.<sup>92</sup> Three cases that occurred postpartum were associated with hypercoagulability from protein C<sup>93</sup> or protein S<sup>90,94</sup> deficiency. Two cases were associated with thromboembolic occlusions attributed to mitral valve prolapse<sup>95</sup> and amniotic fluid embolism.<sup>96</sup> The final two cases developed BRAO in the first trimester in association with migraine headaches.<sup>97</sup> Ten more cases of BRAO were reported specifically in the context of Susac syndrome, which will be discussed below.

## Susac Syndrome

Susac syndrome (SS) is a clinical triad of encephalopathy, branch retinal artery occlusion (BRAO), and sensory neural hearing loss (SNHL), first described by Susac in 1979.<sup>99</sup> It is a rare syndrome with 304 cases reported in the literature as of 2013.<sup>100</sup> SS is more common in females between the ages of 20 and 40 years of age. SS is thought to be due to an autoimmune-mediated vascular endothelial injury, and therefore reported treatments include immunosuppressive/immunomodulatory, anticoagulation, and early induction of labor. There have been 10 cases of SS presenting or recurring during pregnancy with findings of one or multiple BRAOs, more often bilaterally.<sup>101-108</sup> One series reported three patients with recurrence of disease that occurred months to years after the onset of SS.<sup>106</sup> It appears that pregnancy may affect the course of SS, with BRAO occurring as an initial presentation or recurrence of disease during pregnancy or in the postpartum period. It should be noted that SS has a variable course and is not self-limited as previously thought. A pregnant female with a BRAO should be evaluated for possible SS, and those with SS should be followed closely during pregnancy and in the postpartum period.

## Retinal Vein Occlusion

Retinal vein occlusion associated with pregnancy is rare. Few pregnancy-related central retinal vein occlusions (CRVO) have been reported to date, and we are not aware of any branch retinal vein occlusions.<sup>109–115</sup> Most cases were unilateral; some cases improved but not completely; and some cases were associated with preeclampsia, eclampsia, HELLP syndrome, or an undiagnosed arteriovenous malformation. A recent Korean study found a prevalence of 33 pregnancy-related retinal vein occlusions (RVO) in 1.8 million women during their study period, of which 36.4% had preeclampsia or eclampsia. They hypothesized that pregnancy was not a risk factor for RVO, but preeclampsia/eclampsia was.<sup>115</sup>

## Disseminated Intravascular Coagulopathy

Disseminated intravascular coagulopathy (DIC) is an acute, life-threatening process of widespread microvascular thrombosis due to uncontrolled activation of the hemostatic system leading to multiorgan failure. It is reported to occur in 0.03–0.35% of pregnancies and is associated with obstetrical complications such as abruptio placentae, uterine atony, HELLP syndrome, and more.<sup>116</sup> This process has a tendency to occlude the posterior choroidal vessels leading to RPE ischemia, dysfunction of the RPE pump mechanism, and subsequent serous retinal detachments in the macular and peripapillary regions.<sup>117–120</sup> The development of serous retinal detachments in pregnancy, especially late pregnancy, may be an early ocular sign of DIC.<sup>120</sup> These detachments tend to be bilateral and symptomatic. With recovery from the systemic disorder, vision generally returns to normal with only residual pigmentary changes.<sup>117,120</sup> Patel reported a case of bilateral retinochoroidal infarction associated with preeclampsia and DIC with permanent vision loss.<sup>121</sup>

## Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a rare, idiopathic, acute, systemic coagulopathy characterized by platelet consumption and thrombus formation in small vessels. TTP occurs at any age with a peak incidence in the third decade of life and a female to male preponderance of 3:2. Visual changes occur in

approximately 8–20% of cases due to thrombus formation in the choriocapillaris with secondary RPE ischemia.<sup>122–128</sup> Clinical findings are usually bilateral and include serous retinal detachments, yellow spots at the level of the RPE, and localized arteriolar narrowing. Sequelae include RPE pigmentary changes and Elschnig spots with a return to baseline vision over several weeks to months in most cases. There are several reported cases of peripartum and early postpartum associated TTP with the aforementioned ocular findings. All cases were managed via systemic treatment of the TTP with generally good visual outcomes.<sup>122,123</sup> HELLP, DIC, and TTP are discussed in more detail in [Chapter 63](#), Coagulopathies.

## Amniotic Fluid Embolism

Amniotic fluid embolism is a serious complication of pregnancy with high mortality. Those who survive the initial event usually develop DIC<sup>129</sup> with the potential ocular complications described above. Two patients developed multiple BRAOs, presumably related to particulate material from the amniotic fluid.<sup>96,130</sup> One of these patients was a 28 year-old who developed the BRAOs during labor. [Fig. 95.2](#) is a color fundus photograph of the right eye (left side of image), demonstrating parafoveal edema and glial optic disc remnants, and of the left eye (right side of image), demonstrating macular BRAO by multiple glistening particles with diffuse superficial retinal edema. [Figs. 95.3A–B](#) are intravenous fluorescein angiography images delineating the parafoveal capillary nonperfusion and occluded vessels (indicated by arrows), respectively.<sup>96</sup> Another patient had massive blood loss from an amniotic fluid embolism leading to severe unilateral ischemic optic neuropathy.<sup>131</sup>

## Uveal Melanoma

Pregnancy is heralded by a hormone-dependent hyperpigmentation and well-known cutaneous changes like chloasma and darkening of preexisting nevi owing to increased levels of melanocyte-stimulating hormone in pregnancy.<sup>132</sup>

Although estrogen and progesterone may stimulate melanogenesis, there is no evidence that this can cause malignant transformation of melanocytic cells.

A case-control study by Holly et al. found a decreased risk of uveal melanoma for women who had ever been pregnant with an increase in protective effect with more live births. The largest effect was observed between nulliparous and parous women.<sup>133</sup> Others, however, have reported a trend toward a larger-than-expected number of ocular melanomas presenting during pregnancy.<sup>134,135</sup> There are also a number of anecdotal reports of uveal melanomas presenting or growing rapidly during pregnancy.<sup>136-141</sup> These reports led to speculation that uveal melanoma may be hormone-responsive, but two studies have failed to show any estrogen or progesterone receptor expression in ocular melanomas.<sup>139,142</sup> A large retrospective study showed no association of uveal melanoma with the use of oral contraceptives or hormone replacement therapy.<sup>143</sup> It is possible that other hormones may be involved<sup>139</sup> or that tumor growth may be related to pregnancy-associated immune modulation.

Pregnancy-related uveal melanoma does not seem to differ histologically from uveal melanoma not associated with pregnancy. Shields reported that among 10 pregnancy-related choroidal melanomas evaluated after enucleation, the tumors did not differ in cell type, mitotic activity, and other features when compared to a matched group of tumors in nonpregnant women.<sup>144</sup>

The treatment of pregnancy-associated uveal melanoma has been described in two studies. Among 16 cases reported by Shields, 10 eyes were enucleated, four received plaque radiotherapy during or after pregnancy, and two cases were observed. Among 14 of 16 patients who elected to carry the pregnancy to term, all delivered healthy babies with no infant or placental metastases.<sup>144</sup> Romanowska-Dixon reported eight cases in which there were no treatment-related pregnancy complications. The authors do suggest

that brachytherapy is safer towards the end of pregnancy or after delivery.<sup>145</sup>

Childbearing may be associated with improved survival in uveal melanoma. Egan et al. performed a large prospective cohort study in which death rates from metastasis were 25% higher in nulliparous women and men than in women who had given birth. The protective influence of parity was greatest in the first 3 years of follow-up and increased with the number of live births.<sup>146</sup> These results contradict a small earlier study by the same group that concluded rates of metastasis were not higher among women who reported pregnancies or oral contraceptive use.<sup>147</sup> A much smaller study by Shields also showed similar 5-year survival between pregnant and nonpregnant women with posterior uveal melanoma.<sup>144</sup>

## Other Changes Arising in Pregnancy

Two choroidal osteomas presenting during pregnancy have been reported,<sup>148,149</sup> one with visual loss due to choroidal neovascularization.<sup>148</sup> Macular neuroretinopathy,<sup>150,151</sup> Valsalva maculopathy,<sup>152</sup> and cystoid macular edema<sup>153</sup> have been observed in the immediate postpartum period. Placental metastases from orbital rhabdomyosarcoma<sup>154</sup> and primary ocular melanoma<sup>155</sup> have been reported.

## Preexisting Conditions

### Diabetic Retinopathy

The prevalence of diabetic retinopathy (DR) in pregnant women with type 1 diabetes mellitus (DM) has been reported in the range of 57–62%, while pregnant women with type 2 DM have DR in the range of 17–28%.<sup>156</sup> Well-controlled blood glucose and adequate glycosylated hemoglobin (HbA<sub>1c</sub>) before conception and throughout the pregnancy may reduce the risk of spontaneous abortion, congenital anomalies, and fetal morbidity.<sup>157–159</sup> Two studies suggest that the severity of diabetic retinopathy may be a significant factor in predicting adverse fetal outcomes, and

glycemic control may or may not counteract these adverse fetal effects.<sup>160,161</sup>

Diabetic women who may become pregnant should establish excellent glucose control before conception, since the major period of fetal organogenesis may take place before the mother is even aware that she is pregnant. In addition, a diabetic woman's retinopathy status should be evaluated and stabilized prior to conception. This is particularly important for patients with severe nonproliferative (NPDR) or proliferative diabetic retinopathy (PDR) because scatter laser photocoagulation may reduce progression during pregnancy.<sup>162</sup> Laser treatment or intravitreal injections for diabetic macular edema (DME) before pregnancy may also be important, although the effects of pregnancy on macula edema have not been adequately studied.

Data from the Diabetes in Early Pregnancy Study (DIEP), a study of 155 insulin-dependent diabetic pregnancies,<sup>163</sup> the Diabetic Control and Complications Trial<sup>164</sup> (DCCT), and the previous data summarized by Sunness<sup>162</sup> all provide evidence that better metabolic control before pregnancy diminishes the progression of DR. The institution of tight glycemic control is associated with short-term DR progression.<sup>163,165-167</sup> Nerve fiber layer infarctions commonly are associated with the institution of tight metabolic control of chronic hyperglycemic patients. One study described the retinopathy status of 13 patients managed by insulin pump during pregnancy. Two patients who had a rapid decrease in the HbA<sub>1c</sub> level developed acute ischemic changes and ultimately PDR.<sup>168</sup> However, a study of 102 type 1 diabetic pregnant women found no correlation between progression of DR and decline in HbA<sub>1c</sub> levels or prevalence of severe hypoglycemia.<sup>169</sup> It is prudent to stabilize the patient's diabetic status before becoming pregnant if at all possible so that there are no abrupt changes in glycemic control. The long-term benefits of adequate blood glucose control outweigh concerns about the transient worsening of retinopathy that has been associated with the sudden imposition of tight glycemic control.

The frequency of ophthalmic follow-up of a diabetic patient during pregnancy is determined by her baseline retinopathy status. North American ophthalmologic guidelines recommend that a diabetic woman planning pregnancy within 12 months should be

examined by an ophthalmologist, undergo repeat evaluation in the first trimester, and examinations after that should occur at intervals based on the initial findings.<sup>160,170,171</sup> Attendance at a prepregnancy ophthalmologic evaluation was associated with receiving adequate future eye screening and treatment.<sup>165</sup>

## **Short- and Long-Term Effects of Pregnancy on Diabetic Retinopathy**

Since there is a high rate of regression of DR during the postpartum period, one must consider short-term and long-term changes separately. The DCCT research group reported that pregnant women in the conventional treatment group were 2.9 times more likely to progress three or more levels from baseline retinopathy status than nonpregnant women. The odds ratio peaked during the second trimester and persisted as long as twelve months after delivery.<sup>164</sup> One study of short-term effects included 16 women with mild NPDR. Progression during pregnancy was compared to progression between six and fifteen months postpartum in the same women. The number of microaneurysms (MAs) showed a rapid increase between the 28th and 35th weeks of pregnancy. Six months postpartum the number of MAs decreased but in most cases remained higher than the baseline level and remained stable over the subsequent 9-month postpartum period.<sup>172</sup>

Three other studies compared short-term progression of retinopathy between separate control groups of nonpregnant women and pregnant women over the same time period. The first compared the course of DR in 93 pregnant women and 98 nonpregnant women. Progression was observed in 16% of the pregnant group compared to only 6% in the nonpregnant patients. Furthermore, more (32%) of the nonpregnant group had retinopathy at baseline compared to the pregnant cohort (22%), so one might have expected more progression in the nonpregnant group, making these findings more significant.<sup>173</sup> A second study compared 39 nonpregnant women, 46% with DR at baseline, to 53 pregnant diabetic women, 57% with DR at baseline over a 15-month period. In the nonpregnant group the MAs remained stable, dot-blot hemorrhages appeared in three patients (8%), and no nerve fiber layer infarctions developed. In the pregnant group, MAs

increased moderately, and dot–blot hemorrhages and nerve fiber layer infarctions increased markedly. One patient with NDPR from the pregnant group developed PDR.<sup>174</sup> In the third study, there were 133 pregnant and 241 nonpregnant women, and all were statistically equivalent in terms of baseline retinopathy levels. Within each quartile of HbA<sub>1c</sub>, pregnant women had a greater tendency to have worsening of retinopathy, and the nonpregnant women had a greater tendency to have improvement in their level of DR during the follow-up interval.<sup>175</sup>

A few studies recorded the long-term effects of pregnancy on DR. The first included 40 women followed for 12 months postpartum. Among 19 study participants with no retinopathy at baseline, 30% developed mild NPDR during the second and third trimester. By one year postpartum none had clinically detectable retinopathy. Among the 21 women with retinopathy at baseline, 11 worsened during pregnancy and 2 developed PDR. None of these 11 women had regressed to their initial retinopathy status by one year postpartum.<sup>176</sup> The second study compared 28 diabetic pregnant women to 17 nulliparous matched controls over a 7-year period. Only 5 of 26 (19.2%) women who had been pregnant experienced progression of retinopathy compared to 8 of 16 (50%) nulliparous women, suggesting that pregnancy does not affect long-term progression and may even afford a protective effect.<sup>177</sup> A third study of 30 women who had completed at least one successful pregnancy found no increase in the rate of development of PDR after 2 years of follow-up compared to matched controls.<sup>178</sup> These studies suggest that over time having a history of pregnancy does not appear to confer a higher risk of development/progression of DR.

Two studies suggest that the number of prior pregnancies does not appear to be a long-term factor in the severity of retinopathy present when duration of diabetes is taken into account.<sup>179,180</sup> In fact, a cross-sectional European study reported lower levels of retinopathy in diabetics with multiple pregnancies compared with women matched for age and duration of diabetes.<sup>181</sup> It is not clear if this improved status was caused by a prolonged period of tight metabolic control and better patient education or if pregnancy confers a long-term protective effect. Another possibility involves

the bias that only women with better metabolic control may have undergone the stress of multiple pregnancies.

There has been anecdotal concern that the act of labor can cause significant progression of DR, including vitreous hemorrhage. The second stage of labor includes a series of strong Valsalva maneuvers that may increase intraocular pressure (IOP) and cause retinal hemorrhages. A study by Feghali sought to determine the association between expulsive efforts during the second stage of labor and progression of DR in 192 pregnant women with adequately controlled type 1 DM. There was no difference in DR progression between those who had elective cesarean delivery, those who had cesarean delivery prior to the second stage of labor, and those who had cesarean or vaginal delivery during the second stage. They concluded that vaginal delivery should not be denied to pregnant women with controlled type I diabetes.<sup>182</sup>

## **The Role of Baseline Retinopathy Status, Duration of Diabetes, and Metabolic Control**

The major determinants of the progression of DR in a pregnant woman are the degree of retinopathy and duration of diabetes at the onset of pregnancy.<sup>162,163,174,183–189</sup> Therefore, women with diabetes are encouraged to complete childbearing early in their adult life.<sup>190</sup> The baseline level of retinopathy at conception is the major risk factor for progression of retinopathy, according to the DIEP. When a logistic regression model was used to separate the influence of diabetes duration (shorter duration being less than 15 years, longer duration being more than 15 years) from the effect of a worse baseline level of NPDR, the baseline retinopathy was quite significant but the duration of retinopathy was not. Analysis of pregnant patients with moderate to severe DR in the DIEP showed deterioration (defined as a two-step or more worsening determined on the final scale of the modified Airlie House Diabetic Retinopathy Classification) in 55% of patients with shorter duration and 50% of patients with longer duration of diabetes. However, the rates of development of PDR during pregnancy were 39% of patients with longer duration of diabetes and only 18% of patients with shorter duration of diabetes. The HbA<sub>1c</sub> level at the beginning of pregnancy was used in the DIEP as a measure of metabolic control. Women

with HbA<sub>1c</sub> levels of 6 standard deviations (SD) or more from the control mean had a statistically significant higher risk of progression of retinopathy during pregnancy when compared with patients with baseline HbA<sub>1c</sub> levels within 2 SD of the control mean.<sup>163</sup>

A prospective study of 179 pregnancies in 139 women with type-1 diabetes found that women with moderate to severe DR at baseline had progression in 30%, while only 3.7% progressed with less severe baseline retinopathy.<sup>187</sup> Similarly, in a smaller prospective study of 54 women with type-1 diabetes, there was DR progression in 9.1% with no baseline DR, 20% with NPDR at baseline, and 58.3% with PDR at baseline.<sup>189</sup>

Studies show that duration of diabetes correlates with DR progression, and they delineate that in various ways. One study found that there was a 10% progression rate of DR in women who had type 1 diabetes for 10–19 years compared to a 0% progression rate of those with diabetes less than 10 years.<sup>187</sup> Another study found that women with type 1 diabetes who had DR progression during or soon after pregnancy had an average diabetes onset at age 14 compared to 19 years in those who had no DR progression.<sup>188</sup> Lastly, pregnant women with type 2 diabetes who had progression of DR had diabetes on average for 6.7 years, as opposed to 3.3 years in those who had no progression.<sup>186</sup>

The DCCT group also evaluated the effect of pregnancy on microvascular complications. Pregnant women in the intensive treatment group had a 1.63-fold greater risk of retinopathy progression during pregnancy than nonpregnant women, compared to a 2.48-fold greater risk in the conventional treatment group.<sup>164</sup>

## **Risk Factors for Progression of Diabetic Retinopathy During Pregnancy**

Nephropathy and systemic hypertension are additional risk factors for the progression of DR during pregnancy. A well-known association exists between nephropathy and retinopathy in nonpregnant diabetic patients. One study in pregnant diabetics showed that 8 of 9 patients in whom DME developed during

pregnancy had proteinuria of more than 1 gram per day.<sup>167</sup> Several studies report elevated systolic blood pressure as a risk factor for the progression of DR.<sup>165,169,185,191–193</sup> The DIEP found a 1.3 odds ratio for two-step progression of retinopathy for every 10-mmHg increase in systolic blood pressure.<sup>163</sup>

## **Progression of Diabetic Retinopathy According to Baseline Status**

The following discussion of the progression of retinopathy during pregnancy is subdivided according to the baseline level of retinopathy present. Many of the studies did not use the more recent classification recommended by the Early Treatment Diabetic Retinopathy Study (ETDRS). Whenever possible, the results have been organized according to this classification.<sup>194</sup> All diabetic women, regardless of retinopathy status, should at least have a complete ophthalmic exam before conception, during the first and third trimesters, and within one year after delivery.

### **Gestational Diabetes**

In four studies,<sup>195–198</sup> comprising 397 pregnant women with gestational diabetes, only two women had retinopathy, and both had just one MA each.<sup>195</sup> One of the studies was a 12-year prospective study and did not demonstrate an increased risk of diabetic retinopathy.<sup>195</sup> However, retinal vascular tortuosity in gestational diabetics has been reported, and some degree of tortuosity persisted at 5 months postpartum.<sup>199</sup> There is one case report of a previously healthy nulliparous woman with gestational diabetes diagnosed at 8 weeks' gestation. Glycemic control was instituted, and the patient developed bilateral PDR by 31 weeks' gestation. The patient had a markedly elevated HbA<sub>1c</sub> level at initial diagnosis suggesting that she may have been diabetic before becoming pregnant.<sup>200</sup> It appears that routine examinations have little utility in gestational diabetics.

### **No Initial Retinopathy**

Summarizing several studies, of 674 pregnant diabetic women with no initial DR, 86 (13%) developed NPDR and only one developed

PDR.<sup>162,163,169,186,189,201,202</sup> Sunness summarized nine studies that included 484 diabetic pregnancies (included in the 674 patients above) with no initial retinopathy. In 23 cases with progression for which postpartum follow-up was available, there was some regression of the nonproliferative changes in 57% of patients.<sup>162</sup>

### **Mild Nonproliferative Diabetic Retinopathy**

Hellstedt monitored MA formation and disappearance rates in diabetic pregnant women. They found that there is continuous turnover of MAs during pregnancy with MA count increasing during pregnancy, peaking at 3 months postpartum, and then declining back to baseline.<sup>203</sup> Six studies with 79 pregnant diabetic women with mild NPDR showed that 24.1% developed increased nonproliferative changes, while 2.5% had proliferative changes.<sup>162,163,186,201,202</sup>

### **Moderate to Severe Nonproliferative Diabetic Retinopathy**

Four studies<sup>163,186,201,202</sup> and one large review by Sunness<sup>162</sup> included 297 diabetic pregnant women with moderate to severe NPDR at baseline. Forty-four percent had nonproliferative retinopathy progression, while 9.1% had proliferative changes. Pregnant diabetic women with moderate to severe NPDR should have a complete examination before conception, during the first and second trimesters, every 4–6 weeks thereafter, and within one year after delivery.

### **Proliferative Diabetic Retinopathy**

Compiling the results of two large reviews<sup>162,204</sup> and three additional smaller studies,<sup>175,185,189</sup> 36.7% of 278 pregnant diabetic women with PDR at baseline had progression of retinopathy (ranging from 22% to 63%).

Optimal treatment of proliferative disease before pregnancy reduces the risk of progression during pregnancy. In the 1988 Sunness review,<sup>162</sup> those patients who had scatter laser photocoagulation before pregnancy showed a 26% rate of progression of their proliferative disease and visual loss compared

to 58% of patients without prior treatment. Those patients with complete regression of proliferative disease before pregnancy did not demonstrate progression of proliferative disease during pregnancy. In Rahman's study, out of 12 women with PDR, 4 had laser prior to pregnancy with only one woman having progression during pregnancy. Out of the 8 women who had no laser prior to pregnancy, 6 had retinopathy progression. Three patients had laser treatment during the second trimester with complete immediate regression, and the other 3 had laser treatment during the third trimester with regression taking 3–4 months.<sup>189</sup> Reece found somewhat different results in an earlier study. In this analysis, half of the patients with proliferative disease who underwent laser treatment prior to pregnancy required additional scatter treatment during pregnancy. In addition, 65% of patients who had proliferative disease during pregnancy required photocoagulation postpartum. No patient had proliferative disease that did not respond to laser photocoagulation.<sup>205</sup>

It appears that it is not predictable whether proliferative retinopathy will regress or not at the end of pregnancy or in the postpartum period. One study found that 4/5 women who developed PDR during pregnancy had spontaneous regression to nonproliferative status within 2 months postpartum.<sup>176</sup> However, one study of 8 women with PDR reported no regression by 3 months postpartum<sup>185</sup> and another study of 16 women with PDR showed no regression in 12 years postpartum.<sup>206</sup>

The possibility of spontaneous regression of PDR is a factor to consider when determining if laser photocoagulation is indicated during pregnancy. Most retina specialists would aggressively treat patients who have high-risk PDR; some retinal specialists would treat one eye or both in cases that are not high risk, given the problem of rapid progression during pregnancy. After consideration of high-risk factors such as high initial HbA<sub>1c</sub> and duration of diabetes, these decisions must be made on a case-by-case basis. Pregnant diabetic women with PDR should have a complete examination before conception and bimonthly during pregnancy, with close follow-up in the postpartum period.

Vitreous hemorrhage during labor and delivery has been reported in a few cases.<sup>207</sup> Currently, no evidence justifies

performing a cesarean section on the basis of proliferative retinopathy alone, given the availability of vitrectomy for the treatment of nonclearing vitreous hemorrhage.<sup>162</sup>

## **Diabetic Macular Edema in Pregnancy**

Diabetic macular edema (DME) that involves or threatens the fovea is currently treated with anti-VEGF injections, with or without focal laser photocoagulation, outside the context of pregnancy in order to reduce the risk of moderate vision loss. Patients who develop DME during pregnancy or have DME at conception frequently have different prognoses than nonpregnant patients as spontaneous resolution during or after pregnancy has been reported.<sup>186,208</sup>

Two out of 80 type 2 diabetic women who became pregnant while having DME had regression of the edema as their HbA<sub>1c</sub> levels improved.<sup>186</sup> Sinclair and Nessler reported that 16 of 56 eyes in diabetic women with initial proliferative or nonproliferative retinopathy developed DME during pregnancy. Of these 16 eyes, 14 had improvement in visual acuity and resolution of DME postpartum without laser treatment.<sup>208</sup>

In general, pregnant women with DME should not be treated during pregnancy because of the high rate of postpartum spontaneous improvement. Possible exceptions include cases in which lipid is threatening the fovea or severe, progressive DME develops early in pregnancy. Due to the lack of adequate safety data regarding the use of anti-VEGF treatments (discussed below), the authors recommend focal laser photocoagulation in the rare case where treatment during pregnancy is indicated. However, further study of pregnant women with DME is needed.

## **Diabetic Retinopathy and Maternal and Fetal Wellbeing**

Advanced diabetic retinopathy has been considered a risk factor for adverse fetal outcomes because it may reflect more widespread systemic disease. Pregnancies associated with NPDR may not be at higher risk for adverse fetal outcomes.<sup>204</sup> However, Klein reported an adverse fetal outcome in 43% of women with PDR compared to only 13% of women with NPDR.<sup>160</sup> Another study of 20 pregnancies of 17 women with PDR reported spontaneous abortion in 2 cases,

stillbirth in 1 case, and 3 had major congenital anomalies.<sup>205</sup> Sameshima reported that among 60 pregnant diabetic women, the 7 with PDR had a significantly higher incidence of fetal distress.<sup>209</sup> A final study of 26 women with PDR reported serious neonatal morbidity and mortality (19% and 12%, respectively).<sup>210</sup> A prospective study of 205 women with type 1 diabetes found that low newborn birthweight was associated with retinopathy progression. However, retinopathy progression was not associated with earlier delivery, macrosomia, respiratory distress syndrome, neonatal hypoglycemia, or neonatal death.<sup>211</sup>

Improved medical and obstetrical management has improved the outcome of diabetic pregnancies. In a study of 22 pregnancies complicated by retinopathy and nephropathy in which good glycemic control was present antepartum and throughout pregnancy, there were no infant deaths and only 1 case of mild respiratory distress syndrome.<sup>161</sup> A retrospective study of 482 diabetic pregnancies reported only 3 perinatal deaths, which was statistically equivalent to nonpregnant deliveries over the same period.<sup>212</sup>

Three studies suggest an association between DR and the development of preeclampsia. Hiilesmaa followed 683 consecutive pregnancies with type 1 diabetes and found that retinopathy was a statistically significant independent predictor of preeclampsia.<sup>213</sup> A second study looked retrospectively at 65 pregnant type 1 diabetic patients and reported that deterioration of retinopathy occurred more frequently in those with preeclampsia than those without preeclampsia.<sup>214</sup> Lastly, Gordin followed 158 pregnant type 1 diabetics for 16 years and found that those with pregnancy-induced hypertension and/or preeclampsia had an increased risk of developing severe DR later in life.<sup>187</sup> Perhaps central retinal artery vasospasm associated with preeclampsia exacerbates retinal ischemia that occurs in DR.

## Toxoplasmic Retinochoroiditis

The likelihood of congenital toxoplasmosis occurring in the offspring of a mother with active retinochoroiditis or chorioretinal scars is often a concern. This usually is unfounded, however, since

congenital toxoplasmosis in the fetus results only from infection of the mother that occurs during the pregnancy itself. The presence of focal toxoplasmic retinochoroiditis or scars in a patient reflects congenital infection of that patient in essentially all cases and not new infection of the mother.<sup>215</sup> Therefore, the fetus of a woman with active retinochoroiditis or scars should not be at risk for contracting congenital toxoplasmosis. A study of 18 pregnant patients with active toxoplasmosis or scars, some with elevated toxoplasmosis titers, found that no infants developed congenital toxoplasmosis.<sup>216</sup>

One study of 50 pregnant women<sup>217</sup> and another of 17<sup>218</sup> found that recurrence rates of ocular toxoplasmosis are not higher during pregnancy and may in fact be lower. The ocular characteristics of active ocular toxoplasmosis during pregnancy when compared to attacks during the nonpregnant periods are no different in terms of the severity, duration, or outcome of the attacks.<sup>219</sup>

## Noninfectious Uveitis

Noninfectious uveitis (anterior, intermediate, posterior, or pan) tends to improve during pregnancy but may worsen in the postpartum period. For example, six patients with preexisting Vogt–Koyanagi–Harada (VKH) syndrome have been reported to improve during pregnancy, but all had flare-ups of disease postpartum.<sup>220–222</sup> However, there have been reports of VKH syndrome<sup>223,224</sup> developing de novo during pregnancy, punctate inner choroidopathy (PIC)<sup>225</sup> developing de novo after miscarriage, and sarcoid uveitis<sup>226</sup> developing de novo during the postpartum period.

More specifically, uveitis activity tends to decrease from the second trimester onwards, with the third trimester being associated with the lowest disease activity.<sup>227–230</sup> Rabiah retrospectively evaluated 76 pregnancies of 50 women with noninfectious uveitis including VKH syndrome, Behçet disease, and idiopathic uveitis. A worsening of uveitis occurred within the first 4 months of pregnancy in 64% of pregnancies and later in pregnancy in 22%. No flare-up occurred in 28%. An early pregnancy worsening was typical of VKH and idiopathic uveitis. Postpartum worsening occurred in 64% and was characteristic of Behçet disease.<sup>227</sup> Chiam

retrospectively evaluated 47 women with noninfectious uveitis reporting flare-up rates of 1.188, 0.540, and 0.972 per person year in prepregnancy, gestation, and postpartum, respectively.

Additionally, it was shown that flare-up rates decreased from the first to third trimesters, and that flare-up rates rebounded by 6 months postpartum but did not differ from pre-pregnancy rates.<sup>229</sup>

The severity of uveitis flare-ups was not significantly different between pregnancy and nonpregnant periods, whether assessed by analyzing anterior chamber cell count,<sup>229</sup> or by noting flare-up duration and type of therapy prescribed.<sup>227</sup>

The amelioration of uveitis during pregnancy, and the relapse that often occurs postpartum, is thought to be due to the complex hormonal and immunologic changes that occur to a woman during and after pregnancy.

## Other Retinal Disorders

The stress of labor and delivery does not appear to pose a risk for rhegmatogenous retinal detachment (RD) in high myopes. This conclusion is based on three studies examining pregnant women with ocular history of myopia, RD, retinal holes, lattice degeneration, with no RD found after delivery.<sup>231-233</sup>

Rapid growth of choroidal hemangiomas,<sup>134</sup> and the development of exudative retinal detachments associated with hemangiomas<sup>234</sup> have been reported during pregnancy. The hemangioma may regress in the postpartum period.<sup>235</sup> These changes have been attributed to pregnancy-related hormonal perturbations.

There are eight reported cases of endogenous endophthalmitis that occurred after miscarriage with dilatation and curettage,<sup>236</sup> spontaneously during normal pregnancy,<sup>237</sup> after spontaneous abortion<sup>237,238</sup>, after cesarean section,<sup>237</sup> and after a vaginal delivery albeit with a 1-week history of premature rupture of membranes.<sup>239</sup> Most of the reported cases had poor visual outcomes, with three cases having RD. The infectious etiologies included *Klebsiella pneumoniae*, *Bacillus mycoides*, *Sphingomonas paucimobilis*, and *Candida albicans*. Treatment is beyond the scope of this chapter, but it should be mentioned that fluoroquinolones and voriconazole should be avoided during pregnancy and in nursing mothers, while

cephalosporins and amphotericin B are considered safe to use.<sup>237</sup>

Retinitis pigmentosa (RP) is sometimes characterized by a sudden pregnancy-associated deterioration in visual fields after a period of relative stability. It is difficult to determine whether changes are related to pregnancy or are just coincidental. Five to ten percent of women with RP who have been pregnant reported worsening during pregnancy<sup>162,240</sup> and did not return to baseline after delivery.<sup>162</sup> There is one report in the literature of visual field deterioration during pregnancy, which resolved in the postpartum period.<sup>59</sup> One case reported pericentral retinal degeneration that worsened during pregnancy.<sup>241</sup>

## Diagnostic Testing and Therapy

Fluorescein crosses the placenta and enters the fetal circulation in humans.<sup>242</sup> No reports of teratogenic effects in humans have been reported to the National Registry of Drug-Induced Ocular Side Effects.<sup>162</sup> European investigators have performed research studies involving the administration of fluorescein to 22 pregnant diabetic women and noticed no adverse effects on the fetus.<sup>243</sup> Another study of neonatal outcome of 105 patients who underwent fluorescein angiography (FA) during pregnancy showed no increased rate of adverse neonatal outcomes.<sup>244</sup> This study, however, included only 41 cases of FA during the first trimester, the time when teratogenic effects are more likely to take place and are more severe. Nevertheless, one survey reported that 77% of retinal specialists never perform FA on a patient they know is pregnant.<sup>245</sup> In another survey, 89% of retina specialists who had seen a pregnant woman who required FA withheld testing out of fear of teratogenicity or lawsuit.<sup>246</sup> We recommend that FA in pregnant women can be considered if the results would change the management of a vision-threatening problem and appropriate informed consent is obtained.

Indocyanine green does not cross the placenta, is highly bonded to plasma proteins, and is metabolized by the liver. Reports of only 6 cases of the use of indocyanine green angiography (ICGA) during pregnancy have been published.<sup>22,247</sup> In a survey of 520 retina specialists, 105 had withheld ICGA out of fear of teratogenicity or

lawsuit during pregnancy and only 24% thought it was safe to use ICGA in a pregnant patient. The authors suggest that current practice patterns concerning the use of ICGA in pregnancy may be unnecessarily restrictive.<sup>246</sup> Like FA, we recommend that ICGA in pregnant women can be considered if the results would change the management of a vision-threatening problem and appropriate informed consent is obtained.

## Photodynamic Therapy

Pregnant rats exposed to verteporfin at 40 times the human dose have a high incidence of microphthalmia.<sup>248</sup> Accidental exposure to verteporfin for photodynamic therapy during pregnancy has been reported in three cases. Rosen treated a woman with punctate inner choroidopathy with verteporfin and bevacizumab while she was 1–2 weeks pregnant, before the patient knew of her conception. The pregnancy and childbirth were uncomplicated and yielded a healthy term infant who had no abnormality for at least the first 3 months of life.<sup>249</sup> De Santis reported a similar accidental exposure in the third week of pregnancy without any deleterious effects in the patient or child up to 26 months of life.<sup>250</sup> Rodrigues reported a case of accidental exposure to verteporfin in a 45-year-old woman with a 25-week fetus. The pregnancy appeared to be unaffected, and the child was healthy through 16 months of follow-up.<sup>251</sup> With regard to PDT during pregnancy, caution is recommended.

## Anti-VEGF Therapy

Anti-vascular endothelial growth factor (anti-VEGF) medications have not been well evaluated during pregnancy. Bevacizumab may have an inhibitory effect on pregnancy development based on rat studies. Rats were repeatedly injected either with intraperitoneal bevacizumab or saline during early gestation. The size and number of gestational sacs and serum  $\beta$ -CG levels were significantly lower in those with bevacizumab.<sup>252</sup> Systemic bevacizumab and ranibizumab are contraindicated in pregnancy by the manufacturer and classed as “category C” by the United States Food and Drugs Administration (FDA).<sup>253</sup> Additionally, the FDA recently classed intravitreal aflibercept as category C.<sup>254</sup>

There are 14 cases in the literature of pregnant women being treated with intravitreal bevacizumab or ranibizumab: 13 patients with bevacizumab, 1 patient with ranibizumab.<sup>249,255–260</sup> Eleven patients were treated during the first trimester, and 3 patients were treated in the second or third trimester. Eleven patients had normal deliveries with healthy newborns. One patient with a complicated pregnancy history, who was treated with bevacizumab in the first trimester, had an urgent cesarean section at 29 weeks for preeclampsia. The infant initially suffered from bradycardia, respiratory issues, and intraventricular hemorrhages, but stabilized weeks later.<sup>251</sup> Two other patients suffered miscarriages 7 and 10 days after being treated with intravitreal bevacizumab during the first trimester.<sup>255</sup> It is unknown whether the miscarriages were incidental or perhaps related to the bevacizumab injections.

There is insufficient information to conclude that intravitreal administration of anti-VEGF use is safe during pregnancy, nor is there definitive evidence to suggest that it causes harm to the fetus. Further well-designed studies are required, and until such data become available, caution should be exercised.

## Conclusion

Information about the effects of pregnancy on the course of retinal disease is limited. In most cases the direct cause of pregnancy effects is only speculative and based on what is known about systemic changes in the mother. As our understanding of the natural course of retinal and choroidal diseases and of the effects of pregnancy on the eye improves, the ophthalmic management of both pregnant and nonpregnant patients will improve.

## **Optic Disc Anomalies**

A variety of congenital optic disc anomalies challenge the clinical acumen of ophthalmologists, internists, and pediatricians. Since some of these abnormalities are known by various names, it is worthwhile reviewing the general categories.

### **Megalopapilla**

Megalopapilla is a rare anomaly of the optic disc, involving thinning of the nerve fiber across a large optic nerve head, and is often associated with large refractive errors and with midline congenital deformities.<sup>1</sup>

### **Aplasia**

Aplasia of the optic nerve head is very rare, probably represents an

extreme form of optic nerve head hypoplasia, and may be associated with the absence or gross maldevelopment of the globe.<sup>1</sup>

## Hypoplasia

Optic disc hypoplasia is a congenital underdevelopment of the optic nerve head with a reduced number of axons. Hypoplastic optic discs are often underdiagnosed and may vary in level of development, leading to variable levels of visual acuity and visual field defects.<sup>2</sup> Small crowded hyperopic discs can have the appearance of a hypoplastic optic disc but this is an anatomical variant in a small hyperopic eye.

## Papilledema

Papilledema is elevation of the optic nerve due to elevated intracranial pressure. Thus for a diagnosis of papilledema the intracranial pressure must be measured, typically by lumbar puncture opening pressure in the lateral decubitus position. An elevated disc or nerve fiber layer swelling without elevated intracranial pressure is optic disc edema not papilledema.

## Pseudopapilledema

Pseudopapilledema is disc elevation in the absence of nerve fiber layer edema. This can occur for a variety of reasons, including optic nerve head drusen, diabetic papillitis, vascular disorders including central retinal vein occlusion, intraocular and peripapillary inflammation, Leber's hereditary optic neuropathy, hamartomas, and infiltrative processes including infection and neoplasms.<sup>3</sup>

## Congestion of the Optic Nerve Head

Most causes of pseudopapilledema are acquired and relate to an underlying ocular or systemic disease. The most common congenital cause of congestion at the optic nerve head is optic disc drusen.<sup>4,5</sup>

While not typically present at birth, optic disc drusen first develop between the disc surface and the lamina cribrosa.<sup>6</sup> They

can cause elevation of the optic nerve head and anomalous branch patterns of the retinal vasculature.<sup>7</sup> Typically optic disc drusen become more noticeable over time and can appear on the surface of the optic nerve head by the end of the first decade of life.<sup>7</sup> Disc drusen are discussed in greater detail below.

## Cavities in the Optic Nerve Head

Excavated and colobomatous defects of the optic nerve head encompass a spectrum of abnormalities, including tilted discs, peripapillary staphylomas, morning glory disc anomalies, colobomas, and congenital optic disc pits. Optic disc pits were regarded as atypical colobomas by Greear.<sup>8</sup>

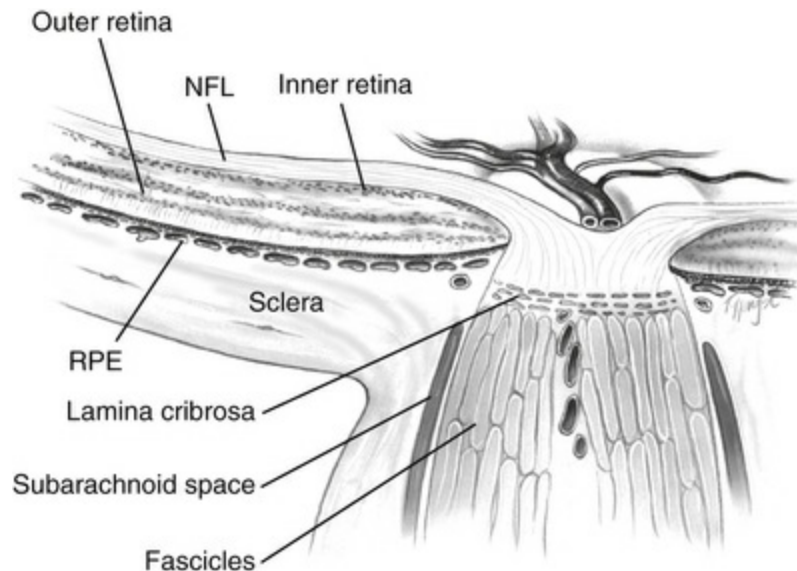

Optic disc pits should probably be considered one manifestation along a spectrum of cavitory optic disc anomalies. Slusher and coworkers<sup>9</sup> described a family of 35 members spanning five generations with an autosomal dominant pattern of congenital optic disc abnormalities. Remarkably, a myriad of morphologic variations of phenotype were expressed, including optic disc pits, morning glory syndrome, and coloboma of the optic nerve. One gene defect can result in a variety of optic disc abnormalities; the traditional classification schemes that describe varieties of cavitory optic disc anomalies should therefore be reconsidered.

## Anatomy

A brief review of the anatomy and embryology of the optic nerve head permits a better understanding of these abnormalities.

The retinal ganglion cells of each retina contribute approximately 1.2 million unmyelinated axons that converge at a point approximately 4 mm nasal to the foveola, through which they exit the globe, acquire a myelin sheath, and form the optic nerve. These axons project to various primary visual nuclei in the brain,<sup>10</sup> constitute a fiber tract rather than a nerve, and, as such, have histologic and functional similarities to brain tissue. The optic nerve is enclosed by three meningeal sheaths that are contiguous with the meningeal coverings of the brain. Before exiting the eye, however, the axons of the retinal ganglion cells must converge centripetally,

make a sharp turn, traverse the lamina cribrosa, form nerve bundles enclosed by connective tissue septa, and then, once posterior to the lamina cribrosa, become ensheathed by myelin (Fig. 96.1).<sup>11</sup>

**FIG. 96.1** Axial view of optic nerve head and surrounding tissues. Fibers from the retina collect at the optic disc, pass down through the lamina cribrosa, become myelinated, and form fascicles. Note the three parts of the optic nerve: I, anterior portion (retinal); II, midportion (prelaminar or choroidal); III, posterior portion (lamina cribrosa or scleral) at optic nerve head. *NFL*, nerve fiber layer; *RPE*, retinal pigment epithelium.

Thus, the optic nerve head is remarkable in several respects. Axons deriving from the retina become part of the nerve, go from an unmyelinated to a myelinated state, traverse the sieve-like lamina cribrosa, are partitioned into groups by glial columns, and go from an area of high intraocular pressure to relatively low interstitial pressure. Not surprisingly, anomalies of structure at this critical juncture often lead to marked physiologic consequences.<sup>12</sup>

## Optic Disc Drusen

In 1856 Müller<sup>13</sup> described concretions of the optic nerve head from a series of histopathologic studies of eyes. This was followed in

1868 by Liebrich,<sup>14</sup> who described the fundus appearance of optic disc drusen and made the link to the histopathology findings of Müller.<sup>13</sup> Niden introduced the word *Drusenbildung* (German) to describe the concretions.<sup>15,16</sup> Optic disc drusen are composed of acellular concretions predominantly made up of calcium but can also contain amino and nucleic acids, mucopolysaccharides, and iron.<sup>16</sup>

There is no known genetic predisposition for the formation of optic disc drusen. Retrospective studies of relatives of individuals with optic disc drusen found that only one of 27 relatives of seven probands with optic disc drusen also had optic disc drusen.<sup>17</sup> The primary pathogenesis of optic disc drusen also remains unknown, with some hypothesizing an inherited dysplasia of the optic disc and its blood supply. Vascular maldevelopment has been theorized to cause increased transudate release into the intercellular space which in turn acts as a nidus for the formation of optic disc drusen.<sup>17,18</sup>

Optic disc drusen are usually found incidentally on routine examination, with a clinical prevalence reported of 1 in 500 eyes.<sup>19,20</sup> Histopathologic studies, however, have reported a prevalence of approximately 1 in 40<sup>21</sup> with 60% of the drusen buried deep in the optic nerve tissue.<sup>16</sup> The lack of diagnostic techniques to examine the deep portions of the optic nerve head might account for the difference in prevalence as the initial studies were published prior to the advent of B-scan ultrasonography in 1977.<sup>16</sup> Some studies have also reported a higher incidence in women, and there is some discordance in the literature about the percentage of cases which are bilateral, ranging from 69% to 91.2%.<sup>16</sup> This may reflect the asymmetric nature of optic disc drusen and how no single modality can detect all optic disc drusen.<sup>22</sup> There is no clear pattern of inheritance in optic disc drusen, and this may be compounded by the inheritance pattern of optic disc size, which by itself may be a risk factor for optic disc drusen.<sup>15</sup>

Optic disc drusen are the most common cause of pseudopapilledema and distinguishing them from true optic disc edema is of clinical importance. True disc edema is potentially a life threatening process, unlike the more benign nature of optic disc drusen.<sup>5,22</sup>

## Visual Defects

Optic disc drusen are associated with two major types of visual field defects. The first is the result of direct compression or displacement of the fibers by the drusen and is typically arcuate in nature, usually in the inferior nasal quadrant.<sup>23</sup> The second is an enlarged blind spot, which is likely related to pseudopapilledema or leaking blood vessels.<sup>24,25</sup>

The visual field defects may be present from childhood<sup>6</sup> and may progress over time. The progression, however, is slow and patients may not be aware of the field defect without formal visual field testing. The reported frequency of visual field defects varies widely, from 24% to 87%, with the highest occurrence in eyes with superficial optic disc drusen.<sup>26-28</sup>

It is unusual for optic disc drusen to impair central acuity by direct compression of the axons in the papillomacular bundle.<sup>16</sup> This is in part due to the decreased number of fibers in the temporal region of the optic disc which would require the optic disc drusen to be much larger before they are able to affect the papillomacular bundle. In cases where the vision has been affected there is typically an accompanying severe visual field defect,<sup>29-31</sup>

Optic disc drusen alter the conformation of the vasculature and are able to displace blood vessels. This can cause transient visual loss, or in some cases anterior ischemic optic neuropathy can occur.<sup>12,32</sup> In a study of 20 patients with optic disc drusen-associated anterior ischemic optic neuropathy (AION), Purvin reported that patients with optic disc drusen and AION were typically younger and more likely to have transient visual obscurations prior to the episode of AION. Interestingly the optic disc drusen patients with AION also had the same vascular risk factors associated with AION in the general population, suggesting that risk factor modification is important in decreasing the likelihood of AION in optic disc drusen patients.<sup>32</sup>

Importantly, patients with optic disc drusen can have other pathologies responsible for their vision loss and there have been case reports of field defects caused by intracranial tumors being misdiagnosed as optic disc drusen.<sup>30,33</sup> It is therefore essential to ensure that there is no other reason for vision loss in patients with optic disc drusen, especially when there is decreased acuity without

visual field changes.

## Detection

The appearance of the optic nerve head with optic disc drusen can be quite variable, with some discs showing superficial drusen that are readily visible.<sup>16</sup> There are several techniques that can be used to help identify optic disc drusen which take advantage of various properties of the drusen.

The simplest technique is by direct visualization with fundoscopy. This technique can be further enhanced by looking for autofluorescence, a characteristic of optic disc drusen first described in the 1960s (Fig. 96.2).<sup>34-36</sup> However, autofluorescence is only seen in superficial drusen and in some series is present in as few as 12% of cases.<sup>22</sup>

**FIG. 96.2** Fundus photograph of patient with optic nerve drusen: (A) low magnification and (B) high magnification color fundus photos of the left eye showing obscuration of the disc margin, absence of a central cup and elevation of the disc due to drusen (*arrows*). (C) Fundus autofluorescence image of the same eye showing characteristic autofluorescence of optic disc drusen.

Combining autofluorescence with fluorescein angiography can help distinguish drusen from papilledema. Pineles was able to demonstrate that optic disc drusen showed a characteristic pattern of early (25%) or late (29%) nodular staining and circumferential parapapillary staining (80%) which was distinct from the leakage seen with papilledema.<sup>22</sup>

The depth of disc drusen can, however, pose a problem for superficial imaging techniques, and the main method for looking for buried drusen until recently has been ultrasonography. The use of B-scan ultrasound to detect optic disc drusen was described as far back as the 1970s.<sup>37</sup> Taking advantage of the inherent high reflectivity of calcium, which is present in drusen, it is possible to detect drusen with low gain ([Fig. 96.3](#)). The technique is also useful for detecting buried drusen, but the echogenicity of drusen is dependent on the calcium content. While there are no reports of the percentage of drusen that are calcified, some studies have found less than 50% of buried drusen are detected by ultrasound.<sup>38</sup> The variable degree of calcification also hampers the ability of CT scans to detect optic disc drusen. CT scans are further limited by sectioning, as slices greater than 1.5 mm can easily miss drusen in the optic nerve head.

**FIG. 96.3** B-scan ultrasound images of the optic nerve from the same patient with optic disc drusen demonstrating the inherent high reflectivity of calcium present in the drusen and the ability to detect the drusen at both high (A) and low (B) gain.

Buried drusen can also be detected by spectral domain optical coherence tomography (OCT)<sup>39</sup> and more recently, enhanced depth OCT<sup>40</sup> (Fig. 96.4). These devices provide an unprecedented ability to evaluate optic disc drusen to the depth of the lamina cribrosa and to evaluate the interplay with structures of the optic nerve. A direct comparison of enhanced depth OCT and B-scan ultrasound has yet to be published, but it is clear that no single modality is perfect for detecting drusen and a combination of modalities in the right clinical context is required to make the appropriate diagnosis.<sup>22</sup>

**FIG. 96.4** Enhanced depth optical coherence tomography of optic nerve drusen from the same patient showing clearly demarcated superficial and deep drusen (*arrows*) corresponding to area of *gray arrow* of [Fig. 96.2B](#).

## Associated Retinal Changes

The retinal vasculature in eyes with optic disc drusen is often anomalous with increased tortuosity, vascular loops, and abnormal branching patterns including optociliary shunt vessels<sup>7,41</sup> There is also an increased incidence of cilioretinal arteries in patients with optic disc drusen with up to 40% of patients having the vascular aberration versus 15% in the normal population.<sup>42,43</sup>

These vascular anomalies appear to predispose patients with optic disc drusen to vascular occlusions including central retinal artery (CRAO) and central retinal vein occlusions (CRVO). The first description of a vascular disturbance associated with optic disc drusen was in 1895 when Gifford described an 11-year-old girl with a central retinal artery occlusion.<sup>44</sup> As with Gifford's case report, patients with optic disc drusen who suffer from a CRAO tend to be younger than individuals who do not have optic disc drusen, but the presence of optic disc drusen alone is usually insufficient to

cause a CRAO. Most cases are associated with other known risk factors for CRAO, including hypertension, contraceptive use, and migraines.<sup>16</sup>

Unlike CRAOs, the anatomical changes caused by optic disc drusen may alone increase the risk of CRVO. The presence of drusen alters the flow dynamics of the central retinal vein by altering the path and potentially constricting the vascular diameter.<sup>45</sup> As a result drusen may represent an independent risk factor for CRVO.

Optic disc drusen are also associated with subretinal neovascularization. Typically in a juxtapapillary location, the neovascularization extends towards the macula but rarely involves it.<sup>46</sup> The neovascular membranes, however, may be associated with hemorrhages that can disrupt vision. Some case reports describe relatively good vision in optic disc drusen-associated neovascular membranes without treatment, but there are also cases of neovascular membrane extending subfoveally causing permanent visual impairment.<sup>28</sup>

Hemorrhages can also occur with optic disc drusen in the absence of a subretinal neovascularization. These spontaneous hemorrhages occur with an incidence of up to 10%.<sup>16</sup> There are four anatomical variations of hemorrhages associated with optic disc drusen: (1) hemorrhages that extend into the vitreous; (2) splinter hemorrhages of the retinal nerve fiber layer; (3) deep hemorrhages of the optic disc; and (4) peripapillary hemorrhages, which may extend into the macula.<sup>16</sup> These hemorrhages do not typically cause visual impairments except when they extend into the macula, which is not common.<sup>29</sup> The pathophysiology of retinal hemorrhages in optic disc drusen is unclear, with some proposing that they are the result of enlarging drusen which can erode into the blood vessels or cause venous stasis leading to hemorrhage.<sup>16</sup>

## Treatment

There is no proven treatment for optic disc drusen, and as patients with optic disc drusen often do not suffer from vision loss, treatment may not be warranted. Once the diagnosis is established, however, regular examinations are important to ensure that

treatable complications of optic disc drusen are appropriately managed.

The presence of optic disc drusen can predispose the patient to glaucomatous optic nerve damage at lower intraocular pressures. Assessment for glaucoma can also be complicated by the presence of the optic disc drusen as a small crowded nerve can mask the appearance of cupping. Furthermore, OCT retinal nerve fiber layer (RNFL) measurements may be distorted by the presence of optic disc drusen necessitating serial monitoring of both RNFL and visual fields.

Glaucoma may coexist with optic disc drusen<sup>47</sup> and determining which portion of the field loss is due to glaucoma and which is due to optic disc drusen is difficult. In the presence of visual field damage, lowering the IOP should be considered, particularly in patients with field loss at a young age, as the natural attrition of the optic nerve that occurs with aging may be worse in patients with optic disc drusen. The use of pressure-lowering medications should consider the risks and benefits, tailored to each individual patient. Regardless of treatment, serial monitoring with visual fields and OCT RNFL is warranted to assess for progression.

Unlike typical glaucoma, which is a degenerative process in older patients, individuals with optic disc drusen may develop glaucomatous changes at a younger age as optic nerve fibers in the presence of optic disc drusen appear to be compromised and more sensitive to IOP.<sup>16</sup>

Management of vascular complications associated with optic disc drusen such as CRAO and CRVO is similar to the management of these disorders in the absence of drusen (see [Chapter 54](#), Retinal artery occlusions; [Chapter 56](#), Branch retinal vein occlusion; [Chapter 57](#), Central retinal vein occlusion). The presence of a neovascular membrane was historically treated with photocoagulation depending on the location.<sup>48</sup> More recently, anti-VEGF agents such as ranibizumab have been used with some success.<sup>49</sup> Unlike age-related macular degeneration, treatment of neovascularization in optic disc drusen is not always required as the prognosis is usually good.<sup>47</sup>

## Optic Disc Pits

In 1882, Wiethe described abnormalities in both optic discs of a 62-year-old woman.<sup>50</sup> His description of dark-gray depressions in the optic nerve heads was probably the first report of optic disc pits. Since Wiethe's initial description, excavations of the optic disc have variously been described as craters, holes, cavities, and, most recently, congenital pits of the optic nerve head.

Studies suggest that optic pits occur in approximately 1 in 10,000 eyes, although there is considerable variance among studies.<sup>8,51</sup> Men and women are equally affected. Approximately 10–15% of optic disc pits are bilateral. Most optic disc pits are nonfamilial; however, there are a few reports with an autosomal dominant pattern of inheritance.<sup>52</sup> One such report describes a family for which several members had small iris colobomas, some in combination with the pit, providing insight as to the etiology.<sup>53</sup> About 70% of the pits are on the temporal side of the disc, and about 20% are situated centrally; the remainder are found inferiorly, superiorly, and nasally.<sup>54</sup>

Serous retinal detachments may be associated with optic disc pits. These may occur at any age but are most frequent in early adulthood. However, there have been reports of associated retinal detachment occurring as early as 6 years of age and in patients as old as in the ninth decade of life.<sup>55</sup> Some have suggested that the clinical course differs and leads to better visual acuity in children as spontaneous resolution is the rule.<sup>55,56</sup> Through the analysis of stereoscopic transparencies, it has been proposed that the fluid that enters through the optic disc pit actually travels between the inner and outer layers of the retina to produce a retinoschisis.<sup>57,58</sup> OCT has shown such inner retinal schises preceding outer-layer detachment.<sup>59</sup> Following this, detachment of the outer retinal layer may occur as a secondary process.<sup>59</sup> Although no histopathologic studies have confirmed this, the application of OCT has provided compelling evidence for at least two levels of retinal separation (Fig. 96.5).<sup>60</sup> OCT has also been used to demonstrate a marked reduction in thickness of the retinal nerve fiber layer in the quadrant corresponding to the optic nerve pit.<sup>61</sup>

**FIG. 96.5** Spectral domain optical coherence tomography image of optic disc pit maculopathy, with cystoid spaces and schisis in multiple layers as well as subretinal fluid.

In the series from Brown et al.,<sup>54</sup> most optic disc pits were gray in color, although they varied from yellow to black. Their size can range from minute to large, occupying most of the surface of the optic disc.

## Visual Defects

The optic disc pit is most often associated with two types of visual field defects.<sup>62</sup> The first type is exemplified by arcuate scotomas that probably reflect the absence of the wedge of nerve fibers displaced by the optic disc pit. Larger pits may be associated with large Bjerrum-type scotomas or even altitudinal visual field defects. Nasal or temporal steps are often detectable; less frequently, paracentral scotomas and generalized constriction may be seen.<sup>54</sup> However, Walsh and Hoyt<sup>63</sup> reviewed several studies that demonstrated only an enlarged blind spot as a forme fruste of the visual field defect in association with optic pits.

The second type of visual field defect is that associated with serous detachment of the macula. In 1960 Kranenburg<sup>64</sup> described the association of optic nerve pits and central serous retinopathy. He found that 16 of his 24 patients with optic disc pits had serous detachments of the macula, with corresponding central scotomas or other central visual field changes.

## Associated Retinal Changes

Optic nerve head pits that are centrally located are least likely to be associated with retinal changes. Optic disc pits along the rim of the optic disc are usually seen in association with peripapillary chorioretinal atrophy and retinal pigment epithelium changes (Fig. 96.6). These peripapillary changes may develop over time with or without central serous retinal detachments. In following the development of a serous macular detachment, Walsh and Hoyt<sup>63</sup> described the appearance of what they termed an “occult hole” in the optic nerve head.

**FIG. 96.6** Optic disc pits near the temporal margin are common and are most likely to lead to serous macular detachments (*arrows*).

Serous detachment of the macula is now known as a common complication of the optic disc pit. The natural history of this complication has been well described by Sobol et al.<sup>65</sup> They followed 15 patients with optic disc pits and macular detachments for an average of 9 years and found that 80% lost vision to 20/200 or worse. The visual loss was generally complete within 6 months of presentation. Long-term macular changes included full-thickness or lamellar (through the outer retina), retinal holes, retinal pigment

epithelium mottling, and general cystic changes of the macula.<sup>65</sup> Vascular telangiectasis has been reported in connection with intraschistic hemorrhage from a temporal optic disc pit.<sup>66</sup>

A gray fibroglial membrane appears to overlie the pit in many cases (Fig. 96.7). This membrane may be intact or may incompletely cover the pit. The fact that patients with serous macular detachments almost invariably have defects in their diaphanous membrane has prompted theories on how optic nerve pits lead to serous macular detachments.

**FIG. 96.7** Optic nerve pit. Note overlying gray fibroglial membrane.

## Macular Detachment

Several investigators have estimated that between 40% and 50% of patients with optic nerve pits have either an associated nonrhegmatogenous, serous retinal detachment, or retinal changes suggestive of previous detachment.<sup>54,67</sup> The macular serous detachment (or retinoschisis) seen in association with optic disc pits appears most commonly when the pit is located in the temporal region of the optic disc and in larger pits. Conversely, small pits and those located more centrally are less likely to lead to serous

retinal detachments.<sup>54,64</sup>

## Appearance of Maculopathy

In 1908, Reis<sup>68</sup> described a case of an optic nerve pit with associated maculopathy. However, this association was not taken seriously until Petersen,<sup>69</sup> in 1958, described several patients with what he called crater-like holes in the optic disc; these patients also had a central serous chorioretinopathy. This relationship was firmly emphasized by Kranenburg<sup>64</sup> in 1960, who described 24 cases of optic disc pits. One-third of these patients had serous retinal detachments, and another third had macular changes that he interpreted as reflecting a previous episode of nonrhegmatogenous serous retinal detachment.

Most of the retinal detachments are temporal to the disc and confined between the superior and inferior vascular arcades. Infrequently, a serous retinal detachment is located outside the arcades if the pit is situated on the nasal side of the optic disc. Often, the serous retinal detachment is contiguous with the optic disc, sometimes through a visible isthmus of subretinal fluid.

The serous macular detachments are generally low (less than 1.0 mm in height). The elevated retina often contains cystic regions that have been demonstrated on histologic examination to exist within the inner nuclear layer.<sup>51</sup> Occasionally the cystic areas rupture outward, producing a lamellar macular hole that, unlike idiopathic lamellar macular holes, retains an intact internal limiting membrane.

The variability of the retinal separation is also consistent with an alternative description of the maculopathy proposed by Lincoff and colleagues.<sup>70</sup> In a case report they provide clear OCT evidence of a schisis cavity between the inner and outer retina and a larger outer-layer retinal detachment. The two are connected by a hole in the outer layer near the fovea.<sup>70</sup>

## Course of Associated Serous Macular Detachment

It is difficult to determine the time interval between the beginning

of a serous macular detachment and the earliest visual changes, because the patient usually seeks evaluation after symptoms of blurred vision and metamorphopsia occur secondary to foveal involvement. However, Brown and Tasman<sup>71</sup> described one case in which the retinal detachment started at the temporal margin of the optic disc. This serous retinal detachment expanded slowly in a temporal direction until, after several months, it covered the entire macular area. They also described small yellow precipitates seen under the elevated retina late in the course of serous macular detachment.

In analyzing their 15 patients followed over an average of 9 years, Sobol et al.<sup>65</sup> found that most eyes with optic disc pits presented with visual acuities of about 20/40–20/60. However, each patient lost three or more lines of vision within the next 6 months. After 6 months, a few of those patients got worse and a few got better. Ultimately, only 20% of the patients maintained visual acuities of better than 20/200.<sup>65</sup> Generally, however, patients with optic disc pits present later in the course of their macular detachments when their visual acuities are already worse than 20/70.<sup>71</sup>

## Theories of Pathophysiology

By 1960 it was clear that serous macular detachments often occurred as complications of optic disc pits. Ferry<sup>51</sup> had the opportunity to histologically examine two eyes with optic disc pits associated with macular detachments. He suggested that progressive gliosis and “contraction of the retinal elements” contained in the pit produced a traction detachment of the macula. In 1964 Sugar<sup>72</sup> suggested that fluid from the vitreous cavity could enter the subretinal space through a macular hole. However, this is most unlikely because macular holes seen with optic pits are usually lamellar and are only infrequently seen in association with the serous detachment.

Fluorescein angiography may reveal late hyperfluorescence of the optic disc pit.<sup>67</sup> It was therefore postulated that blood vessels in this area leaked fluid, which then entered the subretinal space.<sup>67</sup> However, Brown et al.<sup>54</sup> reported that many patients with serous macular detachments had no leakage on their fluorescein

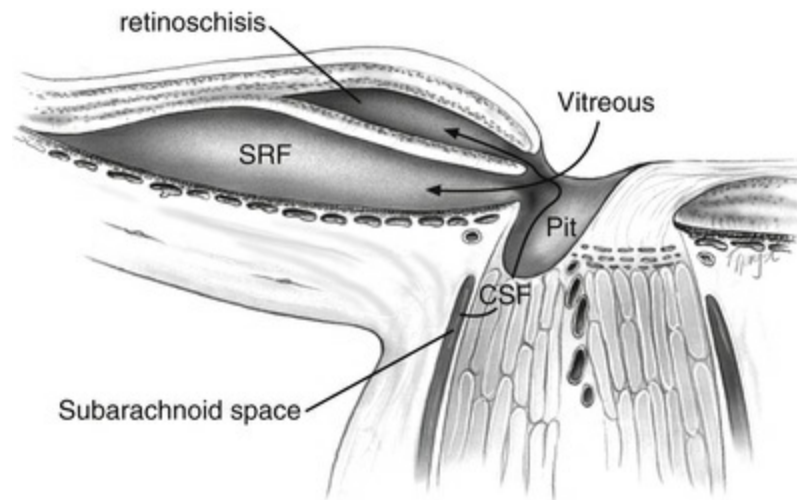

angiogram.

Others have speculated that there may be a direct source of fluid from the choroid that penetrates through Bruch's membrane under the macular detachment; it was hypothesized that peripapillary chorioretinal atrophic changes permitted this leakage.<sup>73</sup> However, fluorescein angiographic findings do not support this theory. Moreover, many other diseases produce extensive chorioretinal atrophy that does not lead to serous macular detachment.<sup>54</sup>

A few investigators,<sup>74</sup> including Gass,<sup>75</sup> have suggested that cerebrospinal fluid may leak from the optic nerve subarachnoid space into the optic pit and from there into the subretinal space. However, intrathecal fluorescein injections in humans and in animals and histologic studies have failed to demonstrate any such connection.<sup>51,52,76,77</sup>

Currently, the most widely accepted explanation is that originally proposed by Sugar<sup>78</sup> in 1962 and later endorsed by Brockhurst<sup>79</sup> in 1975. It was postulated that fluid from the vitreous leaked through the optic disc pit to fill the subretinal space (Fig. 96.8). In corroboration of this theory, Brown et al.<sup>54</sup> demonstrated that more than 75% of patients with optic disc pits and associated serous macular detachments have posterior vitreous detachments. This would allow liquefied vitreous to be contiguous with the optic disc cavity. Moreover, most of the patients in their series who had pits without macular serous elevations did not have posterior vitreous detachments.<sup>54</sup> Additionally, Brown and his colleagues<sup>77</sup> demonstrated experimentally in dogs a direct connection between the posterior vitreous space and the subretinal space via a congenital optic disc pit. Irvine et al.<sup>74</sup> demonstrated in vivo that there is a continuity between the posterior vitreous cavity and the optic nerve subarachnoid space by observing bubbles percolating out of an optic nerve sheath window after pars plana vitrectomy and gas injection.

**FIG. 96.8** Schematic drawing of axial view of optic nerve head. Various theories describe mechanisms by which fluid enters the subretinal space. Cerebrospinal fluid (CSF) could derive from the subarachnoid space. However, the more widely accepted explanation is that fluid in the vitreous space passes into the optic pit and from there directly into the subretinal space. An optic disc pit located near the margin of the optic nerve head is far more likely to permit fluid to leak subretinally. CSF, cerebrospinal fluid; SRF, subretinal fluid.

The most recent variation on these theories of pathophysiology is that proposed by Lincoff et al.<sup>70</sup> who suggested that the primary communication from the optic disc pit is to the retina temporal to the optic disc.<sup>57</sup> Fluid slips under the inner retina, lifting it and the nerve fiber layer up and away from the outer retina. This has been corroborated by OCT<sup>60</sup> and extended to show both this retinoschisis and an outer retinal detachment connected by a hole in the outer retinal layer (see Fig. 96.6).

Although the theory of direct vitreous fluid entry via the optic pit into the subretinal space is appealing, it does not explain why serous macular detachments tend to occur first in young adulthood. Brown and Tasman<sup>71</sup> suggest that posterior vitreous detachments may be a precipitating factor. Another possibility is the role of macular traction, which occurs with age.

## Prognosis

Although the optic nerve head pits, being congenital, are stationary,

their associated retinal abnormalities may be progressive. The prognosis for return of vision after serous macular detachment is variable. Walsh and Hoyt<sup>63</sup> described a patient followed between the ages of 14 and 23 years who developed multiple serous macular detachments that remitted to near-normal vision after each episode. A more rigorous study was conducted by Brown et al.<sup>54</sup> in a group of 20 eyes with optic disc pits and serous macular detachments. These eyes were followed for 5 years, untreated. The mean visual acuity at the end of this time was about 20/80. The authors found very little correlation between the visual acuity at the time of detachment and the long-term visual outcome. They also noted that some detachments resolved spontaneously, whereas others persisted for years. Most patients still had some subretinal macular fluid present after 5 years. Other macular changes, as described above, also persisted. Long-term studies confirm the earlier impressions that untreated macular detachments caused by optic disc pits have an overall poor prognosis.<sup>65</sup>

## Treatment

Given the rarity of optic disc pits, most studies examining purported treatments are small and nonrandomized, leading to difficulty in coming to a consensus on the best management for the associated serous macular detachments. Observation, systemic steroids, optic nerve sheath decompression, and scleral buckling procedures have not been demonstrated to be very effective.<sup>79</sup> However, several series have favorably compared the outcome of photocoagulated eyes with untreated eyes in the resolution of the serous macular detachment and in final visual outcome.<sup>74,79,80</sup> The argon laser procedure was used in most of these series to produce photocoagulation burns in one or several rows between the area of serous retinal detachment and the optic disc. The burns were usually applied to areas of elevated retina. Brockhurst,<sup>79</sup> Gass,<sup>80</sup> and Theodosiadis<sup>81</sup> used similar photocoagulation protocols, and all reported that their patients were likely to have good resolution of the serous detachment to a flat macula.

Combining their results, 15 of the 18 patients in these three series had reattachments of their maculas, as opposed to only 5 of 20

untreated patients in the series of Brown et al.<sup>54</sup> However, the difference in final visual outcome between the treated and untreated groups was less pronounced. The photocoagulated eyes in the three studies had ultimate visual acuities that averaged a little worse than 20/80. This does not compare favorably with the 20/80 final visual outcome in the series of Brown et al. In making a similar comparison, Brown and Tasman<sup>71</sup> concluded that photocoagulation therapy is effective for flattening the retinal detachment, but not for improving final visual outcome.

A macular buckling procedure successfully treated cases of serous detachment in optic disc pit. In such cases, OCT showed a resultant closure of the connection between the pit and the retinoschisis with resolution of the schisis.<sup>82</sup> Multifocal electroretinography was performed in 10 patients with optic disc pit with serous macular detachment before and after treatment with macular buckling procedures.<sup>83</sup> Improvement was measured in all eyes at 12 months, though often this was not accompanied by an increase in visual acuity.<sup>83</sup> Follow-up evaluation 11 years after surgery found that the patients maintained the improvement they had achieved 2 years postoperatively, suggesting a good long-term result.<sup>84</sup> Silicon oil has also been used successfully in cases of macular hole in association with the optic disc pit.<sup>85</sup>

More recent attempts to combine photocoagulation therapy with posterior vitrectomy and gas–fluid exchange have led to more encouraging long-term visual outcomes.<sup>86</sup> Bonnet<sup>87</sup> looked at 25 eyes with optic disc pits in 24 patients who presented with visual loss due to serous macular detachments. High-magnification biomicroscopy and fluorescein angiography of these eyes revealed evidence of vitreous traction on the retina and on the optic nerve head. Most particularly, Bonnet noted that none of the patients had posterior vitreous detachments at presentation and that in the 2 patients that subsequently developed a posterior vitreous detachment, reattachment of the macula occurred spontaneously. Fluorescein dye was seen to stain the optic nerve head, especially at the pit and temporal margin of the disc. This dye leakage was not seen in cases that underwent surgical peeling of the posterior vitreous face. Moreover, Bonnet observed a small hole in the roof of the optic pit in several cases, and small bubbles of gas passing from

the vitreous cavity into the subretinal space via the optic disc pit in a case that underwent vitrectomy and gas injection but not photocoagulation. Hence, Bonnet concluded that macular detachments in optic disc pits have a rhegmatogenous component (at the optic disc), that they are associated with vitreous traction, and that the subretinal fluid comes from the vitreous space via the optic disc pit.<sup>87</sup>

Cox and colleagues<sup>88</sup> looked at three treatment approaches. They concluded that the combination of vitrectomy plus gas tamponade plus photocoagulation of the retina temporal to the disc was more effective than vitrectomy and gas or photocoagulation alone. They obtained short-term surgical success in all of their 8 eyes and long-term attachment in 4 out of 8 eyes using the three-part combination therapy.<sup>88</sup> Others have also obtained good anatomic results in optic disc pit with macular detachment using the combination of vitrectomy, air–fluid exchange, and photocoagulation in patients whose final visual acuities averaged 20/60.<sup>89</sup> Various precipitating events may combine with the mechanism described above, leading to macular detachment by vitreous fluid entry into the subretinal space via the optic disc pit.

Novel techniques for treatment of optic disc pit-associated serous macular detachments have also been described. Spaide et al.<sup>90</sup> published a case report describing the use of a bent 25-gauge needle to create half-thickness cuts to the inner retina. This maneuver was combined with a vitrectomy in an attempt to allow intraretinal and subretinal fluid to escape. This procedure did not use intraocular gas to avoid premature closure of the surgical fenestrations and the posterior hyaloid was left intact. One month after surgery, the patient's visual acuity improved from 8/400 preoperatively to 20/20. Schaal et al.<sup>91</sup> described a similar procedure with the use of a 27-gauge cannula to make three-quarter-depth cuts, in combination with a limited preretinal vitrectomy.

Jalil et al.<sup>92</sup> actively drained subretinal fluid with a 42-gauge cannula. This procedure included vitrectomy, induction of posterior vitreous detachment, and internal limiting membrane peel, but without the use of laser photocoagulation around the retinotomy site. Fluid–air exchange followed by internal gas tamponade with 14% C<sub>3</sub>F<sub>8</sub> concluded the procedure. The patient's preoperative

visual acuity of 1.00 logMAR improved at 8-months follow-up to 0.4 logMAR. Ziahosseini et al.<sup>93</sup> utilized a similar approach with the addition of argon laser to the cannula insertion site.

### **Introduction**

**Diabetic Retinopathy and Diabetic Macular Edema**

**Vein Occlusions**

**Age-Related Macular Degeneration and Other Conditions  
Associated With Choroidal Neovascularization**

**Retinopathy of Prematurity**

**Posterior Uveitis**

**Other Retinal and Retina-Related Conditions**

**Retinal Surgery**

## **Introduction**

The subspecialty of Retina has seen some of the most innovative changes in the field of ophthalmology, largely owing to groundbreaking randomized clinical trials, with several or many centers

typically participating, conducted to test new treatment strategies or to compare two or more effective strategies for the management of ocular complications of diabetes, age-related macular degeneration, and retinal vaso-occlusive disease, among others. During the past four decades, large clinical trials of interventions for retinal disorders have laid the foundations for evidence-based clinical practice; foremost among these was the Diabetic Retinopathy Study, which was one of the first initiatives of the National Eye Institute upon its creation as one of the United States National Institutes of Health. The Diabetic Retinopathy Study was one of the largest and best-conducted clinical trials of the safety and effectiveness of panretinal photocoagulation in diabetic retinopathy. This trial provided ophthalmologists with the evidence that was needed to show that proliferative diabetic retinopathy could be managed effectively with laser and also demonstrated the potential of the retinal community to generate the evidence base for treatment of retinal disorders through a networked approach. Since the Diabetic Retinopathy Study, the number of clinical trials in retinal disorders has burgeoned, with increasing sponsorship from industry and agencies in other countries.

The purpose of this chapter is to provide the retinal specialist with a bibliography of selected publications in peer-reviewed journals that report information from important clinical trials of interventions for common retinal disorders. The organization of the citations is by retinal condition and then by specific randomized trials or sets of trials, with trials that focus on the same condition grouped together. The order of the conditions is chronologic by publication of findings from the first major clinical trial. Whenever a randomized trial was conducted as part of a larger study, was preceded by a pilot study, or was continued as an observational study, selected publications from the pilot study or from the follow-up study have been included in the bibliography for the clinical trial. The focus is on large, typically multicenter, randomized trials.

Some publications from early trials have been omitted but may be found in previous editions of this textbook. Cochrane systematic reviews published in the *Cochrane Database of Systematic Reviews* have been cited for many interventions for retinal disorders. Publications from many small trials have been cited within the

Cochrane systematic reviews.

## **Early Treatment Diabetic Retinopathy Study (ETDRS)**

The ETDRS was designed to evaluate the effectiveness of laser photocoagulation and aspirin, together and singly, in delaying or preventing progression of early diabetic retinopathy to more severe stages and blindness and to determine the optimum time to initiate photocoagulation in diabetic retinopathy. Initiation of the ETDRS was a motivating factor in the development of a new visual acuity chart for use in prospective clinical research studies; articles that report on the design and evaluation of the chart are listed at the end of the ETDRS bibliography.

## **Diabetes Control and Complications Trial (DCCT)**

The DCCT was designed to compare intensive with conventional glucose control with respect to development and progression of early vascular and neurologic complications of insulin-dependent diabetes mellitus. The DCCT was sponsored by several institutes of the US National Institutes of Health, including the National Eye Institute, and various corporate sponsors. A follow-up study of members of the DCCT cohort, the Epidemiology of Diabetes Interventions and Complications (EDIC), was undertaken to assess the long-term effects of intensive and conventional diabetes therapy during the DCCT.

## **Diabetic Retinopathy Clinical Research Network (DRCRnet)**

The DRCRnet investigators have conducted a number of randomized clinical trials and observational studies of diabetic retinopathy. A complete list of publications from the DRCRnet is maintained on the DRCRnet Public Web Site (<http://drcrnet.jaeb.org/Publications.aspx> [cited 2015 28 Sep]).

Diabetic Retinopathy Clinical Research Network. A phase 2 randomized clinical trial of intravitreal bevacizumab for diabetic macular edema. *Ophthalmology* 2007;114(10):1860–7.

Bhavsar AR, Ip MS, Glassman AR for the DRCRnet and the SCORE Study Group. The risk of endophthalmitis following intravitreal triamcinolone injection in the DRCRnet and SCORE clinical trials. *Am J Ophthalmol* 2007;144:454–6.

Writing Committee for the Diabetic Retinopathy Clinical Research Network. Comparison of the modified Early Treatment Diabetic Retinopathy Study and mild macular grid laser photocoagulation

strategies for diabetic macular edema. *Arch Ophthalmol* 2007;124:469–80.

Diabetic Retinopathy Clinical Research Network. A randomized trial comparing intravitreal triamcinolone acetonide and focal/grid photocoagulation for diabetic macular edema. *Ophthalmology* 2008;115:1447–59.

Scott IU, Bressler NM, Bressler SB, et al. and the Diabetic Retinopathy Clinical Research Network. Agreement between clinician and reading center gradings of diabetic retinopathy severity level at baseline in a phase 2 study of intravitreal bevacizumab for diabetic macular edema. *Retina* 2008;28:38–40.

Diabetic Retinopathy Clinical Research Network. Three-year follow up of a randomized trial comparing focal/grid photocoagulation and intravitreal triamcinolone for diabetic macular edema. *Arch Ophthalmol* 2009;127(3):245–51.

Bressler NM, Edwards AR, Beck RW, et al. for the Diabetic Retinopathy Clinical Research Network. Exploratory analysis of diabetic retinopathy progression through 3 years in a randomized clinical trial that compares intravitreal triamcinolone acetonide with focal/grid photocoagulation. *Arch Ophthalmol* 2009;127(12):1566–71.

Bhavsar AR, Googe JM, Stockdale CR, et al. for the Diabetic Retinopathy Clinical Research Network. Risk of endophthalmitis after intravitreal drug injections when topical antibiotics are not required. The Diabetic Retinopathy Clinical Research Network Laser-Ranibizumab-Triamcinolone Clinical Trials. *Arch Ophthalmol* 2009;127(12):1581-3.

Scott IU, Danis RP, Bressler SB, et al. for the Diabetic Retinopathy Clinical Research Network. Effect of focal/grid photocoagulation on visual acuity and retinal thickening in eyes with non-center-involved diabetic macular edema. *Retina* 2009;29:613-7.

Diabetic Retinopathy Clinical Research Network. Randomized trial

evaluating ranibizumab plus prompt or deferred laser or triamcinolone plus prompt laser for diabetic macular edema. *Ophthalmology* 2010;117:1064–77.

Aiello LP, Edwards AR, Beck RW, et al. for the Diabetic Retinopathy Clinical Research Network. Factors associated with improvement and worsening of visual acuity 2 years after focal/grid photocoagulation for diabetic macular edema. *Ophthalmology* 2010;117:946-53.

Lauer AK, Bressler NM, Edwards AR for the Diabetic Retinopathy Clinical Research Network. Frequency of intraocular pressure increase within days after intravitreal triamcinolone injections in the Diabetic Retinopathy Clinical Research Network. *Arch Ophthalmol* 2011;129(8):1097-9.

Diabetic Retinopathy Clinical Research Network Writing Committee: Googe J, Brucker AJ, Bressler NM, et al. Randomized trial evaluating short-term effects of intravitreal ranibizumab or triamcinolone acetonide on macular edema after focal/grid laser for diabetic macular edema in eyes also receiving panretinal photocoagulation. *Retina* 2011;31:1009–27.

Diabetic Retinopathy Clinical Research Network. Expanded 2-year follow-up of ranibizumab plus prompt or deferred laser or triamcinolone plus prompt laser for diabetic macular edema. *Ophthalmology* 2011;118:609-14.

Dewan V, Lambert D, Edler J, et al. Cost-effectiveness analysis of ranibizumab plus prompt or deferred laser or triamcinolone plus prompt laser for diabetic macular edema. *Ophthalmology* 2012;119(8):1879-84.

Glassman AR, Stockdale CE, Beck R, et al. for the Diabetic Retinopathy Clinical Research Network. Evaluation of masking study participants to intravitreal injections in a randomized clinical trial. *Arch Ophthalmol* 2012;130(2):190-4.

Diabetic Retinopathy Clinical Research Network. Randomized

clinical trial evaluating intravitreal ranibizumab or saline for vitreous hemorrhage from proliferative diabetic retinopathy. JAMA Ophthalmol 2013;131(3):283-93.

Bressler SB, Qin H, Melia M, et al. for the Diabetic Retinopathy Clinical Research Network. Exploratory analysis of the effect of intravitreal ranibizumab or triamcinolone on worsening of diabetic retinopathy in a randomized clinical trial. JAMA Ophthalmol 2013;131(8):1033-40.

Bressler SB, Almukhtar T, Aiello LP, et al. for the Diabetic Retinopathy Clinical Research Network. Green or yellow laser treatment for diabetic macular edema. Exploratory assessment within the Diabetic Retinopathy Clinical Research Network. Retina 2013;33:2080-8.

Bhavsar AR, Torres K, Bressler NM, et al. for the Diabetic Retinopathy Clinical Research Network. Evaluation of results 1 year following use of short-term ranibizumab for vitreous hemorrhage due to proliferative diabetic retinopathy. JAMA Ophthalmology 2014;132(7):889-90.

Bressler SB, Almukhtar T, Bhorade A, et al. for the Diabetic Retinopathy Clinical Research Network. Repeated intravitreal ranibizumab injections for diabetic macular edema and the risk of sustained elevation of intraocular pressure or the need for ocular hypotensive treatment. JAMA Ophthalmol 2015;133(5):589-97.

Elman MJ, Ayala A, Bressler NM, et al. for the Diabetic Retinopathy Clinical Research Network. Intravitreal ranibizumab for diabetic macular edema with prompt versus deferred laser treatment: 5-year randomized trial results. Ophthalmology 2015;122:375-81.

Diabetic Retinopathy Clinical Research Network. Aflibercept, bevacizumab, or ranibizumab for diabetic macular edema. N Engl J Med 2015;372:1193-203.

Bressler SB, Melia M, Glassman AR, et al. for the Diabetic Retinopathy Clinical Research Network. Ranibizumab plus

prompt or deferred laser for diabetic macular edema in eyes with vitrectomy before anti-vascular endothelial growth factor therapy. *Retina* 2015;35(12):2516-28.

## Other Intervention Trials

Sorbinil Retinopathy Trial Research Group. A randomized trial of sorbinil, an aldose reductase inhibitor, in diabetic retinopathy. *Arch Ophthalmol* 1990;108:1234-44.

Krypton Argon Regression of Neovascularization Study Research Group. Randomized comparison of krypton versus argon scatter photocoagulation for diabetic disc neovascularization. *Ophthalmology* 1993;100:1655-64.

Chaturvedi N, Sjolie A-K, Stephenson JM, et al. and the EUCLID Study Group. Effect of lisinopril on progression of retinopathy in normotensive people with type 1 diabetes. *Lancet* 1998;351:28-31.

## ACCORD Eye Study

Chew EY, Ambrosius WT, Howard LT, et al. for the ACCORD Study Group. Rationale, design, and methods of the Action to Control Cardiovascular Risk in Diabetes Eye Study (ACCORD-EYE). *Am J Cardiol* 2007;99(Suppl):103i-111i.

ACCORD Study Group and ACCORD Eye Study Group. Effects of medical therapies on retinopathy progression in type 2 diabetes. *N Engl J Med* 2010;363:233-44.

Ambrosius WT, Danis RP, Goff DC, et al. for the ACCORD Study Group. Lack of association between thiazolidinediones and macular edema in type 2 diabetes. *Arch Ophthalmol* 2010;128(3):312-8.

Gangaputra S, Lovato JP, Hubbard L, et al. for the ACCORD Eye Research Group. Comparison of standardized clinical classification with fundus photograph grading for the assessment of diabetic retinopathy and diabetic macular edema severity.

Retina 2013;33:1393-9.

Chew EY, Davis MD, Danis RP, et al for the Action to Control Cardiovascular Risk in Diabetes Eye Study Research Group. The effects of medical management on the progression of diabetic retinopathy in persons with type 2 diabetes. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) Eye Study. *Ophthalmology* 2014;121:2443-51.

## **ADVANCE/AdRem**

Stolk RP, Vingerling JR, Cruickshank JK, et al. on behalf of the AdRem project team and ADVANCE management committee. Rationale and design of the AdRem study: Evaluating the effects of blood pressure lowering and intensive glucose control on vascular retinal disorders in patients with type 2 diabetes mellitus. *Contemp Clin Trials* 2007;28:6–17.

Stolk RP, Thom SAMcG, van Schooneveld MJ, et al. on behalf of the AdRem Project Team and ADVANCE Management Committee. Retinal vascular lesions in patients with Caucasian and Asian origin with type 2 diabetes. Baseline results from the ADVANCE Retinal Measurements (AdRem) study. *Diabetes Care* 2008;31:708–13.

Beulens JWJ, Patel A, Vingerling JR, et al. on behalf of the AdRem project team and ADVANCE management committee. Effects of blood pressure lowering and intensive glucose control on the incidence and progression of retinopathy in patients with type 2 diabetes mellitus: a randomised controlled trial. *Diabetologia* 2009;52:2027–36.

Lee CC, Stolk RP, Adler AI, et al. on behalf of the AdRem project team and ADVANCE management committee. Association between alcohol consumption and diabetic retinopathy and visual acuity – the AdRem Study. *Diabet Med* 2010;27:1130–7.

## **DA VINCI Study**

Do DV, Schmidt-Erfurth U, Gonzalez VH, et al. The DA VINCI Study: Phase 2 primary results of VEGF Trap-Eye in patients with diabetic macular edema. *Ophthalmology* 2011;118:1819-1826.

Do DV, Nguyen QD, Boyer D, et al. for the DA VINCI Study Group. One-year outcomes of the DA VINCI study of VEGF Trap-Eye in eyes with diabetic macular edema. *Ophthalmology* 2012;119:1658-65.

## **Dexamethasone DDS Study**

Haller JA, Kuppermann BD, Blumenkranz MS, et al. for the Dexamethasone DDS Phase II Study Group. Randomized controlled study of an intravitreal dexamethasone drug delivery system in patients with diabetic macular edema. *Arch Ophthalmol* 2010;128(3):289-96.

Kuppermann BD, Chou C, Weinberg DV, et al. for the Dexamethasone DDS Phase II Study Group. Intravitreal dexamethasone effects on different patterns of diabetic macular edema. *Arch Ophthalmol* 2010;128(5):642-3.

## **DIRECT**

Sjolie AK, Klein R, Porta M, et al. for the DIRECT Programme Study Group. Effect of candesartan on progression and regression of retinopathy in type 2 diabetes (DIRECT-Protect 2): a randomised placebo-controlled trial. *Lancet* 2008;372:1385-93.

Chaturvedi N, Porta M, Klein R, et al. for the DIRECT Programme Study Group. Effect of candesartan on prevention (DIRECT-Prevent 1) and progression (DIRECT-Protect 1) of retinopathy in type 1 diabetes: randomised, placebo-controlled trials. *Lancet* 2008;372:1394-402.

Sjolie AK, Klein R, Torta M, et al. Retinal microaneurysm count predicts progression and regression of diabetic retinopathy. Post-hoc results from the DIRECT Programme. *Diabet Med* 2011;28:345-51.

## **FAME**

Campochiaro PA, Brown DM, Pearson A, et al. for the FAME Study Group. Long-term benefit of sustained-delivery fluocinolone acetonide vitreous inserts for diabetic macular edema. *Ophthalmology* 2011;118:626-35.

Campochiaro PA, Brown DM, Pearson A, et al. for the FAME Study Group. Sustained delivery fluocinolone acetamide vitreous inserts provide benefit for at least 3 years in patients with diabetic macular edema. *Ophthalmology* 2012;119:2125-32.

## **Macugen 1013 Study**

Macugen Diabetic Retinopathy Study Group. A phase II randomized double-masked trial of pegaptanib, an anti-vascular endothelial growth factor aptamer, for diabetic macular edema. *Ophthalmology* 2005;112:1747-57.

Sultan MB, Zhou D, Loftus J, et al. for the Macugen 1013 Study Group. A phase 2/3, multicenter, randomized, double-masked, 2-year trial of pegaptanib sodium for the treatment of diabetic macular edema. *Ophthalmology* 2011;118:1107-18.

Loftus JV, Sultan MB, Pleil AM for the Macugen 1013 Study Group. Changes in vision- and health-related quality of life in patients with diabetic macular edema treated with pegaptanib sodium or sham. *Invest Ophthalmol Vis Sci* 2013;52(10):7498-7505.

## **PKC-DRS Studies**

PKC-DRS Study Group. The effect of ruboxistaurin on visual loss in patients with moderately severe to very severe nonproliferative diabetic retinopathy. Initial results of the Protein Kinase C  $\beta$  inhibitor Diabetic Retinopathy Study (PKC-DRS) multicenter randomized clinical trial. *Diabetes* 2005;54:2188-97.

PKC-DRS Group. Effect of ruboxistaurin on visual loss in patients with diabetic macular retinopathy. *Ophthalmology*

2006;113:2221-30.

Davis MD, Sheetz MJ, Aiello LP, et al. for the PKC-DRS Study Group. Effect of ruboxistaurin on the visual acuity decline associated with long-standing diabetic macular edema. *Invest Ophthalmol Vis Sci* 2009;50:1-4.

Sheetz MJ, Aiello LP, Shahri N, et al. for the MBDV Study Group. Effect of ruboxistaurin (RBX) on visual acuity decline over a 6-year period with cessation and reinstatement of therapy. Results of an open-label extension of the Protein Kinase C Diabetic Retinopathy Study 2 (PKC-DRS2). *Retina* 2011;31:1053-9.

Aiello LP, Vignati L, Sheetz MJ, et al. for the PKC-DRS and PKC-DRS2 Study Groups. Oral protein kinase C  $\beta$  inhibition using ruboxistaurin. Efficacy, safety, and causes of vision loss among 813 patients (1,392 eyes) with diabetic retinopathy in the Protein Kinase C  $\beta$  inhibitor-Diabetic Retinopathy Study and the Protein Kinase C  $\beta$  inhibitor-Diabetic Retinopathy Study 2. *Retina* 2011;31:2084-94.

## **READ-2**

Nguyen QD, Shah SM, Heier JS, et al. for the READ-2 Study Group. Primary end point (six months) results of the Ranibizumab for Edema of the mAcula in Diabetes (READ-2) Study. *Ophthalmology* 2009;116:2175-81.

Nguyen QD, Shah SM, Khwaja AA, et al. for the READ-2 Study Group. Two-year outcomes of the Ranibizumab for Edema of the mAcula in Diabetes (READ-2) Study. *Ophthalmology* 2010;117:2146-51.

Do DV, Nguyen QD, Khwaja AA, et al. for the READ-2 Study Group. Ranibizumab for Edema of the Macula in Diabetes Study. 3-year outcomes and the need for prolonged frequent treatment. *JAMA Ophthalmol* 2013;131(2):130-45.

## **RESTORE**

Mitchell P, Bandello F, Schmidt-Erfurth U et al. on behalf of the RESTORE Study Group. The RESTORE Study. Ranibizumab monotherapy or combined with laser versus laser monotherapy for diabetic macular edema. *Ophthalmology* 2011;118:615-25.

Mitchell P, Annemans L, Gallagher M, et al. Cost-effectiveness of ranibizumab in treatment of diabetic macular edema (DME) causing visual impairment: evidence from the RESTORE trial. *Br J Ophthalmol* 2012;96:688-93.

Mitchell P, Bressler N, Tolley K, et al. for the RESTORE Study Group. Patient-reported visual function outcomes improve after ranibizumab treatment in patients with vision impairment due to diabetic macular edema. Randomized clinical trial. *JAMA Ophthalmol* 2013;131(10):1339-47.

Lang GE, Berta A, Eldem BM, et al for the RESTORE Extension Study Group. Two-year safety and efficacy of ranibizumab 0.5 mg in diabetic macular edema. *Ophthalmology* 2013;120:2004-12.

Schmidt-Erfurth U, Lang GL, Holz FG, et al. on behalf of the RESTORE Extension Study Group. Three-year outcomes of individualized ranibizumab treatment of patients with diabetic macular edema. The RESTORE Extension Study. *Ophthalmology* 2014;121:1045-53.

## **RISE/RIDE**

Nguyen QD, Brown DM, Marcus MD, et al. on behalf of the RISE and RIDE Research Group. Ranibizumab for diabetic macular edema. Results from 2 phase III randomized trials: RISE and RIDE. *Ophthalmology* 2012;119:789-801.

Brown DM, Nguyen QD, Marcus DM, et al. on behalf of the RIDE and RISE Research Group. Long-term outcomes of ranibizumab therapy for diabetic macular edema: The 36-month results from two phase III trials, RISE and RIDE. *Ophthalmology* 2013;120:2013-22.

Bressler NM, Varma R, Suner IJ, et al. for the RIDE and RISE Research Groups. Vision-related function after ranibizumab treatment for diabetic macular edema. Results from RIDE and RISE. *Ophthalmology* 2014;121:2461-2472.

Domalpally A, Ip MS, Ehrlich JS. Effects of intravitreal ranibizumab on retinal hard exudates in diabetic macular edema. Findings from the RIDE and RISE phase III clinical trials. *Ophthalmology* 2015;122:779-86.

Brown GC, Brown MM, Turpcu A, et al. The cost-effectiveness of ranibizumab for the treatment of diabetic macular edema. *Ophthalmology* 2015;122:1416-25.

## **VISTA and VIVID**

Korobelnik J-F, Do DV, Schmidt-Urfurth U, et al. Intravitreal aflibercept for diabetic macular edema. *Ophthalmology* 2014;121:2247-54.

Brown DM, Schmidt-Urfurth U, Do DV, et al. Intravitreal aflibercept for diabetic macular edema. 100-week results from the VISTA and VIVID studies. *Ophthalmology* 2015;122:2044-52.

## Vein Occlusions

### Branch Vein Occlusion Study (BVOS)

The BVOS was sponsored by the National Eye Institute and designed to assess in eyes with retinal branch vein occlusion whether scatter photocoagulation could prevent development of neovascularization, peripheral scatter photocoagulation could prevent vitreous hemorrhage, and macular photocoagulation would improve visual acuity in eyes with macular edema and visual acuity of 20/40 or worse. Argon laser photocoagulation improved visual acuity in eyes with macular edema secondary to retinal branch vein occlusion, macular edema, and visual acuity of 20/40 or worse, with a gain of 2 or more lines of visual acuity in

more laser-treated eyes than untreated eyes.

Finkelstein D, Clarkson J, Diddie K, et al. Branch vein occlusion: retinal neovascularization outside the involved segment. *Ophthalmology* 1982;89:1357–61.

Branch Vein Occlusion Study Group. Argon laser photocoagulation for macular edema in branch vein occlusion. *Am J Ophthalmol* 1984;98:271–82.

Branch Vein Occlusion Study Group. Argon laser scatter photocoagulation for prevention of neovascularization and vitreous hemorrhage in branch vein occlusion: a randomized clinical trial. *Arch Ophthalmol* 1986;104:34–41.

## Central Vein Occlusion Study (CVOS)

The CVOS included two randomized trials and two observational studies in its design. The goals of the CVOS were: (1) to determine whether photocoagulation therapy could prevent iris neovascularization in eyes with central vein occlusion and evidence of ischemic retina; (2) to assess whether grid photocoagulation could reduce loss of central visual acuity due to macular edema secondary to central vein occlusion; and (3) to describe the course and prognosis for eyes with central vein occlusion.

## **Age-Related Macular Degeneration and Other Conditions Associated With Choroidal Neovascularization**

Because of the numerous trials that have been conducted for these conditions during the past three decades, the clinical trials cited have been subdivided by type of intervention. A Cochrane systematic review has summarized the findings from all Cochrane reviews of interventions for neovascular age-related macular degeneration:

Evans JR, Virgili G, Gordon I, et al. Interventions for neovascular age-related macular degeneration. Cochrane Database of Systematic Reviews 2009, Issue 1, Art. No.: CD007650. doi: 10.1002/14651858.CD007650.

### **Laser Treatment**

#### **Macular Photocoagulation Study (MPS)**

The MPS was initiated in 1979 under the sponsorship of the National Eye Institute to evaluate laser photocoagulation for choroidal neovascularization secondary to age-related macular degeneration and ocular histoplasmosis. In addition, small trials of laser photocoagulation for idiopathic choroidal neovascularization

were conducted. In total, the MPS Group conducted eight multicenter randomized trials of laser photocoagulation of choroidal neovascularization. The 1982 publication from the MPS Study Group reports the early results of the first randomized trial to demonstrate a benefit of a treatment for this retinal disorder. Findings from the MPS trials informed both scientific and methodologic aspects of the designs of many subsequent trials of treatments for neovascular age-related macular degeneration.

### **Complications of AMD Prevention Trial (CAPT)**

CAPT was a multicenter randomized trial designed to evaluate low-intensity laser treatment of large drusen as a method of preventing vision loss among patients at risk of choroidal

neovascularization and other manifestations of advanced age-related macular degeneration. CAPT was preceded by a pilot study, the Choroidal Neovascularization Prevention Trial (CNVPT).

## **Cochrane Systematic Review**

Evans JR, Sivagnanavel V, Chong V. Radiotherapy for neovascular age-related macular degeneration. Cochrane Database of Systematic Reviews 2010, Issue 5, Art. No.: CD004004. doi: 10.1002/14651858.CD004004.pub3.

## **Anti-VEGF Therapy for Choroidal Neovascularization**

Anti-vascular endothelial growth factor agents for treatment of neovascular age-related macular degeneration and neovascularization secondary to other conditions have changed the treatment paradigm and the prognosis for patients with these conditions. Trials of anti-VEGF agents for neovascular age-related macular degeneration have been sponsored primarily by industry.

## **Retinopathy of Prematurity**

Initiation of the Multicenter Trial of Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) was stimulated by an increase in the incidence of retinopathy of prematurity following a decline after early clinical trials demonstrated that exposure to 100% oxygen in incubators had been responsible for the epidemic of retinopathy of prematurity in the United States in the 1950s. Increased incidence in the 1970s and 1980s was attributable to advances in neonatal medicine that had increased survival among very-low-birthweight premature infants. CRYO-ROP was designed to determine the safety and efficacy of transscleral cryotherapy of the peripheral retina in selected low-birthweight infants with retinopathy of prematurity and to study the natural history of retinal vessel development and outcome in such children. Following completion of CRYO-ROP, additional trials were undertaken to evaluate proposed approaches to reduce the complications of retinopathy of prematurity, all with sponsorship by the National Eye Institute, either alone or in collaboration with other institutes of the National Institutes of Health.

## Other Retinal and Retina-Related Conditions

### Collaborative Ocular Melanoma Study (COMS)

The COMS was conducted to compare length of survival after radiotherapy or standard enucleation for primary treatment of choroidal melanoma. Two randomized trials were completed: the COMS randomized trial of iodine-125 brachytherapy and the COMS randomized trial of pre-enucleation external beam radiation. A small nonrandomized observational study of small choroidal melanoma was conducted at a subset of COMS centers. A parallel prospective study of quality of life among patients in the brachytherapy trial (COMS-QOLS) also was conducted. The COMS design and findings are discussed in detail in [Chapter 154](#) (Collaborative Ocular Melanoma Study), which cites most publications from the COMS; only primary outcome publications are provided here.

Collaborative Ocular Melanoma Study Group. The Collaborative Ocular Melanoma Study (COMS) randomized trial of pre-enucleation radiation of large choroidal melanoma. II: Initial mortality findings. COMS report no. 10. *Am J Ophthalmol* 1998;125:779–96.

Collaborative Ocular Melanoma Study Group. The COMS randomized trial of iodine 125 brachytherapy for choroidal melanoma, III: Initial mortality findings. COMS report no. 18. *Arch Ophthalmol* 2001;119:969–82.

Collaborative Ocular Melanoma Study – Quality of Life Study Group. Quality of life after I-125 brachytherapy versus enucleation for choroidal melanoma: 5-year results from the Collaborative Ocular Melanoma Study. COMS-QOLS report no. 3. *Arch Ophthalmol* 2006;124:226–36.

Collaborative Ocular Melanoma Study Group. The COMS randomized trial of iodine 125 brachytherapy for choroidal melanoma. V. Twelve-year mortality rates and prognostic factors. COMS report no. 28. *Arch Ophthalmol* 2006;124:1684–93.

### **Studies of the Ocular Complications of AIDS (SOCA)**

In order to address issues regarding treatment of eye involvement, primarily cytomegalovirus retinitis, in patients with the acquired immune deficiency syndrome (AIDS), the National Eye Institute has sponsored SOCA, a clinical trials network. Most of the SOCA clinical trials have been conducted in collaboration with the AIDS Clinical Trials Group. Several of the trials also had industry sponsorship. A longitudinal observational study (LSOCA) was undertaken by the SOCA investigators to provide information on ocular complications during the HAART era.

*Sebastian Wolf, Martin Zinkernagel*

**Introduction**

**Major Types**

**Rhegmatogenous Retinal Detachment**

**Tractional Retinal Detachment**

**Combined Tractional and Rhegmatogenous Retinal Detachment**

**Exudative and Hemorrhagic Retinal Detachment**

**Conclusion**

## Introduction

The term retinal detachment is used to describe a separation of the neurosensory retina from the retinal pigment epithelium (RPE). This chapter discusses the mechanisms that keep the retina attached and the pathogenetic mechanisms that cause the most commonly encountered types of retinal detachments. Details of specific types

of retinal detachment and their treatment are addressed in other chapters.

## Major Types

Retinal detachments can be classified into categories based on the presence of a tractional component.<sup>1</sup> Those with a tractional component include rhegmatogenous, tractional, combined tractional–rhegmatogenous, and central retinal detachments in myopic eyes. Retinal detachments without tractional components include exudative and hemorrhagic retinal detachments.

The most common form is rhegmatogenous (derived from the Greek word *rhegma*, meaning break) retinal detachment, which occurs as the result of a full-thickness retinal break secondary to or in combination with vitreous traction. The second category, traction retinal detachment, occurs when vitreoretinal adhesions mechanically detach the retina from the underlying RPE. In combined tractional–rhegmatogenous retinal detachments the tractional component precedes the retinal break and therefore is the causative component. Retinal detachment without a tractional component can be caused by subretinal fluid production due to a process, such as a tumor or inflammation, or by blood and/or serum accumulation in the subretinal space.

Accumulation of subretinal fluid is a feature of all retinal detachments. When the normal physiologic forces that maintain contact between the retina and the RPE (e.g., the metabolic pump of the RPE,<sup>2</sup> the osmotic pressure of the choroid,<sup>3</sup> and the more minor mechanical forces of the interphotoreceptor matrix) are compromised or overwhelmed, a retinal detachment occurs. Various pathologic conditions can upset the balance of the normal transretinal pressure gradient and result in subretinal fluid accumulation.<sup>4</sup>

## Rhegmatogenous Retinal Detachment

As noted above, rhegmatogenous retinal detachments are those arising from one or more full-thickness retinal breaks in combination with vitreous traction.<sup>1</sup>

Most of these are “horseshoe tears” occurring at sites of strong vitreoretinal adhesions, most commonly at the irregular posterior margin of the vitreous base during posterior vitreous detachment (PVD). They are more common in the superior temporal quadrant followed by the superior nasal quadrant. “U-tears,” another term for horseshoe tears, consist of a flap in which its apex is pulled anteriorly by the vitreous while the base remains attached to the retina (Fig. 98.1). The actual tear consists of two anterior extensions (horns) running forward from the apex.

**FIG. 98.1** Rhegmatogenous retinal detachments with multiple full-thickness retinal breaks.

The term “retinal break” refers either to a retinal tear or to a retinal hole. Retinal tears are commonly associated with well-defined vitreoretinal traction at the posterior margin of the vitreous base during PVD. In contrast, retinal holes occur more commonly as a result of localized retinal atrophy or deterioration. The overlying operculum generally indicates relief of vitreoretinal traction in this area.<sup>5-7</sup>

In some cases, however, operculated retinal holes may be associated with vitreous traction in the near vicinity of the hole. This is especially true for retinal holes within lattice lesions. These round holes may behave like tears with persistent traction and have a higher likelihood to lead to rhegmatogenous detachment.

The characteristics of a rhegmatogenous retinal detachment are

(1) the existence of abnormal mobility of partially liquefied vitreous gel; (2) tractional forces that can precipitate a retinal break; and (3) the presence of a retinal break that will allow the passage of liquefied vitreous into the subretinal space (Fig. 98.2). All three factors need to be present to cause a rhegmatogenous retinal detachment. For example, if a tear or hole is present in the absence of tractional forces and liquid vitreous, it is unlikely that the retina will detach. Examination of postmortem eyes indicates that approximately 5–10% of eyes have full-thickness retinal defects without any apparent detachment.<sup>8</sup> A spontaneous rhegmatogenous retinal detachment is usually preceded by a PVD. With age, fragmentation of collagen fibers and an aggregation of proteoglycans around these fragments are believed to be responsible for destabilizing the vitreous gel and leading to liquefaction (syneresis).<sup>9,10</sup> The subsequent reduced volume of the vitreous gel is associated with the collapse and aggregation of the collagen fibrillar network. The liquefied vitreous gel may coalesce into a large lacuna, which mimics a true PVD.<sup>11</sup>

**FIG. 98.2** Characteristics of rhegmatogenous retinal detachment. 1 The presence of a retinal break. 2 Tractional forces from the vitreous on the retinal break. 3 Existence of liquefied vitreous able to pass through the retinal break into the subneurosensory space.

When the denser posterior vitreous cortex ruptures, the liquefied vitreous can pass into the subhyaloid space and separate the posterior vitreous surface from the internal limiting membrane of the retina producing a true PVD. Vitreous syneresis can be seen with the slit lamp in more than 90% of patients after the age of 40 years.<sup>12</sup> Both the degree of vitreous liquefaction and the prevalence of PVD are age-related.<sup>10</sup> In one study PVD was found in 27% of patients aged 60–69 years and in 63% of patients after age 70.<sup>13</sup> Other factors that accelerate liquefaction of vitreous gel include enzymatic vitreolysis with ocriplasmin, cataract extraction, high myopia, inflammation, and trauma.<sup>14,15</sup>

In the presence of a PVD, the condensed vitreous moves about

within the vitreous cavity, and rotational movements of the eye exert traction where the vitreous remains attached to the retina, most often at the vitreous base. These tractional forces may lead to a retinal break.

Ocular trauma can lead to traumatic complete or partial PVD which may result in retinal breaks and subsequent rhegmatogenous retinal detachment. In young patients trauma may lead to retinal dialysis which represents a disinsertion of the retina at the ora serrata and is generally not associated with PVD. Dialyses, in general and following trauma, are more common in the inferotemporal quadrant although most of the dialyses in the superonasal quadrant are associated with a definite history of preceding trauma.<sup>16</sup> Giant retinal tears (circumferential retinal breaks of  $\geq 90^\circ$ ) commonly arise from circumferential vitreous traction in the region of the posterior vitreous base, in the presence of a PVD. Giant retinal tears most commonly develop just posterior to the ora but also may be found at the equator (15%) and sometimes posterior to the equator.<sup>17,18</sup> Most giant retinal tears are idiopathic. However trauma, previous surgery, myopia, and inherited vitreoretinopathies have been reported to be risk factors.<sup>19</sup> Inherited vitreoretinopathies include a group of genetic disorders that result in abnormalities of the vitreous and retina with susceptibility to rhegmatogenous retinal detachment (RRD). The most common hereditary vitreoretinopathy is associated with the Stickler syndromes.<sup>20,21</sup> This inherited condition is associated primarily with the *COL2A* gene and also with the *COL11A1* gene.<sup>22</sup> Rhegmatogenous retinal detachment is a very common complication in these patients.<sup>23,24</sup>

Rhegmatogenous retinal detachments originating posterior to the equator are characteristic for high myopia.<sup>25</sup> Posterior pole retinal detachments are very rare, accounting for approximately 1% of retinal detachments in the United States, but the prevalence may be much higher in Asia.<sup>26,27</sup> Most of the nontraumatic retinal breaks located in the posterior pole are secondary to macular holes and associated with a posterior staphyloma.<sup>20</sup> We found that posterior breaks may also be associated with the use of ocriplasmin (Fig. 98.3). Vitreoretinal traction based on epiretinal membranes after incomplete posterior vitreous separation (“vitreoschisis”)<sup>28,29</sup> and

reduced retinal adherence to the choroid due to RPE atrophy<sup>30</sup> are speculated to be pathophysiologic factors in retinal detachments associated with myopic macular holes. Some authors believe that operative failure in these instances is related to axial elongation and posterior staphyloma formation.<sup>31</sup>

**FIG. 98.3** Rhegmatogenous retinal detachments 1 week after ocriplasmin injection. The posterior breaks are marked with *arrows*.

Aphakia and pseudophakia are commonly associated with peripheral retinal breaks at the posterior edge of the vitreous base near the ora serrata. In this region the retina is relatively thin and less developed. The incidence of retinal detachment associated with cataract extraction has decreased with the changes in surgical technique over the years, from intracapsular cataract extraction and aphakic correction to phacoemulsification, combined with the placement of a posterior chamber intraocular lens in the presence of an intact posterior lens capsule.<sup>32</sup> The incidence of retinal detachment depends on the technique of cataract extraction surgery, ranging from 1% to 8.1% with intracapsular cataract extraction, from 0% to 7.5% with extracapsular cataract extraction and up to 1.8% for phacoemulsification surgery.<sup>33-36</sup>

This is attributed by some to a forward shift of the vitreous after cataract surgery: Modern phacoemulsification surgery has been associated with PVD induction of up to 60% one year after surgery.<sup>37</sup> Rowe et al.<sup>38</sup> predicted that 10 years after either phacoemulsification or extracapsular cataract extraction, the cumulative probability of retinal detachment was 5.5 times higher than expected. The incidence of subsequent detachments in fellow eyes of patients experiencing a pseudophakic rhegmatogenous retinal detachment in their first eye has been reported to be 7.8% over a mean follow-up period of 57.4 months.<sup>39</sup> Nd:YAG laser posterior capsulotomy is associated with an increased incidence of subsequent retinal detachment.<sup>40</sup>

Various intraocular inflammatory and infectious conditions can cause vitreous gel liquefaction, PVD, and retinal breaks. Ocular toxoplasmosis,<sup>41</sup> ocular toxocariasis,<sup>42</sup> and pars planitis<sup>43</sup> are associated with morphologic vitreoretinal changes leading to vitreoretinal traction and retinal breaks. Some forms of infectious retinitis, such as acute retinal necrosis syndrome and cytomegalovirus retinitis, can result in multiple small breaks along the border between atrophic and normal retina and within necrotic retina.<sup>44,45</sup> Uveitis itself is an overall risk factor for a rhegmatogenous retinal detachment.<sup>46</sup> In addition, patients presenting with a rhegmatogenous retinal detachment from uveitis will also have a higher rate of proliferative vitreoretinopathy (PVR) at presentation and an overall worse prognosis.<sup>46</sup> However, uveitis may also be masqueraded by a longstanding rhegmatogenous detachment.

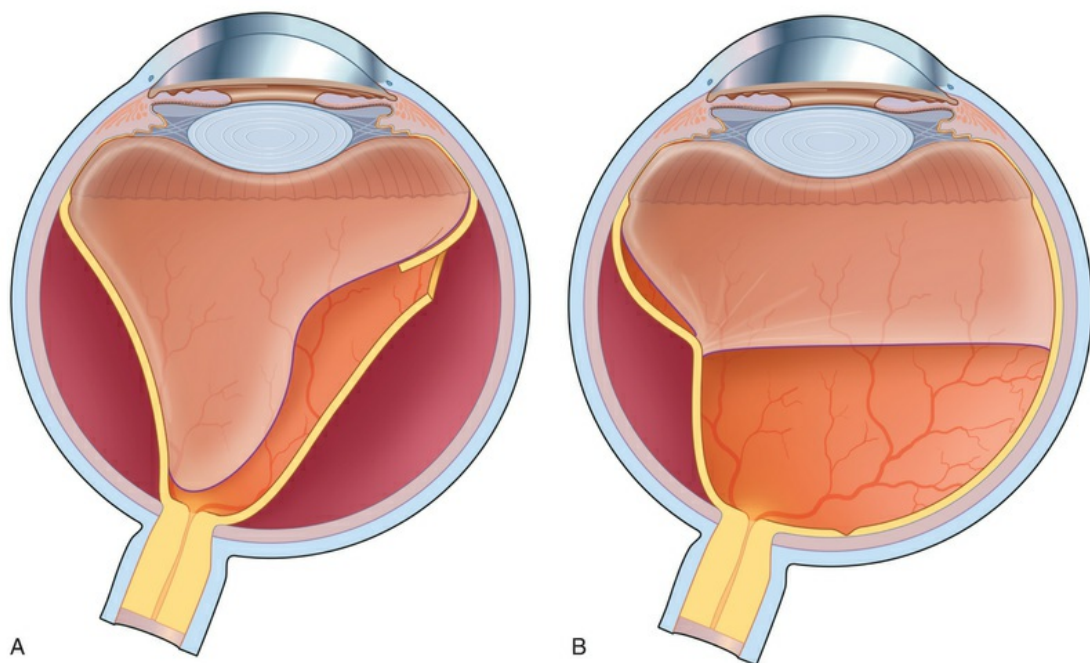

Retinal detachment resulting from retinoschisis is a subcategory of rhegmatogenous retinal detachment. This occurs when there are holes in both the inner and outer layers of the retina, allowing fluid to enter the retinoschisis cavity and the subretinal space and hence produce a retinal detachment. The incidence of retinal detachment with retinoschisis was up to 1.6% in a large series of patients with retinal detachment.<sup>47</sup>

## **Tractional Retinal Detachment**

The second most common cause of tractional retinal detachment is

that from vitreoretinal forces that mechanically pull the retina away from the underlying RPE. Tractional retinal detachments are commonly seen in diabetic retinopathy, PVR, penetrating trauma, branch retinal vein occlusion, and retinopathy of prematurity (ROP). Tractional forces can occur within the vitreous body, on the inner surface of the retina, or even beneath the retina as in subretinal fibrosis. In the majority of cases, the traction is associated with a clinically apparent membrane. Such membranes typically have fibroblasts and glial and RPE cells as cellular constituents. Experimental evidence has demonstrated the contractile nature of these groups of cells.<sup>48</sup>

In contrast to the rhegmatogenous retinal detachment, which often has a convex, even bullous, surface, the typical traction retinal detachment has a more concave surface and is likely to be more localized, often not extending to the ora serrata (Fig. 98.4).

**FIG. 98.4** (A) Rhegmatogenous retinal detachment with a bullous configuration. (B) Traction retinal detachment with a concave surface.

Tractional retinal detachments are a common feature of diabetic retinopathy.<sup>49</sup> Contracture of the vitreous gel often occurs in eyes with proliferative retinopathy. As the vitreous gel contracts with

the fibrovascular tissue, these vessels and the underlying retina are drawn anteriorly toward the vitreous base. Because of relatively strong vitreoretinal adhesions along the temporal arcades these areas are most prone to detach, and the detachment can spread both peripherally and centrally toward the macula. Diabetics who develop posterior neovascularization in childhood are prone to this form of traction retinal detachment. However, traction detachments related to diabetes do not inevitably go on to involve the macula. In one series, only 14% progressed to macular detachment within 1 year.<sup>50</sup>

ROP is the leading cause of childhood blindness in the United States, with more than 500 new cases diagnosed each year (see [Chapter 118](#), Surgical management of retinopathy of prematurity). Approximately 90% and in some series up to 100% of ROP, stages 1 and 2, regress. However, it has been reported that up to 17% of infants with aggressive posterior ROP develop a tractional retinal detachment.<sup>51</sup> A gestational age of less than 29.5 weeks, posterior zone 1 disease, and preretinal hemorrhages before laser treatment were identified as the most significant risk factors despite photocoagulation. The pathophysiology is believed to be from endothelial cell proliferation at the junction of the vascularized and avascular retina and migration onto the vitreous scaffold. Contraction of these membranes and the marked adherence of the posterior hyaloid to the retina can produce a complete retinal detachment if untreated.<sup>52</sup>

Retinal vascular diseases such as Eales disease and Coats disease can occasionally cause a fibrous proliferation and membrane formation in the vitreous and a secondary tractional retinal detachment in addition to primarily causing exudative retinal detachments.<sup>53,54</sup>

With the introduction of anti-vascular endothelial growth factor (VEGF) agents for the treatment of exudative and neovascular retinal diseases, there have been concerns that anti-VEGF treatment may lead to contraction of fibrovascular tissue thereby increasing tractional forces leading to tractional detachment.<sup>55,56</sup>

## Combined Tractional and

# Rhegmatogenous Retinal Detachment

Some retinal detachments combine tractional and rhegmatogenous components. Such detachments are characterized by a full-thickness retinal break and a significant tractional component. Despite the presence of a retinal hole, these detachments are often not bullous and have a concave appearance. They tend to remain localized but may progress to become complete retinal detachments.

Combined tractional–rhegmatogenous retinal detachments are most often seen in proliferative diabetic retinopathy (Fig. 98.5A), PVR, proliferative sickle-cell retinopathy, and penetrating intraocular injuries. PVR (see Chapter 101, Pathogenesis of proliferative vitreoretinopathy, and Chapter 111, Proliferative vitreoretinopathy) is a complication of a rhegmatogenous retinal detachment and is the most common cause of failure of surgical repair of these cases, occurring in 7–10% of primary operations and in a higher percentage of reoperations (Figs. 98.5B–C).<sup>57</sup> In general, PVR develops when cells are dispersed into the vitreous cavity through a retinal break. These cells form membranes on the inner retina surface and on the posterior vitreous surface capable of redetaching the retina and may lead to the reopening of retinal breaks or the creation of new ones.<sup>58</sup>

**FIG. 98.5** (A) Epiretinal membranes originating together with neovascularizations from the optic disc and the temporal vascular arcade. (B) Two posterior starfolds and inferior retinal detachment under silicone complicating rhegmatogenous retinal detachment. (C) Subretinal strand detaching formerly attached retina from the periphery to the posterior pole of the eye.

Macular pucker has some cellular features in common with PVR

but is usually not classified as this entity. It is not classically associated with retinal breaks and usually not complicated by retinal detachment. Macular pucker has a much better overall prognosis compared with PVR, even though it often compromises central vision. The formation of abnormal membranes on the outer retinal surface is clinically known as subretinal fibrosis. Subretinal fibrosis can disrupt the normal intercellular relationship between the photoreceptors and RPE, thus preventing the regeneration of photoreceptor outer segments after reattachment. (For more details see [Chapter 101](#), Pathogenesis of proliferative vitreoretinopathy.)

In advanced proliferative diabetic retinopathy, combined tractional–rhegmatogenous retinal detachments generally start as tractional retinal detachments that are secondarily complicated by posterior retinal breaks. At this stage, they often have the appearance of a mobile retina with a convex surface and may extend to the ora serrata. The retinal break is commonly located near an area of fibrovascular proliferation.

## **Exudative and Hemorrhagic Retinal Detachment**

Retinal detachments can occur in the absence of a retinal break or vitreoretinal traction. These detachments are the result of a collection of subretinal fluid secondary to diseases of the choroid and RPE or of the retina itself. The RPE is largely responsible for the absorption of the subretinal fluid. Normally, the RPE maintains retinal adherence and absorbs subretinal fluid by means of active transport, creation of an osmotic gradient, and, to a lesser degree, hydrostatic forces. Exudative retinal detachments occur when the balance between fluid production and fluid absorption is disrupted, either by damage to the RPE or by excessive fluid production.

Inflammatory diseases and neoplastic lesions are the leading causes of exudative (serous) retinal detachments. Exudative conditions include Vogt–Koyanagi–Harada disease, posterior scleritis, collagen vascular disease, malignant hypertension, sympathetic ophthalmia, preeclampsia, and neoplasms such as malignant melanoma, choroidal hemangioma, and metastatic lesions of the choroid. In

conditions such as central serous chorioretinopathy (idiopathic central serous choroidopathy), the metabolic activity of the RPE can be diffusely compromised,<sup>59</sup> and subretinal fluid is presumably less effectively absorbed. Hyperpermeability of choroidal vessels as demonstrated by indocyanine green angiography are also seen as part of the disease process.<sup>60</sup> Steroids as well as hypercortisolism are risk factors for the development and exacerbation of central serous chorioretinopathy.<sup>61</sup> Retinal vascular diseases, including Coats disease (Fig. 98.6) and familial exudative vitreoretinopathy, may cause excessive production of subretinal fluid and exudates and, consequently, an exudative retinal detachment.<sup>62</sup> Paraproteinemia has been reported to cause serous macular detachment, responding poorly to therapy.<sup>63</sup> “Idiopathic uveal effusion” can produce a serous retinal detachment along with a similar detachment of the choroid, possibly resulting from impaired choroidal venous outflow. This condition when associated with nanophthalmos (mean axial length 16 mm) or high hyperopia (mean +16 diopters) is associated with disorganization of collagen fiber bundles and deposits of proteoglycans in the scleral matrix and can be successfully managed by sclerectomies.<sup>64</sup>

**FIG. 98.6** Exudative retinal detachment: Patient is a

## 12-year-old boy with an extensive exudative retinal detachment due to Coats disease.

Subretinal blood may occur with trauma especially after contusion. Drainage of subretinal blood facilitates retinal RPE apposition, and adequate retinopexy of retinal tears may help to accomplish long-term anatomic attachment in eyes with massive subretinal hemorrhage or bullous retinal detachment.<sup>65</sup> Presumed ocular histoplasmosis syndrome, polypoidal choroidal neovascularization, trauma, and subretinal neovascular membranes, as seen in age-related macular degeneration, may also produce massive hemorrhagic retinal detachment.<sup>55</sup> For the latter the use of anticoagulant medication is a major risk factor, besides high blood pressure and cardiovascular disease.<sup>56</sup> Blood has been proven toxic to the retina and to the retinal pigment epithelium.<sup>66</sup> Displacement of subretinal blood using a gas bubble for subretinal hemorrhage in neovascular age-related macular degeneration decreases the blood's toxicity to the foveal photoreceptors.<sup>67</sup>

A peripheral localization of subretinal hemorrhage is often misinterpreted as choroidal melanoma (pseudomelanoma).<sup>68</sup> Suprachoroidal hemorrhage has been observed after filtering surgery, cataract surgery, trauma, and pars plana vitrectomy.<sup>69,70</sup>

Risk factors for suprachoroidal hemorrhage include high preoperative intraocular pressure, previous retinal detachment, age, gender, and the use antiplatelet or anticoagulant drugs.<sup>69,71</sup>

## Conclusion

Retinal detachment is the result of various conditions that compromise or overwhelm the normal physiologic forces that maintain contact between the retina and the RPE. The retinal detachments can be classified as detachments with and without a tractional component. The major types of detachment with tractional components are rhegmatogenous, tractional, and combined tractional–rhegmatogenous, whereas exudative and hemorrhagic detachments have no tractional component. The mechanisms that lead to the first types of retinal detachment include liquefaction of the vitreous gel and the interaction between

retinal traction and retinal breaks. The mechanism of traction retinal detachment is the vitreoretinal traction that mechanically pulls the retina away from the RPE. The mechanisms for exudative and hemorrhagic retinal detachment involve excessive production of fluid, such as from a neoplasm, reduced RPE function, such as from inflammation, poor outflow, such as with idiopathic uveal effusion syndrome, and blood, such as from choroidal neovascularization. Each type of retinal detachment requires treatment addressing the underlying pathogenic process.

## **Conclusion**

## **Introduction**

A wide variety of diseases may present with sensory retinal detachment without retinal breaks. Nonrhegmatogenous retinal detachment may be exudative in nature or caused by vitreoretinal traction. Some diseases with elevated retina may have both exudative and traction components. Occasionally, communication between the subretinal space and other structures of the eye, such

as the vitreous cavity, may lead to retinal detachment. In exudative retinal detachment, the subretinal fluid may be confined to a localized area, usually the posterior pole, or may extend to the periphery, even forming bullous retinal detachment. The characteristic feature of a significant exudative retinal detachment is the presence of shifting subretinal fluid.<sup>1</sup> The fluid shifts to the most dependent location when patients change body position. The surface of the detached retina is usually smooth; however, retinal folding may occur in some diseases associated with subretinal fibrosis. To reach an accurate diagnosis among many diseases presenting with exudative retinal detachment, careful fundus examination, fluorescein angiography (FA), indocyanine green angiography (ICGA), optical coherence tomography (OCT), ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) may be necessary.

## Pathophysiology

There are three potential sources for fluid accumulation within or under the retina: vitreous fluid, retinal vessels, and choroidal vessels. The main route for vitreous water turnover is by way of the retina, choroid, and the vortex veins. Choriocapillaries of the choroidal circulation, a single-layered capillary structure with numerous fenestrations on the vessel walls, are freely permeable to the intravascular fluid. The main mechanisms for keeping the retina in a dehydrated state are the presence of inner and outer blood–retinal barriers, and the fluid movement across the retinal pigment epithelium (RPE). The inner barrier is made of an endothelial tight junction of the retinal vessels; the outer barrier is produced by the tight junction of retinal pigment epithelial cells. Three mechanisms guarantee the one-way movement of fluid across the RPE: (1) active transport of the RPE; (2) plasma oncotic force, which is higher in the choroidal side; and (3) hydrostatic pressure. Thus, RPE and retinal vascular endothelium are of utmost importance to keep the retina dry in the normal condition. When the RPE is injured, the tight junction may be damaged, causing breakdown of the outer retinal barrier; further, the active transport of fluid may be affected, compromising the unilateral mode of fluid movement. Any disease

capable of significantly increasing the permeability of the choroidal capillaries along with afflicting an injury on the RPE causing breakdown of the outer barrier may result in the accumulation of subretinal fluid. Alternatively, diseases affecting the retinal vascular endothelium causing significant breakdown of the inner barrier may lead to fluid first gathering in the intraretinal space and then gaining access into the subretinal space, if the amount surpasses the intraretinal water retention capacity.

Besides the anatomical structures and physiologic properties restricting fluid entering the subretinal space, adequate fluid outflow is required for the retina to maintain a state of dehydration. There are several outflow pathways that function to drain fluid: vitreoretinal–choroidal outflow carries the vitreous fluid to the RPE and to the choroid through the pumping action of RPE as previously mentioned; the uveoscleral outflow pathway in turn carries the fluid from the choroid to leave the eye through choroidal vortex outflow; transscleral outflow allows protein and fluid draining out through the emissary channels. When diseases cause outflow obstruction, fluid may accumulate in the subretinal space or/and suprachoroidal space, leading to exudative or hemorrhagic retinal detachment or choroidal detachment. In this chapter, commonly encountered disease categories associated with exudative retinal detachment and other nonrhegmatogenous retinal detachment unrelated to traction will be summarized.

## Idiopathic

### Central Serous Chorioretinopathy

Central serous chorioretinopathy (CSC) is a relatively benign retinal disease characterized by a circular area of serous detachment of the posterior retina usually in young and middle-aged healthy persons. While CSC is mostly self-limiting, there are clinical variants of this disease that have atypical presentations and may reduce the vision tremendously. Most of these atypical CSCs or variant CSCs are associated with excessive accumulation of fluid beneath the sensory retina or RPE. These atypical manifestations can be separated into two major categories: acute bullous retinal detachment and chronic

CSC.

## Bullous Retinal Detachment

Some patients with acute bullous retinal detachment (bullous RD) may have the following medical history: long-term corticosteroid taken for systemic diseases, such as systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), or renal or cardiac transplantation; regular taking of herb drugs (some may contain steroid-like ingredients or have steroid added to the drug); or under steroid treatment for presumed Harada disease. Other affected patients do not have a specific history of steroid intake.

Bullous RD usually has an acute onset with simultaneous or sequential involvement of the two eyes. Fundus examinations reveal multiple areas of serous RD in the posterior retina with lower bullous RD. There may be multiple retinal pigment epithelial detachment (RPED) and one or more grayish or yellow patches of subretinal exudates mimicking focal chorioretinitis (Fig. 99.1). In some cases, retinal folds may form by the contraction of fibrinous patches or fibrotic membrane or bands on the outer surface of the detached retina. Small scattered yellowish granular subretinal deposits may have a tendency to settle along the retinal vessels (Fig. 99.2). The vitreous is usually clear, but may have 1–2 plus cells. The disc is not hyperemic.

**FIG. 99.1** Subretinal fibrin-like deposition mimicking chorioretinitis in a case of acute bullous detachment.

**FIG. 99.2** Exudates along retinal vessels in a case of bullous retinal detachment.

FA shows multiple hyperfluorescent spots or patches with late enlargement; intense fluorescein leakage from the edge of the RPE detachment may be seen and correlates with the focal grayish-white or yellow patches seen in the color fundus. Retinal vessels show no leakage.

ICGA shows an ill-defined hyperfluorescent area, which may become more intense in the late phase, suggesting choroidal permeability alteration.

OCT may show retinal pigment epithelial detachment with or without sensory detachment adjacent to or overlying it; the subretinal fluid may be clear or slightly turbid with multiple granular deposits above the RPE and on the outer surface of the detached retina, sometimes forming incomplete septa within the subretinal space (Fig. 99.3); subretinal fibrinous mount with surrounding sensory detachment may be seen.<sup>2</sup> Recent studies show thickened choroid in the involved eyes as well as the fellow eyes.<sup>3,4</sup>

**FIG. 99.3** Optical coherence tomography image in a case of acute bullous detachment showing subretinal incomplete vertical septa.

Complications of bullous RD include large RPE tear; broad retinal folding; submacular plaques or fibrotic bands; peripheral paravascular exudates; and peripheral retinal telangiectasia, occlusion, or even fibrovascular proliferation.<sup>2,5</sup> Peripheral vascular changes may be secondary to longstanding sensory detachment.

In treating bullous RD, systemic steroids should be discontinued; patients should keep the head elevated during sleep to prevent fluid shifting to the macular area; FA-guided laser to the leaking points may decrease the subretinal fluid. Once the fluid level recedes, FA should be repeated to identify persistent leaking points and other leaking sites previously hidden by the detached retina. Multiple sessions of laser treatment are usually needed for complete fluid reabsorption. If subretinal fluid (SRF) persists after the measures described above, external drainage of SRF may be undertaken.<sup>6</sup> Care should be taken to make sure that the surgical drainage site is posterior enough to access the subretinal space, which is in the dependent area. Alternatively, pars plana vitrectomy with perfluorocarbon liquid injection and simultaneous external drainage through anterior sclerotomy may be performed, followed by focal laser to the exposed leaking sites and air–fluid exchange. The effect of vitrectomy with internal drainage and silicone oil tamponade is controversial. Recently, bevacizumab injection has been shown to rapidly reduce active fluid leakage into

the subretinal space as well as to decrease the deposition of fibrinous or proteinaceous substances.<sup>7</sup> Photodynamic therapy (PDT) with reduced fluence may also reduce choroidal hyperpermeability and facilitate subretinal fluid reabsorption with RPE tear being the major complication.<sup>8</sup> Prognosis of bullous RD is variable and is affected by the duration of macular detachment, the presence of submacular fibrosis, the development of submacular RPE tears, and occurrence of fibrovascular proliferation under the macula or in the periphery.

Differential diagnoses of bullous RD include diseases associated with large areas of retinal detachment. Harada disease is the most common disease confused with bullous detachment. Both have bilateral exudative detachment with multiple leaking sites and normal retinal vasculatures. Hyperemic discs, vitreous cells, pinpoint leaking spots, subretinal RPE folding radiating from the disc, choroidal thickening, and the unique OCT pictures showing outer retinal septated spaces containing optically heterogeneous substances favor the diagnosis of Harada disease. Misdiagnosis may lead to the use of steroid and aggravation of bullous RD. The condition may sometimes be mistaken for rhegmatogenous RD and wrongly operated upon. Other causes of unilateral or bilateral exudative RD should be ruled out, such as hypertensive retinopathy, collagen vascular diseases, leukemia, toxemia, choroidal metastasis, uveal effusion, posterior scleritis, multifocal choroiditis (tuberculosis, syphilis, Lyme), chorioretinitis, sarcoidosis, and lymphoma. Polypoidal choroidal vasculopathy (PCV) may mimic CSC, and severe PCV without subretinal hemorrhage may have similar manifestations to bullous detachment.

### **Chronic Central Serous Chorioretinopathy**

Because of the characteristic angiographic picture of multiple areas of RPE disturbance with late staining or mild leakage, the condition is also named RPE decompensation, diffuse retinal pigment epitheliopathy. This entity should not be confused with typical CSC with persistent subretinal fluid. It is more commonly seen in middle-aged patients of Hispanic or Asian extraction. Personal and medical history may elicit chronic steroid usage.

Typical clinical manifestation is multiple poorly defined areas of chronic persistent or recurrent retinal detachment in the posterior pole. Subtle or obvious areas of RPE changes are noted in the posterior pole and in the juxtapapillary regions; a gravity tract-forming vertical band or reverse funnel-shaped depigmentation, along with pigment migration or bone-spicule pattern of pigmentary changes within the tract and in the inferior part of the retina, are usually found (Fig. 99.4); shallow or bullous detachment in the inferior retina is a frequent finding.

**FIG. 99.4** Retinal pigment epithelium changes and gravity tract in a case of chronic central serous chorioretinopathy.

FA may show patchy hyperfluorescent areas or mottled hyperfluorescent areas corresponding to, and more obvious than, those areas of pigmentary changes found ophthalmoscopically. These areas may show late dye leakage or staining of different degrees. Round enlarging spots or jet spots commonly seen in typical CSC may be noticed within or in between the hyperfluorescent areas. Band- or reverse funnel-shaped gravity tracts of window defect changes are usually present. Peripheral vessels within the area of retinal detachment may show leakage, vascular occlusion, or neovascularization.

OCT examination may reveal subretinal fluid under the macula or several areas of retinal detachment separated by attached retina; some may have localized submacular fluid similar to acute CSC.

There may be cystic changes in the overlying retina, suggesting a chronic condition.

Photocoagulation remains the main treatment method. Conventional laser or the more recently developed micropulse laser to leaking points and areas of RPE changes with late fluorescein staining and leakage may stop the leakage.<sup>9</sup> PDT with reduced fluence has been advocated to treat leaking points and areas with late oozing shown on FA with good effect. Intravitreal bevacizumab has also been shown to have some therapeutic effect.<sup>10</sup> However, the prognosis is guarded because of multiple recurrence and permanent macular RPE disturbance.

## Uveal Effusion Syndrome

Patients with idiopathic uveal effusion syndrome (IUES) are usually middle-aged men with normal ocular size, presenting with unilateral or bilateral serous choroidal, ciliary, and retinal detachment. There may be central vision decrease or distortion secondary to macular serous detachment or upper visual field defect from lower serous retinal detachment. External eye examination may reveal episcleral vessel dilation; the anterior chamber is usually free of cells; intraocular pressure (IOP) is normal; there may be blood in the Schlemm's canal; and vitreous cells are common findings. Initial disease severity ranges from macular serous detachment with insignificant ciliary and choroidal detachment to obvious ciliochoroidal detachment and bullous retinal detachment. The protein concentration of the subretinal fluid is 2.5–3 times that of the normal plasma. The fellow eye may be affected within a few weeks or a few months after lesions developed in the first eye. The disease may have a protracted course, with wax and wane of the subretinal fluid, eventually leaving areas of mixed RPE atrophy and pigment clumps in a leopard-spot pattern. Some patients may develop a yellowish plaque of exudation in the macular area or severe chorioretinal degeneration causing visual field loss.

FA may not show specific leaking points in the early stage of the disease. As disease progresses FA may highlight the leopard-spot pattern, which was not obvious in fundus examination; choroidal

perfusion may be slow, and focal leaking areas in multiple places may be seen.

Ultrasonography or ultrasound biomicroscopy (UBM) can clearly demonstrate ciliochoroidal detachment, and usually form an annular pattern in the periphery, even before detectable fundus changes. There is no thickened sclera and sub-Tenon fluid adjacent to the optic nerve to form the classic T-sign of the posterior ocular coat typical of posterior scleritis.

Histopathologic examination shows accumulation of protein-rich extracellular materials in the suprachoroidal and subretinal spaces. Choroidal vessels are dilated without inflammatory cell infiltration. Subarachnoid space around the optic disc is enlarged. The sclera shows deranged fibers with deposition of glycosaminoglycans within.<sup>11</sup> Cell culture of the scleral cells reveals intracellular deposition of a glycogen-like substance.<sup>12</sup> Histopathologic studies have shown disorganization of collagen fiber bundles and variation in size of collagen fibrils in nanophthalmic eyes and eyes with short axial length.<sup>11,13</sup> A loss of chondroitin sulfate proteoglycan was observed in nanophthalmic sclerae. This alteration may be related to the abnormal organization of collagen fibrils.<sup>13</sup>

The pathogenesis is unclear, possibly related to congenital anomaly of the sclera and vortex veins hypoplasia. Excessive glycosaminoglycans accumulate within the sclera, combined with defective vortex veins, resulting in decreased drainage of extravasated protein through scleral emissary channels of the transscleral outflow pathway; fluid drainage is also compromised from the decreased function of uveoscleral outflow pathways, leading to excessive protein and fluid accumulation in the suprachoroidal space. Later on, the protein and fluid enter the subretinal space when the extracellular protein concentration becomes equal to that within the vessels. Protein in the suprachoroidal space around the disc may gain access to the subarachnoid space and subdural space resulting in an increase in the CSF protein content even without pleocytosis in 50% of the patients.<sup>14</sup> Forrester and associates believe that IUES is a kind of ocular mucopolysaccharidosis, with the initial defect resting in the proteodermatan synthesis and/or degradation by the scleral fibroblasts.<sup>15</sup> Other evidence also shows that abnormal

mucopolysaccharides of the sclera play an important role in the pathogenesis of IUES. IOP is usually within normal limits because the IOP rising tendency from uveoscleral outflow obstruction is neutralized by decreased aqueous production from the ciliochoroidal detachment.

Best treatment methods have been debated. Vortex vein decompression with scleral resection was initially advocated to treat uveal effusion associated with nanophthalmos. Gass believed that the treatment effect had less to do with vortex vein decompression than with scleral resection to facilitate protein and fluid drainage through the sclera.<sup>16</sup> He suggested partial-thickness sclerectomies or full-thickness sclerectomies. After treatment, exudation may gradually disappear within a few months (Fig. 99.5). However, chorioretinal degeneration may continue to develop from chronic mild recurrence of exudation or abnormal metabolism of mucopolysaccharide.

**FIG. 99.5** Bullous retinal detachment (A) and multiple subretinal yellow patches (B) in a 36-year-old nanophthalmos patient. One year after sclerectomy in two quadrants, the retina became flat and showed similar yellow patches as the fellow eye (C). The fellow eye had the same changes as the other did one year ago (D).

Other diseases capable of causing uveal effusion include nanophthalmos, dural arteriovenous fistula, scleritis, Harada disease, diffuse tumors of the uveal tract, prolonged hypotony, etc.

Leopard-spot pigmentation may appear in systemic large cell lymphoma, leukemia, bilateral uveal melanocytic proliferation, and organ transplant chorioretinopathy.

## Vascular

## Coats Disease

This is a nonfamilial developmental retinal vasculopathy. The disease is more common in males, is usually unilaterally affected, and may occur in infants. Symptoms often develop in children or young adults; one-third had symptoms onset over 30 years of age. All vessels – arteries and veins alike – would be affected, showing telangiectasis combined with a large amount of hard exudates; hemorrhagic retinopathy is occasionally seen. On the other hand, a minor form of the disease mainly involving juxtafoveolar areas may occur; decreased vision will not occur until adulthood when hard exudates and edema develop in the macula. The prognosis is directly influenced by the size of the involved area. Occasionally, other vascular anomalies may appear in the lesion eye or the fellow eye, such as macular macrovessels or arterial tortuosity (Fig. 99.6). The condition may be occasionally associated with other abnormalities such as progressive facial hemiatrophy, facial scapulohumeral muscular dystrophy and deafness, or Alport syndrome.<sup>17</sup> It may rarely accompany systemic vascular anomalies.

**FIG. 99.6** Retinal arterial tortuosity in a case of Coats disease. The fundus picture shows dense macular exudates with submacular fibrosis, retinochoroidal anastomosis, indicated by arrowheads.

Fundus examinations reveal changes of various severities. The mild form presents with focal telangiectasia and microaneurysms, usually at the temporal side of the macula, with or without mild hard exudates. The moderate form ranges from cystoid macular

edema with significant hard exudates surrounding the area containing telangiectatic vessels or microaneurysms, to the more extensive vascular abnormalities with massive exudates which may gain access to the subretinal space. The severe form shows wide and scattered vascular lesions, with hard exudates accumulating around the disc and in the posterior pole, causing exudative detachment. The macula may be detached with massive intraretinal and subretinal exudates, which later may transform to organized subretinal disciform mass or atrophic scar. These changes are likely to be found in infants and children, who visit the ophthalmic clinic because of manifest strabismus secondary to unilateral poor vision or abnormal red reflex from massive exudates in the posterior pole. The accumulation of exudates in the macula may be due to gravity-induced migration of subretinal exudates toward the central area during sleep. The deposition of lipid-rich substance along with macrophage evolves into fibrous tissue. Retinal or choroidal vessels may grow into the lesion to form a disciform scar. The most advanced form presents with bullous detachment with the retina coming in direct contact with the crystalline lens; cholesterol crystals accumulate in the subretinal space.<sup>18</sup> There may be dilated abnormal vessels, hard exudates, or hemorrhage on the surface or in the retina. However, the abnormal tortuous vessels do not dip into the subretinal space, a sign typical of exophytic retinoblastoma.

FA clearly demonstrates aneurysmal dilatation of retinal vessels, including arteries, veins, and capillaries; capillary nonperfusion is also obvious. Normal-appearing vessels do not show dye leakage. Cystoid macular edema may be noted.

The clinical course varies. The macula may not be involved initially until later in life if the lesions are peripherally located, especially in the lower part of the retina. Retinal neovascularization is uncommon despite a wide area of capillary nonperfusion. However, some severe cases develop increasing capillary nonperfusion leading to neovascularization with subsequent vitreous hemorrhage, vitreous membrane formation, exudative and tractional retinal detachment, and neovascular glaucoma, resulting in no light perception; others may develop intraocular inflammation or even acute orbital cellulitis secondary to stimulation from toxic products. Some patients develop mid-

peripheral or peripheral elevated, organized exudative nodule or mass, yellowish in color and mixed with hemorrhagic patches, similar to granuloma, exophytic retinal capillary hemangioma or melanoma (Fig. 99.7). Occasionally, spontaneous resolution may occur.

**FIG. 99.7** Mid-peripheral elevated exudative nodule surrounded by massive exudates in a 17-year-old boy with Coats disease.

Histopathologic studies show irregular dilation of affected retinal arteries, veins, and capillaries; PAS-positive exudates may be seen in the outer retinal layer; lipid-laden macrophages are seen in the outer retina and the subretinal space. In the severe form of the disease in infants, severe vascular endothelial proliferation and hemorrhagic infarction may be observed. Genetic testing has revealed a somatic mutation on the *NDP* gene on chromosome Xp11.2.

Treatment usually involves laser or cryotherapy aiming at the lesions to decrease exudates and preserve vision (Fig. 99.8). For severe exudative detachment, external drainage should be performed first, followed by cryotherapy to the abnormal vessels. Scleral buckling may facilitate retinal reattachment, enhance the effect of cryotherapy, and promote regression of abnormal vessels. However, new lesions may develop in nearby or remote areas. Follow-up is crucial to detect and treat new lesions. Sector panretinal photocoagulation (PRP) may be used for a nonperfusion

area. For severe cases, vitrectomy to release vitreous traction with external subretinal fluid drainage, laser, or cryo may be considered. Recently, repeated intravitreal injection of bevacizumab has been reported to reduce subretinal fluid, facilitating subsequent laser or cryotherapy.<sup>19</sup>

**FIG. 99.8** (A) Coats disease. (B) Resolution of hard exudates 1 year after peripheral cryotherapy to the abnormal vascular structures.

Differential diagnoses include all possible causes of white pupil in infants. Localized telangiectasis associated with arterial and venous aneurysms and exudates may be similar to cavernous hemangioma of the retina, acquired retinal macroaneurysm, old branch retinal vein occlusion, bilateral idiopathic retinitis, vasculitis, aneurysms, and neuroretinitis (IRVAN).

## Accelerated Hypertension and Pregnancy-Induced Hypertension

Prolonged or severe hypertension may damage the retinal vascular system, choroidal circulation, and disc circulation. The difference in vascular structures, autoregulation, and tissue resistance determines the different susceptibility of these three systems to increased blood pressure. Although leakage from retinal vessels and the optic disc may be a source of subretinal fluid, hypertension-induced choroidopathy is the main category that causes exudative retinal detachment.

While chronic moderate hypertension is rarely associated with choroidopathy, choroidal ischemia is more frequently associated with accelerated hypertension. Unlike retinal circulation, choroidal vessels do not possess autoregulation; the blood flow during fluctuation of systemic blood pressure is mainly regulated by sympathetic tone. When blood pressure is high, raised sympathetic tone can prevent direct pressure damage to the choriocapillaries; however, if there is a rapid rise in blood pressure, excessively increased sympathetic tone may prompt severe constriction of choroidal arteries and arterioles, leading to ischemic changes of the choriocapillaries. Choroidopathy may be separated into three stages: (1) acute ischemic phase; (2) chronic occlusive phase; and (3) chronic reparative phase.<sup>20</sup> In the first two phases, fundus examination may observe white or reddish patches in the outer retina, possibly caused by RPE necrosis; exudative detachment is often present. FA may show a large confluent area or scattered areas of choroidal filling delay; in the mid and late phases, multiple dots or a mosaic pattern of hyperfluorescence from RPE leakage may be seen. In the reparative phase, large areas of irregular RPE atrophy, Elschnig spots (a central hyperpigmented lesion surrounded by a hypopigmented ring of RPE changes), or Siegrist spots (spots of pigmentary changes similar to Elschnig spots arranged linearly along choroidal vessels in the equatorial region) may be seen; exudative detachment disappears, but choroidal delayed filling remains.

## Pregnancy-Induced Hypertension

About 1–2% of pregnant women who develop severe hypertension, proteinuria, and edema during the third trimester suffer from vision impairment secondary to exudative retinal detachment. Exudative detachment may be limited to the macular area or appear as bullous detachment. The retina may or may not show cotton-wool patches or other changes secondary to hypertension retinopathy (Fig. 99.9). Yellowish-white patches of RPE necrosis may be seen. FA shows delayed choroidal filling and multiple leaking points where RPE has been damaged. After delivery, with control of hypertension, exudative detachment rapidly subsides.

Most patients have good visual recovery. The posterior pole may show RPE changes forming hyperpigmented lines or patches mixed with yellow spots of RPE atrophy. The bilateral changes may be mistaken for macular dystrophy. Severe cases may have extensive exudative detachment. Widespread RPE changes similar to tapetoretinal dystrophy and severely compromised vision may result. The cause of chorioretinal changes in pregnancy-induced hypertension is not clear. Blood pressure may not be very high before the onset of exudative detachment. Affected patients may have other symptoms and signs related to disseminated intravascular coagulation, such as hemolysis, low platelet count, and elevation of liver enzymes. It is possible that mechanisms capable of inducing disseminated intravascular coagulation (see below) are also functional in the choroid, causing choroidal ischemia, RPE damage, and exudative detachment.

**FIG. 99.9** Color photograph (A) and fluorescein angiography image (B) showing exudative retinal detachment and multiple subretinal yellow patches in a case of pregnancy-induced hypertension.

## Diabetic Retinopathy

Severe diabetic macular edema (DME) may sometimes accompany localized macular detachment. Fluid leaking out from the vessels first accumulates within the retina; beyond a certain critical point, fluid may gain access into the subretinal space causing sensory

detachment. Severe macular edema not only leads to detachment but may be associated with massive hard exudates (Fig. 99.10). Hard exudates are one of the independent risk factors for vision decrease.<sup>21</sup> In addition to vascular hyperpermeability related to diabetic vasculopathy, taut posterior hyaloid membrane may also contribute to macular edema and localized detachment either from the mechanical traction force or from traction-induced increased vascular permeability.

**FIG. 99.10** Color photograph (A) and optical coherence tomography image (B) showing massive hard exudates with macular cystic changes and sensory retinal detachment in diabetic retinopathy.

Clinically, early fundus changes leading to severe macular edema may present as a central retinal vein occlusion-like picture with flame-shaped hemorrhage around the disc and scattered perivascular exudates but without FA evidence of disc leakage and venous delayed filling. In other cases, multiple clusters of microaneurysms may distribute in the posterior pole, accompanied by significant capillary nonperfusion. Sensory detachment and massive exudates may later develop. Exudative detachment combined with macular edema represents severe breakdown of the

inner retinal barrier. Laser alone has little effect in such cases. Multiple sessions of intravitreal anti-VEGF (vascular endothelial growth factors) alone or in combination with sub-Tenon or intravitreal steroid administration may effectively flatten down the retina in most cases. It has not been confirmed if subsequent focal laser to the leaking vascular segments or microaneurysms may obtain a more lasting effect. However, the Diabetic Retinopathy Clinical Research Network, as well as other multicenter clinical studies, showed no additional effect of focal laser compared with multiple sessions of intravitreal anti-VEGF using the studies' protocol in treating DME.<sup>22-26</sup> In some cases, exudative detachment is present without significant cystoid macular edema. It may be because the edema is in a resolving phase; thus the response to treatment may be quicker. In severe cases, exudates may consolidate and deposit within or below the macula. If the condition does not improve after several sessions of medical treatment, pars plana vitrectomy combined with hyaloid membrane and internal limiting membrane removal may be performed to reduce edema and hard exudates (Fig. 99.11).<sup>27</sup> Because the development of massive hard exudates indicates that the retina is in a relatively hypoxic state or has already gone into the early proliferative stage, panretinal photocoagulation during the operation is required to inhibit production of angiogenic factors, which may induce further macular edema or neovascularization, leading to postoperative vitreous hemorrhage or even neovascular glaucoma.<sup>27</sup> In the case of preexisting posterior vitreous detachment, epiretinal membrane peeling and internal limiting membrane peeling may be considered.<sup>28</sup> Massive exudates usually form submacular plaques, affecting vision severely. After surgery, the plaque may reduce in size but does not disappear completely, leaving residual fibrosis or crystal-like deposition, causing permanent decrease of vision. Surgical removal of subretinal exudates through iatrogenic retinotomy has been reported;<sup>29</sup> the effect has not been firmly established. Patients with severe edema should have a systemic check-up, including blood pressure, blood lipid, and renal function; any abnormalities should be treated, as these may interfere with local response to the treatment.

**FIG. 99.11** (A) Excessive hard exudates in a case of diabetic retinopathy. (B) Reabsorption of hard exudates 8 months after vitrectomy, posterior hyaloid removal, and scattered laser. Best-corrected visual acuity improved from 20/800 to 20/200.

## Vascular Occlusive Diseases

Severe retinal vein occlusion occasionally is accompanied by serous retinal detachment. Exudative detachment has been described in branch, hemispherical, and central retinal vein occlusion (CRVO). Vascular leakage from congested retinal veins outside the macular area is the major source of subretinal fluid at the fovea. In addition, ischemic retina produces angiogenic factors, such as VEGF, which in turn increase vascular permeability. Both increased intravascular pressure and vascular permeability cause leakage of fluid and blood components into the subretinal space. In eyes with retinal vein occlusion, serous RD is typically located beneath the fovea, and the height of the RD was greatest in the fovea (Fig. 99.12).

**FIG. 99.12** Color photograph (A) and optical coherence tomography image (B) showing central retinal vein occlusion with marked macular edema and localized sensory macular detachment.

Recent studies with OCT revealed that macular serous retinal detachment is a common complication of retinal vein occlusion. Serous RD secondary to branch retinal vein occlusion was first described by Spaide et al.<sup>30</sup> Of the 14 eyes included in that study, 10 (71.4%) had serous RD. Yamaguchi et al. studied 109 eyes with branch retinal vein occlusion (BRVO) by OCT examination, and found that the incidence of serous RD was higher in the group with major BRVO (63%) than in the group with macular BRVO (21%).<sup>31</sup> Ozdemir et al. found a high incidence (81.8%) of serous macular detachment in CRVO.<sup>32</sup> In a series of 91 patients with retinal vein occlusion examined by OCT, Tsujikawa et al. reported that 76 eyes (83.5%) had serous RD involving the fovea.<sup>33</sup> They suggested from their observations that in eyes with retinal vein occlusion a small pointed RD developed initially just beneath the fovea, but subsequently changed into a dome-shaped RD; the foveal architecture, especially that of the Müller cell cone, might be involved in the formation of serous RD.

Application of laser photocoagulation to the affected area of

branch retinal vein occlusion has been reported to treat serous RD and can lead to resolution of subretinal fluid. The beneficial effect of laser treatment may be due to the ablation of ischemic retina, decrease of the production of VEGF, closure of incompetent vessels, and stimulation of RPE to enhance the reabsorption of fluid. Intravitreal injection of bevacizumab, ranibizumab, triamcinolone, and Ozurdex has been reported to treat serous RD due to retinal vein occlusion;<sup>34-38</sup> repeated injection may be necessary for frequent recurrence of macular edema. Laser or surgical instrument-induced chorioretinal anastomosis has been reported to achieve resolution of macular edema;<sup>39-41</sup> vitrectomy with ILM peeling has also been used with variable results.<sup>42,43</sup>

The visual prognosis of serous RD in retinal vein occlusion is variable. In an eye with serous RD associated with retinal vein occlusion, the outer retinal discontinuity does not necessarily lead to poor vision. If the surrounding outer segment of the foveal photoreceptors is preserved, good visual acuity will retain after macular edema and serous RD resolve. However, even after complete resolution of the macular edema and serous RD, diffuse disorganization of the outer photoreceptor layer beneath the fovea often results in poor visual acuity (see [Fig. 99.13](#) online). In addition, a dome-shaped RD sometimes accompanies a focal defect of the outer segment of the photoreceptors above the serous RD. When the defect involves the fovea, visual prognosis is usually poor.

**FIG. 99.13** (A,B) Fundus photograph and optical coherence tomography image showing severe macular edema in a case of nonischemic central retinal vein occlusion. (C,D) Resolution of macular edema after intravitreal bevacizumab 1.25 mg twice and posterior sub-Tenon triamcinolone acetate 40 mg.

## Collagen Vascular Diseases

Collagen vascular diseases such as systemic lupus chorioretinopathy during exacerbation of the disease activity may show similar choroidopathy and retinopathy as hypertension-induced changes. Blood pressure may or may not be high. Exudative detachment may develop secondary to breakdown of outer retinal barriers from RPE damage. It should be noticed that exudative detachment can also appear during the quiescent phase of the disease when large doses of steroid treatment have been given, similar to CSC with bullous RD. While steroid should be used in the first condition, it should be withheld or reduced when a CSC-like condition develops.

## Inflammatory and Infectious

### Vogt–Koyanagi–Harada Syndrome

Vogt–Koyanagi–Harada (VKH) syndrome is a multisystem

inflammatory disease capable of causing neurologic, ocular, and cutaneous symptoms. The ocular involvement includes anterior and posterior uveitis. Multiple serous retinal detachments (SRD) with congested disc is the typical finding. Bullous retinal detachment may appear in severe cases. VKH has been found to be linked with human leukocyte antigen DR4 (HLA-DR4) and HLA-DRw53, with strongest associated risk for HLA-DRB1\*0405 haplotype.

These associations are high in many populations, including Japanese, Hispanic, Korean, Indian, Italian, Mexican, and Chinese.<sup>44</sup>

The course of VKH includes three phases: acute, convalescent, and chronic phases. The presentation of VKH usually starts with headache, associated with or followed by red eye, blurred vision, tinnitus, and vertigo. Ophthalmic signs include anterior chamber and vitreous cellular reaction and multiple patchy SRD or bullous detachment. In mild form, the vitreous cells are scanty; only mild choroidal folding with slightly hyperemic disc may be seen. The symptoms of headache along with disc edema and mild pleocytosis in cerebral spinal fluid may be mistakenly diagnosed as aseptic meningitis.

FA shows an early patchy choroidal hypofluorescent area with later multiple pinpoint leakage and dye pooling, usually forming multiple lobulated pattern. The early hypofluorescence and late hyperfluorescence of the scattered mildly elevated yellowish-white lesions may resemble acute posterior multifocal placoid pigment epitheliopathy. ICGA may show early hyperfluorescent choroidal stromal vessels, hypofluorescent dark dots in the intermittent phase, and diffuse late choroidal hyperfluorescence.<sup>45</sup> The hypofluorescent dark dots most probably represent the inflammatory foci. In longstanding VKH disease, 75% of patients have such persistent disease-related choroidal inflammation shown in ICGA.<sup>45,46</sup>

OCT has unique features. In addition to the usual pattern of subretinal fluid accumulation, the subretinal space may develop cystic spaces external to the external limiting membrane (Fig. 99.14); the floors of the cystoid spaces consist mainly of a membranous structure, continuous with the line representing the junction of the photoreceptor inner and outer segments in attached areas. It has

been suggested the membranous structures are composed not only of inflammatory products, but also of retinal tissue, probably the outer segment. The inner choroid may have a wavy appearance.

**FIG. 99.14** Color photograph (A) in a case of Vogt–Koyanagi–Harada syndrome showing exudative retinal detachment in the posterior pole. Optical coherence tomography image (B) showing multilobulated sensory detachment and cysts formation in the outer retinal area.

The treatment of choice in acute stage is high-dose corticosteroid. Some advocate the use of pulse therapy with methylprednisolone 1 g daily in divided doses followed by gradual tapering over 2–3 months. Insufficient dosage may result in more frequent relapse of the disease. When steroid is tapered too early or too fast, recurrence of serous detachment may occur. Restarting high-dose steroid or supplementary periocular injection of triamcinolone may be required. In severe cases of VKH, immunosuppressive treatment may be needed. The prognosis is usually good unless there is chronic inflammation or choroidal neovascularization (CNV).

In the convalescent stage there may be skin and hair changes, including hair loss, alopecia, and vitiligo 2–3 months after the disease onset. Sunset glow appearance of the fundus, which

indicates diffuse loss of melanin pigment in the RPE and the choroid, may develop. Pigmented lines radiating from the disc after the subsidence of choroidal thickening indicate previous acute inflammation (Fig. 99.15). Scattered punched-out whitish lesions in the peripheral retina (corresponding to the histologic diagnosis of Dalen–Fuchs nodules) are often visible. Recurrence after the convalescent stage usually takes the form of chronic iritis instead of exudative detachment. Subfoveal CNV may occur in around 2% of patients with VKH and may require intravitreal injection of an anti-VEGF agent.

**FIG. 99.15** Fluorescein angiography highlighting the radiating pigmented line in a case of convalescent Vogt–Koyanagi–Harada syndrome.

Around 10–20% of VKH may evolve into chronic inflammation. Chronic inflammation manifests as chronic anterior uveitis in most cases. The management of chronic VKH frequently involves the use of cyclosporine. It is the chronic anterior uveitis that results in most of the complications from this disease, such as cataract and glaucoma.

## Sympathetic Ophthalmia

Sympathetic ophthalmia (SO) is a bilateral granulomatous uveitis that occurs after ocular trauma or intraocular surgery to an eye. The disease incidence is about 0.3% of eyes with nonsurgical ocular wounds; it is 0.01% for surgical wounds. The inflammation may

develop in the contralateral sympathizing eye as early as 2 weeks after trauma to the initial exciting eye. About half of the cases develop this disorder within 1 year after injury. In surgically induced SO, although this disorder is more likely to occur in eyes suffering from multiple intraocular surgeries for complicated vitreoretinal lesions, simple transscleral subretinal fluid drainage procedure has been reported to be associated with SO.<sup>47</sup>

SO has various types of fundus changes, from one similar to multifocal choroiditis with minimal subretinal fluid to one resembling VKH with evident exudative detachment. The clinical course and treatment response resemble those of VKH in many aspects.

The presenting symptoms include blurred vision, especially accommodation deficit-associated near vision reduction, redness, and ocular pain. The classic clinical signs include cells in the anterior and posterior chambers, multiple patchy or confluent serous detachments, and peripheral scattered cream-colored patches corresponding to Dalen–Fuchs nodules. FA also shows early multiple pinpoint leakage and late subretinal pooling. At the convalescent stage, skin and hair changes can also appear. The mainstay of treatment is corticosteroid. In corticosteroid-resistant cases, immunosuppressive agents may be required. Choroidal neovascular membrane can occur at the late stage. The treatment of choice for CNV is anti-VEGF agents.

## Posterior Scleritis

The presenting symptoms of posterior scleritis are blurred vision and ocular pain associated with eye movement. Clinical signs include serous retinal detachment, choroidal folding on fundus examination, multiple pinpoint leakage in FA, and the pathognomonic T-sign by ultrasonography. When there is additional disc swelling and proptosis, CT scan or MRI should be performed to rule out pseudotumor. In rare conditions, posterior scleritis may present with solitary mass instead of diffuse scleritis.<sup>48</sup>

Posterior scleritis is a subgroup of scleritis, which also includes anterior scleritis. The etiology and treatment of posterior scleritis are similar to those of anterior scleritis, except that the anterior

necrotizing type is very rare in posterior scleritis. Reports from most university or tertiary referral centers found that about half of the scleritis cases were associated with systemic diseases.

Rheumatoid arthritis is the most commonly associated systemic disease, followed by Wegener granulomatosis and relapsing polychondritis. In community-based referral practice, one-third of the scleritis cases are associated with systemic diseases; most develop after the diagnosis of the systemic disease. Rheumatoid arthritis is the leading cause, with spondyloarthropathy and infectious origin being the second and the third most common etiologies.<sup>49</sup> Other systemic diseases associated with scleritis include: Cogan syndrome, herpes simplex and zoster, aspergillosis, inflammatory bowel disease, and sarcoidosis.

Topical corticosteroid only is successful in controlling scleritis in less than 10% of cases. Noninfectious, non-necrotizing scleritis should be initially treated with topical corticosteroids and oral nonsteroidal antiinflammatory drugs (NSAIDs). Patients with necrotizing scleritis or those with non-necrotizing scleritis recalcitrant to NSAIDs are often started on oral prednisone. If the patient does not respond to the treatment within a month, immunomodulatory therapy (IMT) may be introduced. Steroid-sparing IMT may include antimetabolites (i.e., methotrexate, azathioprine, and mycophenolate mofetil); alkylating agents (i.e., chlorambucil and cyclophosphamide); T-cell inhibitors (i.e., cyclosporine and tacrolimus); tumor necrosis factor-alpha inhibitors (i.e., infliximab or adalimumab), and rituximab – a chimeric monoclonal antibody against CD-20 found on B cells. Subconjunctival and sub-Tenon triamcinolone injections are another therapeutic alternative.<sup>50</sup>

## Infections Associated With Exudative Detachment

Many pathogens, including bacteria, rickettsia, fungus, and viruses have been reported to be able to infect either the choroid or the retina and result in exudative retinal detachment. Increased choroidal vascular permeability from infection-induced inflammation is the major reason for the fluid accumulation. The

visual recovery after appropriate treatment varies.

## Bacterial Infection

Syphilis, *Mycobacterium tuberculosis*, cat scratch disease from *Bartonella henselae*, and brucellosis have been reported to cause exudative retinal detachment.

Ocular syphilis may sometimes be concurrent with human immunodeficiency virus (HIV) infection, leading to a more violent and destructive course.<sup>51</sup> Ocular syphilis with or without concurrent HIV infection may be associated with exudative retinal detachment.

Exudative retinal detachment may be seen in severe cases of intraocular tuberculosis. Subretinal neovascularization may later develop and result in choroidal hemorrhage in some cases.

Peripapillary serous retinal detachment and central serous chorioretinopathy-like manifestations have been reported in patients with cat scratch syndrome.<sup>52</sup> The exudates may be absorbed spontaneously, with or without antibiotic treatment, but some severe neuroretinitis cases may be left with optic disc pallor, abnormal color sensation, and a relative afferent papillary defect.<sup>53</sup>

Brucellosis invading the eye is rare, but every structure of the eye could be involved by the disease. The clinical presentations are visual loss, optic disc edema, and serous retinal detachment.<sup>54</sup>

## Fungal Infection

Ocular fungal infection usually comes from systemic fungemia, which causes multifocal choroiditis. In ocular fungal infection, serous and hemorrhagic retinal detachments have been found. In some diabetic or immunocompromised patients, mucormycosis may be a fatal fungal infection. Severe rhino-orbital mucormycosis complicated by serous retinal detachment and retinal necrosis has been reported.<sup>55</sup>

## Viral Infection

The most common viruses capable of causing serous retinal detachment belong to the herpesvirus family. The *Herpesviridae*

induce acute retinal necrosis, vitritis, retinal arteritis, retinal hemorrhage, exudative retinal detachment, and optic neuropathy. Cytomegalovirus (CMV) retinitis usually occurs in HIV-infected patients. CMV retinitis may also have simultaneous rhegmatogenous and exudative retinal detachment.<sup>56</sup>

## Other Infections

Ocular toxoplasmosis is caused by *Toxoplasma gondii*, which is a cosmopolitan protozoan parasite. Clinically, ocular toxoplasmosis may cause retinal vasculitis and focal necrotizing retinochoroiditis, which presents as an oval or circular yellow-white elevated lesion with overlying vitritis. In nearly half of ocular toxoplasmosis cases, serous retinal detachment occurs during active toxoplasmic retinochoroiditis and responds well to conventional therapy, regardless of the total fluid volume.<sup>57</sup> Q fever is a zoonosis caused by infection with *Coxiella burnetii* (*Rickettsia burnetii*), a strictly intracellular organism. Q fever might alter immune system and induce autoimmunoreactive disease. Therefore, it could unleash VKH syndrome or simulate a VKH syndrome via a similar immunologic process and result in exudative retinal detachment.<sup>58</sup>

## Degenerative

### Age-Related Macular Degeneration and Polypoidal Choroidal Vasculopathy

In age-related macular degeneration (AMD) with CNV, serous and hemorrhagic detachment of the retina occurs frequently. The neovascular membrane causes leakage of serous exudates and red blood cells into the sub-RPE space and subsequently into the subsensory retinal space. Fundus examination typically reveals a light-grayish elevated mass corresponding to a serous and hemorrhagic detachment of the RPE and sensory retina. This mass-like lesion should be differentiated from choroidal melanoma. FA is helpful in the differential diagnosis. In AMD with CNV, the new vessels leak and present as a hyperfluorescent area, and the hemorrhagic lesion shows hypofluorescence because it is blocked

by the subretinal blood. A melanoma shows mottled hyperfluorescence in the early phase and increased staining in the late phase. In addition, a mass-like lesion induced by CNV tends to change configurations within a short period of time. A disciform scar eventually evolves from CNV with massive exudates. Extensive hemorrhagic macular detachment may lead to a breakthrough vitreous hemorrhage; the color of the vitreous opacity tends to be yellow instead of red, indicating the presence of old blood or blood degeneration products in the vitreous. In rare cases, massive hemorrhage from active lesion or disciform scar may cause severe hemorrhagic choroidal and retinal detachment (Fig. 99.16).

**FIG. 99.16** Massive subretinal, sub-RPE (retinal pigment epithelium), and suprachoroidal hemorrhage in a case of age-related macular degeneration.

Polypoidal choroidal vasculopathy has been recognized recently as a distinct exudative macular disorder.<sup>59</sup> It is generally thought to be a primary choroidal vascular abnormality characterized by two distinct components: a complex of branching vascular networks and multiple, terminal, reddish-orange, aneurysms, or polypoidal lesions. Clinically, PCV shows multiple, recurrent serosanguineous detachments of the RPE and neurosensory retina secondary to leakage and bleeding from choroidal vascular lesions (Fig. 99.17).<sup>60</sup> It may be a cause of severe hemorrhagic choroidal and retinal detachment. Whether PCV is a variant of exudative AMD has not been definitively determined. However, there are significant

differences between PCV and exudative AMD in the demographic profile, fundus pictures, natural history, visual outcomes, and response to different treatment modalities. ICGA to identify the characteristic polypoidal vascular dilations is the main method for definite diagnosis of PCV. Recently, OCT has been used extensively to study exudative macular lesions. OCT images can also distinguish the exudative changes associated with PCV from that with exudative AMD. In the study reported by Ozawa et al., serous RD were observed in 78% of the eyes with PCV and in 53% of the eyes with exudative AMD.<sup>61</sup> In addition, eyes with a PCV had a greater height of serous RD, and a higher incidence of large sensory detachment than eyes with exudative AMD. The active polypoidal lesions tend to leak more severely, and the fluid from polypoidal lesions may leak into the subretinal space through the RPE and cause large serous RD, although polypoidal lesions are situated beneath the RPE.

**FIG. 99.17** Color fundus photograph in a case of polypoidal choroidal vasculopathy showing multiple orange-colored subretinal nodules, hemorrhagic retinal pigment epithelial detachment, subretinal hemorrhage, and sensory detachment.

In some cases of PCV, a serous neurosensory detachment at the macula without hemorrhage is the major clinical feature associated with RPE atrophy. FA shows only multifocal areas of granular hyperfluorescence. This type of PCV can masquerade as CSC. ICGA might help to establish a more definitive diagnosis. Yannuzzi et al.

reported a series of 13 patients who were previously diagnosed with CSC, but with further evaluation and follow-up, were diagnosed with PCV.<sup>62</sup> These eyes showed the characteristics of exudative macular detachments with a small-caliber, polypoidal vascular abnormality revealed by ICGA. Therefore, the authors recommended that ICGA should be done in the following situations: (1) patients not at risk of CSC, based on age, sex, or race; (2) eyes with persistent serous detachment at the macula associated with lipid accumulation; and (3) recurrent serous detachments with subretinal blood.

Peripheral exudative hemorrhagic chorioretinopathy is an uncommon chorioretinal mass-like lesion. It is characterized by an increased patient age, female preponderance, frequent pigment epithelium detachment, temporal equatorial location, and a highly hemorrhagic and exudative presentation, sometimes extending to the macula. It shares many features with PCV, including polyp-like choroidal telangiectases, abnormal choroidal vascular networks, and exudative and hemorrhagic presentation.<sup>63</sup> In the study done by Mantel et al., ICGA showed hyperfluorescent polyp-like structures in the choroid of the lesion area in 69% of eyes and an abnormal choroidal vascular network in 50% of eyes. OCT showed the typical dome-shaped elevation of the pigment epithelium over the vascular polyps.<sup>64</sup> The relationship between peripheral exudative hemorrhagic chorioretinopathy and PCV needs further investigation.

The serosanguineous retinal detachments in AMD or PCV can be managed by surgical intervention. Pneumatic displacement of submacular hemorrhage from the macula by intravitreal injection of expansile gas with or without tPA is now the first treatment of choice in most cases (see [Fig. 99.18](#) online).<sup>65</sup> Major complications include vitreous hemorrhage and rhegmatogenous retinal detachment. Vitrectomy with subretinal injection of tissue plasminogen activator (tPA) and use of perfluorocarbon liquid to evacuate the liquefied clot from the submacular space has been reported.<sup>66</sup> Oshima et al. described the surgical results of patients with massive subretinal hemorrhage extending to the periphery and involving two or more quadrants with hemorrhagic and bullous retinal detachment.<sup>67</sup> tPA was injected intravitreally 12–24

hours preoperatively; vitrectomy was performed with peripheral retinotomy, drainage of the subretinal hemorrhage through the retinotomy using perfluorocarbon liquid, and finally gas tamponade with postoperative prone positioning. However, the final visual outcome is limited by the underlying macular pathology.

**FIG. 99.18** (A) Massive subretinal hemorrhage in a case of polypoidal choroidal vasculopathy. (B) Reabsorption of the blood after pneumatic displacement with 0.2 mL C<sub>3</sub>F<sub>8</sub> and intravitreal injection of bevacizumab 1.25 mg.

## Tumor and Malignancy

### Choroidal Hemangioma

Choroidal hemangioma (CH) can be separated into the focal, solitary type and the diffuse choroidal thickening type. Both may be associated with extensive exudative retinal detachment.

Patients with focal choroidal hemangioma are mostly middle-aged men or women, complaining of unilateral vision decrease or distortion. Fundus examinations may find localized elevated orange-colored lesions ranging in size from 2 disc diameters (DD) to 10 DD in the juxtapapillary, macular, or extramacular area in the posterior pole. The surface is usually smooth, but retinal thickening with cystic space may be seen above the lesion. Yellow specks or

yellowish-white plaque of fibrous metaplasia sometimes exist between the tumor and the overlying retina. The lesion usually does not have pigmentary proliferation within but may have a mild hyperpigmented ring around it. Exudative detachment above and surrounding the tumor or in the inferior peripheral retina, may develop. Cystoid macular edema (CME) may be present when the macula is involved. Gravity tract of pigmentary disturbance may be seen between the tumor and the lower detached retina. Although the detachment is usually limited, severe bullous detachment may occur (see Fig. 99.19 online<sup>Ⓞ</sup>). Vision is affected by the presence of submacular tumor, submacular fluid or CME.

**FIG. 99.19** Bullous retinal detachment in a case of solitary choroidal hemangioma.

FA shows the characteristic features of perfusion of large vessels within the tumor in the prearterial phase followed by irregular hyperfluorescence on the tumor surface; a multiloculated pattern of cystoid macular edema may appear in the late phase.<sup>68</sup> A ring of hypofluorescence may be seen surrounding the tumor. In small tumors without significant retinal or pigmentary changes, the lesion shows only mild hyperfluorescence, sometimes difficult to distinguish from the surrounding normal choroid. ICGA

examination can demonstrate tumor vessels in the early phase more clearly.

OCT demonstrates choroidal elevation, RPE disturbance, cystic change in the overlying retina, and subretinal fluid (Fig. 99.20). Schisis-like change may be seen in the outer retina over or adjacent to the tumor, sometimes during treatment sessions of PDT or transpupillary thermotherapy (TTT). Ultrasonography shows high internal reflectivity.<sup>69</sup>

**FIG. 99.20** Optical coherence tomography images in a case of choroidal hemangioma showing macular fluid pocket and cystic changes overlying the tumor.

Histologically, cavernous choroidal hemangioma consists of large, dilated, thin-walled vessels with few stromal tissues and blends into surrounding normal choroidal vessels.

Tumors not causing macular changes do not need treatment. Conventionally, an extramacular tumor with submacular fluid accumulation is treated with a laser, aiming at the leaking tumor surface. Multiple sessions of treatment may be necessary to obtain submacular fluid reabsorption. The tumor size may or may not be reduced with this treatment modality. ICGA-enhanced diode laser is another treatment option to facilitate fluid reabsorption. Recently, TTT and PDT have been advocated to treat the tumor.<sup>70,71</sup> With one or a few sessions of treatment at an interval of 2–3 months, fluid reabsorption and tumor reduction, and in some instances, complete

flattening down of the tumor, may occur (see [Fig. 99.21](#) online). Large tumors may be treated with transscleral cryotherapy, thermotherapy, external beam irradiation, or episcleral plaque. In severe cases, the tumor may be hidden under the detached retina, thus inaccessible to laser or other treatment. In such cases, surgical drainage of the subretinal fluid may be performed to reexpose the tumor for a better treatment effect. Alternatively, repeated injection of bevacizumab may be used to facilitate fluid reabsorption.<sup>72</sup> The effect of this treatment has not been well established.

**FIG. 99.21** (A) Optical coherence tomography image of the macular area in a case with upper part choroidal hemangioma showing submacular fluid and intraretinal cysts. (B) Resolution of the macular changes after photodynamic therapy to the choroidal hemangioma.

The second type is Sturge–Weber syndrome with diffuse choroidal hemangioma. Compared with the fellow eye, the lesion eye has a more reddish fundus background color; normal choroidal markings are not visible ([Fig. 99.22](#)). This may be the only significant fundus finding in some cases. Most cases had mild tortuosity of retinal vessels or scattered pigmentary changes of various degrees. Ultrasonography may detect a thickened choroid. Other more severely affected cases may present with bullous RD, associated with glaucoma secondary to increased resistance of aqueous outflow or abnormalities of the trabecular meshwork.

There may be focal choroidal thickening in addition to diffuse thickening. FA may show minimal abnormality or only patchy hypofluorescent and hyperfluorescent areas from pigmentary disturbance. Late phase leakage and cystoid space may be seen in cases with exudative retinal detachment.

**FIG. 99.22** Diffuse choroidal hemangioma with dark red background color, indistinct choroidal markings, and tortuous retinal vessels.

Glaucoma in Sturge–Weber syndrome is difficult to control with medication and usually requires operation. A filtering operation is frequently complicated by severe choroidal detachment, with spontaneous recovery in most cases. For exudative detachment with potentially useful vision, argon laser photocoagulation may be performed to the leaking area to facilitate subretinal fluid reabsorption. Other treatment modalities include low-dose external beam irradiation (1200–2000 cGy) divided into several sessions.<sup>73</sup> Recently, PDT applied with multiple spots and sessions has been used to treat diffuse choroidal hemangioma aiming to reduce exudative detachment as well as choroidal thickness.<sup>74</sup> Further studies may be needed to confirm its usage.

## Choroidal Melanoma

Choroidal melanoma is commonly associated with exudative retinal detachment. The tumor lesion is often found during a routine eye examination or during specific fundus check-up for

blurred vision or visual field defect secondary to a macula involved sensory detachment or enlarged tumor itself. Flashing lights may be a complaint during tumor growth or tumor invading into the retina.

Melanoma often presents as a wide-based or dome-shaped pigmented mass under the retina (see [Fig. 99.23](#) online). A small tumor may contain orange pigment on the surface and part or the entire lesion may be amelanotic. Exudative detachment may develop above and surrounding the tumor or in the lower dependent part away from the tumor location. During tumor growth, choroidal melanoma may invade choroidal capillaries, leading to subretinal hemorrhage. It may later break through the Bruch's membrane to form a pigmented or amelanotic mushroom-like lesion. Tumor vessels may be visible, especially if the part above the Bruch's membrane is amelanotic. When the tumor breaks through the Bruch's membrane, it may cause choroidal, subretinal, or vitreous hemorrhage. Melanoma may invade the optic disc causing disc edema. When invading the vitreous, it may cause pigment dispersion within the vitreous and pigment deposition on the surface of the retina. When invading the retina, the drainage vein may become tortuous and engorged. Rarely, the tumor may assume a diffuse growing pattern causing diffuse choroidal thickening.<sup>75</sup> Clinically the diffuse lesion is a more aggressive type than the dome-shaped lesion, and more likely to invade the optic disc and spread outside the sclera, thus having a much worse prognosis.

**FIG. 99.23** Malignant choroidal melanoma inferior to the macula.

Histopathologic studies have shown that different tumors may contain different types of cells: spindle A, B, epithelioid cells, or mixed cell types. Epithelioid cell type has the worse visual prognosis. On FA, a typical lesion shows early pinpoint hyperfluorescence with late leakage. If there is a Bruch's membrane breakthrough, both tumor vessels and retinal vessels can be seen, presenting the so-called double-circulation sign.<sup>76</sup> ICGA may show tumor vessels in the late stage. Ultrasonography is valuable in showing the size, height and nodular extraocular extension. Typical lesions present as dome- or mushroom-shaped choroidal elevation with acoustic hollowness and choroidal excavation. A scan usually shows an initial spike with rapid attenuation in tumors with compact spindle A or B cell types.<sup>77</sup> The epithelioid cell type is more prone to have a moderate high and low spike within the tumor. MRI inevitably shows the paramagnetic effect of melanin with T1, T2 reverse sign: the lesion shows a hyperdense image in T1 and hypodense in T2, in reverse to the vitreous density (see [Fig. 99.24](#) online).<sup>78</sup> In uncertain cases, fine-needle biopsy with 25-gauge needle through the pars plana into the tumor to obtain cells may be used for cytologic examinations.

**FIG. 99.24** Magnetic resonance imaging study of the above-mentioned case showing typical hyperintense T1 (A) and hypointense T2 (B) images with respect to the vitreous.

Malignant melanoma should be differentiated with choroidal nevi. Important points favoring the diagnosis of melanoma include (1) dome-shaped elevation over 3 mm; (2) orange pigmentation on the surface; (3) sensory detachment over and surrounding the tumor in the absence of CNV; (4) evidence of Bruch's membrane breakthrough; (5) multiple pinpoint leakage on FA.

Some investigators suggest that any melanocytic lesion having a basal diameter greater than 16 mm and a height more than 3 mm should be considered as malignant; lesions with typical fundus picture and showing signs of growth and a basal diameter greater than 2.5 mm should also be considered as malignant and should be treated as such. Others suggest that size itself is not the only element to consider, and emphasis should be put on signs of acute or chronic changes. The following signs indicate chronic changes and favor a benign condition: (1) the tumor shows areas of fibrous metaplasia, presenting either as a fibrotic plaque or CNV; (2) there is evidence of subretinal pigment clumps or intraretinal pigment migration or gravity tract indicating longstanding exudative detachment; (3) drusen is present.

Treatment choice should consider growth potential, size, location, and age. For a small tumor, laser may be used to treat only the leaking points to promote reabsorption of subretinal fluid if exudative detachment involves the macula.<sup>79</sup> For definite small-

sized malignant melanoma, consider laser or transpupillary thermotherapy.<sup>80,81</sup> PDT has been used with mixed results. For medium-sized or large posterior tumors, radiation with plaque or charged particles may be considered. Co-60 plaques or I-125 episcleral plaques are commonly used.<sup>82</sup> Ruthenium-106 plaques have also been widely used in Europe.<sup>83</sup> Other treatment options include photoirradiation similar to PDT for AMD, local resection, ultrasonic hyperthermia and irradiation, and radiation plaque with photocoagulation. Teletherapy with gamma knife or cyberknife may be used. Severe inflammatory reaction is the most common complication.

The Collaborative Ocular Melanoma Study (COMS) found that preoperative radiation for large choroidal melanomas (height >8 mm, basal diameter >16 mm) does not improve 5-year survival; enucleation and brachytherapy have a similar rate of survival for medium-sized tumors (height 3–8 mm, basal diameter ≤16 mm).<sup>84</sup> However, there is evidence from a clinical series that failure to achieve local control after radiation therapy, even when treated by subsequent enucleation, is associated with an increased risk of metastasis.<sup>85</sup>

## Metastatic Tumors

Metastatic tumors are the most common malignant neoplasms of the eye,<sup>86,87</sup> with the choroid being the most common site for tumor growth. The breast was the first and the lung the second most common primary site for both choroidal and orbital metastases.<sup>87</sup> Approximately one-third of patients have no history of primary cancer at the time of ocular diagnosis.<sup>87</sup> About 50% of these patients fail to have a primary site detected, despite systemic evaluation by medical oncologists. The most common presenting symptom of intraocular metastasis was blurred vision. When visual acuity was affected, it usually decreased to the range of 20/200 to counting fingers. Other presenting symptoms included flashes, floaters, and pain. The symptom of pain is rarely found in patients with other primary uveal malignancies, such as malignant melanoma.

On fundus examination, typical choroidal metastases show one or more solitary yellow, creamy, flat, or slightly elevated lesions

with overlying pigment disturbance forming a spotted pattern usually located in the posterior retina; bilateral involvement is found in 20–40%, and multifocal in 20%; three-quarters are associated with exudative detachment. It is not possible to determine the origin of the lesions from examining the fundus alone.

FA of most metastatic carcinomas shows hypofluorescence in the arterial and early venous phases and progressive hyperfluorescence in the subsequent frames. Pinpoint foci of hyperfluorescence appear over the tumor in the venous phase and persist in the late angiograms. There may be moderate late hyperfluorescence of the serous subretinal fluid adjacent to the metastatic tumor. FA has limited value in determining the origin of the choroidal tumors, but is useful in differentiating metastatic tumors from non-neoplastic conditions, such as inflammatory processes, subretinal neovascular membranes, and organized hemorrhage.

Ultrasonography shows that metastatic tumors tend to be flat and extend in surface area rather than thickness. Most choroidal metastases have a plateau- or dome-shaped contour and measure approximately 3–4 mm in thickness. Thicker tumors generally were observed with metastases from the gastrointestinal tract, kidney, lung, and prostate. Shield and associates reported that the mean thickness was 4 mm for metastatic gastrointestinal cancers.<sup>87</sup>

A CT scan demonstrates the presence and configuration of intraocular metastases. On MRI, metastatic carcinomas are characteristically isointense or slightly hyperintense to the vitreous on T1-weighted images and hypointense to the vitreous on T2-weighted images. They show mild to moderate enhancement with gadolinium-enhanced examination.

Other ancillary ophthalmic procedures may aid in the diagnosis of metastatic tumors, including radioactive phosphorus test, fine-needle aspiration biopsy, and wedge biopsy.

Differential diagnoses of choroidal metastasis include amelanotic melanoma, amelanotic choroidal nevus, choroidal osteoma, choroidal hemangioma, posterior scleritis, and rhegmatogenous retinal detachment.

Workup for a choroidal metastasis includes an MRI of the head to rule out brain metastases and to determine the extent of the tumor.

The incidence of central nervous system (CNS) metastases increases from 6% to 28% after development of ocular metastasis.<sup>88</sup> Patients with an unknown primary site of origin should obtain a thorough physical examination and have a chest radiograph and a mammogram. In women without breast cancer and in men, the evaluation should be directed initially towards the detection of a primary tumor in the lung, alimentary tract, kidney, thyroid, pancreas, and other organs. Kole et al. suggested that positron emission tomography (PET)-CT might be helpful for detecting a malignancy of unknown origin.<sup>89</sup>

Common treatment options include chemotherapy, external beam radiation, plaque radiation, hormone therapy, resection, observation, and combination therapy (Fig. 99.25). TTT has been proposed to enhance reabsorption of subretinal fluid.<sup>90</sup>

**FIG. 99.25** Choroidal metastasis in a case of breast adenocarcinoma. Choroidal tumor with localized sensory detachment and subretinal deposit was noted initially (A). Rapid tumor enlargement was noted in subsequent examinations. Resolution of the tumor with widespread retinal pigment epithelium changes was noted after systemic chemotherapy. Note the presence of tumor infiltration of the optic disc (B).

Prognosis is poor for patients diagnosed with choroidal metastasis. The average survival time is 8–9 months after diagnosis.<sup>91</sup> Cutaneous tumors have the worst prognosis (of 1–2 months survival time), and breast tumors have the best prognosis (7–31 months). Data of 36 patients with choroidal metastases were

collected in 11 years in a teaching hospital in Taiwan. The mean age was  $53.9 \pm 12.8$  years. The primary sites of tumors were lung in 18 (50%); breast in 8 (22.2%); gastrointestinal tract in 3 (8.3%); pancreas in 2 (5.6%); ovary in 2 (5.6%); kidney in 1 (2.8%); liver in 1 (2.8%), and unknown in 1 (2.8%).<sup>92</sup>

## Lymphoma

Primary intraocular lymphoma (PIOL) is a rare disease and can rarely induce serous retinal detachment. It belongs to a subset of primary central nervous system lymphoma (PCNSL). Up to 80% of PIOL patients have CNS involvement at the time of, or following, PIOL diagnosis. Around one-quarter of PCNSL patients develop intraocular involvement.<sup>93</sup> It is known as the most important cause of the uveitis masquerade syndrome (see [Chapter 82](#), Intermediate uveitis and [Chapter 126](#), Diagnostic and therapeutic vitrectomy for uveitis). The clinical signs include cellular infiltration of the vitreous, which mimics vitritis, and multiple creamy subretinal infiltrative mounds with surface pigmented clumps ([Fig. 99.26](#)). Some cases may show localized subretinal yellowish infiltration with exudative detachment or intraretinal infiltration resembling acute retinal necrosis. The diagnosis of PIOL requires a high index of suspicion. When elderly patients develop vitreous opacity with vitreous cells, PIOL should be kept in the list of differential diagnoses, especially when the so-called vitritis is refractory to corticosteroid treatment. When there is a suspicion of PIOL, pars plana vitrectomy and lumbar puncture are the two important diagnostic procedures. Cytologic examination of the vitreous sample leads to a definite diagnosis. A negative result is likely to occur when patients are receiving treatment with corticosteroid. Some found a higher interleukin (IL)-10 level, or higher IL-10 to IL-6 ratio, in the vitreous of patients with PIOL. Although the cytokine levels are not diagnostic of PIOL, they are useful adjuncts to the cytologic examination. When the clinical suspicion of PIOL is high, and IL-10 level or IL-10 to IL-6 ratio is high, even if the initial vitrectomy and lumbar puncture are negative, more aggressive diagnostic procedures are warranted. In some cases with only scanty vitreous infiltration, cytologic examination of samples from a

subretinal biopsy may be required.<sup>94</sup>

**FIG. 99.26** Intraocular lymphoma showing multiple yellowish subretinal mounds with overlying pigmented clumps.

The treatment of choice for PCNSL, with or without PIOL, is high-dose methotrexate intravenously, which can pass the blood–brain barrier and blood–ocular barrier and reach the therapeutic level in the vitreous. Some advocate additional intravitreal methotrexate (0.4 mg/0.1 mL) injections in patients with PCNSL and PIOL (Fig. 99.27). The side-effects of intravitreal methotrexate injection include corneal epithelial toxicity and cataract. In relapsing cases with intraocular involvement only, treatment success has been reported with intravitreal injection of methotrexate only. In refractory cases, radiotherapy on the brain and the involved eye may be an option. However, recurrence is the rule with radiotherapy only. Intravitreal rituximab is a promising alternative for treatment of PIOL, with no significant side-effect.<sup>95</sup>

**FIG. 99.27** (A) Color fundus photograph in a case of cytology-proven intraocular lymphoma showing massive subretinal infiltration of lymphomatous cells and exudative retinal detachment. (B) Resolution of the exudates after systemic chemotherapy and intravitreal injection of methotrexate.

## Leukemia

About 40–70% of the patients with leukemia have eye involvement.<sup>96</sup> Pathologic changes from anterior segment to posterior segment may occur, including corneal ring ulcer, iris infiltration, glaucoma, retinopathy, choroidopathy, and optic neuropathy.<sup>96</sup> Structural alteration may be caused by direct leukemic cell infiltration or by accompanied hematologic abnormalities, such as anemia, hyperviscosity, or both.<sup>96</sup> Posterior segment manifestations are usually associated with retinal vascular changes, retinal hemorrhage or even retinal infiltrations. Exudative retinal detachment may occasionally be seen secondary to leukemic choroidopathy.<sup>96</sup>

Previous study has shown about half of leukemia cases have uveal infiltration.<sup>97</sup> Most do not have clinical symptoms or fundus changes. Ultrasonography may show mild choroidal thickening. Some patients may present with localized or diffuse leopard-spot changes secondary to retinal pigment epithelium damage by either extensive leukemic infiltration of the choroid capillaries or chemotherapy. Focal or diffuse choroidal elevation may occasionally be seen from choroidal infiltration of leukemia, especially acute lymphocytic lymphoma. Exudative detachment

may occur as well as RPE detachment (Fig. 99.28). When localized, it may be similar to CSCR; in more extensive detachment, FA may show pinpoint leakage secondary to RPE damage, similar to Harada disease, posterior scleritis, or other infiltrative diseases of the choroid. Systemic chemotherapy may prompt reabsorption of subretinal fluid.<sup>98</sup> During this process, numerous yellow exudate-like patches may be seen beneath the retina (Fig. 99.29).

**FIG. 99.28** (A) Confluent nodular subretinal infiltration with surrounding exudative detachment in the left eye in a case of acute myelocytic leukemia. (B) Resolution of the lesions with residual subretinal exudates after systemic chemotherapy.

**FIG. 99.29** (A) Hemorrhagic choroidal detachment and retinal detachment in a case of acute leukemia. (B) Resolution of the lesions with residual subretinal

exudates after systemic chemotherapy.

## Others

Other benign tumors, such as osteoma or astrocytoma, may be associated with exudative retinal detachment adjacent to the lesion site. (Fig. 99.30).

**FIG. 99.30** Choroidal osteoma in a 25-year-old woman. The lesion was in the upper juxtapapillary area with localized retinal detachment involving the macula in the left eye (A,B). CT scan (C) shows the lesion to be calcified. Subretinal fluid subsided after one session of transpupillary thermotherapy (D,E).

## Disc Anomalies

### Optic Nerve Pit

Optic pit is a congenital defect within the optic nerve head and appears as a gray dimple. It varies in size but on average is less than one-third of the DD in width. Clinical examination shows a localized excavation of the disc that typically measures less than one-half of the DD; 50% of the pits locate on the temporal side, and

one-third locate centrally without association with retinal detachment. The incidence of the disease is 1/11 000;<sup>99</sup> 25–75% (40%) are associated with retinal detachment.<sup>100</sup> The condition is unilateral in 90% of cases. In 85% of cases, the abnormal optic disc is larger than the contralateral one. The color of the pit may be gray, yellow, or, less frequently, black. Various juxtapapillary changes including peripapillary retinal pigment epithelial change or choroidal atrophy or both are present in 95%. Visual field defect is caused by retinal elevation in 40% and enlarged optic pit in 60%. The patterns of visual field defect are nasal and temporal steps, altitudinal defects, paracentral scotomas, arcuate scotomas, or generalized or localized constriction.<sup>99</sup> The macula may show the following changes: serous macular elevation, macular cystic degeneration and schisis formation, or macular mottling without evidence of RD. Schisis and RD may be present simultaneously (see [Fig. 99.31](#) online<sup>Ⓞ</sup>). There is communication between the schisis cavity or subretinal space and the optic disc pit. Retinal detachment including schisis occurs in 40% of cases, usually extending into the macular region or slightly beyond.<sup>101</sup> Larger pit, temporal location pit, and macular hole may be predisposing factors for RD. Longstanding serous retinal detachment can eventually lead to cystic degeneration of the macula and loss of pigment in the underlying retinal pigment epithelium. Lamellar and, rarely, a full-thickness macular hole may develop. Spontaneous resolution of the macular detachment is reported in 25% of cases.

**FIG. 99.31** Color fundus picture (A) and optical coherence tomography image (B) showing optic pit with macular sensory detachment with subretinal yellow deposit and retinoschisis nasal to the fovea.

The origin of the schisis fluid or subretinal fluid remains controversial. A Collie dog model suggested a connection between the vitreous cavity and the subretinal space (India ink).<sup>102</sup> OCT may show a thin fenestrated sheet of tissue covering the pit. In addition, some patients treated with vitrectomy and tamponade have gas extending into or under the retina postoperatively. Regenbogen et al. proposed the idea that subretinal fluid could be derived from cerebrospinal fluid.<sup>99,103</sup> Lincoff and Kreissig suggested fluid emanating from an optic disc pit was creating a schisis-like separation of the inner layers of the retina. A detachment of the outer layers from pigment epithelium was a secondary process that began in the center of the macula and did not connect with the optic

disc pit.<sup>104</sup>

The natural course of untreated RD was poor. VA eventually may drop to less than 20/100 in 50–80%, especially when macular detachment develops.

Persistent macular elevation may require surgery (Fig. 99.32). The greater the separation between the peripapillary RPE and the retina, the less the chance of a successful treatment. Laser photocoagulation (along the disc margin adjacent to RD), pneumatic displacement, pars plana vitrectomy, pars plana vitrectomy with autologous platelets, and macular buckling (vertically at posterior pole) have been reported.<sup>104–106</sup> Cox and associates compared various surgical modalities. They concluded that combined surgery of vitrectomy, gas injection, and laser photocoagulation to the temporal margin of the disc is the most effective therapy.<sup>106</sup>

**FIG. 99.32** Color fundus photograph (A) and optical coherence tomography (OCT) image (B) showing optic pit (*arrow*) with macular sensory detachment. Color fundus photograph (C) and OCT image (D) showing resolution of the subretinal fluid after one procedure of gas tamponade and three sessions of laser photocoagulation on the temporal margin of the disc.

In some cases, macular RD and schisis were noted without a pit. It may be due to a small pit or chronic CSCR. In some of these cases,

a sheet of tissue with small fenestration may be detected over the disc margin with OCT.

Differential diagnosis includes: macular schisis with/without optic pit; macular detachment with/without optic pit; CSC; myopic and age-related macular degeneration; peripapillary detachment in pathologic myopia (PDPM); malignancy; and PCV.

## Morning Glory Syndrome

Morning glory syndrome (MGS) is a congenital optic disc anomaly caused by abnormal closure of the embryonic fissure with outward herniation of the disc and peripapillary tissues. It is characterized by a large-sized excavated disc overlaid with a tuft of glial tissue on the center and surrounded by an elevated pigmented ring. Narrow and straight retinal vessels cross the disc margin in a radial pattern. The disease may be diagnosed in infants or young children because of strabismus or other associated anomalies such as cataract, microphthalmos, or anterior segment anomaly or in school-age children, after vision screening. The visual acuity is usually below 20/200. Some rare cases with minor changes may be found during routine eye examinations.

RD is noted in about one-third of the cases.<sup>107</sup> It may be confined to the peripapillary area or involve a large part of the entire retina (Fig. 99.33). The detachment may be rhegmatogenous or nonrhegmatogenous; the cause is difficult to determine from clinical presentation alone, although bullous detachment is more likely to occur in rhegmatogenous detachment. Definite diagnosis relies on the identification of retinal breaks, which are usually small and slit-like on the surface or margin of the abnormal disc. Because of poor contrast, retinal breaks are difficult to find preoperatively. During operation, SRF may be seen coming out from the hidden break by active or passive suction.

**FIG. 99.33** Color fundus photograph showing a case of morning glory syndrome with sensory retinal detachment of the upper retina.

For nonrhegmatogenous detachment, the condition may undergo spontaneous improvement and recurrence. The source of fluid is debated. There may be communication between the subretinal space and subarachnoid space or the vitreous cavity, as in the optic pit. The fact that certain cases had a successful reattachment after an optic nerve fenestration operation suggests that CSF may be an important source of the subretinal fluid.<sup>108,109</sup>

Localized detachment may be observed and more widespread detachment may be treated with vitrectomy, posterior hyaloid and glial tissue removal, internal drainage, and laser around the break, if found. Intractable cases may be treated with silicone oil tamponade, although there is a small danger of silicone oil migrating to the optic nerve sheath. An optic nerve fenestration procedure may be done for cases that did not respond to vitrectomy.

## Peripapillary Intrachoroidal Cavitation

Peripapillary intrachoroidal cavitation (ICC) is a yellow-orange lesion usually located in the inferior aspect of the optic disc in a high-myopic eye. ICC has been thought to be a stable lesion without causing vision disturbance. However, in rare patients, macular detachment may develop; vision may thus be compromised. Clinical and imaging studies suggest the accumulation of subretinal fluid may have originated from the

communicating tracts with ICC, which in turn may have communication with the vitreous cavity (Fig. 99.34). The best treatment method is unknown, although intravitreal gas tamponade has been shown to prompt macular reattachment.<sup>110,111</sup> This condition has recently been reported in non-high-myopic eyes.<sup>110</sup>

**FIG. 99.34** Color fundus photograph (A) and optical coherence tomography (OCT) image (B) showing intrachoroidal cavitation (ICC) situated at the nasal lower juxtapapillary area in a high-myopic patient. Color fundus photograph (C) and OCT image (D) showing peripapillary ICC with macular detachment in a high-myopic patient.

## Other Conditions

### Postsurgical Exudative Retinal Detachment

Transient exudative detachment in the early postoperative period may sometimes be seen after diabetic vitrectomy, especially if excessive photocoagulation (Fig. 99.35) or peripheral cryotherapy has been done. The detachment is usually located in the inferior

part; significant fluid is noticed 1 or 2 days after surgery. Choroidal detachment may also develop. Sometimes the fluid accumulates in the posterior pole causing severe decrease of vision a few days after surgery. In such cases, ultrasonography demonstrates dome-shaped macular elevation; the condition usually improves within 1–2 weeks. Management of the exudative detachment requires careful examination and proper monitoring of intraocular pressure. If the detachment is associated with abnormally low IOP, rhegmatogenous retinal detachment should be highly suspected.

**FIG. 99.35** Serous choroidal detachments and submacular fluid after panretinal photocoagulation (360°). Visual acuity improved to 20/20 after the fluid resorbed. (Courtesy of Dr. Yong Ren and Dr. Chirag Jhaveri.)

Exudative detachment may occur after scleral buckling and cryopexy to treat rhegmatogenous retinal detachment.<sup>112</sup> Excessive high circumferential buckle placement or multiple vortex veins compression may induce choroidal detachment with or without exudative retinal detachment. Old age and a medical history of cardiovascular disease are risk factors.<sup>112</sup> Excessive cryopexy may induce exudative retinal detachment causing delayed reabsorption or transient increase of subretinal fluid. As long as retinal breaks sit on the buckle, no specific treatment needs to be done. Choroidal detachment may be treated with systemic steroid especially if the

anterior chamber depth becomes shallow or intraocular pressure is high.

Kim et al. have reported that around 20% patients were found to have multiple subretinal fluid blebs after successful retinal detachment surgeries, especially in young patients. Serial measurements of subretinal fluid blebs using spectral domain (SD)-OCT showed these blebs might result from the active reattachment of retinal pigment epithelium and photoreceptors during the resolution of retinal detachment.<sup>113</sup>

Retinopathy with prematurity treated with laser may develop acute exudative retinal detachment.<sup>114</sup> The condition may respond well to systemic steroid or intravitreal steroid injection.

External drainage may induce choroidal hemorrhage entering into the subretinal space in the detached area. If subretinal blood deposits under the macula, visual acuity may be greatly compromised. The complication rate is high if drainage is done after cryotherapy because of the engorgement of choroidal vessels. To avoid this complication, one should perform external drainage as infrequently as possible or shift to vitrectomy when drainage is judged necessary with a scleral buckling procedure. Once subretinal hemorrhage and choroidal hemorrhage occur, gas injection with head-down positioning may help to push the blood away from the macula.<sup>115,116</sup> Simultaneous use of intravitreal tPA to better mobilize the blood clot has been advocated.<sup>117</sup>

Prolonged hypotony during or after intraocular surgery may induce serous or hemorrhagic choroidal detachment with or without exudative or hemorrhagic retinal detachment. This complication may occur in cataract operations, either phacoemulsification or extracapsular cataract extraction; filtering operation for glaucoma; penetrating keratoplasty; secondary intraocular lens implantation, especially sutured lens; or vitrectomy. The popularization of small gauge vitrectomy may result in more cases experiencing postoperative hypotony secondary to sclerotomy wound leakage, leading to choroidal detachment, particularly in high myopic eyes.<sup>118</sup> Indications and timing for surgical intervention depend on the extent of the detachment, the degree of blood clot lysis within the suprachoroidal space, the level of intraocular pressure, severity of

the symptoms, and whether or not rhegmatogenous retinal detachment exists. Additional information is available online.

Serous choroidal detachment with normal intraocular pressure and without rhegmatogenous retinal detachment can be safely followed. High intraocular pressure not controllable by medication, loss of intraocular contents, and a high suspicion of rhegmatogenous retinal detachment are indications for surgery. A 1–2-week waiting period, during which time systemic steroid may be administered, is required for the partial lysis of the suprachoroidal blood clot. During surgery, the surgeon should make certain that the tip of the infusion cannula is placed within the intraocular cavity. Drainage sclerotomy should be placed where choroid is most elevated. Suprachoroidal drainage and intraocular infusion should proceed at the same time to keep intraocular pressure and to obtain a maximal drainage. Pars plana vitrectomy is then performed to release vitreous traction, followed by perfluorocarbon liquid infusion to settle the retina and push the residual blood out through the drainage sclerotomy.

## **Disseminated Intravascular Coagulopathy**

Disseminated intravascular coagulopathy (DIC) may result in an abnormal clotting state. A variety of systemic conditions are associated with DIC, including malignancy, malignant or pregnancy-induced hypertension, abruptio placentae, collagen vascular diseases, burns, sepsis, and organ transplantation. DIC tends to cause excessive fibrin clot formation, leading to occlusion of small blood vessels in the choroidal, rather than the retinal, circulation. This is thought to be caused by rapid deceleration, followed by stasis of blood in the choriocapillaries. The thrombus formation results in fibrinoid necrosis and disruption of the overlying RPE, which may result in serous RD.

## **Post-Organ Transplantation or Hemodialysis Exudative Detachment**

There are two types of fundus changes: type 1 has orange-colored RPE proliferation mixed with RPE atrophic changes, forming a

leopard-spot pattern, associated with exudative retinal detachment. FA shows multiple RPE leaking points, but no RPE detachment. Subretinal fluid usually disappears within weeks or months; recurrence is common. The onset of the lesions may not be related to graft rejection. Most patients are under treatment with steroid or other antimetabolites such as cyclosporine or azathioprine. The lesions are compatible with acute RPE damage. The RPE flecks may resemble fundus flavimaculatus. The underlying cause may be due to choroidal ischemia secondary to localized intravascular coagulopathy. The other type shows multifocal RPE detachment associated with subretinal serofibrinous substance and bullous detachment, similar to atypical CSC.<sup>119,120</sup> The condition tends to develop in patients under hemodialysis or after kidney transplantation. Most reported hemodialysis cases were taking systemic steroids. The pathogenesis may be similar to those inducing atypical CSC, and laser photocoagulation or PDT with reduced fluence to the leaking areas may be effective in flattening down the retina.

## Miscellaneous

Other conditions associated with localized or extensive exudative retinal detachment include familial exudative vitreoretinopathy, acute exudative polymorphous vitelliform maculopathy, retinoblastoma, reactive lymphoid hyperplasia, bilateral diffuse uveal melanocytic proliferation, carotid–cavernous fistula, and systemic diseases such as chronic renal failure, hypoalbuminemia.

## Conclusion

Many diseases are capable of developing exudative retinal detachment secondary to imbalance between inflow and outflow of the fluid across the retina. The majority are caused by the increased permeability of choroidal vessels along with RPE dysfunction. Some are caused by excessive leakage from retinal vessels, and less often, caused by outflow obstruction. Treatment should be directed to the underlying mechanisms and aimed to correct the etiology.

## **Definitions and Pathology**

First reported in 1933 by Bartels,<sup>1</sup> degenerative retinoschisis results from an acquired splitting of the retinal layers. It is closely related

to cystoid degeneration – cyst-like spaces within the retinal layers that extend approximately 3 mm posteriorly from the ora serrata and occur in nearly all adults. Histologically, cystoid degeneration is subdivided into typical and reticular types. Typical cystoid degeneration develops in the outer plexiform layer immediately adjacent to the ora serrata. In contrast, reticular cystoid degeneration arises within the nerve fiber layer immediately posterior to typical cystoid degeneration. Scleral depression helps to visualize cystoid degeneration but clinical differentiation between the two types is difficult.

Retinoschisis results from coalescence of cystoid degeneration into frank splitting of the retinal layers (Fig. 100.1). Retinoschisis likewise has typical and reticular forms that localize histologically to the outer plexiform layer and to the nerve fiber layer, respectively.<sup>2</sup> A viscous fluid, rich in mucopolysaccharide, gradually accumulates between the layers. The etiology of retinoschisis is unknown.

**FIG. 100.1** Typical cystoid degeneration leading into typical retinoschisis. (Courtesy of Ralph Eagle, MD.)

Retinal breaks can occur within the inner retinal layer, the outer retinal layer, or both, and do not necessarily cause a retinal detachment.<sup>3</sup> In fact, as there is no path for the intraschisis fluid to enter the subretinal space, inner layer breaks by themselves cannot

lead to a retinal detachment.

Two types of retinal detachments are associated with retinoschisis:

1. **Schisis-detachment** describes a situation in which outer layer holes without inner layer holes enable intraschisis fluid to migrate into the subretinal space.<sup>3</sup>

2. **Progressive rhegmatogenous retinal detachment (RRD) associated with retinoschisis** occurs when breaks in both the inner and outer layers allow liquefied vitreous to gain access to the subretinal space.

## Retinoschisis

Although degenerative retinoschisis may occasionally be present in young adults, most patients are over age 50.<sup>3</sup> It occurs in 1–4% of the population over age 50,<sup>4,5</sup> is bilateral in 85%, and is found equally between the sexes.<sup>3</sup> In contrast to retinal detachment and myopic foveal schisis, degenerative retinoschisis is associated with hyperopia, although it may develop in any eye.

In contrast to a retinal detachment, which causes a sloped relative or absolute scotoma, areas of retinoschisis cause a sharply demarcated absolute scotoma on visual field testing. However, even patients with very posterior retinoschisis are almost always asymptomatic.<sup>3</sup>

Ophthalmoscopically, retinoschisis usually appears as a thin and smooth elevation of the peripheral retina (Fig. 100.2), best appreciated with scleral depression. Although the corrugated appearance of an acute, symptomatic rhegmatogenous retinal detachment would rarely be confused for retinoschisis, it is important to differentiate retinoschisis from a chronic, subclinical retinal detachment typically associated with small atrophic holes. Table 100.1 compares features of retinoschisis and rhegmatogenous retinal detachment. Retinoschisis occurs in the inferotemporal quadrant in 70% and in the superotemporal quadrant in 30% of affected eyes.<sup>3</sup> Seventy-five percent of cases are postequatorial in furthest extent.<sup>3</sup> During scleral depression, the entire schisis area is

displaced inward as a unitary enclosed structure. This feature helps to differentiate it from a retinal detachment, in which scleral indentation tends to decrease the area of elevation as subretinal fluid escapes through retinal breaks into the vitreous cavity. Small white dots colloquially called “snowflakes” may be present. These are thought to be Müller cell footplates and/or neurons that bridge or formerly bridged the schisis cavity. The retinal vessels in the affected area may be sclerotic. Also, in contrast to retinal detachment, because the photoreceptors and retinal pigment epithelium remain in contact with each other, application of laser will cause whitening of the outer layer of retinoschisis.<sup>6</sup>

**FIG. 100.2** Bullous retinoschisis is seen inferotemporally.

**TABLE 100.1**

**A Comparison of Retinoschisis and Retinal Detachment**

	<b>Retinoschisis</b>	<b>Retinal Detachment</b>
Typical patient age	Middle age to elderly	Middle age
Refractive association	Hyperopia	Myopia
Symptoms	Almost always absent	Acute: present Chronic: absent
Scotoma	Absolute	Relative

Avitreous hemorrhage or pigment	Absent	Common
Location	Inferotemporal, Superotemporal	Acute: Usually superior Chronic: Usually inferior
Texture	Smooth	Acute: Corrugated Chronic: Smooth
Müller footplates	Common	Absent
Mobility	Relatively immobile	Acute: Often very mobile Chronic: May be relatively immobile
Movement with scleral depression	Moves as single unit	Height decreases
Color with scleral depression	“White with pressure” may be seen in outer layer	No “white with pressure”
Breaks	May be present	Present
Lattice in elevated retina	Unlikely	Suggestive
Retinal pigment epithelium	Normal (unless associated with retinal detachment, current or regressed)	Acute: Normal Chronic: Atrophy and demarcation lines may be present
Optical coherence tomography	Splitting of retinal layers	Subretinal fluid
Effect of laser application through retinal break <sup>6</sup>	Through inner layer break: Uptake	Through full-thickness break: no uptake
Natural history	Progression rare and if present, slow	Acute: Progressive Chronic: May be nonprogressive or slowly progressive

Typical and reticular retinoschisis cannot be distinguished by assessing retinal layer thickness ophthalmoscopically, but the following clues point toward one or the other: (1) typical retinoschisis is low-lying, while reticular is bullous; (2) typical retinoschisis is located anterior to the equator while reticular retinoschisis may be located posterior to the equator; (3) outer layer holes are only seen in the reticular form.<sup>2</sup>

Ultrasonography is of limited utility in cases of suspected retinoschisis, and it is not precise enough to differentiate retinoschisis from retinal detachment based on thickness of the elevated retinal layer. There are, however, some signals on ultrasonography that can be useful. A-scan ultrasonography of retinoschisis produces a single-peaked spike.<sup>7</sup> B-scan ultrasonography of retinoschisis shows a low-lying or dome-shaped, relatively immobile retinal elevation. A serous choroidal detachment also appears as a dome-shaped, immobile elevation on B-scan. However, the elevated layer of a choroidal detachment is notably thicker than retinoschisis and causes a double-peaked spike

on A-scan.<sup>7</sup>

Optical coherence tomography (OCT) of retinoschisis shows exquisite, in vivo detail of the anatomy of the retinoschisis (Fig. 100.3). OCT is a reliable and useful means of distinguishing between retinoschisis and retinal detachment. In retinoschisis the outer retina is in contact with retinal pigment epithelium (RPE), whereas in retinal detachment the outer retina is separated from the RPE. The peripheral location of retinoschisis can be difficult to image with OCT, but wide-field OCT may make it easier to image peripheral pathology.

**FIG. 100.3** Optical coherence tomography shows both schisis of the middle retina and bullous schisis of the nerve fiber layer.

A large series of 218 eyes, none of which received treatment during an average follow-up of 9 years, gives us the best natural history data available for retinoschisis.<sup>3</sup> Enlargement of the schisis cavity occurred infrequently: lateral expansion occurred in 6%, height increased in 5%, and posterior extension even up to 3 disc diameters from the macula occurred in 3% of eyes. No cases of macular involvement occurred. Among those who had posterior extension of the schisis cavity, the rate of progression was slow (on the order of 2.5 disc diameters/10 years). None of the patients in the study reported symptoms and none was treated. Reports of retinoschisis enlargement involving the macula are exceedingly

rare.<sup>8-11</sup> Neither posterior vitreous detachment nor cataract surgery appeared to destabilize the retinoschisis. This observation may be explained by the fact that retinoschisis is an intraretinal abnormality and is not caused by traction at the vitreoretinal interface.

A large variety of variably invasive techniques have been reported for the treatment of retinoschisis, including diathermy, cryopexy, photocoagulation, several types of scleral surgery (e.g., resection or plication), scleral buckling, external drainage of schisis fluid, and pars plana vitrectomy with internal drainage.<sup>3,12</sup> No treatment has been shown to definitively halt posterior progression of retinoschisis, while complications from even a relatively noninvasive treatment with laser retinopexy have been reported.<sup>13</sup> It is reasonable to follow patients with retinoschisis every one to two years.

## Summary

Differentiating degenerative retinoschisis from retinal detachment is very important. Degenerative retinoschisis is usually asymptomatic and nonprogressive, even when very posterior. Proposed treatments for it have not proven to be effective and may cause complications. Therefore, degenerative retinoschisis should be observed without treatment.

## Retinoschisis With Retinal Breaks

Reticular retinoschisis may feature inner and/or outer layer breaks. Inner layer breaks are usually small, round, and difficult to detect (Fig. 100.4). As they cannot result in retinal detachment without concomitant outer layer breaks, they are less clinically significant than outer layer breaks.

**FIG. 100.4** Laser retinopexy had been attempted to surround the round inner layer break superotemporally (\*), but the telltale laser uptake within the break proves that this is an inner layer break of retinoschisis, not a full-thickness hole. Temporal to the macula is an irregularly-shaped outer layer break (\*\*). The smudged pigment along the posterior border of the outer layer break suggests chronic subretinal fluid at the edge of the break. The extent of this posterior fluid was followed for 3 years without treatment and remained stable. Nearly the entire temporal periphery is a region of retinoschisis, and a sclerotic vessel is seen within it (*arrow*).

The prevalence of outer layer breaks in eyes with retinoschisis is between 11% and 24%.<sup>3,14,15</sup> Measuring 1–3 disc areas or more, outer layer breaks are usually larger than inner layer breaks. Outer layer breaks are also often posterior to the equator and may have rolled edges (Figs. 100.4 and 100.5A–B).

**FIG. 100.5** (A) Several large, round, posterior outer layer breaks. (B) Demarcation lines around outer layer breaks denote chronicity. Note the retinal vessels traversing the outer layer breaks. (Courtesy of William Tasman, MD.)

It has been suggested that large outer layer breaks may be more susceptible to progression to retinal detachment.<sup>16-18</sup> In Byer's natural history study, 14/24 (58%) of eyes with outer layer breaks developed a schisis-detachment. Twenty-five out of 218 (11%) eyes had or developed retinal breaks. Five eyes had breaks in both layers. However, none of the patients in this study developed symptoms or underwent treatment.<sup>3</sup>

Because outer layer breaks are asymptomatic, generally have a favorable natural history, and treatments may result in complications, observation alone is reasonable. However, until more conclusive data is available, the surgeon's judgment and patient's wishes should be taken into account on a case-by-case basis. Follow-up every 6 months is reasonable.

## Summary

Retinoschisis with inner and/or outer retinal breaks is unlikely to result in progressive retinal detachment. Observation alone is reasonable.

## Schisis-Detachment

Schisis-detachment occurs when, in the absence of an inner layer break, intraschisis fluid migrates through an outer layer break into the subretinal space. Schisis-detachment was seen in 14/24 (58%) eyes with outer layer breaks and 14/218 (6.4%) of eyes with retinoschisis.<sup>3</sup> Since schisis-detachments usually do not progress posterior to the posterior border of the schisis cavity, they are almost always asymptomatic.

Four clues pointing to a schisis-detachment include:<sup>19</sup>

- An outer layer break is present.
- The appearance of the schisis is not uniform in height, texture, or transparency.
- There may be a curved yellowish line deep to the inner layer corresponding to the outer layer.
- There may be a pigmented demarcation line in chronic cases.

Symptomatic posterior extension of the subretinal fluid posterior to the area of schisis is rare ([Fig. 100.6](#)).<sup>16,20,21</sup> When the fluid does progress posteriorly, it does so very slowly.<sup>21</sup> The relative stability of a schisis-detachment likely is due in part to the viscous nature of the intraschisis fluid, resulting in only some of the fluid traversing the outer layer break into the subretinal space.<sup>19</sup>

**FIG. 100.6** A rare case of posterior extension of subretinal fluid from schisis detachment. Note the two large superotemporal outer wall breaks. The posterior extent of the schisis cavity is seen at the temporal macula (*arrow*). The posterior extent of the subretinal fluid (*arrowhead*) involves the fovea.

Natural history data reported by Byer shows that patients with schisis-detachment are usually asymptomatic and stable with long-term follow up.<sup>3</sup> Even patients with very posterior schisis-detachments can remain stable for many years.<sup>19</sup> Therefore, observation is reasonable in asymptomatic patients, although again, the surgeon's judgment and patient's wishes should be taken into account until more definitive data are available. Patients with schisis-detachment can be followed every 6 months or so.

Cases with posterior, symptomatic extension of subretinal fluid are exceedingly rare. When they do occur, the posterior fluid is shallow; a large progressive retinal detachment does not develop.<sup>22</sup> A 1972 report of 25 cases of schisis-detachment showed 100% success in reattaching the outer layer using several modalities: scleral buckle, diathermy, cryopexy, and laser retinopexy.<sup>23</sup>

However, posterior buckling of outer layer breaks can cause significant macular distortion, requiring removal of the implants.<sup>16</sup> A combination of cryotherapy to the outer retinal breaks, external drainage of subretinal fluid, and intraocular air has also been successful in a small number of patients.<sup>24</sup> More recently, 18 patients with symptomatic schisis-detachment with large posterior outer layer breaks were variously treated with laser retinopexy, cryopexy, scleral buckling, and/or vitrectomy. Although they achieved anatomic success in 13/18, visual acuity improved in only 3 and worsened in 6.<sup>25</sup> Given the rarity of cases of symptomatic schisis-detachment in the literature, there can be no definitive opinion on the best management; surgeon judgment based on solid surgical principles must guide clinical decisions. With current technology, however, it is likely that the often posterior outer layer breaks are best treated using vitrectomy techniques. The special considerations in addressing retinal detachment associated with retinoschisis are discussed in the next section.

## Summary

Schisis-detachment is a common finding in eyes with outer layer breaks. It is rarely symptomatic and observation alone is reasonable. The optimal treatment in the rare cases with symptomatic posterior extension of fluid is not known.

## Progressive Rhegmatogenous Retinal Detachment Associated With Retinoschisis

Concomitant inner and outer layer breaks (which are likely not in the same area of the schisis) can result in liquefied vitreous accessing the subretinal space and creating a progressive RRD. Progressive RRD associated with retinoschisis is uncommon and has been calculated to occur in only 0.05% of patients with retinoschisis. Progressive RRD is much less common than schisis-detachment. Byer calculated that the ratio of progressive RRD to schisis-detachment is 1 to 178.<sup>3</sup>

Like most RRDs, these progressive RRDs associated with retinoschisis are usually symptomatic. Examination reveals an opacified, corrugated retina typical of acute retinal detachment, but with evident outer layer breaks. Inner layer breaks may be difficult to detect (Fig. 100.7).<sup>22</sup>

**FIG. 100.7** A progressive rhegmatogenous retinal detachment associated with retinoschisis. Elevated, opacified, corrugated retina is seen, with subretinal fluid extending through the macula. A large superotemporal outer layer break is present, but no inner layer breaks are easily identified. Note the retinal vessels traversing the outer layer break.

Progressive RRD associated with retinoschisis clearly requires treatment. A 1973 report using cryopexy with scleral buckling and SF6 gas boasted a 96% anatomic success.<sup>26</sup> Another small study reported scleral buckling techniques being successful in 5/6 patients.<sup>17</sup> In the 1990s, several authors reported the use of pars plana vitrectomy for progressive RRD associated with retinoschisis.<sup>27-29</sup> One study with an average follow-up 11 years reported anatomic success in 43/45 (96%) with scleral buckle and 6/6 with pars plana vitrectomy.<sup>30</sup> In a retrospective comparison of

scleral buckle and pars plana vitrectomy, other authors found that the scleral buckle group had a somewhat better final best-corrected visual acuity and single surgery success rate than the pars plana vitrectomy group (76% vs 62%). The authors concluded that scleral buckle was superior to pars plana vitrectomy in eyes with peripheral outer layer breaks and that pars plana vitrectomy should be reserved for eyes with posterior outer layer breaks.<sup>31</sup>

It appears that treatment of progressive RRD associated with retinoschisis follows the same principles as treatment of any RRD, but with a few special considerations. First, the primary surgical goal is to close the outer wall breaks; treating inner wall breaks and collapsing the schisis cavity is optional.<sup>22</sup> If the schisis cavity is collapsed intraoperatively, it will likely recur postoperatively. Even if the schisis cavity remains collapsed, the scotoma from this area is not reversed.<sup>32,33</sup>

Pars plana vitrectomy and/or scleral buckle may be used to fix the RRD. Factors favoring pars plana vitrectomy include posterior location of outer wall breaks and presence of PVD. Anterior location of outer wall breaks and absence of PVD favor scleral buckle.<sup>31</sup> When performing pars plana vitrectomy, a drainage retinotomy in the inner wall overlying the outer wall break may be created to drain subretinal fluid.<sup>22</sup> Alternatively, the inner wall of the schisis cavity may be resected entirely. Although this technique could theoretically help to elucidate the anatomy and help identify outer layer breaks, outer layer breaks can usually be readily identified, particularly once the retina is flattened. Furthermore, resecting the inner wall of the schisis cavity could lead a surgeon into the accidental resection of full-thickness retina. Endolaser can then be used to treat all breaks, followed by gas or oil tamponade, as usual.<sup>22</sup>

## Summary

Progressive RRD associated with retinoschisis is unlikely to develop in most patients with retinoschisis – even those with breaks. It is symptomatic and progressive. Fortunately, surgical treatment is often effective and should be instituted promptly.

## Conclusions

Clinical differentiation of retinoschisis and retinal detachment is important because these entities have different natural histories and require different management. Retinoschisis, retinoschisis with retinal breaks, and schisis-detachment all have favorable natural histories and so observation is generally warranted. The only clear indications for treatment are cases of symptomatic posterior extension of schisis-detachments (which are rare) and progressive RRD. Treatment of these disorders utilizes the same surgical principles as treatment of RRD without retinoschisis and is generally effective.

## Acknowledgments

We acknowledge Dr Norman Byer, for his foundational work on the natural history of retinoschisis; Dr. William Benson, for generously providing numerous images and critically reviewing the figures for accuracy of description; and Elaine Gonzalez, RN, ophthalmic photographer, for her unflagging efforts to obtain publication-quality images for use in this chapter.

## Introduction

Proliferative vitreoretinopathy (PVR) is a nonangiogenic fibrotic disease caused by a complex cellular reaction representing a vitreoretinal wound-healing response that results in a characteristic clinical appearance. PVR can be induced by diverse events including rhegmatogenous retinal detachment (RRD), surgical intervention, or trauma. PVR is the leading cause for failure in surgical repair of RRD.

PVR is reported to have an incidence of 5–10% of all RRD,<sup>1</sup> and it is believed to be the most common cause of ultimate failure of a surgery for RRD. A high rate of PVR has also been reported following posterior segment procedures or disorders such as giant retinal tears, macular relocation surgery, endoresection of tumors, and chip implantation. Nearly one-third of human immunodeficiency virus (HIV)-positive patients with cytomegalovirus retinitis-related retinal detachment (RD) had PVR at first surgery.<sup>2</sup> In children, postoperative PVR occurs in higher incidence and is characterized by a rapid and aggressive

development.<sup>3</sup> PVR is also a common complication of ocular injuries, with the highest frequency after perforating and penetrating wounds.<sup>4</sup> PVR is a specific indication for vitrectomy.

The changing understanding of PVR pathogenesis is reflected in the different classification systems. Initially, it was assumed to be primarily due to changes in the vitreous gel (“massive vitreous retraction,” “massive preretinal retraction”). Then the involvement of cells was recognized, and the condition was retermed “massive periretinal proliferation.”<sup>5</sup> The Retina Society classification was an attempt to categorize the severity of the disease by biomicroscopic parameters.<sup>6</sup> A major problem of this system was that it did not reflect prognosis and surgical difficulty. The Cologne classification<sup>7</sup> and the Silicone Oil Study classification<sup>8</sup> took these aspects into account by separating anterior and posterior PVR. The updated Retina Society classification is a compromise, which describes severity (A, B, C), localization, and updated grade and contraction type.<sup>9</sup> A future classification should provide additional relevant clinical information, such as the biologic activity and the degree of surgical difficulty.<sup>10</sup>

Clinically, early stages of PVR are characterized by an increased reflectance and a cellophane appearance of the inner retinal surface. Additionally, tortuosity of both small and larger vessels is regularly observed. The pathologic hallmarks of advanced PVR include periretinal membrane formation, causing surface wrinkling and single or multifocal star-folds (Fig. 101.1). In the final stages, multidirectional tractional forces produced by posterior and/or anterior PVR form a narrow or closed funnel of the detached retina.<sup>11</sup>

**FIG. 101.1** Human proliferative vitreoretinopathy showing typical surface wrinkling and multifocal star-folds after rhegmatogenous retinal detachment.

A retinal break is a prerequisite for the development of PVR. Almost all risk factors for PVR are associated with intravitreal dispersion of retinal pigment epithelial (RPE) cells or the breakdown of the blood–retinal barrier (BRB).<sup>12,13</sup> The size of breaks, the extent of detachment, the presence of preoperative inflammation or low-grade PVR, and iatrogenic complications are important factors in the pathogenesis of severe PVR after the surgery for RRD.<sup>14,15</sup>

Several investigators have underlined the parallels between PVR and the general wound-healing process.<sup>16,17</sup> PVR develops in a sequence of three overlapping phases: inflammation, cellular proliferation, and extracellular matrix (ECM) remodeling. The time course of PVR development is poorly investigated. Clinical data show that on average it takes 4–8 weeks for PVR development after surgery.<sup>10,18</sup> Detailed chronobiology was evaluated in the experimental animal model of PVR induced by macrophages. The inflammation phase is initiated immediately in response to macrophage injection. Cellular proliferation can be detected as early as days  $4 \pm 7$  and peaks on days  $10 \pm 14$ . The scarring-induced RD occurs during the second and third weeks after macrophage injection.<sup>19</sup>

## Cellular Basis of PVR

After the recognition of the cellular basis of PVR, the identification of cells involved in the PVR process and their roles has been the subject of a large number of experimental and clinical-morphologic studies. The interplay between various cytokines/growth factors (GF), matrix proteins, and the different cell types drives the undesirable formation of periretinal membranes.<sup>20</sup>

## Composition of Membranes

The hallmark of the PVR process is the formation of periretinal fibrocellular membranes and intraretinal fibrosis. Membrane formation results from an interaction of retinal and extraretinal cells with components of the ECM. The membranes consist of cells of different origins: retinal glial cells (including Müller cells, microglia cells, and fibrous astrocytes), epithelial cells from the RPE and ciliary body, hyalocytes, blood-borne immune cells (macrophages, lymphocytes, and neutrophils), fibrocytes, and finally myofibrocytes.

The composition of the membranes changes with time, from early cellular to late paucicellular and rather fibrotic membranes.<sup>21</sup> In fibroproliferative membranes, glial cells, RPE cells, and fibrocytes transdifferentiate into contractile myofibrocytes,<sup>22</sup> which generate tractional forces through the expression of the contractile protein  $\alpha$ -smooth-muscle actin. Fibroblastic transdifferentiation of cells causes a reduction in cell-specific proteins such as glial fibrillary acidic protein (GFAP; glial cells) and cytokeratins (RPE cells), while proteins involved in motility and proliferation such as  $\alpha$ -smooth-muscle actin (which is normally not expressed by the cells) are upregulated.<sup>22-24</sup> This cellular transdifferentiation may be the reason for the paradox that relatively few glial and pigment epithelial cells can be detected in periretinal membranes with the commonly used immunocytochemical markers.

## RPE Cells and Epithelial–Mesenchymal Transition

RPE cells are the major cell type involved in the development of PVR. The major pathologic process is the epithelial mesenchymal transition (EMT), in which epithelial cells morphologically and phenotypically transdifferentiate into mesenchymal cells.<sup>25</sup> Pathogenetic steps in the proliferative tractional cascade include EMT, proliferation<sup>26</sup> and directional migration of transformed RPE cells, resulting in the formation of traction-generating fibrocellular membranes in the vitreous and on both surfaces of the retina.

During disease progression, RPE cells lose cell–cell adhesion, undergo EMT, and deposit ECM leading to tissue fibrosis. When RRD occurs cytokines leak into the subretinal space and induce resident RPE cells to migrate, which is the initial step of PVR.<sup>27</sup> RPE cell migration is a complex process that includes changes in cell attachment, spreading, and cytoskeletal reorganization, and it is regulated by cell matrix, matrix-dependent enzymes, cytokines, and GF. Migration is also mediated by cell membrane-associated signaling.<sup>28</sup> The disruption and loss of cell–cell contacts initiate EMT and proliferation of RPE cells.<sup>29,30</sup>

EMT is an important process during normal development in which epithelial cells transform to mesenchymal cells, show alterations in polarized organization and intercellular adhesion, and become migratory and invasive. Its critical role has also been recognized in numerous pathologic conditions, including tumor progression and fibrosis. EMT plays a critical role in PVR. When RPE cells gain access through retinal breaks into the vitreous cavity, they adhere to the detached retina and undergo EMT. During EMT, RPE cells lose their epithelial phenotypes and acquire mesenchymal, fibroblast-like properties and phenotype. Various factors such as cytokines,<sup>31</sup> modified GF signaling,<sup>32</sup> loss of normal matrix adhesion, and changes in cell–cell adhesion profile may initiate the EMT process. Characteristic features of EMT are the upregulation of  $\alpha$ -smooth-muscle actin and vimentin, the loss of the zona occludens protein ZO-1, the reduced intercellular adhesion, and the increased motility and enhanced migration,<sup>33</sup> which is supported by the enhanced matrix metalloproteinases (MMPs) activity.

## Glial Cells

Whereas the role of RPE cells has been widely discussed in the literature over the last 40 years, the impact of glial cells on the pathogenesis of PVR was frequently overlooked. Glial cells and, in particular, Müller cells, play a central role in retinal physiology. They support the neuronal activity, the integrity of the BRB, and maintain the ionic and osmotic homeostasis. Virtually all retinal diseases are associated with reactive gliosis, which is characterized by cellular hypertrophy and upregulation of the intermediate filaments vimentin and GFAP. Müller cells are active players in all forms of retinal injury and disease.<sup>34</sup> Moreover, Müller cell gliosis is associated with proliferation, and PVR is a key example of massive and long-lasting cellular proliferation.<sup>35</sup> Reactive gliosis is observed within minutes after experimental RD and proceeds so long as the retina remains detached.<sup>36</sup> In the course of PVR, Müller cells proliferate and migrate out of the retina where they are a constant part of fibrocellular membranes. Fibroproliferative membranes are focally connected to the retina via hypertrophied processes of Müller cells, rising from the retinal tissue into the membranes.<sup>1,37,38</sup>

The proliferation of Müller cells is accompanied by alterations in their membrane conductance. Müller cells of patients with PVR, and those from animal models of PVR, display a severe downregulation of the potassium conductance mediated by inwardly rectifying potassium (Kir) channels.<sup>39–42</sup> The downregulation of functional Kir channels causes a depolarization of the cells which is a prerequisite for the reentry of the cells into the proliferation cycle.<sup>43</sup> Moreover, the impaired retinal potassium homeostasis may favor neuronal hyperexcitation and glutamate toxicity. Therefore, the depolarization of Müller cells may contribute to an impairment of the regular glial–neuronal interactions in the retina and, thus, to the neuronal degeneration observed in PVR.<sup>44</sup> Furthermore, activated Müller cells may act as modulators of immune and inflammatory processes, for example by producing proinflammatory cytokines.<sup>45</sup> Reactive gliosis is a limiting factor in the recovery of vision after retinal reattachment.<sup>38</sup> In the healthy retina, Müller cells serve as soft, compliant embedding for neurons and also as a soft substrate required for neurite growth and facilitating neuronal plasticity.<sup>46</sup> The hypertrophied and proliferating glial cells fill the spaces left by

dying neurons and degenerated axons and generate so-called glial scars. Reactive gliosis is associated with an increased stiffness of Müller cells.<sup>47</sup> Such rigid glial scars may constitute a mechanical obstacle for regenerative axon growth. Therefore, attempts to reduce Müller cell gliosis may be a promising tool to inhibit retinal degeneration and to support neuroregeneration after retinal reattachment.<sup>38,44</sup> Internal limiting membrane peeling seems to reduce the occurrence of a postoperative ERM, considered an early sign of PVR, in patients with primary RRD.<sup>48,49</sup>

## Blood-Borne Cells

Inflammation is an important step in the pathogenesis of PVR and is associated with influx of blood-derived cells into the retinal tissue and vitreous. Blood-borne cells such as macrophages and fibrocytes are frequently found in PVR membranes. Macrophage-like cells might be also derived from RPE cells which have undergone EMT. Circulating fibrocytes and macrophages may function as precursors of myofibroblasts in PVR membranes and may contribute to the fibrocellular membranes directly.<sup>50,51</sup> Hyalocytes (cells in the cortical vitreous) belong to the monocyte/macrophage lineage and play a significant role in the synthesis of ECM, modulation of immune reaction, and modulation of inflammation. The strong contractile properties of hyalocytes suggest also a critical role in the genesis of PVR.<sup>52</sup>

## Stimulation of Cellular Proliferation and Migration

There is a great deal of evidence supporting the idea that soluble factors including GF and cytokines play a central role in the pathogenesis of PVR, inducing key cellular responses such as chemotaxis, proliferation, migration, and extracellular matrix remodeling.<sup>53</sup> **Growth factors** are proteins that bind to receptors on the cell surface, with the primary result of activating cellular proliferation and/or differentiation. **Cytokines** specifically denote signaling proteins that are used extensively in cellular communication. They often exhibit growth factor activity and can

exert autocrine, paracrine, and endocrine effects as do the hormones. **Interleukins** are cytokines specifically directed to leucocytes. Many soluble factors contribute to PVR, but the evidence accumulated so far is greatest for the factors below.

### **Blood Components (Thrombin, Fibronectin, Plasmin)**

A breakdown of the BRB is a characteristic and essential event in the pathogenesis of PVR. Serum that enters the retina and vitreous seems to play an important role in the transmission of mitogenic signals to both Müller cells and RPE cells. **Thrombin**, a serum component, stimulates the proliferation of retinal glial cells and otherwise quiescent RPE cells.<sup>54-58</sup> Thrombin levels are significantly higher in the vitreous of patients with established PVR, and it is involved in the activation of proinflammatory and profibrotic pathways.<sup>59</sup> Thrombin is known to promote actin stress fiber formation, an important determinant of EMT and migration of RPE cells via autocrine activation of PDGF-receptor signaling. Coagulation cascade-induced EMT of RPE may thus contribute to the formation of fibrotic retinal membranes in PVR.<sup>60</sup> **Fibronectin** stimulates the migration of glial cells<sup>54</sup> and plays an important role in ECM remodeling (see below). The vitreous of experimental PVR animals and retinal surgery patients contains the serum-derived protease **plasmin**. It is responsible for the generation of active platelet-derived growth factor-C (PDGF-C), which is the major PDGF isoform involved in the development of PVR.<sup>61</sup>

### **Platelet-Derived Growth Factor (PDGF)**

PDGF seems to play a critical role in the development of PVR. Vitreal PDGF could be detected in eight out of nine PVR patients, but rarely in patients with other vitreoretinal diseases.<sup>61</sup> Both PDGF and PDGF receptor (PDGFR) are present in PVR membranes.<sup>62</sup> RPE and retinal glial cells produce PDGFs and possess their receptors.<sup>62</sup> PDGF is a potent chemoattractant and mitogen for many cell types, including RPE and glial cells.<sup>63</sup>

Among the four PDGF family members, PDGF-C was the predominant isoform in PVR specimens.<sup>61</sup> Plasmin is the major PDGF-C processing protease.<sup>64</sup> Both RPE and glial cells express activated PDGFR $\alpha$  receptors.<sup>65</sup> Abundant binding of PDGF-C to

PDGFR $\alpha$  explains why PDGFR $\alpha$  activation is more important in the pathogenesis of PVR than PDGFR $\beta$  activation.<sup>61</sup> In a rabbit model of PVR, delivery of retrovirus containing a dominant negative PDGFR $\alpha$  suppresses the development of RD.<sup>66</sup> Furthermore, oral administration of tyrosine kinase inhibitors, which block signaling through PDGF receptors, reduce PDGF-induced epiretinal membrane formation and RD in transgenic mice.<sup>67</sup> It has been shown recently that PDGFR $\alpha$  can also be activated by other GF.<sup>68</sup> This indirect activation of PDGFR $\alpha$  involves the formation of intracellular reactive oxygen species (ROS). Vitreous is able to tirelessly activate PDGFR $\alpha$  by engaging a ROS-mediated, self-perpetuating loop.<sup>69</sup> Initial studies have shown that vitreal injection of the antioxidant N-acetyl cysteine prevents the development of experimental PVR.<sup>70</sup>

## **Transforming Growth Factor-Beta (TGF $\beta$ )**

The cytokine TGF- $\beta$  is implicated in the tissue contraction in different fibrous diseases including proliferative diabetic retinopathy and PVR.<sup>71,72</sup> The vitreous of PVR patients contains high levels of TGF- $\beta$ .<sup>73</sup> TGF- $\beta$  was also localized to subretinal strands of PVR patients.<sup>74</sup> Müller cells are one source of TGF- $\beta$  in the retina.<sup>75</sup> Experimental RD increases the expression of TGF- $\beta$  and TGF receptor II in Müller cells and in hypertrophied Müller cell processes that contribute to the formation of periretinal membranes.<sup>76</sup> Secretion of TGF- $\beta$ 2 in nonpolarized RPE cells is significantly higher supporting the contention that loss of polarity of RPE in PVR leads to rise of intravitreal TGF- $\beta$ 2.<sup>77</sup> TGF- $\beta$ -treated RPE cells differentiate along a myofibroblast pathway.<sup>33</sup> Differentially expressed microRNAs play potential roles in TGF- $\beta$ -induced EMT in RPE cells.<sup>78,79</sup> Snail transcription factor was activated in TGF- $\beta$ 1-induced EMT.<sup>80</sup> TGF- $\beta$ -activated kinase 1 (TAK1), is a key player in the EMT process.<sup>81</sup> Furthermore, gene transfer of a soluble TGF- $\beta$  type II receptor (which traps TGF- $\beta$ ) suppresses the progression of experimental PVR.<sup>82</sup> These experimental and clinical studies indicate that inhibition of TGF- $\beta$  signaling could be a therapeutic approach to prevent the progression of PVR. The contraction inhibitor simvastatin could prevent PVR progression in a dose-dependent manner.<sup>83</sup> TGF- $\beta$

likely mediates cicatricial contraction via activation of the Rho-kinase (ROCK) pathway; this pathway is also activated by various other GF. It makes it an interesting therapeutic target for treating PVR.<sup>84,85</sup>

## **Insulin-Like Growth Factors (IGF)**

The IGF system is known to be present in the vitreous. Studies on RPE and Müller glial cells responsiveness to IGF system indicated that both IGF-1 and IGF-2 are extremely potent tractional force promoters, an activity relevant to PVR pathobiology.<sup>22,86</sup> GFs and their binding proteins have been shown to exhibit both protective and deleterious effects in ocular disease. IGFBP-5 has recently been linked to mediating fibrosis in PVR but also reduces neovascularization.<sup>87</sup> IGFBP-6 participates in the development of PVR and might play a protective role.<sup>88</sup> The regulatory balance between IGF and IGF binding proteins can have profound impact on target tissues.

## **Monocyte Chemotactic Protein-1 (MCP1)**

The chemokine MCP-1 has a role during the initial stage of PVR. In experimental RD, the expression of MCP-1 increases within one hour, and the MCP-1 protein level increases within six hours of detachment.<sup>89</sup> MCP-1 stimulates the migration of RPE cells; this effect is inhibited by dexamethasone.<sup>90</sup> MCP-1 was detected in a substantial percent of vitreous samples of patients with PVR.<sup>91</sup>

## **Basic Fibroblast Growth Factor (bFGF)**

Many observations show that bFGF may be a putative target for PVR therapy. bFGF levels are raised in PVR vitreous.<sup>92</sup> Fibroproliferative membranes contain bFGF.<sup>93</sup> The vitreous bFGF expression levels in PVR-D patients were notably higher than those in PVR-C, vitreous hemorrhage, and control group.<sup>94</sup> A blockade of integrin receptors inhibits bFGF-stimulated RPE cell attachment, migration, and invasion.<sup>95</sup>

## **Hepatocyte Growth Factor (HGF)**

HGF (also known as scatter factor) is a multipotential cytokine that

plays a role in scattering of retinal cells, chemotaxis, and EMT.<sup>96,97</sup> Increased expression level of HGF has been shown in vitreous and in epiretinal PVR membranes.<sup>98,99</sup> In epiretinal membranes of patients with PVR the expression of HGF and its receptor, the c-Met tyrosine kinase, can be localized in various cell types, including glial and RPE cells.<sup>62,100</sup>

### **Connective Tissue Growth Factor (CTGF)**

Both in vivo and in vitro studies demonstrate that CTGF is a crucial factor in the pathogenesis of PVR.<sup>101</sup> CTGF is upregulated in a model of RPE monolayer scrape wounding in vitro. Recombinant human CTGF protein could stimulate RPE migration in a dose-dependent manner; this effect is suppressed by dexamethasone.<sup>102</sup> CTGF is expressed in fibroproliferative membranes and vitreous samples from patients with PVR.<sup>99,103</sup> During the development of PVR the expression of CTGF in epiretinal membranes increases from early to late stage, and localizes to RPE cells in early stage and to glial cells in the late stage of PVR.<sup>62</sup>

### **Epidermal Growth Factor (EGF)**

EGF may activate RPE cells in PVR<sup>104</sup> by inducing migration and proliferation through the EGF–EGFR–MAPK signal pathway in a concentration-dependent manner.<sup>105</sup> EGF could also promote integrin- $\alpha$ 5 expression, which subsequently activates RPE cells.<sup>106</sup> In addition, EMT of RPE cells could be induced by EGF.<sup>33</sup>

### **Vascular Endothelial Growth Factor (VEGF)**

VEGF is a regulatory mediator of cellular proliferation and vascular permeability. Anti-VEGF therapy is widely used to treat retinal or choroidal neovascular disorders. The VEGF concentration in the vitreous of PVR patients is significantly higher when compared with RD and macular hole.<sup>107</sup> VEGF is also expressed in PVR membranes.<sup>108</sup> Chronic PVR is often associated with neovascularization in the far periphery of the retina, the ciliary body, and the anterior segment, and VEGF is likely implicated in the induction of neovascularization. As an autocrine and paracrine stimulator, VEGF secreted by RPE, glial, and other cells may

contribute to the progression of fibrovascular membrane formation. Remarkably, VEGF activates not only VEGF receptors but promotes PVR by a noncanonical ability to engage PDGFR $\alpha$ .<sup>109</sup>

## **Cytokine-Mediated Inflammation (Interleukins and TNF- $\alpha$ )**

It has been suggested that cytokine-mediated pathways of inflammation play an important role in the development of PVR. Inflammatory cells, RPE cells, and retinal glial cells are possible sources of interleukin (IL)-6, IL-1 $\beta$ , TNF- $\alpha$  and interferon-gamma (INF- $\gamma$ ) in the PVR vitreous.<sup>42</sup> Cytokines in the vitreous<sup>110</sup> may stimulate important cellular processes, including migration, proliferation, and production of ECM. In the early stage and proliferative phase of experimental PVR, cytokines are present in large amounts in the vitreous (“storm of cytokines”); the cytokine levels decrease to normal in the remodeling (scarring) phase.<sup>111</sup> Under inflammatory conditions and initiated by tumour necrosis factor-alpha (TNF- $\alpha$ ), a key mediator of ocular inflammation, the ability of RPE cells to maintain the BRB and immune privilege may be lost and proliferation of RPE cells is facilitated.<sup>112</sup> This emphasizes the role of proinflammatory cytokines in the pathogenesis of PVR.

## **ECM Remodeling and Myofibroblasts**

The ECM is composed of a dynamic and complex array of collagens, glycoproteins, glycosaminoglycans, and proteoglycans. All these molecules form the substrate surrounding the cells and tissues to provide a mechanical and structural support and modulate autocrine signaling loops and the recruitment of cells.<sup>113</sup> Moreover, the ECM interacts with the cytoskeleton and with cytokines to transmit biological signals that affect the cell behavior, development, migration, proliferation, transdifferentiation, contraction, and remodeling. Integrins and proteoglycans on the cell surface are the main adhesion receptors that promote signal transduction.<sup>114</sup> Bruch's membrane and the interphotoreceptor matrix are specialized types of ECM that surround the RPE and

photoreceptors. At early stages of RRD and PVR, the neural retina layer detaches from the RPE layer, resulting in a disintegration of the interphotoreceptor matrix.<sup>115</sup> RRD causes a dissociation of RPE cells from Bruch's membrane and a dispersion of the cells into the vitreal cavity (grade A PVR). The time-dependent increase in the extracellular matrix content of PVR membranes suggests that components of the ECM stimulate its production in an autocrine/paracrine manner.<sup>10</sup>

The wound-healing process is a complex and dynamic process of restoring tissue structures and proper organ function. It is detrimental for tissue function when it becomes excessive such as in PVR. ECM components play a central role in all phases of PVR. ECM remodeling with fibrocellular membrane contraction is a culmination of this process. During the remodeling phase, transdifferentiated RPE, glial, and blood-borne cells can generate tractional forces through contraction of vitreal and newly synthesized ECM resulting in retinal surface wrinkling, star-fold formation, and tractional RD. The synthesis and deposition of ECM components on both sides of the retina is a key event of the remodelling phase. Structural proteins, adhesive proteins and antiadhesive proteins are three components of the ECM in PVR membranes.<sup>113</sup> Collagen (which includes various types), one of the major structural proteins and components of PVR membranes,<sup>10</sup> may be produced by RPE, glial, and fibroblast-like cells.<sup>116-118</sup> The expression of fibronectin, an adhesion protein, in the normal retina is low; under pathologic conditions, its concentration in the vitreous humor increases quickly.<sup>119</sup> Fibronectin promotes adhesion between cells and ECM and might stimulate RPE cells to migrate toward membranes.<sup>120</sup> In addition, fibronectin amplifies the EMT of RPE cells induced by TGF- $\beta$ .<sup>121</sup> TGF- $\beta$  also induces the synthesis of ECM components such as collagens and fibronectin.<sup>85,116,122</sup> The function of antiadhesive proteins is contrary to adhesive proteins. Antiadhesive thrombospondin in PVR membranes could facilitate the activated cells to detach from the ECM and to migrate into the wounded area.<sup>123</sup> The balance between MMPs and tissue inhibitors of MMPs (TIMPs) regulates the turnover of the ECM and the tissue remodeling associated with PVR. Cellular components of PVR membranes, including RPE cells, glial cells, and fibroblasts,

synthesize MMPs.<sup>124</sup> The expression of MMP-2 and MMP-9 is upregulated dramatically in PVR membranes.<sup>94</sup> In addition, MMP activity may be required for ECM contraction.<sup>125</sup>

Myofibroblasts play a key role in tissue remodeling. They are the predominant cellular component of PVR epiretinal membranes.<sup>126</sup> They participate in a variety of phenomena and originate from different precursor cells suggesting that the term myofibroblast describes a functional status rather than fixed cell type.<sup>127</sup> The transformation of RPE, glial, and blood-borne cells to myofibroblasts is characterized by expression of  $\alpha$ -smooth-muscle actin, a contractive protein that is thought to be essential for tractional force generation.<sup>127</sup> Transmembrane integrins at the myofibroblast surface link bundles of actin microfilaments with ECM. Through this mechanotransduction system, the contractile force generated by stress fibers can be transmitted to the surrounding ECM.<sup>128</sup> Cytokines and the components of ECM modulate the contractile activities of myofibroblasts. Serum components and the members of PDGF, IGF, and (TGF)- $\beta$  families are considered to be the major mediators of ECM contraction.<sup>22,129</sup>

In an experimental animal model, intravitreal injections of RPE cells or mixtures of RPE and glial cells show a progressively contractive response.<sup>130</sup> Transdifferentiated RPE cells can attach to individual strands of collagen and pull collagen by alternating extension and retraction of the lamellipodia.<sup>131</sup> Vitreous cortex, which consists of densely packed collagen fibrils, may form a scaffold for fibrocellular proliferation and is an active player in the remodeling process. The studies of cell-mediated gel contraction demonstrate that vitreous samples from PVR patients contain sufficient amounts of biologically active factors to induce ECM contraction.<sup>129,132</sup> Clinical data also support the role of vitreous as PVR-stimulating milieu. A tamponade with heavy silicone oil can displace the PVR milieu from the inferior fundus to the upper retina resulting in upper PVR.<sup>133</sup> Removal of the vitreous (scaffold and PVR-stimulated milieu) is a rational treatment goal for PVR.

## Biomarkers and Genetic Profiling

Intensive development of molecular biology techniques has

permitted identification of a wide variety of cellular and biological characteristics of PVR, and the search for predictive molecular risk factors (biomarkers) of PVR susceptibility was intensified in recent years. To find proteins that are specifically involved in distinct pathophysiologic events of PVR, vitreous proteomes were investigated. Significant differences were detected in the composition of vitreous proteins between control and PVR samples.<sup>134,135</sup> More than 100 PVR-specific proteins have been identified, including proteins involved in metabolic dysfunction, immune responses, and cytoskeleton remodeling. While the cytoskeletal and metabolic proteins, such as enolases, are downregulated in severe PVR, complement components, the serine proteinase inhibitor (serpin), and proteins involved in cell proliferation are upregulated.<sup>136–139</sup> In addition, the vitreous of PVR patients contains increased levels of MMPs. The vitreal content of MMPs (MMP-1, -2, -3, -8, -9, and TIMP-1)<sup>140</sup> and chemokine CXCL-1<sup>141</sup> correlates with the grade of PVR. The elevation of the vitreal content of inflammation-associated proteins such as  $\alpha$ 1-antitrypsin, apolipoprotein A-IV, serum albumin, and transferrin is consistent with the significance of inflammation in the pathogenesis of PVR.<sup>142</sup> This suggests that steroids might be helpful as adjuvant therapy of PVR.<sup>143</sup> Kininogen 1 (essential for assembly of the kallikrein–kinin system) is one of the relatively high-abundant proteins in the vitreous *and* serum of PVR patients and may thus represent a serum biomarker of PVR.<sup>137</sup> Laser flare photometry allows simple risk estimation for later PVR development. Elevated laser flare values correspond to an altered profibrotic intraocular cytokine milieu.<sup>144</sup>

Attempts to assess the genetic contribution to PVR have also been made.<sup>145</sup> Interestingly, a strong genetic association between the tumor necrosis factor locus and PVR was observed which underlines the importance of inflammation in the pathogenesis of PVR.<sup>146</sup> Genetic profiling of patients with RRD might improve the predictability of PVR in addition to or in combination with the well-known clinical biomarkers.<sup>147,148</sup>

## Conclusion

The pathogenesis of PVR is incompletely understood. We certainly

are not able to prevent this terrible complication.<sup>149</sup> At present PVR can be considered as an excessive vitreoretinal wound healing process characterized by the phases of inflammation, proliferation, and remodeling (Fig. 101.2). Once the vicious cycle of detachment and “storm of cytokines” has started, a permanent functional failure due to structural retinal changes is initiated. PVR is a complex syndrome, which involves impairment of metabolic function, remodeling of the cytoskeleton and ECM, immune responses, and inflammation. Multiple different cellular and soluble factors are involved in the pathogenesis. Therefore, therapeutic options based on the inhibition of one factor or phenomenon may be regarded with skepticism.

**FIG. 101.2** The vicious cycle of proliferative retinopathy. The breakdown of the retinal integrity is accompanied by breakdown of the blood–retinal barrier (BRB) and inflammatory tissue reaction. These processes result in an influx of blood-derived cells and

soluble factors including growth and inflammatory factors, serum, fibrin, and metalloproteinases into the vitreous and retina. The factors stimulate the scattering, migration, and proliferation of the cells of retinal and extraretinal origins followed by periretinal membrane formation. Myofibroblastic transdifferentiation of cells within the fibroproliferative membranes during epithelial–mesenchymal transition and extracellular matrix remodelling cause membrane contraction resulting in fixed (re)detachment of the retina. (Drawing by J. Grosche, Leipzig.)

Further research to understand the relative importance of distinct factors in the formation and progression of PVR may lead to more effective therapeutic approaches for the treatment of PVR. Until then surgery is the treatment of choice. Removal of activated cells and membranes and “complete” vitreous removal is a rational treatment goal achieved by surgery. However, consensus regarding a preferred surgical strategy remains controversial.<sup>150</sup> In the future, combined analysis of clinical risk factors and biomarkers should improve the identification of patients at high risk of PVR formation and may allow targeted application of appropriate adjunctive therapy to preserve vision.

## Introduction

Ocular trauma is a major cause of ocular morbidity and a leading cause of monocular visual loss. It is estimated that over 2 million eye injuries occur in the United States each year.<sup>1</sup> Children and young adults are particularly at risk, and consequently, society suffers significant socioeconomic loss, as well as human loss, from these common injuries. In 1990, national projections estimated that more than 227, 000 hospital days and US\$175–200 million in hospital charges alone result from ocular injuries every year.<sup>2</sup>

A classification of ocular trauma with standardized terminology was developed by Kuhn and associates.<sup>3</sup> The International Society of Ocular Trauma subsequently used this terminology to develop a classification system for mechanical injuries of the eye (Box 102.1). This system has proved useful for describing ocular trauma without miscommunication and for facilitating the delivery of optimal

### **Box 102.1.**

## **Standardized Classification of Ocular Trauma**

### **Closed globe**

- Contusion (no full-thickness wound)
- Lamellar laceration (partial-thickness wound of the eye wall)

### **Open globe (full-thickness wound of the eye wall)**

- Rupture
- Laceration
- Penetrating (single entry wound; no exit wound)
- Perforating (separate entry and exit wounds by same agent)
- Intraocular foreign body (retained foreign object that caused entry wound)

Different types of ocular injuries have different pathophysiologic and therapeutic ramifications; therefore, knowledge of the initial mechanism of injury to the macula or optic nerve is critical for determining visual prognosis.<sup>4-6</sup> Subsequent wound healing responses leading to intraocular proliferation, tractional retinal detachment, and posttraumatic proliferative vitreoretinopathy (PVR) can play major roles in determining the final visual outcome.<sup>4,6-9</sup>

Before the use of vitrectomy, wound closure often left vitreous incarcerated in the lips of the scleral or corneal edges of the wound, providing a scaffold for future proliferation. In the first large prospective study, conducted between 1952 and 1970, only 6% of patients with open-globe injury gained visual acuity of 5/200 or better.<sup>10</sup> Our improved understanding of wound healing and the advent of vitrectomy techniques in the 1970s permitted more successful repair of posterior segment wounds and resulted in a marked decrease in enucleations.<sup>8,9,11,12</sup>

This chapter reviews the pathophysiology and the therapeutic aspects related to open-globe injury involving the posterior segment. (See also [Chapter 94](#), Traumatic chorioretinopathies; [Chapter 101](#), Pathogenesis of proliferative vitreoretinopathy; and [Chapter 114](#), Surgery for ocular trauma.)

## Anatomic Change

While the direct damage to the ocular tissue depends upon the nature of trauma, the integrity of the vitreoretinal barrier is commonly disrupted by ocular trauma. The vitreous is normally attached to all contiguous structures, including the posterior lens capsule, the pars plana of the ciliary body, the retina, and the optic disc, but the strength of this attachment varies. The vitreous is most firmly attached at its base and is relatively firmly attached to the lens, fovea–parafoveal area, margin of the optic nerve head, and along major retinal blood vessels.<sup>13</sup> Weakening of the vitreoretinal interface induced by mechanical force can lead to acute posterior vitreous detachment (PVD) from the retina. When the detachment reaches a point of firmer attachment to the retina, typically the vitreous base, it exerts traction on the retina. The abrupt PVD

and/or prolapse and incarceration of the vitreous through the penetrating wound predispose the eye to vitreous traction on the retina and tractional retinal detachment (Fig. 102.1).<sup>14-18</sup>

**FIG. 102.1** The development of tractional retinal detachment can be related to two mechanisms. (A) Vitreous is incarcerated in the wound, and fibrous ingrowth from the wound along the vitreous scaffold may result in traction on the peripheral retina, rolling forward at the vitreous base and junctions of the ora serrata. (B) The contraction of epiretinal fibrous tissue on the surface of the peripheral and equatorial retina may result in shortening of the retina. Either of these mechanisms, but usually a combination of both, results in tractional retinal detachment. (Reproduced with permission from

Cleary PE, Ryan SJ. Method of production and natural history of experimental posterior penetrating eye injury in the rhesus monkey. *Am J Ophthalmol* 1979;88:212-20.)

Breakdown of the blood–retina barrier after trauma is a key triggering mechanism in the wound healing sequence. The blood–retinal barrier (BRB) consists of tight junctions between the retinal capillary endothelial cells (inner BRB) and the retinal pigment epithelial (RPE) cells (outer BRB). Disruption of this highly specialized barrier system leads to migration of inflammatory cells and leakage of serum components, allowing a profound change in the biochemical milieu of the retina and vitreous.

## Histopathologic Findings

In reviewing the histopathology of enucleated human eyes, one must be cognizant of the bias of ascertainment of the specimen. Before the introduction of vitreous surgery in 1970, many more injured eyes were enucleated, whether because the eye had become blind and painful in the late stage or as prophylaxis against the possibility of sympathetic ophthalmia in an earlier stage. Regardless of the indication for enucleation, the pathologist and reader must always consider that the circumstances are dictated by clinical indications and not for reasons of optimal timing to determine pathogenesis. We, therefore, review literature from enucleated eyes and then consider experimental models to better understand the pathophysiology.

Histopathologic evaluation of human eyes enucleated after penetrating trauma has shown that healing of limbal and scleral wounds was more rapid than healing of corneal wounds.<sup>17</sup> As early as 4 days after injury, fibroblastic proliferation had occurred from the episclera, and by 1 week, from the stroma of the ciliary body and choroid. At 2 weeks, a mass of vascularized fibrous tissue joined the wound edges; and by 4–6 weeks, a dense fibrous scar had formed. This fibrous ingrowth in limbal or scleral wounds occurred in relation to vitreous incarceration and damage to the lens and/or vitreous hemorrhage. Condensation of vitreous fibrils over the vitreous base was followed by PVD. Typically, the vitreous remained attached anteriorly, and the condensed vitreous fibrils remained attached to the peripheral retina, frequently radiating from a limbal or scleral wound associated with fibroblasts (Fig. 102.2). Retinal detachment was present in most eyes. Although retinal tears were found in a few eyes, it was impossible to exclude a rhegmatogenous component since not all eyes were serially sectioned. Retinal hemorrhage and choroidal hemorrhage were common within the first 2 months and 2 weeks of injury, respectively. Epiretinal membranes were present over both the peripheral and posterior retina by 6 weeks after injury. Subretinal membranes were delicate, branching, and dendritic in appearance 1 and 2 weeks after injury and were thickened and attached to folds in the retina in later phases. Intraocular inflammatory infiltrate,

mainly monocytes, was prominent in the anterior chamber or vitreous. Almost all eyes contained some macrophages, either lining the PVD or accumulated in areas of subretinal hemorrhage. Fibroblastic proliferation within the vitreous was present in the area of the wound, resulting in a cyclitic membrane in the early weeks after injury and containing fibroblast-like cells 2 months after injury.

**FIG. 102.2** (A) Photomicrograph showing the appearance of the peripheral retina in the vitreous base 2 months after a penetrating injury. The peripheral retina (*R*) is detached and appears to be pulled forward over the pars plana (*PP*). The vitreous is condensed and vitreous fibrils are incarcerated in a peripheral corneal wound (*W*). The vitreous was detached from the posterior retina, but remains attached to the peripheral retina over the vitreous base (*Vb*). (B) Photomicrograph showing a multilayered epiretinal membrane (*ERM*) on the surface of the posterior retina in an eye enucleated 2 months after a penetrating injury. A posterior vitreous detachment (*PVD*) is present and a blood clot is loculated within the vitreous gel. The posterior hyaloid is lined with red cell debris. The epiretinal membrane lies between the posterior hyaloid and the inner limiting membrane of the retina. In adjacent sections, full-thickness retinal

folds were present (hematoxylin and eosin, ×37).

## Experimental Models

Human specimens obtained from surgery, such as periretinal membranes, vitreous aspirates, and enucleated eyes, provide information about the pathophysiology of open-globe injury.<sup>17,18</sup> However, since these specimens often represent only the advanced stages of disease and since they encompass the secondary effects of retinal detachment and PVR, their contributions to our understanding of the complex mechanism of trauma-induced injury are somewhat limited. Therefore, animal models that reproduce various types of ocular trauma have played an important role in our understanding of their pathogenesis.

Cleary and Ryan developed penetrating injury models in rabbits and rhesus monkeys using a standard technique.<sup>19–24</sup> A knife wound was made using a stab incision through the pars plana and then lengthened to 8 mm with scissors. Vitreous gel prolapsed through the wound and the vitreous face was ruptured in a manner similar to that encountered in the perforated human eye. The wound was then carefully closed and 0.5 mL of autologous blood was injected into the midvitreous. With this standardized method, tractional retinal detachment was achieved with remarkable reproducibility. During the second week after injury, the blood changed to a contracted clot and the posterior vitreous detached. As early as 4 weeks after the injury, fibrous tissue grew from the wound into the vitreous, the blood clot formed fibrous tissue, and the posterior vitreous detached. Epiretinal membranes became visible around this time and progressed for up to 15 weeks. The retinal detachment typically occurred between 6 and 11 weeks after the injury. The configuration of the retinal detachment was indicative of the key processes involved. When the vitreous detached posteriorly, the anteropipheral portion of the vitreous remained firmly attached to the peripheral retina in the area of the vitreous base.

Subsequently, the peripheral retina was dragged forward toward the pars plana through its entire circumference, forming a funnel-shaped configuration with full-thickness folds.<sup>19,20,25</sup> The presence of intravitreal blood was a potent stimulant to the development of this cascade of the wound healing process. Some 73% of 25 monkey eyes with intravitreal blood injections developed tractional retinal detachments as opposed to only 24% of eyes that received only balanced salt solution injections.<sup>19</sup>

Penetrating injuries in human eyes are often accompanied by contusions. An animal model used to study this combination employed pigs because pig sclera is sturdy enough to withstand a blunt pellet injury.<sup>26–28</sup> An airgun delivered a pellet to the limbus of a pig eye with standardized force at impact. An 8-mm incision was then made in the pars plana as previously described. The main features were the development of intravitreal proliferation and tractional retinal detachment. Additionally, subretinal hemorrhage was frequently associated, leading to subretinal fibrous membrane formation.
