Lili Shi et al.<sup>37</sup> recently reported, in a meta-analysis of 20 studies involving 1960 participants, the accuracy of telescreening. Pooled sensitivity was >80% to detect no DR and PDR, >70% to detect mild and moderate NPDR and macular edema and 53% for detecting severe NPDR. Pooled specificity was >90% except in detecting mild NPDR which was 89%. Accuracy was higher in digital images obtained through mydriasis than nonmydriatic and was highest for wide-angle (100–200°) images, especially for detection of No DR and mild DR.

### Patient Satisfaction

Since telescreening involves remote care without evaluation by the doctor in person, there are concerns regarding lack of satisfaction among patients. Studies have shown, however, that telescreening has equal, if not better, satisfaction than in-person evaluation by a doctor.<sup>38,39</sup> Paul et al. assessed patient satisfaction levels and factors influencing satisfaction during teleophthalmology consultation in India using a patient satisfaction questionnaire. He found that 37.34% of the patients felt that telescreening is more satisfying than an in-person evaluation, and 60% felt that both models are equally satisfying. It was also noted that patients who asked questions

during the screening were 2.18 times more likely to be satisfied with teleophthalmology than those who did not. Mansberger et al.<sup>40</sup> showed that a telemedicine program using a nonmydriatic camera increased participation for diabetic retinopathy screening. Telemedicine could be used to triage patients with diabetes for further evaluation with an eye care provider, especially in minority and low-access settings.

## Cost-Effectiveness

Bjorvig et al.,<sup>41</sup> in an economic analysis, concluded that telemedicine was a less costly option for screening in places with higher patient workloads. Telemedicine was also proven to be cost-effective in the prison populations by Aoki et al.,<sup>42</sup> where it may have special utility due to costs and safety issues associated with transporting prisoners.

Gomez-Ulla et al.<sup>6</sup> did a comparative cost analysis of diabetic retinopathy telescreening versus standard ophthalmoscopy, from both Public Healthcare System (PHS) and patient perspectives. The authors concluded that from the PHS perspective, direct fundus examination is less costly than telescreening owing to the higher capital costs required for the purchase of digital imaging equipment. From a global perspective, however, the digital imaging alternative is more convenient because the travel cost and loss of income for the patient are lower.

Jones et al.<sup>7</sup> reviewed the evidence available on cost-effectiveness. They concluded that telemedicine is cost-effective for retinopathy screening in remote and rural communities and other groups with travel difficulties and the cost-effectiveness increases with an increase in patient workload. Rachanapalle and colleagues<sup>43</sup> evaluated the cost-utility of telescreening for DR in India and found that by using the WHO threshold of cost-effectiveness, the rural teleophthalmology was cost effective (\$1320 per QALY) compared to no screening from a health provider perspective. The study found that screening once in two years was more cost-effective in these rural settings.

## Advances in Telescreening

Recent advances resulting in better and faster telecommunication, miniaturization of diagnostic equipment including digital cameras, and automation of retinal image analysis, offer excellent opportunities to expand telescreening services in more remote areas.

## Smartphones for Diabetic Retinopathy Screening

The latest generations of smartphones feature faster processors, enhanced memory, smaller batteries, and efficient operating systems that are capable of advanced functions, and have paved the way for numerous applications (apps) that are affecting our personal and work environments. The newer generation of portable eye cameras can be configured with smartphone-based attachments and integrated lens adapters.<sup>44-47</sup> They use the smartphone-inbuilt camera for image acquisition, and some later versions have also attempted to utilize apps designed for screening of preliminary abnormalities based on artificial intelligence-driven algorithms. These camera systems and apps offer the prospect of a low-cost retinal screening solution for diabetic retinopathy.

The Welch Allyn iExaminer is a type of adapter that turns the PanOptic Ophthalmoscope into a mobile digital imaging device. It aligns the optical access of the PanOptic Ophthalmoscope to the visual axis of the iPhone 4 or 4S (Apple, Cupertino, CA) camera to capture high resolution (5/8 megapixel; depending upon the iPhone model) pictures of the posterior pole including the macula and optic nerve. Another mobile phone-based retinal camera is the Ocular CellScope.<sup>45</sup> It is comprised of a mobile phone, a housing that contains the illumination and collection optics, and an integrated phone holder that ensures alignment of the illuminating and collecting optics with the phone's camera. It uses a single 54D ophthalmic lens for focusing and capturing reflected light, in turn utilizing the autofocus mechanism of the iPhone's camera to correct for variability in axial length and refractive error in the subject's eye.

Portable eye examination kit (PEEK) is a mobile app and clip-on hardware that can be used for imaging the retina. This system stores GPS data for each patient screened for later reference. The device uses a 20 D or 28 D lens in front of the phone's camera and utilizes the phone's inbuilt flash system as a powerful light source.

Recently, Ryan et al.<sup>47</sup> described the results of comparison of smartphone-based, nonmydriatic and mydriatic photography in DR (CAMARA study). They used a 20 D lens-assisted smartphone photography system and concluded that smartphone and nonmydriatic photography were able to detect DR and sight-threatening DR. However, the nonmydriatic camera was more sensitive at detecting DR than the smart phone.

## Automated Retinal Image Analysis

The shortage of manpower imposes a limitation on the screening capability of telehealth programs serving a steadily growing diabetic population. Therefore, an automated image analysis system able to detect diabetic retinopathy is a vital necessity, especially in the coming years.

Over the past decade several attempts have been made to either semiautomate or fully automate retinal image analysis. Tools have been developed for analyzing and enhancing the image quality (correction of illumination, increasing image contrast, histogram equalization, vessel segmentation, edge sharpening, and image deconvolution), and for providing automated identification of pathologic retinal lesions (neural networks, region growing, morphologic analysis, and classification algorithms).<sup>48</sup> Automated identification of retinal lesions can identify the absence or presence of diabetic retinopathy based on the detection of microaneurysms and dot hemorrhages (dark lesions),<sup>49</sup> or can detect referable retinopathy based on the detection of exudates (bright lesions) and blot hemorrhages (dark lesions).<sup>50</sup>

Winder et al.<sup>48</sup> conducted a structured survey of algorithms for the automatic detection of retinopathy in digital color retinal images. The authors pointed out the need for clear guidelines and goals in image processing research in order to avoid producing results that are difficult to compare in terms of the success of the

algorithms or techniques.

Image reading algorithms must be tested against images that are acquired in actual screening settings, since lower image quality can greatly diminish their performance. Validation against the standard retinal image databases, such as STARE, DRIVE, or MESSIDOR, show sensitivity and specificity above 90% for most algorithms;<sup>51</sup> however, they may not reflect performance in “real-world” settings. Image quality in actual screening settings is often less than optimal due to many factors such as variability of photographer quality, patient cooperation, and media opacity and small pupils, which are frequent with diabetes and advanced age. Future validation studies in actual screening settings are needed.

## Conclusion

Telescreening has the enormous potential to offer remote care to patients with diabetes without compromising the quality of care. However, to maximize the chance for success, it is essential that all telescreening programs should define clear goals, establish appropriate quality control measures, and adhere to regulatory and statutory requirements. Prospective studies demonstrating a reduction in vision loss from diabetic retinopathy as a result of telescreening programs will be of critical importance, before telescreening strategies can be adopted as the standard for routine clinical management of patients with diabetes.

Treatment

## **Branch Retinal Artery Occlusion**

## **Cilioretinal Artery Occlusion**

## **Combined Retinal Artery and Vein Occlusion**

## **Cotton-Wool Spots**

## **Paracentral Acute Middle Maculopathy**

Central retinal artery occlusion was first described in 1859 in von Graefe's report of multiple systemic emboli in the setting of endocarditis causing obstruction of the central retinal artery.<sup>1</sup> Since

then significant literature has accumulated on retinal artery occlusions. Below, we use an arbitrary classification, including the new finding of paracentral acute middle maculopathy, to discuss these disorders in sequence:

- Central retinal artery occlusion (CRAO)
- Branch retinal artery occlusion (BRAO)
- Cilioretinal artery occlusion (CLRAO)
- Combined retinal artery and vein occlusion
- Cotton-wool spots
- Paracentral acute middle maculopathy (PAMM).

## Central Retinal Artery Occlusion

### Epidemiology

The true incidence of CRAO is unknown. The estimated incidence of CRAO is reported to be roughly 1 in 10,000 cases at tertiary referral centers,<sup>2,3</sup> being even lower for the general population, at approximately 8.5 cases per 100,000.<sup>3</sup> Similar to other vascular disorders, CRAOs are largely seen in older adults, but cases in children and young adults have been reported.<sup>4,5</sup> Average age at presentation is in the early sixties with greater than 90% presenting at over 40 years. Men are affected more frequently. No predilection for one eye over the other has been reported; however, 1–2% of cases may manifest bilateral involvement.<sup>6</sup>

### Clinical Features

Typically, patients with acute CRAO present with sudden, monocular, painless, severe vision loss. In some cases, premonitory amaurosis fugax may be reported. Amaurosis fugax represents transient acute retinal ischemia and typically suggests an embolic source of occlusion. Presence of amaurosis fugax also has a higher correlation with stroke compared with retinal emboli alone.<sup>7</sup> The risk of CRAO after amaurosis fugax is estimated to be only 1% per year.<sup>8</sup> Although CRAO rarely presents simultaneously in both eyes, it may occur sequentially.<sup>9</sup>

Presenting visual acuity ranges from counting fingers to light perception in 74–90% of eyes.<sup>6–10</sup> Central visual acuity may be near normal in patients who have a transient CRAO or a cilioretinal artery perfusing the fovea. Connolly et al. reported a trend toward better visual acuities in patients with CRAO secondary to giant cell arteritis as compared with those due to other, largely embolic causes.<sup>11</sup> The presence of an embolus is usually associated with poorer vision. In Hayreh's prospective natural history study of 260 eyes with CRAO, eyes with counting fingers or worse visual acuity presenting within 7 days of onset had the best potential for improved vision.<sup>10</sup> The absence of light perception is rare. In such cases, concomitant choroidal circulation deficit (e.g., due to ophthalmic artery occlusion) or optic nerve involvement should be considered.<sup>6</sup> Visual acuity tends to improve only within the first week of onset with minimal chance for appreciable improvement subsequently.<sup>11</sup> Visual recovery has shown to correlate with presenting visual acuity and the duration of visual impairment.<sup>12</sup> Although visual acuity may spontaneously improve in up to 22% of patients with nonarteritic CRAO,<sup>11</sup> less than 10% of patients report a meaningful recovery.<sup>13</sup>

Typically an afferent pupillary defect develops within seconds following obstruction of the central retinal artery regardless of macular sparing.<sup>4</sup> Intraocular pressure is often normal at presentation but may become elevated in the setting of rubeosis iridis.

In a majority of cases of acute CRAO, the anterior-segment exam is normal initially. If rubeosis iridis is present acutely, presence of concomitant carotid artery obstruction should be considered. The incidence of rubeosis in CRAO is 16.6–18.8%.<sup>14–16</sup> As compared to central retinal vein occlusions (CRVO), iris rubeosis tends to occur earlier after CRAO – at a mean of 4–5 weeks after onset compared to 5 months after onset in CRVO. Not surprisingly, rubeosis is more common in more severe and complete obstructions with extensive nonperfusion. The risk of developing iris neovascularization is greater for obstructions lasting more than 1 week versus those lasting only a few days after onset.<sup>14–16</sup> With carotid obstruction, rubeosis iridis can cause elevated intraocular pressure above perfusion pressure in the central retinal artery leading to an

obstruction via this mechanism. Laser panretinal photocoagulation induces successful regression in approximately 65% of cases.<sup>17</sup>

In his 1891 report, Nettleship described in detail the ophthalmoscopic appearance of CRAO. "The classic dense, white haze of the central region in the retina with a well-marked clear patch at the yellow-spot was very well shown; there were no hemorrhages; the arteries and veins were of about normal size, but no pulsation could be produced in any of them by pressure with the finger upon the globe."<sup>18</sup> Hayreh investigated fundus changes in CRAOs in a large retrospective review in 2007 of 248 eyes of 240 patients. In the acute phase, his group noted a cherry-red spot (90%), posterior pole retinal opacity or whitening (58%), box-carring of retinal arteries and veins (19% and 20% respectively), retinal arterial attenuation (32%), optic disc edema (22%), and optic nerve pallor (39%). The retinal findings were predominantly located in the posterior pole with a normal-appearing periphery.<sup>19</sup>

Typically, retinal whitening in the posterior pole and a cherry-red spot are the earliest characteristic changes in CRAO. Retinal whitening corresponds to ischemic damage to the inner half of the retina with opacification of the retinal nerve fiber and ganglion cell layers from cessation of axoplasmic transport. The opacification is visible ophthalmoscopically where the ganglion cell layer is more than one cell thick, i.e., the macula, except in the foveal region, where a cherry-red spot is seen (Fig. 54.1). The outer nuclear and plexiform layers and photoreceptors remain intact, as demonstrated in histologic studies (Fig. 54.2).<sup>20,21</sup> The size of the cherry-red spot varies depending on width of the foveola. The cherry-red spot is actually normal-appearing retina being observed in high contrast against the surrounding opacified retina. The thin retina in this location is nourished by the underlying choroidal circulation and as a result does not become hypoxic or opacified, permitting visualization of the normal underlying retinal pigment epithelium (RPE) and choroid.<sup>22</sup> Similarly, the retinal periphery in CRAO appears normal because the retina is also thinner with a single layer of ganglion cells, such that the nutrition of the inner retinal layers can be maintained by the choroidal circulation alone. The probability of a cherry-red spot still being present decreases with increasing duration from the onset of CRAO: 88% after 1 week, 59%

after 2 weeks, 47% after 3 weeks, and 19% after 4 weeks after onset. Typically, the retinal opacification resolves over 4–6 weeks, although at least some retinal whitening is noted in 17% of patients with complete, nontransient CRAO after 1 month.<sup>19</sup> Pathologically, this evolution corresponds to a resolution of initial acute ischemia-induced intracellular edema with subsequent loss of neuronal cells and the development of an acellular scar of the inner retinal cell layers (Fig. 54.2).<sup>23</sup>

**FIG. 54.1** Acute central retinal artery obstruction. Color fundus photo demonstrating superficial retinal whitening or opacification in the posterior pole with evidence of a central cherry-red spot. The opacification is most prominent in the perifoveal area. (Courtesy of Dr. Steven Yeh, Emory Eye Center, Atlanta.)

**FIG. 54.2** Histopathologic findings in central retinal artery obstruction. In the chronic stage of the disease, the inner retinal layers show significant atrophy (hematoxylin and eosin,  $\times 25$ ). (Courtesy of Dr. Hans Grossniklaus, Emory Eye Center, Atlanta.)

A patent cilioretinal artery supplying some or all of the papillomacular bundle is seen in approximately one-third of cases. Retinal whitening will be clearly demarcated around the area of preserved macula perfused by the cilioretinal circulation (Fig. 54.3A). In these cases, the visual acuity will be dictated by the location and extent of the papillomacular bundle perfused.<sup>10,24-26</sup> Sparing of the fovea may be associated with excellent visual acuity, albeit with a significant visual field deficit corresponding to the topography of the occlusion.

**FIG. 54.3** Acute central retinal artery occlusion with cilioretinal artery sparing. (A) Retinal opacification is clearly demarcated around the preserved macula perfused by the patent cilioretinal artery. The perfused area includes the fovea; therefore the patient's presenting visual acuity was good. (B) At 25 seconds the cilioretinal artery is perfused with retrograde flow into the retinal veins. (C) At 9 minutes the arterial circulation is still not completely filled, demonstrating a severely delayed arteriovenous transit time (Courtesy of Dr.

John Payne, Emory Eye Center, Atlanta.)

The appearance of the retinal vasculature can be quite variable soon after the onset of CRAO; therefore, the presence of a normal-appearing vasculature should not exclude the diagnosis. In Nettleship's 19th-century description of CRAO, he noted the appearance of the retinal vasculature to have a stagnated arterial blood column without attenuation.<sup>19</sup> In Hayreh's natural history study,<sup>19</sup> only 15% of acute CRAO had normal-appearing retinal arteries. Box-carring or segmentation of the blood column of both

the arteries and veins can occur secondary to separation of blood serum from erythrocytes in a rouleaux formation.

Retinal emboli are visible in 20–40% of eyes with CRAO.<sup>4,27</sup> Retinal emboli are the most common cause of nonarteritic CRAO and BRAO.<sup>28</sup> The most common variant is a yellow, refractile cholesterol embolus (Hollenhorst plaque) (Fig. 54.4). According to a study by Arruga and Sanders, retinal emboli consist of cholesterol in 74% of cases, calcified material in 15.5%, and platelet and fibrin in 15.5%.<sup>29</sup> These cholesterol emboli typically originate from the carotid arteries in the setting of atherosclerotic disease, but can also arise from the aortic arch, ophthalmic artery, or proximal central retinal artery. Cholesterol emboli are often small, do not completely obstruct retinal arterial blood flow, and are frequently found at bifurcation sites (Fig. 54.4). Emboli can often be asymptomatic. Migration with disappearance of retinal emboli is common.<sup>19</sup> Calcific emboli are less common than cholesterol emboli but are typically larger and cause more severe or complete obstruction. They most commonly originate from the cardiac valves.<sup>22,30</sup>

**FIG. 54.4** Cholesterol embolus at an arterial bifurcation along the superotemporal arcade.

The optic nerve is acutely edematous in nearly all cases of arteritic CRAO as a result of associated anterior ischemic optic

neuropathy. In the acute phase of nonarteritic CRAO, the disc may be normal, hyperemic, edematous, and, rarely, pale. Acute-phase optic nerve pallor is due to ischemic opacification of the surface nerve fiber layer since this layer is supplied by retinal circulation.<sup>31</sup> Neovascularization of the disc in acute CRAO is rare but has been reported, typically in association with a chronically hypoxic retina (e.g., concomitant diabetic retinopathy, ischemic CRVO, or ocular ischemia).<sup>18,19</sup>

The most frequent findings in the chronic stage of eyes with CRAO are optic atrophy (91%), retinal arterial attenuation (58%), cilioretinal collaterals (18%), macular RPE changes (11%), and cotton-wool spots (3%) (Fig. 54.5). Chronic-phase optic nerve pallor is due to optic atrophy and nerve fiber loss (see Figs. 54.2 and 54.10). In arteritic CRAO, the associated anterior ischemic optic neuropathy also contributes to the development of pallor.<sup>19</sup> In chronic CRAO, neovascularization of the optic disc rarely occurs, presumably because nonviable tissue is less likely to elaborate angiogenic factors compared with chronically ischemic but viable retinal tissue seen in cases of diabetic retinopathy or retinal vein occlusion.<sup>32</sup> Incidence of neovascularization of the disc in one retrospective study was only 1.8%.<sup>33</sup> Concomitant rubeosis iridis may also occur in the setting of chronic CRAO. Retinal arterial attenuation is more common in the chronic phase than in the acute phase.<sup>19</sup> Months after an acute CRAO, cilioretinal collaterals may develop as a result of a compensatory enlargement of capillary anastomoses between retinal capillaries on the surface of the disc and ciliary capillaries deeper in the optic nerve head. The probability of developing cilioretinal disc collaterals was 4% at 1 month and 18% at 3 months from onset of CRAO in one study.<sup>20</sup> Macular RPE changes are seen with CRAO but are much less common than in ophthalmic artery obstruction, where the choroidal circulation is also involved.

**FIG. 54.5** Chronic central retinal artery occlusion. Optic nerve pallor from atrophy and severe arterial attenuation is seen in this patient with a remote central artery occlusion.

## Ancillary Studies

Initially, fluorescein angiography in CRAO almost always shows some variable residual retinal circulation with delayed and sluggish filling of the retinal vasculature. Complete absence of retinal filling is rare. Appearance of dye in the central retinal artery is typically delayed by 5–20 seconds. However, the delay in retinal arterial branches is even more substantial. The fluorescein dye lines the arterial walls in a pattern similar to the laminar flow filling of normal retinal veins. In cases with visible intraarterial emboli, the arteriovenous transit time can be even further delayed ([Figs. 54.3B–C](#)).<sup>34</sup> The severity of obstruction and retinal ischemia correlates with less favorable initial visual acuities. Staining of the optic disc can be variable; however, staining of the retinal vessels is rare. Typically, the retinal circulation is reestablished after an acute CRAO, but the inner retinal tissue has generally already infarcted by then. Therefore, although the fluorescein angiogram may return to relatively normal appearance, the vision loss, optic nerve atrophy, and arterial narrowing persist.<sup>22</sup> For patients with a normalized

fluorescein angiogram who do not go on to develop optic atrophy, the diagnosis of a true CRAO should be called into question, though it is possible that some individuals may have reperfusion before the irreversible damage has occurred.

In the acute stage, optical coherence tomography (OCT) shows increased reflectivity of the inner retina. This corresponds to intracellular edema and explains the lack of intraretinal, hyporeflective fluid spaces in cases of CRAO or BRAO. The reflectivity of the outer retinal layers and RPE is blocked by the highly reflective inner retinal layer. No retinal thickening secondary to the accumulation of serous fluid escaping from retinal capillaries into the extracellular space is seen (Fig. 54.6). OCT images of chronic CRAO show thinning and atrophy of the inner retina. OCT can be helpful in cases of chronic CRAO where the fundus appears featureless but the OCT shows inner retinal atrophy (not just nerve fiber layer atrophy) with preservation of the outer retina.<sup>35,36</sup>

**FIG. 54.6** Spectral-domain optical coherence tomography (SD-OCT) of acute central retinal artery occlusion (CRAO). An irregular foveal contour is seen with a highly reflective, thickened inner retina. The outer retina is relatively hyporeflective because of blocking from the thickened inner retina. The external limiting membrane, ellipsoid zone, and retinal pigment epithelium are intact, as would be expected with acute CRAO.

Central scotoma is the most common defect observed on visual field testing followed by paracentral scotoma. Patients with cilioretinal sparing show a preserved central island of vision corresponding to the area perfused by the patent cilioretinal artery. Peripheral constriction is the most common visual field deficit noted in these patients.<sup>10</sup> A preserved temporal island may be seen in some patients, presumably secondary to choroid-derived perfusion of the nasal retina.<sup>24</sup> Visual field defects improve in approximately 28% of patients, remain stable in 57%, and worsen in 7%.<sup>10</sup>

Electroretinography typically demonstrates more severe attenuation of the b-wave than the a-wave since the inner retinal layers are more affected – this produces a characteristic negative waveform with the scotopic white stimulus (Fig. 54.7). Diminution of the a-wave and b-wave may suggest outer retinal damage secondary to choroidal vascular hypoperfusion in the setting of an ophthalmic artery occlusion in addition to a CRAO.<sup>37</sup>

**FIG. 54.7** Electroretinogram. The responses from a normal eye are seen on the left. The tracings on the right are from an eye with a central retinal artery occlusion (CRAO). The bottom right tracing shows the maximum response to the scotopic white stimulus. The a-wave is of normal amplitude; however, the b-wave

does not reach the baseline, yielding a negative waveform, as is typically seen with a CRAO.

## Systemic Associations

The distribution of systemic associations for CRAO varies depending on age. Overall, embolism from carotid artery atherosclerosis is the most common etiology; however, carotid disease is relatively rare in patients under the age of 40 in whom cardiac embolism is the most common etiology.<sup>4,5,38</sup> The systemic and ocular abnormalities that have been associated with retinal arterial occlusions are summarized in [Box 54.1](#).

### Systemic and Ocular Abnormalities Associated With Retinal Arterial Occlusion

#### Emboic Sources

- Systemic arterial hypertension (via atherosclerotic plaque formation)<sup>6,22</sup>
- Carotid atherosclerosis<sup>7,98,99</sup>
- Cardiac valvular disease (rheumatic,<sup>45</sup> mitral valve prolapse,<sup>45,46</sup> aortic stenosis,<sup>45</sup> mitral annular calcification<sup>56</sup>)
- Left ventricular hypertrophy and segmental wall motion abnormalities<sup>56</sup>
- Thrombus after myocardial infarction<sup>56</sup>
- Cardiac myxoma<sup>41-43</sup>
- Tumors<sup>47,100</sup>
- Carotid artery dissection<sup>101</sup>
- Intravenous drug use<sup>102</sup>
- Lipid emboli (pancreatitis)<sup>103</sup>

- Purtscher retinopathy (trauma)<sup>104</sup>
- Loiasis<sup>105</sup>
- Radiologic studies (carotid angiography,<sup>101</sup> cerebral angiography,<sup>35</sup> cardiac catheterization,<sup>60</sup> lymphography,<sup>61</sup> hysterosalpingography<sup>106</sup>)
- Carotid endarterectomy<sup>107</sup>
- Deep vein thrombosis (via paradoxical embolus through a cardiac wall defect)<sup>108</sup>

## Trauma

- Retrobulbar injection<sup>67</sup>
- Orbital floor fracture repair<sup>68</sup>
- Anesthesia<sup>69</sup>
- Penetrating injury<sup>71</sup>
- Nasal surgery<sup>109</sup>

## Coagulopathies

- Sickle-cell disease<sup>110</sup>
- Homocystinuria<sup>111</sup>
- Lupus anticoagulant<sup>112</sup>
- Protein C and/or S deficiency<sup>113</sup>
- Antithrombin III deficiency<sup>113</sup>
- Activated protein C resistance<sup>114</sup>
- Factor V Leiden<sup>115</sup>

- Platelet abnormalities<sup>4</sup>
- Oral contraceptives<sup>116</sup>
- Pregnancy<sup>4</sup>
- Leukemia/lymphoma<sup>85</sup>

## Ocular Conditions

- Prepapillary arterial loops<sup>117</sup>
- Optic disc drusen<sup>118</sup>
- Increased intraocular pressure (from intravitreal injection,<sup>87</sup> gas expansion after vitrectomy,<sup>119</sup> prone intraoperative positioning,<sup>120</sup> retrobulbar hemorrhage,<sup>121</sup> orbital emphysema<sup>122</sup>)
- Optic neuritis<sup>123</sup>

## Collagen Vascular Disease

- Giant cell arteritis<sup>124</sup>
- Systemic lupus erythematosus<sup>125</sup>
- Polyarteritis nodosa<sup>126</sup>
- Wegener's granulomatosis<sup>127</sup>
- Fibromuscular dysplasia<sup>128</sup>

## Other Vasculitides and Inflammatory Conditions

- Orbital mucormycosis<sup>129</sup>
- Toxoplasmosis<sup>130</sup>
- Toxocarasis<sup>131</sup>
- Lyme disease<sup>132</sup>

- Behçet disease<sup>133</sup>
- Cat-scratch disease<sup>134</sup>
- Herpes simplex associated acute retinal necrosis<sup>135</sup>

## Miscellaneous Associations

- Susac syndrome<sup>136</sup>
- Cosmetic facial fillers<sup>137</sup>
- Migraine<sup>138</sup>
- Hypotension<sup>22</sup>

Ryan SJ. Retina, 4th edn. Philadelphia: Elsevier/Mosby; 2006.

The Beaver Dam Eye Study, a large population-based study in Wisconsin, found a 10-year cumulative incidence of retinal emboli of 1.5%. The incidence of retinal emboli varied with age; those 65 years of age or older at baseline were 2.4 times as likely to develop a retinal embolus compared with persons 43–54 years old at baseline. Retinal emboli were more likely in men than in women. Incidence of bilateral emboli was rare; however, multiple emboli in the same eye may be seen in up to one-third of cases. Persons with retinal emboli in Beaver Dam were 2.4 times as likely to have a diagnosis of stroke on their death certificate over an 11-year period compared with those without retinal emboli.<sup>39</sup> The large population-based studies, the Atherosclerosis Risk in Communities (North Carolina) and the Cardiovascular Health Study (Australia), both looked at a biracial population and showed that retinal arteriolar emboli were associated with hypertension, higher systolic blood pressure, carotid artery plaque, increased plasma fibrinogen levels, coronary heart disease, increased plasma lipoprotein levels, and current cigarette smoking. In multivariable models, significant independent predictors were carotid artery plaque, hypertension status, and current cigarette smoking.<sup>40</sup> In the heart, sources of emboli are aortic or mitral valve lesions, patent foramen ovale, left atrial tumor, and myxoma.<sup>41–43</sup>

The presence of a Hollenhorst plaque or retinal artery occlusion is associated with a low prevalence of carotid atherosclerosis requiring carotid endarterectomy. Furthermore, in contrast to amaurosis fugax, these ocular findings are not associated with a high risk for hemispheric neurologic events.<sup>44</sup> However, patients with retinal emboli do have an associated higher mortality rate.<sup>39,41,45,46</sup> Pooled data from the Beaver Dam Eye Study and the Blue Mountain Eye study of two older populations suggest that retinal emboli predict a modest increase in all-cause and stroke-related mortality independent of cardiovascular risk factors.<sup>47</sup> The prevalence of diabetes, hypertension, ischemic heart disease, cerebrovascular accidents, and smoking is significantly higher in patients with retinal arterial occlusions.<sup>6,38-40,44,48-50</sup>

## Evaluation

Patients with CRAO typically present to a physician several days after the acute onset; therefore, the etiologic workup is generally recommended on an outpatient basis along with a primary care physician. However, ruling out giant cell arteritis in patients older than 50 years with a positive review of systems does represent a true emergency. Evaluation for giant cell arteritis includes complete blood count with platelets, erythrocyte sedimentation rate, and C-reactive protein. If suspicion is high, the patient should be started on steroid therapy and scheduled for a temporal artery biopsy to prevent vision loss in the fellow eye.<sup>51</sup>

Rarely, a patient with acute CRAO may present within the first few hours of visual deficit. These patients should be admitted for observation, treatment, and immediate workup as their risk is higher for cerebral infarction.<sup>13,52</sup> Patients presenting with transient CRAO or retinal transient ischemic attacks (TIA), or amaurosis fugax, should also be treated as a medical emergency. These patients should undergo immediate evaluation by an ophthalmologist to rule out other causes of transient monocular vision loss and giant cell arteritis before emergent referral to a center with 24/7 stroke treatment teams and the ability to perform emergent brain magnetic resonance imaging.<sup>53</sup> Following the most recent guidelines from the American Heart Association, a Boston

study found the probability of an abnormal MRI was higher in embolic versus nonembolic retinal ischemia (28% vs. 8%) and in permanent vision loss patients versus retinal TIA patients (13% vs. 18%).<sup>54</sup>

The evaluation of an embolic source includes carotid Doppler imaging and echocardiography since the most common sources of retinal emboli are from the carotid artery or the heart. As most retinal emboli are relatively small, when evaluating the results of carotid Doppler ultrasonography, the presence or absence of plaque is more important than whether a hemodynamically significant stenosis is present; the latter is more important in determining the need for carotid endarterectomy. Carotid Doppler is limited by the lack of imaging of the thoracic and intracranial portion of the carotid artery and poor resolution for detection of microemboli.<sup>55</sup>

Although a cardiogenic cause is less common, identification is important as chronic anticoagulation may be indicated to prevent more serious adverse events. A cardiac evaluation is especially important in young patients and those with calcific emboli. In patients with acute retinal arterial obstruction at low cardioembolic risk, transthoracic echocardiography (TTE) results in anticoagulation or cardiac surgery in only 1.5% of patients.<sup>56</sup> Transesophageal echocardiography (TEE) has a higher yield than the transthoracic approach in the cardiovascular evaluation of patients with retinal artery occlusion. In patients without a cardiac history and a normal TTE examination (including normal size and function of cardiac chambers and normal valves with no calcification, along with the absence of atrial fibrillation), the yield of subsequent TEE for identifying intracardiac pathology is low. However, in patients in whom clinical and TTE findings are suggestive of possible intracardiac or aortic thrombus, TEE should be considered as an adjunct to the systemic workup.<sup>57</sup> A computed tomography (CT) angiogram or magnetic resonance imaging angiogram should be considered in special cases such as suspected carotid or aortic dissection. Since the cardiac morbidity and mortality are significant in patients with retinal artery occlusion, a baseline electrocardiogram is recommended.<sup>9,11</sup>

A hypercoagulability evaluation should be considered for patients less than 50 years of age with a suggestive history (e.g.,

prior thrombosis, miscarriage, or family history) or unknown embolic source. Workup includes blood tests for factor V Leiden mutation; protein C, protein S, and antithrombin III deficiencies; homocysteine levels; sickle-cell disease; and antiphospholipid antibodies. Other tests for monoclonal gammopathy, cancer, infection, and disseminated intravascular coagulation may be ordered depending on the clinical circumstance.<sup>13</sup>

## Treatment

CRAO continues to be a challenging disease entity to treat. Typically treatment is either conservative or invasive. Most reports of treatment outcome are anecdotal as a result of low incidence.<sup>58</sup> Spontaneous resolution can occur in up to 22% of patients<sup>11</sup> and has been reported to occur up to 3 days after initial onset.<sup>59</sup> However, less than 10% of patients report meaningful visual recovery.<sup>60,61</sup> Rarely do patients have complete spontaneous recovery.<sup>62</sup>

Based on experimental models of CRAO in rhesus monkeys, the retina suffers no damage up to 97 minutes after an acute CRAO, but after 4 hours the retina suffers massive irreversible damage. Therefore, no treatment instituted after about 4 hours from onset can logically restore any vision in the setting of complete obstruction. Additionally, this model showed the longer the ischemia, the longer the time to recovery.<sup>10</sup> Humans rarely have complete obstruction, unlike the animal model; therefore, treatment for CRAO has been recommended within 24 hours of symptom onset. Given the relative rarity of CRAO and variability in time to presentation, therapeutic trials have been limited in sample size, thus reducing the power to detect small treatment benefits. For a new therapy to have a major impact on the management of this disease, it would need to double or triple the success rate of current conventional therapy yet still maintain a low risk for morbidity and mortality.

Current conventional therapy consists of dislodging emboli, reducing intraocular pressure and increasing retinal blood flow, vasodilating the ocular blood supply, improving retinal circulation, decreasing retinal edema, maintaining retinal oxygenation until spontaneous reperfusion, and acting on the thrombus.<sup>13</sup> None of

these treatments have proven effective. Their use is largely based on anecdotal reports and small case series. In a small study of 11 patients, Rumelt et al. found that a systematic regimen involving multiple, sequential treatment steps had better visual outcomes than arbitrary treatment with conservative measures. The protocol included ocular massage, sublingual isosorbide dinitrate, intravenous acetazolamide, intravenous mannitol or oral glycerol, anterior-chamber paracentesis, intravenous methylprednisolone, streptokinase, and retrobulbar tolazine. Treatment with one or two conservative modalities was usually insufficient.<sup>3,63</sup> In a Cochrane Controlled Trials Register comparing any treatment for CRAO with another treatment, Fraser and Siriwardena found no randomized controlled trials meeting their inclusion criteria. They concluded that insufficient data existed to decide if any beneficial treatments existed for CRAO.<sup>64</sup>

Ocular massage is performed using either a Goldmann contact lens or digital massage to apply ocular pressure with an in-and-out movement to dislodge a possibly obstructing embolus. Repeated massage with 10–15 seconds of pressure followed by a sudden release is recommended. This maneuver can produce retinal arterial vasodilation, thereby improving retinal blood flow.<sup>65</sup> A mixture of 95% oxygen and 5% carbon dioxide (carbogen) can be provided to induce vasodilation and improve oxygenation, but efficacy has not been proven.<sup>66</sup> Hyperbaric oxygen provides oxygen at levels of atmospheric pressure. The purpose of hyperbaric oxygen is to preserve the retina in an oxygenated state until recanalization and reperfusion occur, typically at 72 hours. The hyperbaric oxygen increases the arterial oxygen pressure and thereby increases nitric oxide synthesis, leading to vasodilation. Case reports of successful treatment have been published.<sup>67–69</sup> Anterior-chamber paracentesis causes a sudden decrease in intraocular pressure, possibly causing the arterial perfusion pressure behind the obstruction to force an obstructing embolus downstream. This treatment has shown some success in retrospective analyses;<sup>70,71</sup> however, a study by Atebara et al. compared anterior-chamber paracentesis and carbogen therapy with no intervention and found no significant difference in visual outcome.<sup>66</sup> Vasodilating medications that have been utilized to increase retinal blood flow in retinal arterial occlusion include

pentoxifylline, nitroglycerin, and isosorbide dinitrate.<sup>3,72,73</sup>

Isovolemic hemodilution is used to increase oxygen supply to retinal tissue by replacing 500 mL of blood with the same volume of hydroxy-ethyl starch. In vascular disease, the limiting factor in tissue oxygenation is blood flow and not oxygen-carrying capacity. In this situation lowering blood viscosity by decreasing the hematocrit and plasma viscosity will improve tissue oxygen levels.<sup>64,74</sup>

Various surgical techniques have also been explored for treatment of CRAO. Neodymium : yttrium aluminum garnet (Nd-YAG) laser arteriotomy in patients with CRAO has been reported for extrusion of an embolus, reopening of the central retinal artery, and return of vision. A fundus contact lens is used with the laser in single-burst mode. The laser is focused slightly deep to the vessel wall at the site of the embolus to avoid photodisruption and opacification of the overlying nerve fiber layer. In patients with small emboli, the laser is focused on the center of the plaque. In patients with elongated emboli, the laser is focused slightly on the distal or downstream end to reduce the chance of hemorrhage. Pulses are delivered directly to the emboli, beginning with the lowest power setting and then with increasing energy until either (1) achieving photofragmentation of the embolus within the arteriole without creating an opening in the vessel wall and without vitreous hemorrhage or (2) creating visible removal of the embolus from within arteriole into the vitreous cavity, typically associated with a limited vitreous hemorrhage. Digital pressure can be applied to the globe to help stop bleeding, if it occurs.<sup>75</sup>

Corticosteroids should be used only when arteritic CRAO from giant cell arteritis is suspected. Anticoagulants should be reserved for secondary prevention of cerebral and ocular infarction in those rare patients who have an underlying systemic disease such as atrial fibrillation, acute internal carotid artery dissection, or a hypercoagulable condition.<sup>13</sup>

With the common use of thrombolytics for acute cerebrovascular accidents, their potential application in the setting of acute CRAO has been considered. Intravenously or intraarterially administered thrombolytics currently in use include streptokinase, urokinase, and tissue plasminogen activator (t-PA). Intravenous

administration is relatively easy and workup prior to treatment is minimal, including blood tests and a brain CT; however, intravenous thrombolytics do increase the risk of systemic hemorrhage. Because of the increased systemic risks, most thrombolysis strategies currently in use are intraarterial.<sup>13</sup> In 2010 the European Assessment Group for Lysis in the Eye (EAGLE) study group published the results of the first prospective, randomized clinical trial evaluating the effect of intraarterial t-PA compared with conservative treatment. Of note, no true placebo arm was included in the study. At 1 month, the mean best-corrected visual acuity improved significantly in both groups but no significant difference was noted between groups. Clinically significant visual improvement (0.3 logMAR) was noted in 60.0% of patients in the conventional therapy group and 57.1% of patients in the thrombolysis group. The trial was stopped early because of apparent similarity in efficacy between groups and the higher rate of adverse events, namely cerebral hemorrhage, in the intraarterial t-PA group.<sup>74</sup> The EAGLE study highlights the importance of careful randomized controlled trials, as the rate of visual improvement in the conventional therapy group was higher than one might expect from prior retrospective studies.

## Branch Retinal Artery Occlusion

BRAOs are thought to represent 38% of all acute retinal artery obstructions.<sup>24</sup> Patients generally present with monocular vision loss, which may be restricted to one part of the visual field. Initial visual acuity is better than 20/40 in approximately three-fourths of patients.<sup>76,77</sup> Presenting visual field defects include a central scotoma in 20%, a central altitudinal defect in 13%, and sector defects in 49%.<sup>77</sup>

Fundoscopically, a sectoral pattern of retinal opacification is seen. The whitening is most prominent in the posterior pole along the distribution of the obstructed vessel. Areas of more intense whitening are often seen at the borders of the ischemic area (Fig. 54.8). These probably occur secondary to blocked axoplasmic flow in the nerve fiber layer as it reaches the hypoxic retina. BRAOs typically occur at vessel bifurcations, and 98% of the time the

temporal vessels are affected – this may, however, be due to a presentation bias, as nasal occlusions may be asymptomatic and undetected. Emboli are visible 58–62% of the time.<sup>76,78</sup>

**FIG. 54.8** Branch retinal artery occlusion of the superotemporal arcade. Retinal opacification of the superior macula is seen with segmentation within the superior temporal arterioles.

In the chronic stage of BRAO, sectoral nerve fiber layer loss and arterial attenuation may be seen (Fig. 54.9). Rarely in the chronic phase, posterior-segment and/or iris neovascularization will be seen after BRAO, particularly in patients with diabetes.<sup>79</sup> Artery-to-artery collaterals may also be seen and are pathognomonic for BRAO.<sup>80</sup>

**FIG. 54.9** Spectral domain optical coherence tomography of a chronic branch retinal artery occlusion shows sectoral inner retinal atrophy down to the inner nuclear layer in the inferotemporal macula.

The visual prognosis in eyes with symptomatic BRAO is generally good with acuity usually improving to 20/40 or better in 80% of eyes.<sup>4</sup> Hayreh et al., in their natural history study of 133 eyes, reported visual acuity to correlate with foveal involvement and the extent of irreversible ischemic damage to the retina.<sup>77</sup> Ros et al. showed an improvement in visual field deficit by Goldmann perimetry in 80% of 201 eyes surveyed.<sup>76</sup>

Risk factors for BRAO are similar to CRAO; therefore a similar evaluation is generally recommended.<sup>76</sup> Giant cell arteritis tends to present much less often with a BRAO than a CRAO. In cases of an obstruction at a bifurcation, the etiology is more often embolic.

Since the visual prognosis is typically good for BRAO, aggressive therapy is generally not pursued unless significant foveal involvement is seen. Additionally, the good prognosis makes the positive effect of treatment more difficult to discern from natural history.

## Cilioretinal Artery Occlusion

CLRAOs account for 5% of retinal arterial obstructions.<sup>81</sup>

Cilioretinal arteries enter the retina from the temporal optic disc, separate from the central retinal artery, and can be seen on exam in 20% of eyes. On fluorescein angiography, they are seen 32% of the time and fill concomitantly with the choroidal circulation.<sup>25</sup>

Fundoscopically, an area of superficial retinal whitening is seen along the course of the cilioretinal artery.

When evaluating CLRAO, typically three distinct groups are found: (1) isolated CLRAO; (2) CLRAO associated with CRVO; and (3) CLRAO in conjunction with anterior ischemic optic neuropathy. Brown et al. found 90%, 70%, and 0% of eyes achieved 20/40 or better vision in each group, respectively.<sup>82</sup> Initial visual field defects include cecocentral scotoma, central scotoma, and central superior or inferior altitudinal defect.<sup>77</sup>

Isolated CLRAOs typically have a good prognosis, with nearly 90% achieving 20/40 or better vision and 60% returning to 20/20. Even with severe damage to the papillomacular bundle, potential visual acuity can be quite good, presumably secondary to intact superior and inferior nerve fiber layer bundles supplying the fovea.

CLRAO in conjunction with a CRVO comprises 40% of CLRAO.<sup>82</sup> Approximately 5% of eyes with CRVO also have a CLRAO.<sup>83</sup> Visual acuity correlates with the degree of venous obstruction. The venous obstructions are usually nonischemic and tend not to cause iris neovascularization or neovascular glaucoma.<sup>82</sup> Reduced hydrostatic pressure in the cilioretinal artery may predispose the cilioretinal artery to stasis and thrombosis in the setting of increased hydrostatic pressure within the retinal venous system. Optic disc edema may also contribute by decreasing the area of the cilioretinal artery and thereby the flow.<sup>83</sup>

CLRAO in association with anterior ischemic optic neuropathy is seen in 15% of eyes with CLRAO and has a poor visual prognosis, ranging from 20/400 to no light perception secondary to optic nerve damage. Typically a hyperemic or pale edematous optic disc is seen with superficial retinal whitening along the course of the cilioretinal artery.<sup>82</sup> Acute pale swelling is more suggestive of giant cell arteritis and is usually associated with more severe vision loss. Giant cell arteritis has a selective tendency to involve the posterior ciliary artery, resulting in its occlusion, which in turn results in simultaneous development of both arteritic anterior ischemic optic neuropathy and CLRAO.<sup>77</sup>

Systemic evaluation is similar to CRAO except investigation for embolic sources is likely not indicated for cases associated with CRVO. Ocular treatment is generally not pursued unless concern for underlying giant cell arteritis exists.

# Combined Retinal Artery and Vein Occlusion

CRVO can be seen in association with CRAO,<sup>84</sup> BRAO,<sup>85</sup> and CLRAO.<sup>86,87</sup> Patients with combined CRAO/BRAO and CRVO generally present with sudden decreased vision. The fundus exam shows superficial retinal whitening with a cherry-red spot and signs of venous obstruction, such as dilated, tortuous veins, intraretinal hemorrhages, optic disc edema, cotton-wool spots, and marked thickening of the retina (Figs. 54.10A and 54.11).<sup>84</sup> The CRAO seen with a CRVO may not be a true CRAO but may be secondary to the occlusion of the central retinal vein in the region of the lamina cribrosa. The blood cannot exit out of the retinal vascular bed as a result of complete blockage of the central retinal vein, and secondarily compromises entry of blood into the eye.<sup>55</sup> Fluorescein angiography shows severe widespread retinal capillary nonperfusion with sudden termination or pruning of the mid-sized retinal vessels. Minimal macular leakage is seen as a result of closure of these vessels despite the clinical appearance.<sup>88</sup>

**FIG. 54.10** Combined central retinal vein occlusion with branch retinal artery occlusion. (A) Fundus photograph of an acute central retinal venous occlusion (CRVO) with a branch retinal artery occlusion (BRAO) in a patient with the factor V Leiden mutation. Optic disc hyperemia and edema, dilated and tortuous veins, intraretinal hemorrhages, and cotton-wool spots are seen, consistent with a CRVO. Superotemporal to the disc, retinal opacification is seen consistent with a BRAO. (B) Fluorescein angiography shows initial nonperfusion of the branch retinal artery superior to the fovea. (C) Marked delay in transit consistent with the occlusive process is seen. The arteriole occlusion is not complete as the dye eventually does get into the artery. (D) In the late frames, disc leakage is seen consistent with the CRVO.

**FIG. 54.11** Spectral domain optical coherence tomography of the patient shown in Fig. 54.10. Inner and outer retinal edema can be seen consistent with the combined central retinal venous occlusion and branch retinal artery occlusion. The dense hyperreflectivity of the inner retinal edema from the BRAO induce a shadow effect on the inner retina.

The visual prognosis is generally poor, with visual acuity in the hand motions range.<sup>88</sup> After 6–8 weeks, optic nerve pallor is seen with severe arterial attenuation. Histopathology of the chronic phase shows hemorrhagic retinal necrosis and inner retinal atrophy consistent with a CRVO and CRAO. The macula shows typical cystoid changes. Rubeosis iridis develops in about 80% of eyes, leading to neovascular glaucoma as the end result.<sup>84</sup> This can be seen as early as 1–2 weeks but is seen on average at about 6 weeks. Aggressive treatment with panretinal photocoagulation is recommended.<sup>88</sup>

Combined CRAO and CRVO has been associated with many diverse entities, including syphilis, optic neuritis, leukemia, lymphoma, temporal arteritis, orbital inflammatory disease, posterior scleritis, systemic lupus erythematosus, trauma, retrobulbar injections, and superior ophthalmic vein thrombosis.<sup>85</sup> Intravitreal gentamicin injection may cause a similar appearance; however, angiography would show normal filling of the choroid, retinal arteries, and veins.<sup>89</sup>

## Cotton-Wool Spots

Cotton-wool spots are often referred to using the misnomer “soft exudates” and are described as slightly elevated, small, yellow-white or gray-white, cloud-like lesions with fimbriated borders in the superficial retina (Figs. 54.12A–B). They are usually restricted to the posterior segment of the fundus and they rarely exceed one-third of the area of the optic disc.<sup>90</sup> Cotton-wool spots rarely cause vision loss unless they involve the fovea and typically resolve within 6–12 weeks,<sup>90</sup> though they may last longer in diabetics.<sup>91</sup>

**FIG. 54.12** Cotton-wool spots. (A) Fundus photo showing multiple cotton-wool spots in a patient with interferon- $\beta$ 1a retinopathy. (B) Spectral domain optical coherence tomography through one of the cotton-wool spots shows focal thickening and elevation of the nerve fiber layer.

A cotton-wool spot is hypothesized to develop secondary to obstruction of a retinal arteriole with resultant ischemia. The focal hypoxia causes blockage of axoplasmic flow within the nerve fiber layer with subsequent deposition of intraaxonal organelles.<sup>92</sup> Early light microscopy of cotton-wool spots in the retina revealed the presence of a cytoid body, a round, dark-staining “pseudonucleus” within a grossly swollen nerve fiber layer (Fig. 54.13). The application of electron microscopic techniques revealed the composition of cytoid bodies to be an accumulation of

intracytoplasmic organelles, largely mitochondria, with a major lipid component.<sup>93</sup>

**FIG. 54.13** Light microscopic section of a cotton-wool spot in the retina showing swelling of the nerve fiber layer with the presence of cytooid bodies (hematoxylin and eosin,  $\times 100$ ). (Courtesy of Dr. Hans Grossniklaus, Emory Eye Center, Atlanta.)

Diabetes mellitus and systemic hypertension are by far the most common etiologies of cotton-wool spots, followed by undiagnosed diabetes and hypertension. In patients who have a cotton-wool spot and no known history of diabetes, an elevated blood sugar level is identified in 20% of patients and an elevated blood pressure (diastolic blood pressure of 90 mmHg or greater) in 50% of patients. Cotton-wool spots, however, may be observed in association with numerous other diseases ([Box 54.2](#)). Fortunately, most patients who present with cotton-wool spots have other systemic or ocular findings that help narrow down their specific etiology. The presence of even one cotton-wool spot in an otherwise normal fundus necessitates an investigation for systemic etiologic factors. A giant cell arteritis workup is not necessary unless a positive review of systems is noted. In approximately 95% of cases, a systemic underlying condition can be found. Almost any etiology that can cause a CRAO or BRAO can potentially also produce cotton-wool

## Box 54.2

### Etiologies for Cotton-Wool Spots

#### Ischemic

Diabetes

Hypertension

Retinal vein occlusion

Ocular ischemic syndrome

Severe anemia

Hyperviscosity/hypercoagulable state/dysproteinemia

Radiation

Acute blood loss

#### Embolic

Carotid emboli

Cardiac emboli

- Cardiac valvular disease
- Endocarditis
- Rheumatic heart disease

Deep venous emboli

White cell emboli/Purtscher and Purtscher-like retinopathy (head trauma, long bone fractures, acute pancreatitis, chest compression injury, amniotic fluid emboli, fat emboli)

Foreign-body emboli (intravenous drug abuse, talc)

## Collagen Vascular Disease

Systemic lupus erythematosus

Dermatomyositis

Scleroderma

Polyarteritis nodosa

Giant cell arteritis

## Infectious

HIV retinopathy

Fungemia

Bacteremia

Rocky Mountain spotted fever (*Rickettsia rickettsii*)

Cat-scratch disease (*Bartonella henselae*)

Leptospirosis

Onchocerciasis (*Onchocerca volvulus*)

## Toxic

Interferon ( $\alpha_{2a}$ ,  $\beta_{1a}$ )

## Neoplastic

Leukemia

Lymphoma

Metastatic carcinoma

## Miscellaneous

Traumatic

Tractional (epiretinal membrane)

High-altitude retinopathy

Papilledema/papillitis

Reproduced with permission from Brown GC, Brown MM, Hiller T, et al. Cotton-wool spots. *Retina* 1985;5:206–14.

## Paracentral Acute Middle Maculopathy

PAMM was first described in 2013 as a band-like hyperreflectivity seen on spectral domain optical coherence tomography (SD-OCT) at the level of the inner nuclear layer (INL) correlating with a paracentral area of deep retinal whitening on biomicroscopy or color photography (Fig. 54.14B).<sup>95</sup> As compared to cotton-wool spots, PAMM lesions are deeper, grayer, and smoother (Fig. 54.14A). PAMM is thought to be a result of intermediate capillary plexus (ICP) and/or deep capillary plexus (DCP) ischemia. Therefore, PAMM is difficult to visualize with traditional fluorescein angiography. To date, near-infrared reflectance and SD-OCT imaging are the most sensitive modalities for imaging PAMM. The recent advent of OCT angiography has demonstrated preferential disruption of the ICP and DCP (Fig. 54.15) in these cases. PAMM may complicate other retinal vascular diseases including diabetic retinopathy, hypertensive retinopathy, sickle-cell retinopathy, Purtscher retinopathy, central retinal vein occlusion, and retinal arterial occlusion.<sup>96,97</sup> PAMM may also be idiopathic even developing in young healthy patients and in the context of migraine. Nevertheless, presence of PAMM should prompt a search for contributing systemic or extrinsic vascular risk factors.<sup>96</sup>

**FIG 54.14** Paracentral acute middle maculopathy. (A) Color fundus photo showing inferotemporal parafoveal deep retinal whitening. (B) Spectral domain optical coherence tomography at presentation exhibiting temporal parafoveal band-like hyperelectivity of the inner nuclear layer corresponding to the area of retinal whitening seen in the fundus photo. (Courtesy of Dr. David Sarraf, David Geffen School of Medicine, UCLA.)

**FIG. 54.15** Paracentral acute middle maculopathy. Optical coherence tomography angiography. 3 × 3 mm

macular cube with enface imaging of the deep capillary shows a profound loss of the deep capillary plexus.

# Acquired Retinal Macroaneurysms

*Emily Y. Chew, Robert P. Murphy*

## Clinical Description

### Diagnosis of Retinal Macroaneurysm

### Natural Course and Treatment of Retinal Macroaneurysms

## Clinical Description

Acquired retinal macroaneurysms are fusiform or round dilations of the retinal arterioles that occur in the posterior fundus within the first three orders of arteriolar bifurcation.<sup>1</sup>

Often they are located at the site of an arteriolar bifurcation or an arteriovenous crossing (Fig. 55.1). The supratemporal artery is the most commonly reported site of involvement because patients with such involvement are more likely to have visual impairment.

Women make up the majority of reported cases. Most cases are unilateral, while 10% may be bilateral. Retinal macroaneurysm was estimated to occur in 1 in 9000 in the Beijing Eye Study.<sup>2</sup>

**FIG. 55.1** (A) A 62-year-old woman with hypertension had a subretinal hemorrhage associated with a macroaneurysm in her left supratemporal artery. (B) The fluorescein angiogram demonstrated hypofluorescence from blockage from the retinal hemorrhage and hyperfluorescence of the retinal macroaneurysm itself, apparent as a round dilation located at the arteriolar bifurcation.

Most commonly, retinal macroaneurysm affects patients in the sixth and seventh decades of life. Often associated are vascular problems such as hypertension and general arteriosclerotic cardiovascular disease, as noted by Robertson,<sup>3</sup> who first coined the term *retinal macroaneurysm*. Uncontrolled hypertension can present with a retinal artery macroaneurysm and its accompanying vitreous hemorrhage.<sup>4</sup> Other investigators have confirmed this association with hypertension.<sup>5</sup> Serum lipid and lipoprotein abnormalities have also been reported in patients with this condition.<sup>6</sup> Systemic investigations for hypertension and cardiovascular disease should be conducted in patients who have a retinal arteriolar macroaneurysm.

Although a patient with a retinal arteriolar macroaneurysm may be asymptomatic if the macula is not involved (Fig. 55.2), the most common clinical symptom is decline in central visual acuity as a result of retinal edema, exudation, or hemorrhage.<sup>7</sup> Bleeding from macroaneurysms can occur in the subretinal space, into the retina, beneath the internal limiting membrane, or into the vitreous. So-called hourglass hemorrhages are typical. Hemorrhage in the space beneath the retinal pigment epithelium may produce a dark lesion simulating an ocular tumor such as malignant melanoma,<sup>8</sup> or a

lesion associated with age-related macular degeneration. A complication of the vitreous hemorrhage also includes the development of angle closure glaucoma.<sup>9</sup>

**FIG. 55.2** (A) The retinal hemorrhage superior to the optic disc, associated with a retinal macroaneurysm, caused no ocular symptoms. (B) Six months later, the retinal macroaneurysm is partially obstructed by the resolving retinal hemorrhage, with a surrounding ring of lipid. (C) Eight months later, the macroaneurysm has spontaneously involuted, with complete resolution of the hemorrhage and a decrease in the lipid.

The hemorrhage may also partially or completely obscure the aneurysm (Fig. 55.3). Occasionally, multiple macroaneurysms occur. Other retinal microvascular changes associated with macroaneurysms include widening of the periarterial capillary-free zone around the area of the aneurysm, capillary dilation and nonperfusion, microaneurysms, and artery-to-artery collaterals.

**FIG. 55.3** (A) A preretinal hemorrhage partially obscures the retinal macroaneurysm. (B) The fluorescein angiogram shows the hyperfluorescence that corresponds to the hemorrhage and the hyperfluorescence of the retinal macroaneurysm. (C)

At 20 months later, there is spontaneous resolution of the hemorrhage and the retinal macroaneurysm.

## Diagnosis of Retinal Macroaneurysm

Fluorescein angiography initially may fail to demonstrate the macroaneurysm because of blockage by the surrounding hemorrhage. Dense hemorrhage in the retina can cause marked hypofluorescence. In such cases of dense hemorrhage, indocyanine green angiography may be useful because its absorption and emission peak in the near-infrared range allow the light to penetrate the hemorrhage to a greater extent than fluorescein angiography.<sup>10</sup> A small case series using indocyanine green angiography has demonstrated these lesions to be pulsatile and contiguous with the arterial wall, pathognomonic of an insolated retinal artery macroaneurysm.<sup>11</sup> The macroaneurysm typically fills in the early arterial phase of the angiogram. The appearance of the late phase of the fluorescein angiogram varies, ranging from little staining of the vessel wall to marked leakage. Leakage of surrounding dilated capillaries also may be seen. The lipid often present in the macular area fails to block fluorescein unless the amount of lipid is massive. Macular hole formation following rupture of a retinal arterial macroaneurysm has been reported.<sup>12,13</sup>

Histopathologic studies of macroaneurysms have shown gross distension of the involved retinal arteriole. Surrounding this are fibroglial proliferation, dilated capillaries, extravasated blood, lipoidal exudates, and hemosiderin deposits.

Evaluation of the retinal structure with optical coherence tomography was conducted in a series of patients with retinal macroaneurysm.<sup>14</sup> Although most of the retinal structure was intact at the initial exam, subretinal hemorrhage or extensive exudative changes from retinal macroaneurysm can cause the deterioration of the foveal outer photoreceptor layer with a poor visual outcome. In a study of exudative macular diseases, including retinal macroaneurysms and other pathologic processes, the “pearl necklace” sign was seen as hyperreflective dots in a contiguous ring around the inner wall of cystoid spaces in the outer plexiform layer

of the retina.<sup>15</sup> This is not specific for retinal macroaneurysms but may alert the clinician to the several causes associated with such exudative disease.

## Natural Course and Treatment of Retinal Macroaneurysms

Several series have reported on the natural history and treatment response of macroaneurysms.<sup>6,16,17</sup> Some investigators believe the visual prognosis is excellent in most patients who have macroaneurysms and do not have treatment because the lesions can thrombose and undergo spontaneous involution with clearing of the macular exudate.<sup>2</sup> However, the exudative process may progress in some patients and cause structural damage to the macula with loss of vision (Fig. 55.4).<sup>18</sup> Moderate visual loss also may occur if bleeding causes secondary morphologic changes in the macula. No clear indication for treatment with laser photocoagulation has been established, and the beneficial effects of such treatments have not been proven.

**FIG. 55.4** A 65-year-old man noted decreased vision in his right eye to 20/32. He had a history of hypertension and was borderline diabetic. (A) The macroaneurysm is located along the inferior temporal retinal artery with evidence of subretinal hemorrhage as well as marked hard exudate, extending into the center of the macula. (B) Observation over 9 months demonstrated a

gradual clearing of the retinal hard exudate. Visual acuity was 20/25.

More recently, 37 patients with macroaneurysms and symptoms for at least 2 months were treated with a course of three doses of intravitreal bevacizumab.<sup>19</sup> Improvement in visual acuity at week 12 was documented with an accompanying decrease in central retinal thickness that appeared clinically and statistically significant. A retrospective case-control study evaluating the use of intravitreal bevacizumab found that treated eyes tended to have a more rapid resolution of the hemorrhage and macular edema.<sup>20</sup>

Vitreotomy was performed for clearing the macular hemorrhage associated with the rupture of a macroaneurysm.<sup>21</sup> The results of vitrectomy are variable depending on the location of the hemorrhage from the retinal macroaneurysms. The vision is particularly poor in those patients who have dense submacular hemorrhage.<sup>22</sup>

Pneumatic displacement with or without tissue plasminogen activator has also been used for the therapy of submacular hemorrhage associated with a macroaneurysm.<sup>23</sup> Yag laser has also been used to treat such premacular hemorrhage.<sup>24</sup> The surgical excision of the retinal macroaneurysm with scissors and diathermy followed by the drainage of the submacular hemorrhage was also explored in two cases, with some improvement in vision.<sup>25</sup>

Many investigators consider direct laser photocoagulation of the macroaneurysm if the lipid exudate coming from it threatens the fovea. Treatment when hemorrhage is present is fraught with difficulties. There is also the danger of occluding the retinal arteriole during treatment. This potential complication must always be considered when the distal portion of the arteriole being considered for treatment supplies the macula.

A recent retrospective review of patients treated and untreated found that visual acuity results in the long term were comparable, whether they were observed or treated with laser photocoagulation or vitrectomy.<sup>26</sup>

The investigators concluded from this case series that at longer follow-up, most had reasonably good vision with or without treatment. When macular holes occur as a consequence of the disease, the visual acuity is not likely to improve.

The differential diagnoses of retinal macroaneurysms include other retinal vascular abnormalities, including diabetic retinopathy, retinal telangiectasia, retinal capillary angioma, cavernous hemangioma, malignant melanoma,<sup>8</sup> and the hemorrhagic pigment epithelial detachment of age-related macular degeneration.<sup>27</sup>

## **Introduction**

Branch retinal vein occlusion (BRVO) is a common cause of retinal vascular disease.<sup>1</sup> A recent meta-analysis of 50,000 participants from 11 studies found a prevalence of 4.42 per 1000 adults and estimated that 13.9 million adults worldwide are affected by BRVO.<sup>2</sup>

Systemic vascular diseases such as hypertension and arteriosclerosis are risk factors for BRVO. Age is also a strong risk factor for BRVO, and many epidemiologic studies have confirmed that the prevalence increases with increasing age. It occurs most frequently between the ages of 60 and 70 years. Men and women are affected equally, and additional studies are needed to determine

whether racial/ethnic variations exist or are secondary to a higher prevalence of uncontrolled risk factors in at-risk populations.<sup>2-4</sup> The pathologic interruption of venous flow in these eyes almost always occurs at a retinal arteriovenous intersection, where a retinal artery crosses over a retinal vein. This section discusses the pathophysiology, clinical features, evaluation, and treatment of patients with BRVO.

## Risk Factors

In addition to age, systemic hypertension and the retinal arteriolar changes associated with it, including arteriovenous nicking and retinal arteriolar narrowing, are well-established risk factors for BRVO.<sup>3-7</sup> Other cardiovascular risk factors, such as diabetes, smoking, hyperlipidemia, atrial fibrillation, renal dysfunction, and atherosclerosis, have also been associated with an increased risk of BRVO.<sup>3-8</sup> The role of hypercoagulability in the pathogenesis of BRVO is controversial and studies have shown conflicting results. Rehak and associates reported an increased prevalence of Factor V Leiden mutation in patients with RVO; however, a meta-analysis of thrombophilic risk factors by Janssen and colleagues found an association with hyperhomocysteinemia and anticardiolipin antibodies, but not with Factor V Leiden mutation.<sup>9,10</sup> Another meta-analysis identified elevated plasma homocysteine and lower serum folate as risk factors.<sup>11</sup> Thus, while hypercoagulability may play a role in younger patients and in patients without typical cardiovascular risk factors,<sup>10</sup> more studies are needed to provide a more definitive link. In contrast, higher serum levels of high-density lipoprotein and light to moderate alcohol consumption may be protective.<sup>8</sup> Studies have also suggested a correlation between certain ocular risk factors and BRVO, including shorter axial length and a history of glaucoma.<sup>3,8,12-15</sup> Retinal and systemic vasculitides have been associated with the development of BRVO.<sup>16-18</sup>

## Pathogenesis

The pathologic interruption of venous flow in eyes with BRVO almost always occurs at an arteriovenous crossing.<sup>19-22</sup> In 99% of 106

eyes with BRVO, the artery was found to cross over the obstructed vein.<sup>20</sup> This observation coupled with the strong association of BRVO with systemic hypertension and arteriosclerosis support the theory that mechanical compression plays a role in the pathogenesis of BRVO.<sup>20,21</sup> Histopathologically, the retinal artery and vein share a common adventitial sheath, and in some cases, a common medium.<sup>23</sup> The lumen of the vein may be compressed up to 33% at a normal arteriovenous crossing site, and this may be further exacerbated by increased rigidity and thickening of the arterial wall due to arteriosclerosis.<sup>22-24</sup> The vitreous may also play a role in compression of susceptible arteriovenous crossing sites, as evidenced by studies demonstrating that eyes with decreased axial length and higher likelihood of vitreomacular attachment at the arteriovenous crossing are at increased risk of BRVO.<sup>12,15,22</sup>

Some have postulated that turbulent blood flow at the crossing site causes focal swelling of the endothelium and thicker vein wall tissue, leading to venous obstruction.<sup>22,23,25</sup> Based on histopathologic studies, others have suggested that venous thrombus formation at the point of occlusion is the primary pathologic event.<sup>26</sup>

It is likely that the pathogenesis of BRVO is multifactorial with contributions from mechanical obstruction, degeneration of the vessel wall, and hematologic abnormalities, such as inflammatory disorders and thrombophilia, in at-risk individuals.<sup>24,27</sup>

The resulting venous obstruction leads to elevation of venous pressure upstream of the crossing that may overload the collateral drainage capacity resulting in intraretinal hemorrhages, macular edema, and ischemia.<sup>22,28</sup>

## Clinical Features

### Symptoms

Patients with BRVO present with sudden painless loss of vision or a visual field defect. Subclinical presentations may occur if a tributary distal to the macula or a nasal retinal vein is involved. Rarely, patients with BRVO will present with floaters from a vitreous hemorrhage if the initial vein occlusion was unrecognized and retinal neovascularization has occurred.

## Signs

Patients typically present with a wedge-shaped distribution of intraretinal hemorrhage that is less marked if the occlusion is perfused (or nonischemic), and more extensive if the occlusion is nonperfused (or ischemic) and associated with retinal capillary nonperfusion. The Branch Vein Occlusion Study Group (BVOS) defined ischemic BRVO as those with greater than a total of five disc diameters of nonperfusion on fluorescein angiography (FA).<sup>1</sup> The location of the venous blockage determines the distribution of the intraretinal hemorrhage; if the venous obstruction is at the optic nerve head, two quadrants of the fundus may be involved, whereas if the occlusion is peripheral to the disc, one quadrant or less may be involved. If the venous blockage is peripheral to tributary veins draining the macula, there may be no macular involvement and consequently minimal to no decrease in visual acuity.

The most common location for BRVOs is in the superotemporal quadrant.<sup>20,29</sup> This favored location may be attributed to a larger number of arteriovenous crossings in the superotemporal quadrant.<sup>20</sup> Fig. 56.1 demonstrates the typical acute appearance of a BRVO involving the superotemporal quadrant of the right eye. A narrowed branch retinal vein passing under a retinal artery can sometimes be identified proximal to the hemorrhage. Rarely, a patient may present initially with very little intraretinal hemorrhage, which then becomes more extensive in the succeeding weeks to months. In these instances, it is presumed that an incomplete block at the arteriovenous crossing has progressed to more complete occlusion.

**FIG. 56.1** Acute branch retinal vein occlusion.

Intraretinal hemorrhages in a wedge-shaped pattern delineating the area drained by the occluded vein. The occluded vessel is often seen passing underneath a retinal artery (*arrowhead*). Cotton-wool spots (*asterisk*) are sometimes seen. Note the dilated and tortuous occluded vein (*arrow*) compared to the normal retinal vein in the inferior arcade.

Over time the intraretinal hemorrhage may completely resorb. Without the characteristic segmental distribution of intraretinal hemorrhage, the ophthalmoscopic diagnosis may be more difficult in this situation, but the segmental distribution of retinal vascular abnormalities that occurred during the acute phase will persist and be apparent on FA. In many cases, macular edema can be detected by optical coherence tomography (OCT). The presence of intraretinal fluid, subretinal fluid, or cystoid macular edema is visible on OCT B-scans, and three-dimensional (3D) views or retinal thickness maps can reveal areas of localized increased retinal thickening. In the chronic phase of the disease, after intraretinal hemorrhage absorption, the diagnosis may depend on detecting a segmental distribution of retinal vascular abnormalities that may include capillary nonperfusion, dilation of capillaries, microaneurysms, telangiectatic vessels, and collateral vessel formation ([Fig. 56.2](#)).

**FIG. 56.2** Chronic branch retinal vein occlusion. (A) Color fundus photograph showing microaneurysms, exudates, and a sclerosed retinal vein (*arrowhead*) draining into a sheathed vessel (*arrow*). (B) Corresponding mid- to late-phase fluorescein angiogram shows abundant collaterals (*arrowhead*) and highlights the microvascular abnormalities.

## Complications

There are three common vision-limiting complications of BRVO: (1) macular edema; (2) macular ischemia; and (3) sequelae of neovascularization.

During the acute phase, extensive intraretinal hemorrhages may block the view of macular ischemia and leakage on the FA. Under these circumstances it is impossible to evaluate the perfusion status because the hemorrhage itself blocks the view of the vasculature. In addition, the hemorrhage in the foveal center may reduce visual acuity independently of any macular edema or ischemia. Since this reduction in visual acuity may completely recover if there is no other cause for the visual loss, such as macular edema or macular capillary nonperfusion, observation in these cases can be considered. When there is extensive foveal hemorrhage, OCT is an important ancillary test to look for macular edema.

Retinal and iris neovascularization, vitreous hemorrhage, traction retinal detachment, and neovascular glaucoma are complications that manifest late in the course of the disease due to ischemia. With the exception of macular ischemia, these complications can largely

be treated or prevented. Thus, it is important that patients with BRVO be closely followed.

## Natural History

In order to accurately counsel patients on prognosis and weigh the effectiveness of different treatment options, it is important to understand the natural history of BRVO. To this end, Rogers and associates performed a systematic review of all BRVO articles published through 2008 and found that, in 1608 eyes, visual acuity generally improved without treatment although improvement beyond 20/40 was uncommon. Macular edema developed in 5–15% of eyes over a period of 1 year and of those presenting with macular edema, 18–41% resolved by 1 year.<sup>2</sup>

BRVO is a broad classification of one type of retinal vascular disease which may be subtyped to better predict visual prognosis and the development of vision-limiting complications. In the Branch Vein Occlusion Study, 31–41% of patients with ischemic BRVO (defined as >5 disc diameters of nonperfusion on FA) developed neovascularization or vitreous hemorrhage compared with 11% of patients with nonischemic BRVO.<sup>1</sup> Thus, eyes with ischemic BRVO may need to be followed more closely.

BRVO may also be subtyped as a major BRVO where one of the four major branch retinal veins is affected or macular BRVO where only a smaller, macular vein is occluded. Hayreh et al. found that retinal and optic disc neovascularization occurred only in major BRVO. Although time to resolution of macular edema was similar in both major and macular BRVO (20.8 months vs. 18.2, respectively), eyes with macular BRVO did not show the same improvement in visual acuity with resolution of macular edema as eyes with major BRVO (58% vs. 76% improved, respectively).<sup>30,31</sup>

## Clinical Evaluation

### Clinical Examination

A complete ophthalmic examination should be performed, paying particular attention to the history of glaucoma and signs of

intraocular inflammation, since these may be risk factors for BRVO. Careful examination of the iris and angle should be performed in appropriate cases to monitor for early signs of rubeosis or neovascular glaucoma. Initially, when the risk of macular edema and neovascularization is higher, patients should be followed every month. Once stable, and if visually significant macular edema and other complications are not present, follow-up can be extended.

## Fluorescein Angiography

To help verify the diagnosis and evaluate for complications, FA should be obtained to delineate the retinal vascular characteristics that may have prognostic significance: macular leakage and edema, macular ischemia, and large segments of capillary nonperfusion that may portend eventual neovascularization. FA is the only technique that will accurately define the capillary abnormalities in BRVO; it is therefore particularly important that high-quality angiography be obtained (Fig. 56.3).

**FIG. 56.3** Fluorescein angiogram of branch retinal vein occlusion. (A) Blocked fluorescence from intraretinal hemorrhage is common in acute branch retinal vein occlusion. Note the telangiectatic vessels forming collaterals across the horizontal raphe. The hemorrhages obscure underlying areas of capillary nonperfusion and edema. (B) Six months later, the hemorrhages have cleared, revealing small patches of nonperfusion and macular edema.

The characteristic finding on FA is delayed filling of the occluded retinal vein. Varying amounts of capillary nonperfusion, blockage from intraretinal hemorrhages, microaneurysms, telangiectatic collateral vessels, and dye extravasation from macular edema or retinal neovascularization are other features encountered. In chronic cases, when the hemorrhages have resolved, microvascular changes on FA may provide the only clues of a previous BRVO.

When FA demonstrates macular leakage and edema with cystoid involvement of the fovea, but no capillary nonperfusion, it is presumed that the macular edema is the cause of vision loss. When macular edema is present ophthalmoscopically within the first 6 months after a BRVO and there is little or no leakage on FA, macular ischemia may be the cause of the macular edema. In such circumstances, the edema almost always spontaneously resorbs in the first year after the occlusion, often with improvement in visual acuity.<sup>32</sup> Studies have shown conflicting results as to whether the severity of capillary nonperfusion in the macular region is associated with the degree of improvement in visual acuity. Finkelstein showed that eyes with a broken foveal capillary ring had greater improvement in visual acuity than those with intact capillary perfusion, while a retrospective study by Hayreh failed to demonstrate any such correlation.<sup>31,32</sup>

Unfortunately, acute BRVOs with dense intraretinal hemorrhages may make FA interpretation challenging due to blockage of fluorescence by the hemorrhages. Thus, it is advisable to obtain FA only after the intraretinal hemorrhages have cleared significantly from the macula. Other diagnostic tests, such as OCT, can be obtained in the acute phase to aid in the diagnosis of macular edema.

## **Wide-Field Angiography**

Ultrawide-field fluorescein angiography (UWFA) is not yet a commonly used imaging modality for patients with BRVO; however, it may help elucidate the role of peripheral retinal vascular pathology in the pathogenesis of vision loss in eyes with RVOs. It is very useful to delineate areas of peripheral nonperfusion and help categorize a patient based on perfusion status. A retrospective study of patients with branch and

hemiretinal vein occlusions using the Optos C200MA ultrawide-field imaging system revealed that peripheral retinal nonperfusion (Fig. 56.4) is correlated with both macular edema and retinal neovascularization.<sup>33</sup> Future studies are needed to determine whether laser photocoagulation targeted to areas of peripheral retinal nonperfusion decreases macular edema, reduces treatment burden, and regresses neovascularization in patients with BRVOs.

**FIG. 56.4** Wide-field fluorescein angiogram using the Optos200TX ultrawide-field imaging system demonstrating extensive area of peripheral nonperfusion (*outlined by solid arrows*) and collateral formation (*hollow arrow*) in a patient with a superotemporal BRVO and chronic macular edema.

## Optical Coherence Tomography

OCT has arguably become the most important imaging modality in the treatment of patients with BRVO and macular edema. OCT offers a noninvasive and rapid method of quantitatively measuring macular edema and its response to treatment. The characteristic findings of BRVO on OCT B-scans are cystoid macular edema, intraretinal hyperreflectivity from hemorrhages or exudates,

shadowing from edema and hemorrhages, and occasionally subretinal fluid<sup>34,35</sup> (Fig. 56.5A). Cube or 3D scans are also useful to delineate the areas of retinal thickening and to monitor for changes with treatment. OCT has been shown to be more sensitive in detecting macular edema and subretinal fluid in patients with BRVO than clinical examination or FA, and may be especially helpful in the acute setting when blockage from intraretinal hemorrhages limits the interpretation of FA.<sup>34</sup> In chronic cases, photoreceptor ellipsoid zone and external limiting membrane abnormalities from longstanding macular ischemia and macula edema may also be seen (Fig. 56.5B). Integrity of the ellipsoid zone on baseline OCT in patients with macular edema from BRVO has been associated with better visual outcome after treatment of the macular edema.<sup>36</sup> When these structures are disrupted or absent, visual improvement is less likely.

**FIG. 56.5** Spectral-domain optical coherence tomography (OCT) of an eye with a branch retinal vein occlusion (BRVO). (A) Raster scan of the BRVO in Fig. 56.1 reveals cystoid macular edema, intraretinal fluid, and shadowing (*between arrowheads*). Intraretinal heme (*arrow*) appears hyperreflective and produces a shadow on OCT. (B) Raster scan of a chronic BRVO with inner/outer-segment abnormalities and a large cyst.

## Diagnostic Workup

### Young Patient

BRVO typically occurs in patients beyond their sixth decade of life.<sup>2</sup> Younger patients with BRVO may have a higher prevalence of cardiovascular risk factors than their age-matched counterparts, including hypertension, hyperlipidemia, and an increased body mass index.<sup>37</sup> However, if no cardiovascular risk factors are identified, it is important to rule out any other predisposing condition. Although the role of thrombophilic risk factors in retinal vein occlusion is still controversial, there have been case series that suggest a higher risk of thrombophilic disorders, such as Factor V Leiden mutation, in younger patients presenting with RVO.<sup>38,39</sup> A detailed history should be taken focusing on personal or family history of venous thromboembolism or underlying hypercoagulable condition. A thorough ophthalmologic history and examination should evaluate for ocular diseases such as glaucoma or uveitis that may predispose to RVO.

Based upon the results of the history and examination, workup should be tailored to the patient and performed in consultation with an internist. Systemic blood pressure should be checked and the patient should be screened for undiagnosed cardiovascular risk factors, including hyperlipidemia and diabetes.

In young patients without cardiovascular risk factors or with systemic symptoms suggestive of a coagulopathy, workup should include a complete blood count, prothrombin time/partial thromboplastin time/international normalized ratio, lipid panel, serum homocysteine, anticardiolipin antibodies, antinuclear antibodies with lupus anticoagulant, protein C/S, antithrombin III, activated protein C resistance, and factor V Leiden.<sup>10,40</sup>

### **Older Patient**

In patients older than 60 years, additional workup is usually not necessary since the majority of these cases are idiopathic or due to hypertension or atherosclerosis.

### **Bilateral or Numerous BRVO Patients**

In bilateral cases and cases with a history of multiple BRVOs, searching for an infectious or inflammatory disorder or hypercoagulopathy may be warranted. Although the vast majority of these cases can be attributed to systemic hypertension, there are

numerous case reports of patients with bilateral vein occlusions and systemic inflammatory disorders or hypercoagulopathies.<sup>41-43</sup> The workup should proceed in the manner described for young patients.

## Treatment Options

### Treatment of Underlying Etiology

#### Systemic Anticoagulation

In cases where a hypercoagulopathy has been identified, anticoagulation may be considered in consultation with an internist. In most cases, however, anticoagulant therapy has not been shown to be beneficial in either the prevention or the management of BRVO. Since the systemic administration of anticoagulants can be associated with systemic complications, and could, in theory, increase the severity of intraretinal hemorrhage occurring in the acute phase, such therapy is generally not recommended.

#### Vitrectomy With Sheathotomy

The majority of the venous lesions in BRVO occur downstream from the arteriovenous crossing site. In a retrospective review of color photographs and FAs of patients with BRVO, Kumar and associates<sup>22</sup> identified venous narrowing at the crossing site, and in the majority of cases, evidence of downstream hemodynamic changes on angiogram, including venous-phase leakage, abnormal flow, and presumed thrombi. The authors suggested that removal of the compressive factor by sectioning the adventitial sheath (sheathotomy) was a potentially effective treatment for BRVO.

In the first report of sheathotomy for BRVO, Osterloh and Charles<sup>44</sup> reported significant visual improvement in the one case (20/200 to 20/25+ over 8 months). In the second report, Opremcak and Bruce<sup>45</sup> reported equal or improved visual acuity in 12 of 15 patients (80%). Ten of those patients (67%) had improved postoperative visual acuities, with an average gain of four lines of vision. Three patients had a decline in visual acuity, with an average of two lines of vision lost. All patients had marked resolution of the intraretinal hemorrhage and edema. Mester and

Dillinger reported 43 cases of BRVO treated with sheathotomy with similar results. In 16 of the cases, removal of the internal limiting membrane in the area of the arteriovenous crossing was also performed.<sup>46</sup> Despite these promising results, there have been many case series and retrospective reviews of patients treated with vitrectomy and sheathotomy that have not shown a statistically significant improvement in postoperative median visual acuity.<sup>47-48</sup> Some authors have experienced difficulty in separating the artery from the vein at the crossing site. Han and colleagues reported 20 cases of vitrectomy and attempted sheathotomy. While the visual outcome results were similar to those reported by Opremcak and Bruce, in 19 of the 20 cases, the authors were unable to separate the artery from the vein.<sup>49</sup> No randomized, controlled study evaluating the benefit of sheathotomy has been published. Given the potential complications of the procedure, including retinal tear, retinal detachment, vascular bleeding, nerve fiber layer defects with associated scotoma, vitreous hemorrhage, and postoperative cataract,<sup>50</sup> vitrectomy with sheathotomy is currently not employed as first-line therapy.

## Treatment of Vision-Limiting Complications

### Treatment of Neovascularization and Vitreous Hemorrhage

#### Laser Treatment.

The collaborative BVOS,<sup>1</sup> a multicenter randomized clinical trial supported by the National Eye Institute, randomized patients with BRVO to receive panretinal scatter photocoagulation to prevent neovascular complications.<sup>1</sup> They reported that eyes with ischemic BRVO that show large areas (>5 disc diameters) of retinal capillary nonperfusion have approximately a 40% chance of developing neovascularization (NV) and that about 60% of those eyes with NV will experience periodic vitreous hemorrhage. If peripheral scatter laser photocoagulation is applied in eyes with large areas of nonperfusion, the incidence of neovascularization can be reduced from about 40% to 20%. However, if one were to treat prophylactically, many eyes (60%) that would never develop

neovascularization would receive peripheral scatter laser photocoagulation and the subsequent side-effects of such treatment. The BVOS data also strongly suggest that photocoagulation after the development of neovascularization is as effective in preventing vitreous hemorrhage as is photocoagulation before the development of neovascularization.<sup>1</sup> For these reasons, it is recommended that laser photocoagulation be applied only after neovascularization is observed.

Iris neovascularization is a rare complication of BRVO; it appears, however, that diabetes (with or without retinopathy) may increase this risk. Retinal neovascularization is particularly difficult to recognize in BRVO because the collaterals that develop frequently may mimic neovascularization. Arising presumably from preexisting capillaries, these collaterals occur as vein-to-vein channels around the blockage site, across the temporal raphe, and in other locations to bypass the blocked retinal segment. These collaterals frequently become quite tortuous, mimicking the appearance of neovascularization if they are evaluated by ophthalmoscopy alone. When it is unclear whether an abnormal vascular pattern represents collateral formation or true neovascularization, FA (Fig. 56.6) can be helpful because leakage from neovascularization is more prominent than from collateral vessels.

**FIG. 56.6** Retinal neovascularization with leakage (*arrow*) can be differentiated from collaterals that are not leaking (*arrowhead*).

When neovascularization is unequivocally confirmed by FA or UWFA, peripheral scatter laser photocoagulation can reduce the likelihood of vitreous hemorrhage from about 60% to 30%.<sup>1</sup> As demonstrated in Fig. 56.7, the scatter laser photocoagulation can be applied with argon blue–green laser to achieve “medium” white burns (200–500  $\mu\text{m}$  in diameter) spaced one burn width apart and covering the entire area of capillary nonperfusion, as defined by FA, but extending no closer than two disc diameters from the center of the fovea and extending peripherally at least to the equator. Retrobulbar anesthesia can be used as needed for discomfort associated with the scatter photocoagulation, but generally is not required.

**FIG. 56.7** Immediate posttreatment fundus photograph showing pattern of peripheral scatter photocoagulation.

Familiarity with the laser treatment technique is required to individualize the treatment. Important variables, such as residual intraretinal hemorrhage, thickness of the retina from edema, location of collaterals, and presence of retinal traction, influence the exact mode of therapy within the above general treatment guidelines. There are numerous complications of laser photocoagulation; however, it is generally recognized that with proper attention to detail, complications are infrequent. Side-effects of treatment, including generation of scotoma, merit careful consideration and discussion with the patient before initiation of treatment. It is particularly important to recognize that laser photocoagulation should never be placed over extensive intraretinal hemorrhage in the acute phase of branch vein occlusion because the laser energy will be absorbed by the intraretinal hemorrhage rather than at the level of the pigment epithelium, likely damaging the nerve fiber layer and possibly enhancing the development of preretinal fibrosis.

Of patients who develop neovascularization, approximately 60% experience episodes of vitreous hemorrhage if the condition is left untreated. The short- and long-term visual consequences of vitreous hemorrhage in BRVO have not been carefully studied. In some cases, the hemorrhage may be mild or may clear spontaneously without causing permanent visual impairment.

However, in some patients, vitreous hemorrhage from neovascularization can lead to prolonged visual disability in the affected eye. When the hemorrhage is dense, B-scan ultrasonography may help rule out an associated traction retinal detachment. Most eyes can be observed. If the vitreous hemorrhage does not spontaneously clear in a few months, a pars plana vitrectomy with sector endolaser photocoagulation can be considered.

## Treatment of Macular Edema

### Laser Treatment

A separate group of patients in the BVOS were randomized to determine whether argon laser photocoagulation may reduce visual loss from macular edema. Important eligibility criteria included fluorescein-proven, perfused macular edema involving the foveal center, clearing of intraretinal hemorrhage from the foveal center, recent BRVO (usually 3–18 months' duration), no diabetic retinopathy, and vision reduced to 20/40 or worse after best corrected refraction.<sup>51</sup> Argon laser photocoagulation was applied in a grid pattern throughout the leaking area demonstrated by FA (Fig. 56.8). Laser treatment extended no closer to the fovea than the edge of the capillary-free zone and no further into the periphery than the major vascular arcade. Recommended treatment parameters included a duration of 0.1 second, a 100- $\mu$ m diameter spot size, and a power setting sufficient to produce a “medium” white burn. FA was repeated 2–4 months after the treatment, and additional photocoagulation was applied to residual areas of leakage if reduced visual acuity persisted.

**FIG. 56.8** Grid macular laser for macular edema. (A) Fluorescein angiogram, late phase, demonstrating macular edema with foveal involvement. (B) Immediate posttreatment fundus photograph showing grid pattern of laser photocoagulation.

Improvement in visual acuity was assessed in several ways.<sup>51</sup> When improvement was defined as reading two or more Snellen lines better than baseline at two consecutive visits, treated eyes showed visual improvement more often than untreated eyes. After 3 years of follow-up, 63% of treated eyes gained two or more lines of vision, compared to 36% of untreated eyes. The average gain in visual acuity for treated eyes was one more Snellen line than in untreated eyes.

Before laser photocoagulation is performed, it is important to obtain high-quality FAs of the macula; the FA must demonstrate that the macular edema involves the center of the fovea and that there is not a large amount of capillary nonperfusion adjacent to the capillary-free zone that could explain the visual loss. In addition, it is important to follow patients for a length of time sufficient to ascertain that macular edema is not resolving spontaneously. During this period of follow-up, it should be demonstrated that there is clearing of intraretinal hemorrhage and that there is no hemorrhage in the center of the fovea that could account for a spontaneously reversible cause of visual loss. In the application of the grid photocoagulation, laser absorption occurs at the level of the pigment epithelium; photocoagulation is not applied to close the leaking and dilated capillary vasculature directly and immediately. Although it is not understood how the laser treatment may act in lessening edema, it is interesting to note that preliminary

experimental studies in the normal primate have shown a decrease in capillary diameter when this form of therapy is used and when laser absorption occurs at the level of the pigment epithelium.<sup>52</sup> One explanation for the effect of grid pattern photocoagulation is that it results in a thinning of the retina (in particular the outer retina), reducing oxygen consumption and increasing choroidal delivery of oxygen to the inner retina, producing a consequent autoregulatory constriction of the retinal vasculature in the leaking area and thereby decreasing the edema.

In the application of grid pattern laser photocoagulation, it is crucial to obtain good definition of landmarks so that the center of the fovea can be identified and avoided. Since landmarks frequently may be obscured in the macula after BRVO, such cases can be managed more effectively and safely by treating well peripheral to the capillary-free zone in the first sitting. When the patient returns in 2 months for follow-up evaluation, a repeat FA may identify more clearly the amount of further treatment that needs to be applied closer to the edge of the capillary-free zone, because the pigmentation of the previous treatment is then visible. Consequently, treatment in this next sitting may be advanced closer to the edge of the capillary-free zone, if that is deemed necessary because of persistent foveal edema and vision loss. The placement of grid laser treatment in this repetitively staged fashion may be safer and appears to be just as effective as a single treatment.

For the grid treatment used in the BVOS, the argon blue–green wavelength was employed.<sup>51</sup> This is the only wavelength that has been proven effective and it is unknown whether argon green and krypton red photocoagulation are equally effective. In other diseases, when laser treatment is applied inside the capillary-free zone, it is recognized that krypton red and argon green laser photocoagulation are absorbed less than blue–green by the xanthophyll pigment of the inner retina that is present in increasing concentrations close to the foveal center. However, because the grid treatment never comes closer to the fovea than the capillary-free zone, the BVOS did not encounter any problems with the argon blue–green laser in this region; consequently, this laser continues to be recommended.

In the past, the summary recommendations for management of

acute branch vein occlusion from the BVOS emphasize waiting for several months before considering laser therapy. If the vision is reduced to 20/40 or worse, clinicians were advised to wait 3–6 months for sufficient clearing of retinal hemorrhage to permit high-quality FA and then evaluate for macular edema and macular ischemia. If perfused macular edema accounts for the visual loss, and vision continues to be 20/40 or worse without spontaneous improvement, grid macular photocoagulation was considered. However, the BVOS conclusions need to be balanced against the improvements in vision seen with anti-vascular endothelial growth factor (VEGF) agents. In general, laser therapy is a second- or even third-line therapy, as the anti-VEGF agents have considerably better efficacy. It should also be noted that if macular ischemia accounts for the visual loss, no laser treatment is recommended.

## **Steroid Treatment**

Macular edema in BRVO results from increased vascular permeability mediated at least in part by upregulation of VEGF.<sup>53</sup> Intravitreal steroids have been shown in animal models to inhibit the expression of VEGF and thus reduce macular edema in retinal vascular disease.<sup>54,55</sup> In addition, inflammatory cells around the site of the occlusion are often present. Although intraocular corticosteroids are generally well tolerated, they can have significant side-effects, including cataract formation and glaucoma. Several trials have evaluated the use of corticosteroids in the treatment of macular edema in BRVO.

### **Triamcinolone.**

In the Standard Care vs. Corticosteroid for Retinal Vein Occlusion (SCORE) BRVO study, the effectiveness and safety of intravitreal triamcinolone acetate (IVTA) for the treatment of macular edema from BRVO were evaluated.<sup>56</sup> In this multicenter, randomized controlled study, 411 patients were randomized to receive macular grid laser, 1 mg IVTA, or 4 mg IVTA. Retreatment was allowed every 4 months for each group unless the treatment was successful, futile, or contraindicated. There was no significant difference in vision or the reduction of macular edema measured by OCT at the end of 12 months between each group. Respectively, 29%, 26%, and

27% of eyes in the laser, 1-mg IVTA, and 4-mg IVTA groups gained a visual acuity score of  $\geq 15$  ETDRS letters. Subgroup analysis of pseudophakic eyes also failed to demonstrate a significant difference in vision. Three-year results from 128 patients suggested that the laser group maintained a significantly greater average increase in vision (12.9 letters) compared with the two IVTA groups (4.4 letters, 1-mg and 8.0 letters, 4-mg). Significant side-effects from IVTA included cataract formation and elevation of intraocular pressure (IOP) requiring treatment. Both side-effects were dose-dependent.<sup>56</sup>

As a result of this study, IVTA is not recommended as first-line therapy for macular edema in BRVO. However, it can be considered in patients where anti-VEGF injections or macular grid laser are ineffective, as the treatment was found to be relatively safe, especially in pseudophakic eyes.

### **Dexamethasone Implant.**

The Global Evaluation of Implantable Dexamethasone in Retinal Vein Occlusion with Macular Edema (GENEVA) study evaluated a sustained-release, biodegradable, dexamethasone intravitreal implant (Ozurdex, Allergan, Irvine, CA) for the treatment of macular edema in central retinal vein occlusion (CRVO) and BRVO patients.<sup>57</sup> Ozurdex is a biodegradable copolymer of poly (d,l-lactide-co-glycolide) acid (PLGA) containing micronized dexamethasone. It is injected intravitreally through a pars plana route using a 23-gauge custom injector, and it gradually releases the total dose of dexamethasone over several months via Krebs cycle breakdown of the PLGA into lactic and glycolic acid, and finally into water and carbon dioxide. In this multicenter, randomized controlled study, the primary outcome of an increase in best corrected visual acuity (BCVA) of  $\geq 15$  ETDRS letters was achieved in 30% of the Ozurdex 0.7-mg group ( $n=291$ ), 26% of the 0.35-mg group ( $n=260$ ), and 13% of the sham group ( $n=279$ ) 60 days after injection (peak response) in patients with BRVO ( $p<.001$  for each group versus sham). A statistically significant difference between both Ozurdex groups and sham was seen up to 90 days after injection. At 90 days after injection, there was a significant improvement ( $p<.001$ ) in central retinal thickness measured by OCT

in both Ozurdex groups, compared with the sham group. The mean SD decrease in central retinal thickness at 90 days was  $208\pm 201$   $\mu\text{m}$ ,  $177\pm 197$   $\mu\text{m}$ , and  $85\pm 173$   $\mu\text{m}$  in the 0.7-mg, 0.35-mg and sham groups, respectively. The OCT results are from pooled data including both BRVO and CRVO patients. The only complications that were significantly greater in the Ozurdex groups compared with sham were elevated IOP and anterior-chamber cell. Most eyes with elevated IOP were successfully managed with topical therapy, but five eyes required a procedure to lower the pressure adequately.

The study was followed by a 6-month open-label extension in which all groups, including sham, were eligible for a 0.7-mg Ozurdex injection at Day 180 on an as-needed basis. The results demonstrated that there is no increase in the risk of serious adverse effects, including IOP rise, with a second treatment; however, there was a statistically significant increase in the development of cataract with repeated injection. The improvement in BCVA after the second treatment was similar to that achieved after the first treatment; however, the improvements in BCVA in the delayed-treatment group (initial sham group) never matched those who received earlier treatment.<sup>58</sup>

A major difference between the GENEVA study and other recent BRVO studies is the absence of a macular grid laser group, or rescue laser treatment for the sham group. The GENEVA study showed that the dexamethasone implant is an alternative treatment to macular grid laser in the appropriate patient population (i.e., no glaucoma, pseudophakic) and is approved by the Food and Drug Administration (FDA) for this indication. Future studies are needed to determine the optimum interval and criteria for retreatment.

## **Anti-VEGF Treatment**

In patients with BRVO, retinal ischemia leads to the secretion of VEGF, which leads to increased vascular permeability, vasodilation, migration of endothelial cells, and neovascularization.<sup>53,59,60</sup>

Increased vascular permeability and perhaps vasodilation lead to retinal edema. Thus, inhibition of VEGF is an attractive treatment for macular edema from BRVO. There are several anti-VEGF agents currently used in the treatment of RVOs. We will discuss the use of

ranibizumab (Lucentis), bevacizumab (Avastin), and aflibercept (Eylea). Ranibizumab is an affinity-matured, humanized monoclonal antibody fragment (Fab) that binds all VEGF-A isoforms. Aflibercept is a fusion protein composed of key binding domains from VEGF receptors 1 and 2 fused to the Fc portion of human immunoglobulin G that binds all isoforms of VEGF-A, VEGF-B, VEGF-C, and placental growth factor (PlGF). Bevacizumab is a full-length, humanized monoclonal antibody that binds all VEGF-A isoforms and is FDA-approved for colorectal cancer, but is used off-label in the eye. At this time, ranibizumab and aflibercept are both FDA-approved for the treatment of macular edema secondary to RVO.

### **Ranibizumab.**

The Branch Retinal Vein Occlusion (BRAVO) study was a prospective, multicenter, randomized controlled study to evaluate the efficacy and safety of ranibizumab in the treatment of macular edema from BRVO.<sup>61</sup> Patients were randomized into three groups: (1) sham injection ( $n=132$ ); (2) 0.3-mg ranibizumab ( $n=134$ ); and (3) 0.5-mg ranibizumab ( $n=131$ ). In the first 6 months, injections were given monthly. A 28-day screening period excluded patients with spontaneous and rapid improvement in vision of  $>10$  ETDRS letters. At month 3, a patient was eligible for rescue laser if a gain of  $<5$  ETDRS letters, or improvement of  $<50$   $\mu\text{m}$  in central subfield thickness, was observed compared with the visit 3 months prior. If rescue laser was not applied at month 3, the same criteria were used to determine eligibility for rescue laser at each subsequent monthly visit. At 6 months, both ranibizumab groups gained  $+16.6$  and  $+18.3$  ETDRS letters (0.3-mg and 0.5-mg groups, respectively) compared with a gain of  $+7.3$  letters in the control group ( $p<.0001$  for each group versus sham). The percentage of patients who improved greater than 15 ETDRS letters was 55.2% and 61.1% (0.3-mg and 0.5-mg groups, respectively) compared with 28.8% in the control group ( $p<.0001$  for each group versus sham). During the first 6 months, 54.5% of the control group required rescue laser therapy compared with 18.7% in the 0.3-mg and 19.8% in the 0.5-mg ranibizumab groups.<sup>61</sup>

After the first 6 months, all three groups were allowed to receive

“as needed” (PRN) intravitreal ranibizumab (0.5 mg for sham group, ranibizumab groups continued to receive their respective doses) at monthly intervals if they had vision  $\leq 20/40$  or mean central foveal thickness  $\geq 250$   $\mu\text{m}$ . Despite receiving only PRN treatments, patients in both ranibizumab groups maintained their vision gain at 12 months. Although the control group showed a benefit from the PRN treatment regimen, the final vision gained at 12 months was not equivalent to that achieved in the eyes started on prompt ranibizumab treatment.<sup>62</sup>

The HORIZON Trial was an open-label extension of BRAVO in which patients were seen at least every 3 months and given 0.5 mg ranibizumab if mean central foveal thickness was  $\geq 250$   $\mu\text{m}$  or if there was persistent macular edema deemed to be affecting the patient's visual acuity. Patients received significantly fewer injections than during the first year of the trial averaging 2.4 injections (0.3/0.5-mg group), 2.1 injections (0.5/0.5-mg group), and 2.0 injections (sham/0.5-mg group); however, visual acuity gains were still maintained. The mean change in BCVA letter score at 12 months from the HORIZON baseline was  $-2.3$ ,  $-0.7$ , and  $0.9$  in the 0.3/0.5-mg, 0.5/0.5-mg, and sham/0.5-mg treatment groups, respectively. No additional adverse events were identified.<sup>63</sup>

### **Aflibercept.**

The VIBRANT study was a double-masked, active-controlled, randomized, multicenter phase III trial comparing the safety and efficacy of intravitreal aflibercept versus macular grid laser in the treatment of macular edema from BRVO. Eyes were randomized to 2 mg intravitreal aflibercept (IAI) every 4 weeks (for a series of 6 injections,  $n=91$ ) or grid laser (with rescue if needed,  $n=92$ ). The primary outcome was percentage of eyes which gained  $\geq 15$  ETDRS letters at week 24. In the IAI group, 52.7% of eyes achieved the primary outcome versus 26.7% of eyes in the laser group. The IAI group gained an average of 17.0 ETDRS letters compared to 6.9 letters ( $p=.0003$ ) in the laser group and achieved a mean reduction of 280.5  $\mu\text{m}$  in central retinal thickness compared to 128  $\mu\text{m}$  in the laser group ( $p<.0001$ ). VIBRANT was the first trial to compare anti-VEGF therapy directly with laser and the results were strongly in favor of aflibercept with similar side-effect profiles in both groups.<sup>64</sup>

## Bevacizumab.

Bevacizumab is currently used off-label for the treatment of macular edema related to BRVO and is an attractive therapeutic option due to its relatively low cost compared to other anti-VEGF agents. Although there have been no multicenter, randomized-controlled trials evaluating the safety and efficacy of bevacizumab in treating macular edema from BRVO, there have been numerous case series and small prospective studies showing that bevacizumab is effective at improving visual acuity and decreasing macular edema, as measured by OCT.<sup>65-69</sup> Recently, the MARVEL study group published a prospective, randomized, noninferiority trial comparing PRN bevacizumab to ranibizumab for the treatment of macular edema secondary to BRVO. Although the study was underpowered to show noninferiority, it did show a similar increase in BCVA (15.6 vs. 18.1 ETDRS letters) and decrease in central retinal thickness (-201.7 vs. -177.1  $\mu\text{m}$ ) in the bevacizumab and ranibizumab groups, respectively.<sup>70</sup> A retrospective study comparing bevacizumab to ranibizumab for macular edema secondary to RVO (CRVO and BRVO) also showed similar efficacy with regard to anatomic and visual outcomes.<sup>71</sup> Thus, bevacizumab is a viable treatment option for macular edema secondary to BRVO. The National Eye Institute is currently conducting the Study of Comparative Treatments for REtinal Vein Occlusion 2 (SCORE2) study. SCORE2 is a multicenter, prospective, randomized noninferiority trial of eyes with macular edema secondary to central retinal vein occlusion, comparing intravitreal bevacizumab every 4 weeks with intravitreal aflibercept every 4 weeks. Eligible participants will be followed for 12 months.

## Vitrectomy Without Sheathotomy

There is evidence that vitreomacular attachment itself may contribute to the development of macular edema in BRVO.<sup>72</sup> Saika and coworkers reported reduction in macular edema and restoration of normal foveal contour in 10 of 19 eyes after vitrectomy, posterior hyaloid separation, and intraocular gas tamponade.<sup>73</sup> In a prospective comparison study, vitrectomy with separation of the posterior hyaloid without sheathotomy was found to be as effective in reducing macular edema and improving visual

acuity as combined vitrectomy with posterior hyaloid removal and sheathotomy.<sup>74</sup> Possible explanations for the clinical improvements in these studies include removal of vitreous traction, increased oxygenation of the macula, and tamponade of the macula by intraocular gas.

Due to the risk of intraoperative complications and the availability of less invasive alternatives, vitrectomy with or without sheathotomy has limited clinical use as a first-line therapy.

## Follow-Up

The major complications that can lead to vision loss in patients with BRVO include macular edema, macular ischemia, and neovascularization. Treatment is available for macular edema and neovascularization and follow-up should be tailored to monitor the development of these complications adequately. Initially, patients should be followed closely every month for the development of macular edema and/or neovascularization. Anti-VEGF therapy should be initiated for patients with macular edema without spontaneous improvement. Grid laser and/or steroids may be considered in patients when anti-VEGF therapy is not showing sufficient therapeutic efficacy. Once macular edema has stabilized or has resolved, the follow-up interval can be extended to 3–6 months or even longer for stable chronic cases. Patients with previously untreated retinal nonperfusion measuring >5 disc diameters should be followed at closer intervals (3 months) due to the increased risk for neovascular complications. Only after failure of medical therapy, should surgery be considered.

## Conclusions

BRVO is a common cause of vision loss, but many treatment options are available and emerging therapies are under investigation. With the advent of so many new treatment options over the past decade, future studies are needed to establish evidence-based guidelines for the treatment of the vision-limiting complications of BRVO. The BRAVO and VIBRANT trials established that intravitreal anti-VEGF therapy results in better

visual and anatomical outcomes than macular grid laser, which had been the standard of care for macular edema associated with BRVO for over 25 years.<sup>64</sup> Currently, there are three available anti-VEGF therapies used in clinical practice. While there have been several studies showing similar efficacy between ranibizumab and bevacizumab,<sup>70-71</sup> there has been no multicenter, randomized trial comparing the efficacy of the three agents for the treatment of macular edema associated with BRVO. The SCORE2 is evaluating aflibercept and bevacizumab head to head. Future studies are also needed to establish the appropriate treatment regimen. In both the VIBRANT and BRAVO trials, patients received monthly injections for the first 6 months.<sup>61,64</sup> It is unknown if patients can maintain the same treatment benefits with PRN injections or a longer duration between injections. PRN treatment does appear to be an effective long-term treatment regimen in extension studies of the clinical trials. The SHORE study randomized patients with macular edema from BRVO to monthly versus PRN ranibizumab after receiving monthly injections for 7 months. The investigators found similar visual acuity outcomes in both groups.<sup>75</sup> Currently, steroid injections are second-line therapy owing to side-effects including increased IOP and cataract. Finally, pilot studies suggest that combination therapy may have a synergistic treatment effect as well as reduce treatment burden. Maturi et al. showed that the combination of intravitreal bevacizumab and dexamethasone resulted in fewer injections and better anatomic outcomes than bevacizumab alone.<sup>76</sup> Another group found that dexamethasone implant and grid laser resulted in better anatomic and visual outcomes than dexamethasone alone.<sup>77</sup> Randomized controlled trials are needed to establish the role and timing of combination therapy with regards to the currently available treatment modalities.

## Introduction

Central retinal vein occlusion (CRVO) is a retinal vascular condition that may cause significant ocular morbidity. It commonly affects men and women equally and occurs predominantly in persons over the age of 65 years.<sup>1-3</sup> In this population, there may be associated systemic vascular disease, including hypertension and diabetes.<sup>4</sup> Younger individuals who present with a clinical picture of CRVO may have an underlying hypercoagulable or inflammatory etiology.<sup>5,6</sup> Population-based studies report the prevalence of CRVO at <0.1 to 0.4%.<sup>2,7,8</sup> CRVO is usually a unilateral disease; however, the annual risk of developing a CRVO in the fellow eye is approximately 1% per year, and it is estimated that up to 7% of persons with CRVO may develop CRVO in the fellow eye within 5 years of onset in the first eye.<sup>1,9</sup> Individuals with CRVO demonstrate a significant decrease in vision-related quality of life as

well as increased illness burden with increased healthcare costs and resource use as compared to a reference group.<sup>10-12</sup> CRVO may impact a person's ability to perform activities of daily living, especially in cases of bilateral CRVO or when concurrent ocular disease limits vision in the fellow eye.

## Clinical Features

CRVO usually presents with sudden painless loss of vision, but it may also present with a history of gradual visual decline. The typical clinical constellation in CRVO includes intraretinal hemorrhages (both superficial flame-shaped and deep blot type) in all four quadrants of the fundus with a dilated, tortuous retinal venous system. The hemorrhages radiate from the optic nerve head, are variable in quantity, and may result in the classic “blood and thunder” appearance (Fig. 57.1). Optic nerve head swelling, splinter hemorrhages, cotton-wool spots, and macular edema (ME) are present to varying degrees (Figs. 57.2 and 57.3). Breakthrough vitreous hemorrhage may also be observed.

**FIG. 57.1** Fundus photograph of a central retinal vein occlusion with extensive intraretinal hemorrhage. Extensive blocking on fluorescein angiography

precludes accurate determination of perfusion status.

**FIG. 57.2** (A) Fundus photograph of a central retinal vein occlusion demonstrating typical features of venous tortuosity, macular thickening, and intraretinal hemorrhage in all four quadrants of the fundus. (B) Early-phase angiogram of the fundus depicted in (A), demonstrating an intact parafoveal capillary network in this perfused central retinal vein occlusion.

**FIG. 57.3** (A) Fundus photograph of an eye with central retinal vein occlusion demonstrating scattered intraretinal hemorrhage, venous engorgement, and cotton-wool spots. (B) Midphase fluorescein angiogram of the eye shown in (A), demonstrating capillary nonperfusion involving the foveal center. This eye also had extensive peripheral nonperfusion and is an

example of the nonperfused form of central retinal vein occlusion.

A cilioretinal artery occlusion rarely occurs in association with CRVO. Together, these occlusions have been hypothesized to constitute a distinct clinical entity arising from a sudden increase in the intraluminal capillary pressure due to CRVO, inducing relative occlusion of the cilioretinal artery whose perfusion pressure is lower than the central retinal artery.<sup>13,14</sup> Rarely, a central retinal arterial occlusion may also accompany a CRVO.<sup>15</sup>

With time, the extent of intraretinal hemorrhage may decrease or resolve completely with variable degrees of secondary retinal pigment epithelium alterations. The time course for resolution of the hemorrhages varies and is dependent on the amount of hemorrhage produced by the occlusion. In the natural history of CRVO, ME often chronically persists despite resolution of intraretinal hemorrhage (Fig. 57.4). An epiretinal membrane and foveal pigmentary alterations may develop.<sup>16</sup> Optociliary “shunt” vessels can form on the optic nerve head, a sign of newly formed collateral channels with the choroidal circulation (Fig. 57.5). Neovascularization of the optic disc (NVD) or retinal neovascularization elsewhere (NVE) may develop as a response to secondary retinal ischemia. The vessels that comprise NVD are typically of smaller caliber than optociliary shunt vessels, branch into a vascular network resembling a net, and leak on fluorescein angiography. Fibrovascular proliferation from NV may result in vitreous hemorrhage or traction retinal detachment.

**FIG. 57.4** Fluorescein angiogram of a chronic central retinal vein occlusion with resolution of intraretinal hemorrhage but persistence of cystoid macular edema demonstrated by petaloid leakage.

**FIG. 57.5** Fundus photograph demonstrating optociliary shunt vessels (aka collaterals) at the inferior border of the optic nerve head in this patient with a chronic central retinal vein occlusion. These vessels do not leak on fluorescein angiography.

Much of our knowledge on the natural history of CRVO stems from the results of the Central Vein Occlusion Study (CVOS), a randomized, multicenter clinical trial of 728 eyes with CRVO. In this study, visual acuity at the time of presentation was variable but an important prognostic indicator of final visual outcome. Baseline visual acuity was 20/40 or better in 29% of affected eyes, 20/50 to 20/200 in 43%, and 20/250 or worse in 28%; median baseline acuity was 20/80.<sup>3,17</sup> Of those with initial visual acuity of 20/40 or better, the majority maintained this acuity. Individuals with intermediate visual acuity (20/50 to 20/200) had a variable outcome: 21% improved to better than 20/50, 41% stayed in the intermediate group, and 38% were worse than 20/200. Persons with poor visual acuity at onset (less than 20/200) had only a 20% chance of improvement.<sup>9</sup>

Anterior segment findings may include iris and/or angle neovascularization (NVI/NVA). NVI typically begins at the pupillary border but may extend across the iris surface. NVA is detected during undilated gonioscopy as fine branching vessels bridging the scleral spur and may develop without any NVI in 6–12% of eyes with ischemic CRVO.<sup>3,9,18</sup> The CVOS used an index of any two clock hours of NVI or any NVA as significant anterior segment NV, which was found in 16% of eyes with 10 to 29 disc areas of angiographic nonperfusion and 52% with 75 disc areas or more of angiographic nonperfusion.<sup>9</sup> In the CVOS, worse initial visual acuity correlated with the development of NVI/NVA: 5% in eyes  $\geq$ 20/40 or better, 14.8% in eyes 20/50 to 20/200, and 30.8% in eyes with  $<$ 20/200 acuity.<sup>9</sup> Longstanding NVA may lead to secondary angle closure from peripheral anterior synechiae formation. Elevated intraocular pressure associated with NVI/NVA is the hallmark of neovascular glaucoma.

## Perfusion Status

The CVOS classified the perfusion status of a CRVO as perfused, nonperfused, or indeterminate based on fluorescein angiographic characteristics. Angiographic assessment of perfusion status is based on the CVOS photographic protocol, which used a

conventional wide-angle fundus camera with sweeps of the midperiphery 30 seconds after intravenous injection of fluorescein.

A perfused CRVO (aka nonischemic, incomplete, or partial) demonstrates <10 disc areas of retinal capillary nonperfusion on angiography (Fig. 57.2). These eyes typically have a lesser degree of intraretinal hemorrhage on presentation. Generally, eyes with perfused CRVO have better initial and final visual acuity. A nonperfused CRVO (aka ischemic, hemorrhagic, or complete) demonstrates ≥10 disc areas of retinal capillary nonperfusion on angiography (Fig. 57.3). Acutely, these eyes often demonstrate a greater degree of intraretinal hemorrhage, macular and disc edema, and capillary nonperfusion than eyes with perfused CRVO. A CRVO is categorized as indeterminate when there is sufficient intraretinal hemorrhage to prevent angiographic determination of the perfusion status. Other examination features that may help in determining the perfusion status include baseline visual acuity, presence of an afferent pupillary defect, electroretinography (a negative waveform may be seen), and Goldmann perimetry.<sup>5,9,19,20</sup>

The CVOS classification of initial perfusion status was important for determining the natural history of the disease.<sup>9</sup> Poor visual acuity and large areas of retinal capillary nonperfusion were significant factors associated with an increased risk of NVI/NVA. In eyes initially categorized as perfused, 10% (56/538) developed NVI/NVA compared to 35% (61/176) of eyes initially characterized as nonperfused or indeterminate. At 3 years, there was a 45% chance of developing neovascular glaucoma after onset of ischemic CRVO.<sup>1</sup> Overall, 34% of initially perfused eyes converted to nonperfused status after 3 years, which has been associated with worsening visual acuity.<sup>9,21</sup> In the CVOS, 38 eyes (83%) with an indeterminate CRVO at baseline were ultimately determined to be nonperfused. Initial visual acuity was highly correlated with degree of nonperfusion – eyes with nonperfused CRVO were much more likely than those with perfused CRVO to have poor visual acuity at initial presentation and final visit.<sup>9,16</sup> Hayreh and Zimmerman have retrospectively studied a large patient cohort and found that the risk for ocular neovascularization is much greater in ischemic than in perfused CRVO and greatest within the first 6 months of onset. In ischemic CRVO, the cumulative probability of development of

NVI in this series was 49%, NVA 37%, NVG 29%, NVE 9%, and NVD 6% within 6 months of CRVO onset. In perfused CRVO, neovascular complications occurred in 1.3% during available follow-up.<sup>20,22</sup>

Ultrawide-field angiography has enabled mapping of peripheral retinal nonperfusion not easily visualized with a conventional camera. Adjusted protocols for grading extent of nonperfusion are being developed from photographs taken with ultrawide-field angiography, which may prove important in redefining characteristics of perfused vs. nonperfused CRVO.<sup>21,23–26</sup>

## Pathogenesis

The pathophysiology of CRVO is not clearly understood. Histopathologic studies of eyes enucleated for CRVO demonstrated a thrombus occluding the lumen of the central retinal vein at or just proximal to the lamina cribrosa,<sup>27</sup> suggesting that the anatomic variations at the level of the lamina cribrosa may be important in the development of a CRVO. Within the retrolaminar portion of the optic nerve, the central retinal artery and vein are aligned parallel to each other in a common tissue sheath where they are naturally compressed as they cross through the rigid sieve-like openings in the lamina cribrosa but typically give off branching collateral vessels just before piercing the lamina. These vessels may be subject to compression from mechanical stretching of the lamina, as with increases in intraocular pressure, which may cause a posterior bowing of the lamina and subsequent impingement on the central retinal vein. Furthermore, local factors may predispose to occlusion of the central retinal vein, including compression by an atherosclerotic central retinal artery or primary occlusion of the central retinal vein from inflammation.

Hemodynamic alterations may produce stagnant flow and subsequent thrombus formation in the central retinal vein, including diminished blood flow, increased blood viscosity, and an altered lumen wall (Virchow triad). Experimentally, occlusion of both the retrolaminar central retinal artery and central retinal vein, posterior to the lamina cribrosa and prior to the branching of collateral channels from the main trunk, was required to produce

the clinical appearance of a hemorrhagic (ischemic) CRVO.<sup>16</sup> This implies that concurrent retinal artery insufficiency or occlusion may play a role in an ischemic CRVO. It is hypothesized that a less hemorrhagic, more likely nonischemic, CRVO may be due to occlusion of the central retinal vein at a site further posterior, allowing normal collateral channels to provide alternative routes of venous drainage.

In the largest histopathologic study of eyes with CRVO, 29 eyes enucleated for acute (within 6 hours) and chronic (up to 10 years) occlusions were reviewed,<sup>27</sup> some of which had concurrent neovascular glaucoma. In acute occlusions, a thrombus at the level of the lamina cribrosa was adherent to a portion of the vein wall devoid of an endothelial lining. Subsequently, there was endothelial cell proliferation within the vein and secondary inflammatory cell infiltrates. Recanalization of the thrombus was demonstrated in eyes 1–5 years after the documented occlusion.

Neovascularization of the anterior and posterior segment and severity of ME are modulated by growth factors released from the ischemic retina. Green and colleagues demonstrated inner retinal ischemic changes in 25% of eyes enucleated for CRVO.<sup>27</sup> In a study of enucleated eyes with CRVO and neovascular glaucoma, intraretinal vascular endothelial growth factor (VEGF) production from areas of ischemic retina was demonstrated.<sup>28</sup> Analysis of vitreous fluid from patients with CRVO demonstrated increased levels of VEGF along with other cytokines and growth factors.<sup>29–31</sup> Intraocular VEGF levels correlate with severity of ocular findings including neovascularization and vascular permeability,<sup>32</sup> prompting the development of anti-VEGF agents for the treatment of CRVO.

## Risk Factors and Associations

Concurrent systemic vascular disease is a risk factor for CRVO (Box 57.1). The Eye Disease Case–Control Study found an increased risk of any type of CRVO in persons with systemic hypertension and diabetes mellitus.<sup>4</sup> Similar associations with systemic hypertension were found in other studies.<sup>36–40</sup> Diabetes mellitus was more prevalent in individuals with nonperfused CRVO than in matched

controls from large population databases.<sup>36,37</sup> Diabetes with end-organ damage in particular may carry an increased risk.<sup>33</sup> Hyperlipidemia, arteriosclerosis, and smoking have also been linked to the development of vein occlusions.<sup>2,34,39</sup> A recent large longitudinal cohort study based on insurance billing codes linked African American race to a higher risk for CRVO.<sup>33</sup>

## Risk Factors and Associations With CRVO

- **Ethnicity:** African race
  - **Systemic vascular diseases:** Diabetes mellitus, hypertension, carotid insufficiency
  - **Ocular diseases:** Open angle glaucoma, ischemic optic neuropathy, pseudotumor cerebri, tilted optic nerve heads, optic nerve head drusen
  - **Hematologic alterations:** Hyperviscosity syndromes: dysproteinemias (multiple myeloma), blood dyscrasias (polycythemia vera, lymphoma, leukemia, sickle-cell disease or trait), anemia, elevated plasma homocysteine, factor XII deficiency, antiphospholipid antibody syndrome, activated protein C resistance, protein C deficiency, protein S deficiency
  - **Inflammatory/autoimmune vasculitis:** Systemic lupus erythematosus
  - **Medications:** Oral contraceptives, diuretics, hepatitis B vaccine
  - **Infectious vasculitis:** HIV, syphilis, herpes zoster, sarcoidosis
  - **Other:** After retrobulbar block, dehydration, Valsalva, pregnancy
- HIV, human immunodeficiency virus.

Data from references 5, 33, 34, 35.

Hematologic abnormalities, particularly conditions that predispose to a hypercoagulable state, have been identified in persons with CRVO. Individuals less than 60 years of age may have

a greater association with hypercoagulable states and inflammatory conditions compared to older persons with a higher incidence of systemic vascular disease risk factors.<sup>5,6</sup> Lahey and colleagues found one abnormal laboratory value suggesting systemic hypercoagulability in 27% of 55 patients younger than 56 years of age.<sup>41</sup> Studies have demonstrated an increased incidence of coagulation cascade abnormalities, including protein C deficiency, protein S deficiency, activated protein C resistance, presence of factor V Leiden, presence of antiphospholipid antibodies, hyperhomocysteinemia, antithrombin III deficiency, prothrombin gene mutations, and abnormal fibrinogen levels.<sup>42-49</sup> Hyperviscosity from blood dyscrasias, dysproteinemias, and dehydration have also been reported with CRVO.<sup>50-53</sup> In addition, abrupt changes in venous or intracranial pressure such as from Valsalva maneuvers have been implicated in the pathogenesis of CRVO.<sup>54,55</sup>

An increased risk of CRVO is present in eyes with open angle glaucoma.<sup>4,56</sup> Other ocular conditions causing deformation or mechanical pressure on the optic nerve head and lamina cribrosa, including ischemic optic neuropathy, tilted optic nerve head, optic nerve head drusen, optic disc traction syndrome, and pseudotumor cerebri,<sup>50,57</sup> have also been associated with CRVO. External compression of the globe and optic nerve from thyroid-related ophthalmopathy, mass lesions, or head trauma with orbital fracture may also result in CRVO.<sup>5</sup>

## Clinical Evaluation

At the time of initial presentation, a careful assessment of the CRVO duration and the degree of ME and retinal ischemia will determine treatment options and the follow-up schedule. An ocular history may determine the onset of the occlusion, although individuals may not have noted vision loss if the fellow eye has maintained good acuity. A history of systemic diseases, such as hypertension, diabetes, and heart disease, and a personal or family history of thrombosis or hypercoagulable state should be determined.

The ophthalmic examination should be performed on both eyes and include visual acuity, pupillary reaction, and intraocular pressure. Undilated slit-lamp examination is performed to detect

NVI. Undilated gonioscopy is essential to determine the presence of NVA or evidence of angle closure from peripheral anterior synechiae, since NVA may be present without any NVI in up to 12% of eyes.<sup>18</sup> Ophthalmoscopic examination will help differentiate a CRVO from intraretinal hemorrhage associated with carotid occlusive disease, in which dot–blot hemorrhage is classically confined to the temporal midperiphery.<sup>58</sup> Adjunctive imaging studies, including optical coherence tomography (OCT) and fluorescein angiography, are helpful in evaluating and following presence of ME and perfusion status.

In general, a systemic workup is not indicated in persons older than 60 years of age with known systemic risk factors for CRVO as above. Younger patients are more likely to have predisposing conditions resulting in thrombotic disease.<sup>6,41</sup> A systemic workup may be considered in younger individuals without risk factors as noted above, and in those with a prior occlusion in the fellow eye, bilateral simultaneous CRVO, mixed type vascular occlusion, severe worsening nonperfusion, prior systemic thrombotic disease, family history of thrombosis, or other symptoms suggestive of a **Box 57.2** **Cardiologic or rheumatologic condition (Box 57.2).**<sup>9,46</sup>

## Suggested Laboratory Workup for CRVO in Appropriate Cases

- **Blood dyscrasias:** CBC with differential, serum protein electrophoresis
- **Hypercoagulable conditions:** serum viscosity, lupus anticoagulant, antiphospholipid antibody, fasting plasma homocysteine, factor V Leiden, antithrombin III, prothrombin gene mutation, protein C, protein S
- **Cardiovascular/diabetes:** fasting lipid profile, hemoglobin A1C, blood pressure

## Therapeutic Options

Treatment for central retinal vein occlusion is directed at treating

the sequelae of CRVO, particularly ME and neovascularization, and not the underlying etiology. The recent development of intravitreal pharmacotherapy has revolutionized the treatment of CRVO-associated ME (Table 57.1; Fig. 57.6).<sup>59–67</sup> While these intravitreal agents can also improve secondary neovascularization, panretinal laser photocoagulation (PRP) remains the definitive treatment. Alternative experimental therapies have sought to modify the anatomic alterations believed to be responsible for CRVO. Of course, appropriate management of blood pressure and other systemic factors is always of paramount importance.

**TABLE 57.1**

**Randomized, Sham-Controlled Trials Investigating Intravitreal Pharmacologic Agents for CRVO-Associated Macular Edema**

Study	Drug	Intervention	Eyes	Duration	Mean Letter Gain	Percentage of ≥15 Letter Gain
Ip et al. 2009 <sup>60</sup> (SCORE)	Intravitreal triamcinolone	IVT 4, 1 mg every 4 months PRN vs. observation	271	12 mth	-1 to 2 (1 and 4 mg) vs. -12 (observation)	26% (4 mg), 27% (1 mg), 7% (sham)
Haller et al. 2010 <sup>61</sup> (GENEVA)	Intravitreal dexamethasone implant	IVDEX 0.7 and 0.35 mg for CRVO and BRVO vs. sham	437	6 mth	N/A	30 days: 21%, 20%, 7% 60 days: 29%, 33%, 9% in 0.7 mg, 0.35 mg and sham groups, respectively 90 days: 24% (0.35) vs. 10% (sham) No significant difference between 0.7 mg and sham 180 days: No differences

**FIG. 57.6** A 67-year-old male with 5-month history of vision loss from a central retinal vein occlusion who received a single intravitreal injection of triamcinolone

acetamide (4 mg) to treat persistent cystoid macular edema. (A) Preinjection optical coherence tomography (OCT) demonstrating prominent retinal thickening in the macular region with inner and outer retinal cysts and subretinal fluid accumulation. (B) 4-month postinjection OCT demonstrating dramatic resolution of retinal thickening and return of normal foveal contour. (C) Retinal thickness map and corresponding color map from (A) with marked macular thickening. (D) Retinal thickness map and corresponding color map from (B) with normal retinal thickness measurements.

## Treatment of Macular Edema

### Observation

The CVOS Group M report studied the effect of grid pattern argon laser photocoagulation to improve visual acuity in 155 eyes with perfused CRVO-associated ME and 20/50 acuity or worse.<sup>68</sup> Laser treatment involved a grid pattern in the area of leaking capillaries within 2 disc diameters of the foveal center but not within the foveal avascular zone. At 36 months, there was no significant difference in mean visual acuity between treated (20/200) and untreated (20/160) eyes despite reduction of angiographic ME. Widespread damage to the perifoveal capillary network has been hypothesized to contribute to the lack of visual recovery. Therefore, the CVOS did not recommend grid laser photocoagulation for CRVO-associated ME. In the absence of robust treatment options before the recent advent of intravitreal pharmacotherapy for retinal diseases,<sup>69</sup> standard of care for CRVO-associated ME was observation.

### Corticosteroid Therapy

The exact mechanism of action of corticosteroids in modulating retinal edema is unknown. It is believed that corticosteroids maintain antiinflammatory effects with modulation of production of cytokines and growth factors, including VEGF. Corticosteroids are also thought to stabilize the blood–retinal barrier with reduction in vascular permeability.<sup>70,71</sup> There is little evidence for systemic

administration of corticosteroids to treat ME from CRVO, unless the vein occlusion is associated with underlying systemic inflammatory disease.<sup>72</sup> Intravitreal delivery of corticosteroids provides targeted delivery of the drug to the retinal vessels and macular tissue while limiting potential systemic toxicity.

Following case reports on the use of intravitreal triamcinolone (IVTA) for the treatment of CRVO-associated ME,<sup>73-76</sup> the Standard of Care vs. Corticosteroid for Retinal Vein Occlusion (SCORE) study compared the efficacy and safety of two doses of preservative-free IVTA (1 mg and 4 mg) vs. standard of care (observation per CVOS) for the treatment of ME in 271 eyes with CRVO.<sup>60</sup> In this randomized, multicenter clinical trial, eyes were retreated with IVTA every 4 months for 1 year unless certain criteria were met.

The SCORE study showed significant improvement in visual acuity with IVTA compared to observation.<sup>60</sup> At 1 year, 26% of eyes in the 4 mg group and 27% of eyes in the 1 mg group gained  $\geq 15$  letters compared to 7% of untreated eyes.

Primary ocular adverse events included cataract formation and elevated IOP.<sup>60</sup> Cataract formation was observed in 26% and 33% in the 1-mg and 4-mg IVTA groups, respectively, compared to 18% in the observation group. Over 2 years, 27% of eyes from the 4-mg group and 3% in the 1-mg group required cataract surgery, but no eyes from the observation group did. Elevated IOP was observed in 20% and 35% of eyes in the 1-mg and 4-mg IVTA groups, respectively, compared to 8% in the observation group.

The limited duration of the response to IVTA therapy has prompted the development of sustained-release corticosteroids for the treatment of CRVO-associated ME. In a prospective series of 24 eyes with vision loss from chronic ME secondary to CRVO, improvements in visual acuity and ME after 3 years were observed in eyes surgically implanted with a sustained-release intravitreal fluocinolone acetonide implant (Retisert; Bausch & Lomb). In this series, all phakic eyes developed visually significant cataracts, 33% required surgical intervention for increased intraocular pressure, and an additional 38% received intraocular pressure-lowering medications.<sup>77</sup>

In 2009, a sustained-release intravitreal dexamethasone delivery

system, Ozurdex (Allergan), was FDA-approved for the treatment of ME secondary to CRVO. A multicenter, international study at 167 sites in 24 countries reported the 6-month outcomes of a 0.35 mg and 0.7 mg Ozurdex dose for ME in eyes with retinal vein occlusion, a group consisting of both branch retinal vein occlusion and CRVO, compared to sham-injected eyes.<sup>61</sup> The Ozurdex implant resulted in improved mean visual acuity, increased rate of  $\geq 15$  letter gain and lower rate of  $\leq 15$  letter loss. Subgroup analysis was performed on 136 CRVO eyes injected with Ozurdex. The 0.7-mg group demonstrated significant gains of  $\geq 15$  letters compared to sham control at 30 days and at 60 days, but not at 90 or 180 days. The 0.35-mg group demonstrated significant gains of  $\geq 15$  letters compared to sham at 30–90 days, but not at 180 days. No significant difference in cataract formation or cataract surgery was identified between the treated and untreated groups. Ocular hypertension occurred in 4% of eyes receiving the drug delivery system, and most were able to be managed with topical medications. Two retinal detachments occurred in the study, one in the sham group and one in the 0.7-mg group.<sup>61</sup> The study was followed by an open-label 6-month extension phase in which all patients received Ozurdex 0.7 mg at day 180 after baseline, which yielded similar results in visual acuity. Cataract progression was reported in 30% and medical treatment for increased intraocular pressure was initiated in 36% in 0.7/0.7 mg Ozurdex group.<sup>78</sup>

## **Intravitreal Anti-VEGF Therapy**

VEGF plays a key role in the pathophysiology of CRVO and its sequelae. Markedly elevated levels of VEGF have been demonstrated in the vitreous of eyes with ischemic CRVO.<sup>29</sup> It has been hypothesized that VEGF may cause capillary endothelial cell proliferation that leads to progressive vascular closure, promoting nonperfusion in CRVO.<sup>79,80</sup> Anti-VEGF therapy may result in enhanced retinal perfusion, lowered intravenous pressure, and the normalization of venous diameter and tortuosity.<sup>22,79</sup> Several intravitreal anti-VEGF treatments are available, including ranibizumab (Lucentis, Genentech), aflibercept (Eylea, Regeneron), bevacizumab (Avastin, Genentech), and pegaptanib (Macugen, Bausch & Lomb).

## Ranibizumab

The double-masked, multicenter, randomized phase III Central Retinal Vein Occlusion (CRUISE) trial prospectively compared monthly intravitreal injections of 0.3 mg or 0.5 mg ranibizumab to sham-injected controls in the treatment of 392 patients with CRVO and ME.<sup>62</sup> Eyes treated with 0.3 mg and 0.5 mg ranibizumab gained 12.7 and 14.9 letters, respectively, at 6 months compared to a 0.8 letter gain in the sham group. Additionally 46% (0.3 mg) and 48% (0.5 mg) of eyes treated with intravitreal ranibizumab gained  $\geq 15$  letters from baseline compared to only 17% in the sham group, with significant reductions in central retinal thickness in the treatment groups. Systemic and ocular adverse events were rare (Table 57.1).

Following the 6-month endpoint, all groups, including the sham group, were treated with monthly ranibizumab on an as-needed basis, limiting further information on the natural history of CRVO and any long-term comparison.<sup>17,81</sup> Overall, ranibizumab groups maintained visual acuity gains, and there was also visual and anatomic improvement in the sham/0.5-mg ranibizumab group.<sup>81,82</sup> The results of the CRUISE study prompted FDA-approval of ranibizumab for the treatment of CRVO.

Long-term effects of ranibizumab therapy and associated burden of treatment have been investigated in two follow-up studies. A prospective, open-label extension trial HORIZON enrolled 304 patients who completed CRUISE.<sup>83</sup> Patients were seen at least every 3 months for 12 months and were eligible for an intravitreal injection if OCT central subfield thickness exceeded 250  $\mu\text{m}$  or if there was recurrent or persistent edema limiting visual acuity. Interestingly, this dosing scheme resulted in reductions in percent of patients who gained  $\geq 15$  letters from initial study baseline compared to the CRUISE 12-month endpoint in the ranibizumab 0.5-mg (45% compared to 59%) and 0.3/0.5-mg group (39% vs. 47%), while the sham/0.5-mg group remained stable (38% vs. 38%). Following this, a prospective open-label extension trial named The Extended follow-up of patients with ME due to branch retinal vein occlusion or central retinal vein occlusion previously treated with intravitreal ranibizumab (RETAIN) investigated a subset who completed HORIZON for 2 additional years.<sup>84</sup> Patients were seen monthly in the first year and at least every 3 months (up to every

month) in the second year. Intravitreal injections of 0.5 mg ranibizumab were given if any intraretinal fluid was identified. At the final visit 53% gained  $\geq 15$  letters. Median letter improvement of 14.0 was not statistically different compared to the CRUISE endpoint. Notably, a small number of patients lost vision 4 years after enrollment into CRUISE compared to baseline. This was associated with recalcitrant ME, pigmentary changes believed to represent photoreceptor damage that was often related to foveal ischemia and epiretinal membrane formation. This study gave insight into long-term treatment burden. The investigators noted great heterogeneity in number of injections and required length of treatment until stabilization of ME. Within year 4 of follow-up, 56% required six injections on average, whereas 44% were stable without any injections. Attempts to reduce injection frequency by adding sector PRP to nonperfused retina thus far have not been promising.<sup>85</sup>

## **Aflibercept**

Two double-masked, randomized, prospective phase III trials named COPERNICUS and GALILEO were carried out to investigate intravitreal aflibercept for CRVO-associated ME.<sup>64,66</sup> COPERNICUS enrolled 189 eyes with ME secondary to CRVO in the United States, and GALILEO enrolled 177 eyes in Europe and the Asia/Pacific region. Both trials evaluated 2.0 mg intravitreal aflibercept given monthly vs. sham injections for 6 months. In COPERNICUS, 56% gained  $\geq 15$  letters in the aflibercept group vs. 12% in the sham group. Mean letter gain was 17.3 in aflibercept eyes, whereas sham eyes lost a mean of 4.0 letters. In GALILEO, 60% gained  $\geq 15$  letters in the treatment group compared to 22% in the sham group, with mean letter gains of 18.0 vs. 3.3. Neither GALILEO nor COPERNICUS reported systemic thromboembolic events in the treatment groups in the first 6 months, and ocular events were rare (Table 57.1). Based on these studies, aflibercept received FDA-approval for ME secondary to CRVO.

Following the initial 6 months, all eyes enrolled in COPERNICUS switched to monthly PRN (as needed) aflibercept, while in GALILEO only the treatment group became eligible for monthly PRN injections, but the control group was maintained on sham

injections.<sup>67,86</sup> The 1-year data from these studies demonstrated that the treatment groups maintained visual acuity gains. Additionally, 2-year results have been published from COPERNICUS and 18-month results from GALILEO, providing further information on long-term visual outcomes as well as associated treatment burden.<sup>87,88</sup> In COPERNICUS, from week 52 forward, all patients were evaluated at least quarterly (but up to every 4 weeks) and were treated on a PRN basis. Results indicated that visual acuity gains slightly diminished during less frequent follow-up.<sup>87</sup> In GALILEO, from week 52 to 76, all eyes received intravitreal aflibercept as needed every 8 weeks. At the last follow-up, visual acuity gains were largely maintained in the treatment group.<sup>88</sup> Both studies demonstrated significant range and heterogeneity in terms of number of needed injections during the PRN treatment period.

## **Pegaptanib**

Pegaptanib (Macugen) is currently the third FDA-approved intravitreal anti-VEGF agent, which received approval for the treatment of neovascular age-related macular degeneration, but not for CRVO. In a phase II double-masked, multicenter, randomized trial, patients with CRVO receiving off-label 0.3 mg or 1 mg pegaptanib every 6 weeks for 24 weeks were prospectively compared to sham-injected controls.<sup>63</sup> There was no significant difference in gain of  $\geq 15$  letters among groups, 0.3 mg and 1 mg. Only the 1 mg group showed slightly statistically significant mean letter improvement compared to sham. Given the enhanced efficacy of other anti-VEGF agents, pegaptanib use for CRVO remains low.

## **Bevacizumab**

Much of our understanding of the role of anti-VEGF agents in the treatment of retinal disease comes from studies with bevacizumab. While bevacizumab is not FDA-approved for intravitreal use, its ophthalmic use quickly grew due to its low cost, reported efficacy, and availability prior to the approval of ranibizumab. Epstein and coworkers evaluated bevacizumab vs sham injection in a prospective, randomized, double-masked study of 60 eyes with ME secondary to CRVO. In the initial 6 months, injections were given every 6 weeks. After 6 months, the percentage of  $\geq 15$  letter gainers

was 60% in the bevacizumab group vs. 20% in the sham group.<sup>65</sup> In the following 6 months, all eyes received intravitreal bevacizumab every 6 weeks. One year after baseline, the percentage gaining  $\geq 15$  letters was 60% in the bevacizumab group and 33% in the sham/bevacizumab group.<sup>89</sup> No cases of endophthalmitis or retinal detachment were reported; likewise no serious nonocular events were reported.

The extensive international intravitreal use of bevacizumab remains off-label. A prospective, randomized study marginally failed to demonstrate noninferiority of bevacizumab against ranibizumab for branch retinal vein occlusion-associated ME, while noninferiority was established by two large trials on neovascular age-related macular degeneration.<sup>90-92</sup> It is unclear if these results are applicable to the treatment of CRVO. The SCORE2 trial is currently evaluating whether bevacizumab is noninferior to aflibercept.

Intravitreal pharmacologic therapeutics including the anti-VEGF agents ranibizumab, aflibercept, and bevacizumab as well as an intravitreal long-term release dexamethasone implant and intravitreal preservative-free triamcinolone have significantly expanded our treatment options. Given the efficacy of intravitreal pharmacologic agents in the treatment of CRVO, and given their favorable side-effect profile, the use of intravitreal pharmacotherapy has replaced observation as the previous standard of care established by the CVOS for treatment of CRVO-associated ME.<sup>59,93</sup> There is good evidence to suggest that earlier treatment with anti-VEGF agents is preferable to delayed treatment and that many eyes will continue to require frequent long-term injections. Reduced follow-up frequencies as well as PRN dosing schemas after initial visual acuity gains may result in visual acuity losses.<sup>93</sup> No sophisticated evidence-based information exists on the relative efficacies of the different anti-VEGF options.<sup>94</sup> Little information is known about the efficacies of intravitreal anti-VEGF vs. corticosteroids. A small prospectively randomized study suggested reduced need for injections with corticosteroids, but these were associated with significantly more adverse events, particularly increases in intraocular pressure and visually significant premacular membranes.<sup>95</sup> Another small prospective

trial tested monotherapy with intravitreal Ozurdex vs. combination therapy with bevacizumab and demonstrated no significant differences.<sup>96</sup>

In the authors' clinical practice, CRVO-associated ME is usually treated with serial anti-VEGF injections. Corticosteroid agents are reserved for severe or refractory cases, particularly in pseudophakic eyes without glaucoma. Further understanding of differences in treatment choices as well as development of sophisticated dosing schemes will likely improve management of our patients.

## **Neovascularization During Anti-VEGF Therapy**

While anti-VEGF treatment alters the natural history of CRVO, neovascular events are reduced but not eliminated. Even under clinical study conditions among CRUISE, COPERNICUS, and GALILEO patients, neovascularization occurred in between 5.3% and 7.8%. Neovascular events in CRVO during anti-VEGF therapy may often be delayed, especially during times of decreased follow-up frequency or after discontinuation of anti-VEGF treatment when the disease was thought to be less active and also to occur to a higher extent in eyes with ischemic rather than perfused CRVO. DeCroos and colleagues retrospectively analyzed 32 patients who developed neovascularization during anti-VEGF therapy.<sup>97</sup> Neovascular events occurred after a mean treatment interval of 17.2 months (standard deviation, 10.3 months) with a mean treatment-free interval of 6.3 months (standard deviation, 7.3 months). Notably, CRUISE excluded patients with a brisk relative afferent pupillary defect or visual acuity worse than 20/320, thereby limiting information on severe nonperfusion. Addressing this, Brown and coworkers prospectively investigated a CRVO cohort of 20 eyes with severe nonperfusion.<sup>98</sup> They found that 50% of eyes developed neovascular complications during concurrent treatment with ranibizumab after a mean follow-up of 24 months (range, 3–44 months).

## **Definitive Treatment of Ocular Neovascularization**

### **Laser Photocoagulation**

The CVOS Group N report compared the efficacy of PRP at the time of study entry in eyes with nonperfused CRVO that did not have evidence of NVI/NVA (early treatment group,  $n=90$ ) with delayed, but prompt, PRP application only when NVI/NVA was detected (no early treatment group,  $n=91$ ).<sup>99</sup> NVI/NVA developed in 20% of early treatment and 34% of no early treatment eyes. There was greater resolution of NVI/NVA by 1 month after PRP in 56% of no early treatment eyes compared with 22% of early treatment eyes. The CVOS therefore recommended that PRP be delivered promptly after the development of NVI/NVA but not prophylactically in eyes with nonperfused CRVO. In approximately 90% of cases, the regression of NVI/NVA occurs within 1–2 months of PRP. Persistent neovascularization after PRP should be followed closely, and additional PRP may be applied in attempts to halt its progression. Persons presenting with NVD/NVE without NVI/NVA should be treated with PRP, as performed in eyes with proliferative diabetic retinopathy or branch retinal vein occlusion, to prevent anterior segment neovascularization. Prophylactic placement of PRP may be considered in eyes with nonperfused CRVO and risk factors for developing NVI/NVA (male gender, short duration of CRVO, extensive retinal nonperfusion, and extensive retinal hemorrhage) or in cases where frequent ophthalmologic follow-up is not possible.

## **Medical Therapy**

Topical or systemic antiglaucoma agents may be required to reduce elevated intraocular pressure due to NVA. Topical corticosteroids can reduce anterior segment inflammation by stabilizing tight junctions in neovascular tissue, thereby reducing vascular exudation. Cycloplegic agents prevent posterior synechiae formation between the iris and lens. Anti-VEGF agents may result in rapid regression of any intraocular neovascularization, but these agents should be used as a temporizing adjunctive measure with subsequent placement of PRP for definitive treatment of NVI/NVA/NVD/NVE.<sup>100</sup> Failure of medical therapy to control intraocular pressure may require surgical intervention (e.g., trabeculectomy or tube placement).

## Treatment of Systemic Medical Conditions

Identification and treatment of systemic vascular risk factors, such as systemic hypertension and diabetes mellitus, is of paramount importance in individuals with CRVO. Coordination with the internist is strongly recommended. The role of systemic anticoagulation is unclear as there is no evidence that agents such as aspirin or heparin can prevent or alter the natural history of CRVO; patients taking warfarin sodium (Coumadin) can still develop CRVO despite maintaining therapeutic levels of anticoagulation.<sup>101</sup> Prophylactic use of these medications, however, may help prevent nonocular thrombotic events, especially in individuals with known systemic vascular disease, and may be considered in coordination with the patient's internist.

Oral pentoxifylline is a vasodilator and enhancer of red blood cell deformability used in systemic vascular diseases to improve perfusion to occluded vessels and enhance the development of collateral circulation. A retrospective series of 11 patients treated with oral pentoxifylline (400 mg three times a day) for an average of 5 months demonstrated a 10% mean reduction in macular thickening by volumetric OCT but did not demonstrate a change in visual acuity or perfusion status.<sup>102</sup>

The reported increased plasma viscosity in persons with CRVO has prompted interest in systemic hemodilution to increase oxygen supply to the retina. Prospective, randomized controlled clinical trial of selected CRVO patients demonstrated significant visual acuity gains, reduced conversion to nonperfusion,<sup>103</sup> and reduced the need for intravitreal bevacizumab injections when used in combination.<sup>104</sup> Hemodilution is likely not appropriate for patients with anemia, renal insufficiency, or pulmonary insufficiency, which may limit its clinical use.<sup>103,105</sup>

## Alternative Treatments Aimed at Underlying Etiology

### Chorioretinal Venous Anastomosis

In eyes with perfused CRVO, investigators have bypassed the occluded central retinal vein by creating a chorioretinal

anastomosis (CRA) between a nasal branch retinal vein and the choroidal circulation. Successful creation of an anastomosis may allow transretinal retrograde flow of venous blood from the eye and prevent the development of retinal ischemia or allow reduction of ME. CRAs have been created through a surgical transretinal venipuncture technique<sup>106,107</sup> or, more commonly, through argon or Nd-YAG laser delivery directly at a branch retinal vein to rupture the posterior vein wall and Bruch's membrane.<sup>108,109</sup> McAllister and colleagues prospectively randomized 113 patients with nonischemic CRVO to laser-induced CRA or sham treatment.<sup>110</sup> Treated eyes demonstrated significant visual acuity gains, but this was counteracted by significant side-effects.

Immediate complications from this technique may include intraretinal, subretinal, or vitreous hemorrhage, while long-term complications include nonclearing vitreous hemorrhage, epiretinal avascular proliferation, fibrovascular proliferation, secondary neovascularization (choroidal, retinal, choroidovitreous, anterior segment), and traction retinal detachment.<sup>106,111,112</sup> Visual recovery may be limited in spite of successful anastomosis creation due to thrombosis of the treated vein with progressive distal retinal ischemia.

## **Tissue Plasminogen Activator**

Thrombolytic agents have been proposed as a treatment of a suspected thrombus in the central retinal vein. If a thrombus is indeed etiologic, lysis is recommended within 21 days of its formation. Recombinant tissue plasminogen activator (r-tPA) is a synthetic fibrinolytic agent that converts plasminogen to plasmin and destabilizes intravascular thrombi. Reduction in clot size may facilitate dislodging of the entire thrombus or recanalization of the occluded retinal vein. Recombinant tissue plasminogen activator has been administered by several routes: systemic, intravitreal, and by endovascular cannulation of retinal vessels.

Systemic administration of low-dose (50 µg) front-loaded r-tPA has been attempted in two pilot studies with visual acuity improvement in 30–73% of patients.<sup>113,114</sup> In a prospective, multicenter randomized trial of 41 patients with CRVO, Hattenbach and colleagues demonstrated significant 1-year improvement of 3

lines in 45% of patients undergoing low dose r-tPA compared to 21% of patients undergoing hemodilution.<sup>115</sup> Another study examining high-dose (<100 µg) systemic tPA for the treatment of 96 patients reported development of intraocular hemorrhage in three patients and a fatal stroke in one patient.<sup>116</sup> While Hattenbach did not observe any serious adverse events in his trial of low-dose r-tPA, these complications highlight the importance of approaching systemic administration of r-tPA with caution.

Intravitreal delivery of r-tPA has potential advantages, including decreased risk of systemic complications, directed delivery to the vitreous cavity, and subsequent access to the retinal vessels with low risk of ocular morbidity from the procedure. Of 47 persons in three noncontrolled studies of intravitreal r-tPA for both ischemic and nonischemic CRVO of less than 21 days' duration, 28–44% had 3 lines of visual acuity improvement with 6 months follow-up.<sup>117-119</sup> Administration of r-tPA did not significantly alter final perfusion status, especially in pretreatment ischemic eyes.<sup>120</sup> Although there were no significant treatment-related complications, differences in inclusion criteria and dosage of r-tPA used (between 66 and 100 µg) limits generalizations from these studies.

Endovascular delivery of r-tPA involves cannulation of retinal vessels, either through a neuroradiologic or a vitreoretinal approach, with delivery of minute quantities of r-tPA directly into the occluded vein to dissolve the suspected thrombus.<sup>121,122</sup> Weiss and Bynoe reported their technique of vitrectomy followed by cannulation of a branch vein and infusion of r-tPA towards the optic nerve head.<sup>123</sup> In their uncontrolled study, 50% of 28 eyes with CRVO of greater than 1-month duration and worse than 20/400 preoperative acuity recovered more than 3 lines by a mean follow-up of 12 months. Complications included vitreous hemorrhage in seven eyes and treated retinal detachment in one eye. In another prospective study of 13 patients undergoing endovascular r-tPA delivery, visual recovery did not correspond with successful thrombolysis, and complications including retinal detachment, phthisis, neovascular glaucoma, and cataract were considered unacceptably high.<sup>124</sup>

## Surgical Treatments

## Vitreotomy

Vitreous surgery may be useful to address complications of CRVO and even to attempt to alter the natural course of the disease. Eyes with nonclearing vitreous hemorrhage from secondary retinal neovascularization may benefit from surgical evacuation. At the time of vitrectomy, clearing of the hemorrhage can be combined with removal of epiretinal membranes and removal of fibrovascular proliferations, if present, and the placement of complete PRP.<sup>125</sup> Although this technique may prevent or aid in regression of anterior segment neovascularization, visual outcomes may be limited due to the extent of underlying retinal nonperfusion.<sup>126</sup> In eyes with extensive anterior segment neovascularization and neovascular glaucoma, vitrectomy and endolaser PRP may be combined with pars plana placement of a glaucoma drainage device to avoid anterior chamber hemorrhage at the time of tube placement.

The potential role of vitrectomy with peeling of the internal limiting membrane has also been investigated for treatment of ME secondary to CRVO. Small studies have demonstrated an improvement in ME accompanied by improvement in acuity.<sup>127-129</sup> In contrast, one study showed no significant improvement in vision despite improvement of central foveal thickness.<sup>130</sup>

The use of vitrectomy with membrane peel in the treatment of CRVO-associated ME requires further investigation with randomized trials to establish its efficacy, particularly given the development of effective and less invasive intravitreal pharmacologic agents. Vitrectomy alters the pharmacokinetics of these intravitreal agents, which may reduce duration of effect and as such, the use of vitrectomy in the treatment of CRVO may result in decreased efficacy of further intravitreal pharmacotherapy.<sup>131</sup> This should be carefully balanced against the expected benefits of vitrectomy.

## Radial Optic Neurotomy

Opremcak and colleagues first reported combining vitrectomy with radial optic neurotomy (RON) involving transvitreal incision of the nasal scleral ring to release pressure on the central retinal vein at the level of the scleral outlet. In a nonrandomized study of 117

consecutive eyes undergoing RON, Opremcak reported anatomic resolution of ME in 95% and visual improvement in 71% of eyes.<sup>132</sup> Interpretation of these impressive results must consider the nonrandomized nature of the study and the absence of a control group. While subsequent reports, including a prospective randomized trial, on radial optic neurotomy have also demonstrated visual improvement,<sup>133–136</sup> no study has replicated the reported 71% improvement, and some studies have reported that visual improvement following RON is comparable to natural history.<sup>135</sup> In contrast, other studies have not demonstrated improvement in visual acuity<sup>137</sup> or in central retinal hemodynamics,<sup>138,139</sup> questioning the role for RON in CRVO treatment. Importantly, RON has been associated with significant risks, including postoperative visual field defects, laceration of central retinal vessels, globe perforation, choroidal neovascularization, subretinal hemorrhage, and retinal detachment.<sup>133,135–137,140</sup> Evidence of the efficacy of RON in the management of CRVO is limited but currently does not clearly demonstrate a beneficial role. With the availability of effective intravitreal pharmacologic agents, the use of RON for CRVO has largely been abandoned.

## Follow-Up

Prior to the availability of intravitreal pharmacotherapy for the treatment of CRVO-associated ME, follow-up for eyes with CRVO to detect neovascular complications was typically guided by visual acuity at initial presentation. Eyes with initial acuity of  $\geq 20/40$  were generally examined every 1–2 months for 6 months, then annually if stable. Eyes with initial acuity  $< 20/200$  were seen monthly for the initial 6-months, then bimonthly for the next 6 months, as these eyes have a greater degree of nonperfusion and a higher risk of developing NVI/NVA. Eyes with acuity between 20/50 and 20/200 have an intermediate risk of developing NVI/NVA and were also typically examined monthly for the first 6 months. Eyes that experienced a drop in visual acuity below the 20/200 level during follow-up were reevaluated with assessment of perfusion status and presence of neovascularization, and monthly follow-up for an

additional 6 months was recommended for these eyes.<sup>9</sup> With the development of intravitreal pharmacologic agents, this paradigm has changed. Follow-up intervals for patients undergoing treatment with intravitreal pharmacotherapy should currently be based on clinical response to treatment. Close monitoring and frequent treatment for several years may be required to prevent recurrent ME and neovascular complications.

## Conclusion

CRVO is a sight-threatening disease with significant ocular morbidity including ME and intraocular neovascularization. Before the recent advent of intravitreal pharmacotherapy in its management, the standard of care was guided by results from the Central Vein Occlusion Study, which recommended observation of ME and retinal ischemia with management of neovascular sequelae using PRP. In the absence of robust treatment options for CRVO,<sup>69</sup> other approaches including the administration of r-tPA, creation of chorioretinal anastomosis, and various surgical interventions had been reported with variable success and often unacceptable side effects. More recently, intravitreal corticosteroids and then anti-VEGF agents have demonstrated improvements in ME, visual acuity, and even neovascular complications with a favorable side effect profile. The use of ranibizumab (Lucentis), aflibercept (Eylea), and a sustained-release dexamethasone implant (Ozurdex) have been FDA-approved for the treatment of CRVO. Intravitreal pharmacotherapy has now replaced observation as the standard of care for the management of CRVO.

## Introduction

Macular telangiectasia (mac tel), or idiopathic perifoveal or juxtafoveal telangiectasia, includes several, different vascular diseases affecting the capillaries of the posterior pole. While complex classifications have been used, there are essentially two basic and distinct forms: (1) a developmental or congenital, usually unilateral vascular anomaly, which may be part of the larger spectrum of Coats disease and now often called mac tel type 1; and (2) a presumably acquired bilateral form found in middle-aged and older persons, which has been termed macular, juxtafoveal, or perifoveal telangiectasia and is now known as mac tel type 2. This chapter will focus on mac tel type 2, the bilateral, acquired form of perifoveal telangiectasia from unknown cause with characteristic alterations of the macular capillaries and neurosensory degeneration.

## Classification of Macular Telangiectasia

In 1968, Gass recognized that Coats disease was a developmental vascular disease and he also introduced a new distinct entity, which

was called idiopathic juxtafoveolar retinal telangiectasis.<sup>1</sup> This resulted in an extensive, detailed classification in 1993.<sup>2</sup> However, this classification was further refined by Yanuzzi in 2006, using the new diagnostic, adjunctive imaging systems such as optical coherence tomography and high-speed stereoscopic angiography in a cohort of 36 patients with mac tel of various types. He introduced the name “idiopathic macular telangiectasia.”<sup>3</sup> He proposed mac tel type 1 for “aneurysmal” telangiectasia, which was formerly known as Coats disease or Leber miliary aneurysm. The former condition, coined as juxtafoveal telangiectasia by Gass, became idiopathic macular telangiectasia or mac tel type 2. Other existing types of juxtafoveal telangiectasia that were associated with other systemic disease were eliminated in this new classification, because of the lack of subjects in the other categories.

## **Epidemiology**

### **Prevalence of Disease: Estimates From Population-Based Studies**

#### **Beaver Dam Eye Study**

The Beaver Dam Eye Study<sup>4</sup> regraded the stereoscopic fundus photographs of the eyes of 4926 subjects aged 43–84, 99% of whom were white, for mac tel type 2. Five individuals, one woman and four men, were identified to have mac tel type 2, which translates into a prevalence of 0.1% (95% confidence interval [CI] 0.09–0.1). The average age was 63 years, with a range from 52 to 68 years. Bilateral manifestations were found in two patients.

#### **Melbourne Collaborative Cohort Study**

This Australian study<sup>5</sup> analyzed 22, 415 Caucasians for the presence of typical features of mac tel type 2 on nonmydriatic color fundus photographs in a population study. Twelve patients with “possible” unilateral mac tel type 2 and five patients with signs of bilateral mac tel type 2 were identified. The average age amongst bilateral cases was 63 and ranged from 53 to 72 years. Three of the five bilateral cases were female. Only one “very convincing case

with early gray sheen and telangiectatic vessels temporal to the fovea” was reported. The authors concluded that the incidence in their studied population ranged from 0.0045% to 0.022%, a prevalence which is significantly lower than the one found in the Beaver Dam Eye Study.

## **Study in Africa**

An additional study was conducted in two populations in African countries.<sup>6</sup> Of the 8599 participants, the prevalence of mac tel type 2 was 0.06% (95% CI 0.02–0.21%) and 0.06% (95% CI 0.01–0.17%) in Kenya and Nigeria, respectively. These were again assessed on color fundus photographs.

The techniques used to evaluate each of these studies were different, likely accounting for the varying rates. It is possible that all three studies may have underestimated the true prevalence because only color fundus images were available. Other imaging technologies such as fluorescein angiography (FA), optical coherence tomography (OCT), or fundus autofluorescence (FAF) have been demonstrated to be sensitive in detecting early and asymptomatic disease stages of mac tel type 2.<sup>7</sup>

## **The Macular Telangiectasia (MacTel) Project**

The Macular Telangiectasia (MacTel) Project, which consists of an international consortium of investigators evaluating the natural history of this ocular condition with the goal of conducting clinical trials to assess potential therapies, also enrolled a mostly white population. The involvement of other ethnicities is not well studied.

Although Gass and Blodi did not find gender differences in their cohort of 140 patients (94 with mac tel type 2),<sup>8</sup> the proportions of women reported by the MacTel Project ( $n=310$ ) and by Yannuzzi were about 64% and 58%, respectively.<sup>9</sup> On average, the MacTel Project participants (mean age  $61 \pm 9$  years) had their disease diagnosed at age 57 ( $\pm 9$  years).

# **Clinical Presentation**

## **Fundus Appearance**

The disease is usually bilateral, but one eye may be more advanced than the other. All lesions tend to begin temporal to the foveal center but may subsequently involve the entire parafoveal area. The earliest fundoscopic manifestation of mac tel type 2 is a subtle loss of retinal transparency in the perifoveal region (Fig. 58.1).<sup>3</sup> This becomes more pronounced over time, and dilation of the parafoveal capillaries in the temporal parafoveal area ensues, and may extend to surround the fovea. These mildly ectatic capillaries were described to affect mainly the deeper capillary network (Fig. 58.2).<sup>2</sup> However, others have identified involvement of both the inner and outer retinal circulation.<sup>3,9</sup> In contrast to mac tel type 1, retinal hard exudate is not seen unless there is evidence of neovascularization. Crystalline deposits at the vitreoretinal interface may be seen throughout the course of the disease (Fig. 58.3).<sup>2,10</sup>

**FIG. 58.1** Loss of retinal transparency, resulting in grayish discoloration of the retina can be seen centered around the fovea.

**FIG. 58.2** (A) Early fluorescein angiographic findings of macular telangiectasia type 2 and (B) late leakage.

**FIG. 58.3** Crystalline dots can be seen at the vitreoretinal interface.

Blunted, dilated venules, either as single or multiple vessels, are often associated with ectatic capillaries. As vessels course towards the fovea, they usually decrease in diameter but, in mac tel type 2, they dilate and may make a right-angle turn, diving into the deeper retinal layers (Fig. 58.4). Eventually, intraretinal pigment migration and RPE hyperplasia along these diving dilated venules may occur<sup>3</sup> (Fig. 58.5). In addition to RPE cell migration, atrophic changes in

the neurosensory retina are another frequent finding.

**FIG. 58.4** Right-angle retinal vessels, manifested as blunted arterioles or venules that connect the superficial and deeper retinal plexus, are typical fundoscopic features of macular telangiectasia type 2. The right-angle vessels may be difficult to appreciate without stereoscopy. A pigment plaque is also seen in this patient's eye.

**FIG. 58.5** Retinal pigment epithelial hyperplasia surrounds the right-angle venule.

A yellow spot, or vitelliform lesion, in the center of the fovea with slight loss of the foveal depression may become apparent in some eyes.<sup>3</sup> Other foveal changes include lamellar or full-thickness macular holes that have been detected on clinical exams and some confirmed by OCT imaging.<sup>3,11-15</sup> The degeneration and atrophy associated with this disease contribute to the formation of such holes. Surgical repair may not necessarily result in either structural or functional improvement.<sup>9</sup>

The development of neovascularization is often, but not always, preceded by the right-angle venule and the intraretinal pigment hyperplasia that is often temporal to the fovea.<sup>2,3</sup> The neovascularization is most commonly seen temporal to the fovea.<sup>16</sup> Retinal hard exudates, intraretinal edema, and subretinal or intraretinal hemorrhage may occur (Fig. 58.6). These neovascular complexes are retinal in origin, as seen by the feeder vessel from the retinal arteries and the drainage into venules (Fig. 58.7). This may be indistinguishable from choroidal neovascularization with chorioretinal anastomosis. A disciform scar may be the advanced stage of this process (Fig. 58.8).

**FIG. 58.6** Subretinal neovascularization is a rare complication of macular telangiectasia type 2. Intra- and subretinal hemorrhage, as shown here, are features of neovascular macular telangiectasia type 2.

**FIG. 58.7** Neovascular macular telangiectasia type 2 shows a subretinal neovascular membrane, which is fed by a retinal arteriole and in turn drained by a retinal venule.

**FIG. 58.8** A fibrovascular scar with chorioretinal anastomosis can be the endpoint of the pathogenic process of macular telangiectasia type 2, and is indistinguishable from disciform scarring in wet age-related macular degeneration. However, there is a lack of drusen, and usually the retinal pigment hyperplasia is prominent.

## Retinal Imaging

### Fundus Autofluorescence

One of the earliest signs of mac tel type 2 is the loss of the hypofluorescent center seen normally on blue-light FAF due to the depletion of macular pigment in this condition (Fig. 58.9). Even in the absence of any fluorescein leakage or any other signs, especially in patients with asymmetric mac tel type 2,<sup>7</sup> this is diagnostic of the ocular condition. The area of retinal pigment hyperplasia will appear hypofluorescent on the FAF (Fig. 58.9).

**FIG. 58.9** A loss of foveal luteopigment is an early finding in macular telangiectasia type 2. (A) Blocking of autofluorescence in the central macula by healthy luteopigment. (B) Unmasking of hyperautofluorescence as well as spotty blocking from intraretinal pigment.

## Fluorescein Angiography

The hallmark finding in mac tel type 2 has been the characteristic telangiectatic capillaries on FA, again starting predominantly temporal to the fovea (Fig. 58.10). Eventually, the entire parafoveal area is involved (Fig. 5.2). Stereoscopic angiography has demonstrated that the deeper vasculature is involved but more superficial capillaries may also contribute to the fluorescein leakage.<sup>2</sup> Traditionally, the use of FA was essential in the diagnosis of mac tel type 2. However, OCT changes, as described below, may precede the development of any FA findings. Imaging with spectral domain OCT angiography has also provided insight into the three-dimensional aspects of the vascular abnormalities in mac tel type 2.<sup>17,18</sup>

**FIG. 58.10** Late staining in the temporal perifoveal area is an early angiographic feature of macular telangiectasia type 2.

## Optical Coherence Tomography

OCT provides valuable information as to the diagnosis and natural course of mac tel type 2. The most subtle and earliest change may be the temporal enlargement of the foveal pit, resulting in an asymmetric pit with the temporal area being thinner than the nasal.<sup>7</sup> There are corresponding changes to the outer nuclear and/or photoreceptor layer. With time, the disruption of the photoreceptor inner/outer-segment (IS/OS) junction (now termed the ellipsoid zone) is seen,<sup>19</sup> again temporal to the fovea. With progression, there will be hyporeflective cavities in the inner retina, and these may clinically be described as “pseudolamellar macular holes.” There are no pockets of leakage from the FA that correspond to these hyporeflective cavities. The disease progresses with increasing hyporeflective cavities in the outer neurosensory retina leading eventually to atrophy (Fig. 58.11). The foci of retinal pigment hyperplasia manifest as hyperreflective intraretinal lesions that appear to migrate into the inner retinal layers, with associated posterior shadowing. The “en face” view rendered from the OCT illustrates the ellipsoid or IS/OS junction loss that may be useful for an outcome measurement in clinical studies of mac tel type 2.

**FIG. 58.11** (A) Midphase fluorescein angiogram showing temporal macular staining secondary to macular telangiectasia type 2. (B) Volume-rendered optical coherence tomography angiography of the same location. The abnormally deep vessels are largely masked from view by the overlying retinal vessels. Note how the retinal vessels seem to be drawn toward a locus in the temporal macula, at the site where the right-angle vein enters the deeper retina (*arrow*). (C) Close-up of (B) showing the vascular anatomy where the retina vein dives down. Note the clarity of the visualization of the vessels provided by the volume-rendering process. (D) When the retina is viewed from behind, the vascular invasion, shown in yellow, is readily seen. (Courtesy of Rick Spaide, MD.)

## Adaptive Optics Imaging

Adaptive optics imaging, a technique that corrects for the optical aberrations of the eye and usually utilizes a scanning laser ophthalmoscope, allows evaluation of the cone photoreceptor mosaic.<sup>20</sup> Cone density evaluations in individuals with mac tel have

identified areas of paracentral cone loss despite the absence of capillary abnormalities seen on FA.<sup>21</sup>

Other investigators have compared the results of the photoreceptor assessment from “en face” views from the spectral domain OCT with those obtained on adaptive optics scanning laser ophthalmoscopy (AO-SLO) using a split detector.<sup>22</sup> Interesting discrepancies have been observed in which the AO-SLO demonstrated a substantial number of photoreceptors in areas of low or missing ellipsoid zone reflectivity on “en face” OCT. However, this was not demonstrated in another study that was conducted using a flood-illumination adaptive optics camera.<sup>23</sup> Additional studies with the AO-SLO using microperimetry showed a remarkable visual sensitivity and recovery of visibility of the cones with adaptive optics in areas previously considered to have loss of cones in two eyes with mac tel lesions.<sup>24</sup> The investigators suggest that such lesions with a preserved external limiting membrane may contain cones that are functional but have abnormal scattering and/or wave guiding characteristics, making them difficult to image by conventional AO-SLO. These studies highlight the need for multimodal imaging in the future to fully evaluate the natural course of this condition in regards to the health of the cones in the so-called “mac tel area.”

## Visual Function

Impaired reading vision is the most common presentation (79%), followed by the presence of metamorphopsia (12%) in the early stages of the disease.<sup>11,25</sup> Visual impairment may be mild; however, loss of vision in one eye is frequently reported.<sup>2</sup> Vision may decrease gradually with the progression of the disease. Visual acuity less than 20/200 (legal blindness) is rare but may be seen in the advanced stages with marked atrophy of the central photoreceptors or secondary to a large area affected by neovascularization.<sup>2,3,16,26</sup> In the MacTel Project, the mean visual acuity at baseline was 20/40 in 522 eyes that had not previously received therapy.<sup>8</sup> Visual acuity was 20/20 or better in 16% and 20/32 or better in approximately 50%. The most common risk factors associated with lower visual acuity in this cohort were characteristics found in more advanced disease, namely retinal

pigment hyperplasia and the right-angle venules. Similar visual acuity results were reported by Gass and Blodi.<sup>2</sup> In a retrospective study, 25% of eyes (6/24) remained stable during a follow-up period of 10–17 years.<sup>26</sup>

Despite the mild visual impairment, the vision-related quality of life is impacted markedly. In the MacTel Project, the National Eye Institute Visual Functioning Questionnaire (NEI-VFQ-25) was administered to all participants.<sup>27</sup> They reported significantly lower vision-related function in all domains compared to a group of participants in a study of age-related macular degeneration and who had similar visual acuities. A subset of these participants, enrolled in the MacTel Project, was tested using the Impact of Vision Impairment questionnaire.<sup>28</sup> Similar results were seen in this second study.

## **Microperimetry**

Another method of evaluating function is the use of microperimetry, which may help to correlate the structural changes with the functional changes.<sup>29–33</sup> Retinal sensitivity defects appear to correlate with the outer retinal atrophy seen on OCT imaging.<sup>34</sup> In areas of retinal pigment hyperplasia, there is often a dense scotoma. The use of microperimetry to correlate with changes seen on OCT may result in a reasonable outcome measurement for measuring changes over time, which may be especially useful for clinical trials that will be designed to test various therapies.

## **Staging and Prognostic Factors**

From their extensive clinical experience and review of fundus photographs, Gass and Blodi concluded that various mac tel type 2 lesions appear in an orderly fashion over time.<sup>2</sup> Some lesions, such as retinal opacification, may be easily missed because of image quality. There was no availability of noninvasive tools such as OCT or FAF to assist in their classification of this condition.

Nevertheless, the authors had remarkable clinical acumen and developed a scale that has been part of this landmark study. However, the present usefulness of this scale is somewhat limited, as it does not incorporate OCT. With further research into the

natural history of mac tel type 2, another scale incorporating newer technologies may be of value. A major challenge for studying therapies for mac tel type 2 is the development of reproducible and clinically meaningful outcome measurements. When structural and functional correlations can be made, such outcome measurements may become more evident.

## Genetics

The occurrence of this condition in monozygotic twins,<sup>7,35-37</sup> siblings, and families<sup>2,7,38-41</sup> suggests a genetic association in mac tel type 2. A vertical transmission pattern would also suggest an autosomal dominant pattern, but there may be variable expressivity or penetrance with monozygotic twins showing different disease severities.<sup>7</sup> Environmental influences or gene-to-gene interaction might account for this variation. The ataxia telangiectasia mutated gene (*ATM*), responsible for the ataxia telangiectasia syndrome, has been implicated in the pathogenesis of mac tel type 2.<sup>42,43</sup> A number of candidate genes known to cause other retinal diseases, such as those causing familial exudative vitreoretinopathy and Norrie disease, or those with a role in retinal neovascularization or macular pigment metabolism, have recently been excluded to play a role in the pathogenesis of mac tel type 2.<sup>44</sup> Evaluation of a gene that might be involved with xanthophyll transport also demonstrated no statistically significant association.<sup>45</sup>

## Association of Systemic Diseases

Early reports have implicated an increased risk of diabetes in patients with mac tel type 2.<sup>38,46</sup> The MacTel Project, the largest population of mac tel type 2 patients to date, found a high prevalence of diabetes mellitus (28%) and also hypertension (52%).<sup>8</sup> Strikingly similar numbers were reported for diabetes and hypertension in another series.<sup>43</sup> Further follow-up of the MacTel Project has demonstrated the important associations with diabetes, obesity, and cardiovascular disease.<sup>47</sup> These risk factors may further our understanding of the pathogenesis of this condition.

## Differential Diagnosis

Retinal capillary telangiectasia may result from a multitude of retinal vascular inflammatory or occlusive conditions. However, mac tel type 2 is quite distinct from other conditions where retinal telangiectasia is a prominent feature. Branch retinal vein occlusions can give rise to segmental capillary changes, but this can be readily distinguished since it involves an area of distribution distal to an arteriolar-venular crossing, and does not cross the horizontal raphe, unless there is already collateral formation. Radiation retinopathy usually involves a larger retinal area, and is accompanied by cotton-wool spots and preretinal neovascularization, both features that are not characteristic of mac tel type 2. A history of radiation to the eye, orbit, or head can be readily elicited. Neovascular mac tel type 2 may masquerade as neovascular age-related macular degeneration, and vice versa. Since digital angiography (often monoscopic) has largely replaced stereo-film FA, precise localization of the retinal layer displaying the hyperfluorescence may be more difficult. However, in neovascular age-related macular degeneration, drusen and RPE changes are usually present and retinal capillary disease is uncommon. OCT imaging will help localize the lesion and demonstrate other typical features, either in the same, or in the contralateral eye. Late stages of neovascular mac tel type 2 may, however, be indistinguishable from a disciform scar with chorioretinal anastomosis in age-related macular degeneration. Another entity to consider in the differential diagnosis would be tamoxifen retinopathy.<sup>48</sup> A recent report demonstrated that tamoxifen retinopathy may have pseudocystic foveal cavitation that mimics cavities seen in eyes with mac tel type 2.

## Clinicopathologic Correlation

It is curious that vascular changes are not prominent features of early mac tel type 2, but blunting of the foveal reflex is typical. Based on the staining of the retina with fluorescein in eyes with minimal edema, Gass has postulated that it is possible that the primary abnormality may be found in the parafoveal retinal neural or Müller cells.<sup>49</sup> This is illustrated in a case where OCT and ERG

changes in the form of inner-lamellar holes and reduced cone responses manifested before the development of typical vascular changes.<sup>50</sup> Xanthophyll is probably primarily stored in Müller cells, and this could be a surrogate measure of the health and concentration of Müller cells in that region. Xanthophyll concentration is already diminished in early mac tel.<sup>51</sup>

Histopathologic examination of the eyes of a 58-year-old woman with mac tel type 2 did not demonstrate telangiectatic capillaries, but did show narrowing of the vessel diameter. Instead, pericyte degeneration and lipid accumulation within the capillary walls, as well as multilaminated basement membrane, were found<sup>52</sup> – all similar to those seen in diabetics and prediabetics. Another histopathologic study<sup>53</sup> demonstrated dilation and proliferation of retinal capillaries into the outer retinal, subretinal, and preretinal spaces. Perivascular pigment migration along the telangiectatic vessels was also seen. A sharp demarcation between the edematous and nonedematous retina was present and involved all layers of the retina, including the nerve fiber layer and the ganglion cell layer. The most detailed histopathologic study to date examined the eye of a 65-year-old patient with mac tel type 2 and found reduced expression of Müller cell-specific markers in the fovea, which correlated with macroscopically visible pigment depletion in this area.<sup>54</sup> These investigators confirmed these findings in another pair of autopsy eyes.<sup>55</sup> The Müller cell loss in MacTel type 2 matches the area of macular pigment depletion. In this example, the loss of the IS/OS junction seen on OCT corresponded to the region where rods were depleted but cones were still present.

## Therapeutic Options

There are no generally accepted therapies for lesions of mac tel type 2 not associated with neovascularization. There are anecdotal case reports, but no randomized controlled clinical trials conducted in this ocular condition. Laser photocoagulation<sup>56</sup> or photodynamic therapy<sup>57</sup> does not appear to improve or stabilize visual acuity in non-neovascular mac tel type 2. Antiangiogenic agents seem to be equally ineffective in most reported series despite angiographic and tomographic effects,<sup>58,59</sup> although individual patients may

experience a functional benefit<sup>60</sup> However, antiangiogenic therapy has been reported to result in potentially deleterious effects in eyes with the non-neovascular form of the disease.<sup>61</sup>

For neovascular complications of mac tel type 2, transpupillary therapy<sup>62,63</sup> and photodynamic therapy<sup>64</sup> have been reported to be somewhat efficacious, but have recently been replaced by antiangiogenic agents, which may be able to stabilize neovascular complications of mac tel type 2 and even improve vision.<sup>65,66</sup> Mac tel type 2 may be complicated by the development of a full-thickness macular hole. The success rate after surgical repair appears to be lower than for idiopathic macular holes, probably depending on the relative contribution of tangential traction versus the neurodegeneration that is part of mac tel type 2.<sup>14,67,68</sup>

To treat the purported neurodegenerative component, a safety trial of implants of ciliary neurotrophic factor was conducted.<sup>69</sup> Seven participants demonstrated no safety concerns 36 months following implantation. Other neuroprotective agents are under consideration for the future.

## Summary and Future Research Directions

Despite a marked increase in our knowledge of mac tel type 2, the pathogenesis remains unknown. It has been well established that it is a bilateral disease that affects patients in the sixth decade of life. Most individuals progress from an asymptomatic, but clinically identifiable state, through a well-characterized pathogenic sequence eventually to develop significant visual disability, despite pharmacologic, laser, and surgical attempts at treatment. Future research will hopefully unravel the molecular basis and identify more specific targets for a cure.

## History

Coats disease is an idiopathic condition characterized by telangiectatic and aneurysmal retinal vessels with intraretinal and subretinal exudation and fluid.<sup>1</sup> Coats disease was first described by Scottish ophthalmologist George Coats in 1908.<sup>2</sup> In his initial classification Coats separated this new entity into three distinct groups. Group I included eyes with massive subretinal exudation and no demonstrable vascular abnormalities. Group II consisted of eyes with massive subretinal exudation and multiple retinal vascular abnormalities with intraretinal hemorrhage. Group III included eyes with massive subretinal exudation and frank retinal arteriovenous malformations.<sup>2</sup> Eugen von Hippel later demonstrated that group III represented the distinctly separate entity of angiomatosis retinae (later retermed retinal capillary hemangioma or retinal hemangioblastoma), prompting Coats to drop this group from his classification. In 1912, and again in 1915, Theodor von Leber described a disease with similar telangiectatic and aneurysmal retinal vessels that lacked the massive subretinal exudation described by Coats.<sup>3,4</sup> This condition was later named Leber multiple miliary aneurysms. In a 1916 paper Leber concluded that what he had described was merely an earlier stage of the disease process identified by Coats.<sup>5,6</sup> This conclusion was later reinforced by Reese, who described an eye with Leber miliary aneurysms that progressed into a classic case of Coats disease during long-term follow-up.<sup>7</sup> Although some authors have disagreed, most authorities today classify Leber disease as an early or nonprogressive form of Coats disease.<sup>5,8,9</sup>

## Histopathology, Etiology, and Pathogenesis

Early descriptions of Coats disease focused primarily on the morphology of the disease and attempted to explain the disease process solely on the basis of fundoscopic and histopathologic changes.<sup>10,11</sup> The first observations published by Coats focused on histopathologic examination of six eyes enucleated for this

condition that he received from various colleagues.<sup>2</sup> From these histopathologic specimens, Coats described subretinal masses of fibrous tissue intimately adherent to the outer retina. Most of the eyes had associated retinal thickening, degeneration, and detachment, as well as diffuse vascular abnormalities. Four of the six eyes had associated retinal hemorrhages, and most had cholesterol crystals. One eye had evidence of bone formation. Coats believed the vascular changes represented secondary manifestations of the underlying disease and that the exudation was secondary to organization and partial resorption of retinal hemorrhages, as he often found hemorrhages in association with the exudation.<sup>2</sup> Coats also postulated that the primary process might be infectious in light of the mononuclear infiltrate found on histopathologic examination. This infectious theory of Coats disease was supported by a number of other reports, including those of Evens,<sup>12</sup> Straub,<sup>13</sup> and Müller,<sup>13</sup> who suspected toxoplasmosis as the underlying cause. Subsequent investigations and the failure of antiinflammatory adrenocorticotrophic hormone and steroid therapies have refuted early theories of a primary infectious or inflammatory etiology.<sup>13,14</sup>

Pathologic samples of eyes with Coats disease were once abundant owing to enucleations for suspected intraocular tumor.<sup>15</sup> Moreover, most histopathologic reports describe findings in eyes with advanced stages of the disease. Gross examination of enucleated eyes typically reveals bullous retinal detachment.<sup>16</sup> Subretinal fluid has a viscous, lipid-rich, yellow appearance with glistening crystals.<sup>16</sup> Microscopically, the subretinal exudation contains collections of foamy histiocytes and cholesterol clefts.<sup>16</sup> The outer retina is thickened by exudation, with variable penetration of inner retinal layers.<sup>16</sup> Areas of the inner retina also contain numerous, large, dilated, and telangiectatic vessels.<sup>16</sup> Other vascular abnormalities include degenerated and hypocellular walls, narrowed lumen with or without thrombi, capillary dropout, neovascularization, as well as perivascular sheathing and/or pigmentation.<sup>1,9,17-23</sup> Thickened vessel walls show characteristic heavy periodic acid–Schiff-positive deposits.<sup>1</sup> Flat preparations prepared by trypsin digestion reveal vascular aneurysms measuring 50–350 µm, often forming large sausage-like

outpouchings and located on shunt vessels.<sup>1</sup> Advanced cases may have intraocular bone formation, with evidence of calcification on echography and computed tomography (CT) scanning that potentially confuses the diagnosis with retinoblastoma.<sup>24,25</sup> Electron microscopy confirms diffuse structural abnormalities of the retinal vasculature. Tripathi and Ashton described prominent structural alterations of retinal vessels in areas of retinal thickening, with thickened walls mostly replaced by a laminated fibrous coating of basement membrane-like material.<sup>18</sup> Most affected vessels were completely devoid of endothelium and pericytes, with red blood cells, plasma, and fibrin filling the lumina. There was patchy thinning or even absence of the vessel wall in some areas, with the vessel lumen extending to the basement membrane of adjacent glial cells.<sup>18</sup> More recently, Kase and associates noted the presence of VEGF immunoreactivity in both subretinal macrophages as well as in the detached retina and blood vessels, with significantly higher VEGF levels in eyes with vascular abnormalities compared to those without. Further, they noted immunoreactivity for VEGF receptor-2 in the endothelia of abnormal vessels.<sup>26</sup> Levels of VEGF in aqueous humor are also significantly elevated in eyes with Coats disease and appear to increase with higher disease severity.<sup>27</sup> These findings support the widely held view that Coats disease is a disorder of vascular integrity as well as point to a potential therapeutic option in anti-VEGF medications.

Indeed, work in molecular genetics suggests that Coats disease may be part of a spectrum of related genetic disorders known as “retinal hypovascularopathies,”<sup>28,29</sup> which includes Norrie disease, familial exudative vitreoretinopathy (FEVR), fascioscapulohumeral muscular dystrophy (FSHD), and the osteoporosis pseudoglioma syndrome.<sup>29-37</sup> These diseases share a similar ocular phenotype, characterized by a failure to vascularize fully the retinal periphery and associated telangiectatic, incompetent remnant vasculature. Each of these conditions can be related to abnormalities in the Wnt signaling pathway during retinal angiogenesis.<sup>28,29,38</sup>

Several reports have implicated a deficiency of Norrin, a retinal protein, in the pathogenesis of Coats disease.<sup>39,40</sup> In one case report, a female with unilateral Coats disease gave birth to a son affected by Norrie disease.<sup>39</sup> Both carried a missense mutation within the

Norrie disease pseudoglioma gene, *NDP*, on chromosome Xp11.2. Further analysis on archival tissue from nine enucleated eyes from males with unilateral Coats disease revealed a mutation in *NDP* in one subject. Knockout mouse models of Norrie disease model demonstrate abnormalities of the retinal vessels, including telangiectasia, bulb-like dilations, and underdevelopment of the capillary bed.<sup>41,42</sup> Elevated levels of hypoxia-inducible factor-1 $\alpha$  and vascular endothelial growth factor (VEGF), as well as characteristic electroretinogram patterns in these mice, confirmed inner retinal hypoxia.<sup>42</sup> Moreover, ectopic lens expression of Norrin in knockout mice induces the formation of normal deep retinal capillaries and completely prevents abnormalities in retinal angiogenesis.<sup>43</sup> These observations suggest a genetic basis for Coats disease and that a *NDP* mutation may be responsible.

Although FEVR and Coats disease share certain clinical features, they likely do not share a common genetic basis. Robataille and associates studied DNA expression of the frizzled-4 gene, *FZD4*, in 68 cases of FEVR and 16 cases of Coats disease.<sup>44</sup> They found 11 *FZD4* mutations in FEVR cases and no mutations in Coats disease cases. They concluded that germline mutations in *FZD4* do not appear to be a common cause of Coats disease, implying that Coats disease does not likely represent asymmetric FEVR and is a distinct ocular condition.

Other genetic pathways have been explored. Cremers and associates found that 55% of eyes with retinitis pigmentosa and Coats-like secondary exudative vasculopathy contained a mutation in the *CRB1* gene.<sup>45</sup> This suggests that *CRB1* could be involved in primary Coats disease as well as other retinal diseases and dystrophies. Recently, “Coats plus” disease was discovered to be the result of mutations in the *CTC1* gene, which encodes telomere maintenance component 1, believed to be necessary for telomere integrity.<sup>46</sup>

## Clinical Presentation

Coats disease is classically a painless ophthalmic condition. The disease affects males three times as often as females and has no reported racial or ethnic predilection.<sup>47</sup> Coats disease is unilateral in

80–95% of cases.<sup>5,47,48</sup> Some of the bilateral cases in older reports could represent secondary bilateral Coats-like retinopathy with systemic conditions and not true primary Coats disease. Any patient with bilateral presumed Coats disease should be evaluated for conditions that cause Coats-like exudative retinopathy, such as retinitis pigmentosa, pars planitis, FSHD, FEVR, or other diseases.<sup>49</sup> Based on a study of 150 consecutive cases, the mean age at diagnosis is 5 years with a range of 1 month to 63 years.<sup>47</sup> Some speculate that the disease could be present at birth.<sup>13,50</sup>

In an analysis of 150 consecutive cases of Coats disease, presenting symptoms included decreased visual acuity (43%), strabismus (23%: Fig. 59.1), leukocoria/xanthocoria (20%: Fig. 59.1), pain (3%), heterochromia (1%), nystagmus (1%), and no symptom (8%).<sup>47</sup> Visual acuity was 20/20 to 20/50 in 12% of all eyes, 20/60 to 20/100 in 11%, 20/200 to counting fingers in 18%, and hand motions to no light perception in 58%. Nearly 90% of eyes had a normal anterior-segment examination. Those with findings included cataract (8%), iris neovascularization (8%), shallow anterior chamber (4%), corneal edema (3%), cholesterol in the anterior chamber (3%: Fig. 59.1),<sup>51,52</sup> and megalocornea (2%). Retinal findings included telangiectasia (100%), intraretinal exudation (99%), exudative retinal detachment (81% with 42% demonstrating partial retinal detachment and 58% with total retinal detachment), retinal hemorrhage (13%), retinal macrocyst (11%), vasoproliferative tumor (6%), and optic disc neovascularization (1%). No eyes in this cohort presented with vitreous hemorrhage. Other studies have described macular fibrosis in up to 23% of patients, developing in an area of previous dense exudation and involving the fovea in all cases.<sup>53</sup>

**FIG. 59.1** Unique clinical features occasionally seen in Coats disease. (A) Young boy who presented with leukocoria and esotropia of the left eye. He had stage 5 disease, including total retinal detachment, cataract, and prephthisis. The decision was made to observe. (B) Young girl with xanthocoria of the right eye. (C) Young girl who presented with a total retinal detachment abutting the posterior surface of the lens. (D) Young girl with anterior-chamber cholesterolosis of the right eye.

Adult cases of Coats disease are similar in clinical presentation and disease course, but generally have a smaller area of involvement, slower disease progression, more frequent hemorrhage near larger aneurysmal dilated vessels, and typically do not present with strabismus.<sup>54</sup> Although the adult form of the disease has been described as frequently associated with hypercholesterolemia, such an association does not appear to occur in the juvenile form.<sup>14,55</sup>

The typical ophthalmoscopic picture in Coats disease is that of localized, yellow, subretinal exudation associated with adjacent vascular anomalies, including sheathing, telangiectasia, tortuosity, aneurysmal dilation, zones of capillary dropout, and occasionally neovascularization.<sup>13,47</sup> There is variability in this clinical picture.<sup>47</sup>

Exudation, hemorrhage, or a combination appears minimal during less active stages of the disease and can progress to massive findings, obscuring the retinal vasculature in more aggressive stages. The vascular abnormalities can be subtle and clinically undetectable or can be obvious as a dominant feature. The clinical course is also variable, but is generally slowly progressive. Spontaneous remission has been observed but is exceptional.<sup>56</sup> Subretinal choroidal neovascularization rarely occurs in areas of lipid deposition. As subretinal fluid and exudation increase, the retinal detachment progresses and can reach a highly elevated state, visible behind the lens (Fig. 59.1). Hemorrhagic and nonhemorrhagic retinal macrocysts can occur as a result of chronic coalescent intraretinal cystoid edema.<sup>57</sup> Secondary complications such as iridocyclitis, cataract, and secondary neovascular glaucoma can lead to phthisis bulbi in severe cases.<sup>2,15,58</sup>

Several staging systems for Coats disease have been proposed.<sup>2,59</sup> The most recent and widely used was introduced by Shields and associates in 2000 (Table 59.1).<sup>60</sup> Stage 1 is characterized by retinal telangiectasia. Stage 2 has telangiectasia and intraretinal exudation, extrafoveal exudation defines stage 2A (Fig. 59.2), whereas foveal involvement defines stage 2B. Stage 3 is defined by exudative retinal detachment; 3A is a subtotal detachment, with 1 and 2 designating extrafoveal and foveal involvement, respectively (Fig. 59.3); and 3B is a total retinal detachment (Fig. 59.4). Stage 4 has total retinal detachment plus elevated intraocular pressure (Fig. 59.3), and stage 5 is endstage disease, occasionally with phthisis bulbi (Fig. 59.1). Using this classification for grouping of 124 cases, Shields and associates found stage 1 in 1%, stage 2 in 14% (2A in 8%, 2B in 6%), stage 3 in 69% (3A1 in 19%, 3A2 in 19%, 3B in 30%), stage 4 in 15%, and stage 5 in 2%.<sup>60</sup> Based on classification and treatment, visual acuity strongly depended on stage at diagnosis.<sup>47,61</sup> At the time of Coats disease control, poor visual acuity (20/200 or worse) was found in 0% of stage 1, 53% of stage 2, 74% of stage 3, and 100% of stage 4 and stage 5.<sup>60</sup>

---

**TABLE 59.1****Staging System for Coats Disease With Prevalence on Presentation**

---

Stage	Simplified Format	Criteria	Prevalence <sup>60</sup>
1	T	Retinal telangiectasia (T) only	1%
2	T+E	Telangiectasia and exudation (E)	14%
2A		Extrafoveal	8%
2B		Foveal	6%
3	T+E+D	Exudative retinal detachment (D)	69%
3A		Subtotal	38%
3A1		Extrafoveal	19%
3A2		Foveal	19%
3B		Total	30%
4	T+E+D+G	Total retinal detachment and glaucoma (G)	15%
5	T+E+D+G+P	Advanced endstage disease often with phthisis (P) bulbi	2%

**FIG. 59.2** Clinical imaging of a 10-year-old Latina girl with stage 2A Coats disease in the left eye. (A)

Montage color photograph. Note the exudation and vascular telangiectasia in the far temporal periphery. (B) Midphase wide-field fluorescein angiogram of the same patient. Note the far peripheral avascularity and adjacent telangiectatic vasculature. (C) Late-phase wide-field fluorescein angiogram of the same patient. Note the mild dye leakage from telangiectasia.

**FIG. 59.3** Clinical images of various stages of Coats disease, including 3A1, 3A2, and 4. (A) Color fundus photograph of a patient with stage 3A1 Coats disease. Note the temporal extrafoveal exudation. (B) Recirculation-phase fluorescein angiogram of the same patient as in (A). Note the temporal vascular abnormalities, areas of capillary nonperfusion, and perivascular dye leakage. (C) Color fundus photograph of a patient with stage 3A2 Coats disease with prominent foveal exudation. Also note the subtle temporal vascular telangiectasia and aneurysmal

vessels. (D) The extent of vascular abnormalities is more apparent in this midphase fluorescein angiogram. Note the telangiectasia adjacent to a wide zone of peripheral avascularity. (E) Color fundus photograph of a patient with stage 4 disease who presented with a total exudative retinal detachment and elevated intraocular pressure. (F) Fluorescein angiography revealed prominent capillary nonperfusion between dilated, abnormal vasculature.

**FIG. 59.4** Clinical imaging of a 17-year-old African American man with stage 3B Coats disease in the right eye. (A) Montage color fundus photograph depicting extensive subretinal exudation, a total retinal detachment, diffuse midperipheral vascular abnormalities, and optic nerve head neovascularization. (B) Early-phase fluorescein angiogram, centered more temporally than the color photo, demonstrating filling of telangiectatic and aneurysmal vascular channels, most prominent in the temporal periphery. Adjacent to telangiectatic vessels are large areas of retinal capillary nonperfusion. (C) In the later phase of the angiogram, leakage of dye from telangiectatic vessels and disc neovascularization are seen. (Courtesy of Carl Regillo, MD, Wills Eye Institute.)

## Diagnostic Testing

Ancillary testing may be useful when the diagnosis of Coats disease is suspected, but other clinical entities must be ruled out, most notably retinoblastoma.<sup>62</sup> Particularly when retinal detachment with subretinal exudation and dilated retinal vessels coexist, even an experienced clinician may have difficulty differentiating these entities ophthalmoscopically. Fluorescein angiography is critical to document classic findings to establish the diagnosis. Echography may enable differentiation between Coats disease and retinoblastoma on the basis of features such as the character of the retinal detachment and the presence or absence of subretinal calcifications. Echography is less useful when the retinoblastoma is poorly calcified and also has shortcomings in detecting optic nerve or extraocular extension of retinoblastoma when heavy calcification exists.<sup>63</sup>

## Fluorescein Angiography

The typical fluorescein angiographic picture of Coats disease is one of numerous localized anomalies of the retinal vasculature with peripheral retinal nonperfusion (Figs. 59.2–59.6). Telangiectasia, aneurysms, beading of vessel walls, and various vascular communicating channels are found with larger vessels. These vessels show early and persistent leakage, which verifies their role as the source of exudation and hemorrhage. This leakage represents breakdown of the blood–retinal barrier, which can further be detected by vitreous fluorophotometry.<sup>64</sup> Microvascular involvement is demonstrated with areas of diffuse loss of the capillary bed or areas of complete capillary nonperfusion on angiography. Geographic zones of microvascular involvement are typically surrounded by areas of arteriolar and venular anomalies. Although some early authors described cases of massive exudation or hemorrhage without areas of obvious vascular involvement, fluorescein angiography and histopathologic specimens invariably show unsuspected anomalous vessels. The ability to identify all anomalous vessels, especially those with the greatest degree of leakage, has made adequate treatment of Coats disease a

possibility.<sup>5,60,65,66</sup>

**FIG. 59.5** Color fundus photography and fluorescein angiography of a patient with stage 4 Coats disease. Macular (A) and inferior (B) color photographs depicting extensive subretinal exudate. Note the elevated retinal detachment in (B). (C) Early-phase fluorescein angiogram of the superonasal retinal periphery. Note the blunted, telangiectatic, and aneurysmal vasculature just posterior to a zone of avascular retina. (D) Midphase fluorescein angiogram of the inferior retina corresponding to (B), depicting similar angiographic findings as well as prominent sausage-like vascular dilations.

**FIG. 59.6** Color fundus photography and fluorescein angiogram of a patient with a total bullous retinal detachment associated with Coats disease. (A) Color fundus photograph depicting the very bullous retinal detachment. (B–D) Fluorescein angiogram images of the same patient depicting typical angiographic features of Coats disease.

Newer techniques have enabled imaging of the retinal periphery using RetCam and Optos cameras. Wide-field angiography enables images of the peripheral vasculature that can aid in the diagnosis of subtle cases as well as facilitate targeted laser treatment and monitoring of disease progression (Figs. 59.2 and 59.5). RetCam photography is particularly important in peripheral imaging in pediatric patients.<sup>67</sup>

## Computed Tomography

Computed tomography (CT) is valuable because of its ability to characterize intraocular morphology, quantify subretinal densities, identify vascularities within the subretinal space through the use of contrast enhancement, and detect other abnormalities that may be

associated in the orbital or intracranial space. Spiral CT has the advantage of reducing anesthesia risk in small children and also decreases acquisition time, and staff and equipment monitoring requirements.<sup>68</sup>

## Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) as an auxiliary test is useful because it permits multiplanar imaging and superior contrast resolution and yields biochemical insight into the structure and composition of tissues.<sup>69,70</sup> It is less useful in detecting calcium than either ultrasound or CT scanning.<sup>63,71</sup> An MRI study of 28 patients with leukocoria or intraocular mass, or both, found that retinoblastomas could be reliably distinguished from Coats disease, toxocariasis, and persistent hyperplastic primary vitreous.<sup>71</sup> Calcification could not be reliably detected on MRI scanning.

## Doppler Ultrasonography

High-resolution Doppler ultrasound has been suggested as a diagnostic adjunct, providing unique information with real-time imaging and duplex pulse Doppler evaluation.<sup>72</sup> This technique may delineate structural abnormalities not shown by CT or MRI.

## Optical Coherence Tomography

Optical coherence tomography (OCT) allows for quantitative documentation of retinal thickening and is particularly useful in monitoring macular involvement over the course of treatment. Typical findings include (1) prominent intraretinal hyperreflective material that corresponds to hard exudate seen on examination and on color fundus photography; (2) intraretinal cystoid edema; and (3) less commonly, subretinal fluid. Hard exudates and cystoid edema are most prominent in the outer retina (Fig. 57.7A). Hard exudates commonly cause a shadowing defect of deeper structures and may form a “string of pearls” configuration with a row of hyperreflective dots along the inner wall of cystoid spaces in the outer plexiform layer.<sup>73</sup>

OCT angiography (OCTA) is an emerging technology with

potential applicability for a variety of retinal vascular diseases, including Coats disease. By comparing backscattered OCT signal intensity across a series of B-scans at the same location, OCTA enables visualization of erythrocyte movement, and as such, blood flow. Volumetric angiographic information is provided that can be evaluated as individual vascular networks from the internal limiting membrane to the choroid. As a noninvasive imaging modality, this is particularly attractive in a disease that affects a large number of pediatric patients. To date, however, there is little published information on the utility of OCTA in Coats disease. Fig. 59.7 shows an OCTA macular scan of a young male patient with Coats disease and associated macular edema affecting the right eye. There is artifact due to poor fixation, which is a common problem with the current technology, but there is evidence of mild reduction in the perifoveal capillary density. As the technology improves and more data are obtained, OCTA may prove useful in the evaluation of patients with Coats disease.

**FIG. 59.7** Optical coherence tomography (OCT) angiography in Coats disease. (A) Montage color

fundus photography of the involved right eye showing subtle evidence of vascular abnormalities in the temporal and inferotemporal periphery as well as mild hard exudates in the central macula. (B) Horizontal OCT B-scan of the central macula demonstrating vitreomacular traction, an epiretinal membrane, and cystoid macular edema. (C,D) Color fundus photograph and macular OCT of the left eye showing normal anatomy. (E) OCT angiogram of the right eye showing fixation artifact and mild reduction of the perifoveal capillary density. (F) Normal OCT angiogram of the left eye showing a healthy superficial capillary plexus.

## Blood Testing

Aqueous lactic dehydrogenase and isoenzyme levels have not proved valuable in distinguishing between Coats disease and retinoblastoma. Examination of subretinal fluid, although rarely used, is accurate in confirming the diagnosis of Coats disease on the basis of cholesterol crystal and pigment-laden macrophages in the absence of tumor cells.<sup>63</sup>

## Differential Diagnosis

The differential diagnosis of Coats disease includes other conditions that produce leukocoria or strabismus,<sup>19</sup> including retinoblastoma,<sup>15,74</sup> retinal detachment, persistent hyperplastic primary vitreous, congenital cataract, Norrie disease, and FEVR,<sup>75</sup> among other diagnoses. Shields and associates reviewed 150 cases of Coats disease and found that the diagnosis was correct in 64 cases (41%).<sup>47</sup> The mistaken referring diagnoses included retinoblastoma in 43 cases (27%), retinal detachment in 12 (8%), retinal hemorrhage in 7 (4%), toxocariasis in 4 (3%), choroidal melanoma in 2 (1%), choroidal hemangioma in 2 (1%), coloboma in 2 (1%), endophthalmitis in 2 (1%), and single cases of cytomegalovirus retinitis, retinopathy of prematurity, traumatic retinopathy, and toxoplasmosis. In 18 cases (11%) there was no submitted diagnosis.

Numerous entities have been described as presenting with a Coats-like picture, including several systemic conditions, and Coats disease can also simulate other exudative retinal conditions such as FEVR, peripheral vasculitis, Eales disease, and FSHD (Table 59.2). FEVR is an important consideration and can present with peripheral avascularity with telangiectasia and exudation. FEVR can be differentiated based on the typical presence of retinal dragging, a positive family history, and bilaterality, all of which are rare in Coats disease. A Coats-like picture of bilateral retinal telangiectasia and exudation has been described in patients with deafness and FSHD.<sup>76,105,106</sup> It is believed that the retinal vascular abnormalities, muscular dystrophy, and deafness in FSHD may all be a consequence of a common mechanism based on abnormal Wnt signaling.<sup>37</sup>

**TABLE 59.2**

**Clinical Conditions That Can Present With Coats-Like Retinal Findings**

SYSTEMIC CONDITIONS	Muscular dystrophy <sup>76-79</sup> Turner syndrome <sup>80</sup> Epidermal nevus syndrome <sup>81</sup> Cornelia de Lange syndrome <sup>82</sup> Alport syndrome <sup>83</sup> Senior-Loken syndrome (familial renal-retinal dystrophy) <sup>84</sup> 13q deletion syndrome <sup>85</sup> Renal transplantation <sup>86</sup> Ch 3 inversion <sup>87</sup> Hallermann-Streiff syndrome <sup>88</sup> Aplastic anemia <sup>89</sup> Multiple glomus tumors <sup>90</sup> Telangiectasia of the nasal mucosa <sup>91</sup> Osteoporosis pseudoglioma syndrome <sup>92</sup> Focal segmental glomerulosclerosis <sup>93</sup>

--	---

A Coats-like picture associated with varied skeletal defects, cerebellar and extrapyramidal movement disorder, epileptic seizures, leukodystrophic changes, and postnatal growth failure has been referred to as “Coats plus syndrome.”<sup>107</sup> In order to avoid confusion, the term “Coats disease” should be reserved for cases of idiopathic retinal telangiectasia associated with intraretinal exudation with or without exudative retinal detachment, without evidence of vitreoretinal traction.<sup>7,47</sup>

Isolated case reports have described a number of other disorders occurring concurrently with Coats disease, including retinitis pigmentosa,<sup>99,108</sup> Senior–Loken syndrome,<sup>84</sup> the ichthyosis hystrix variant of epidermal nevus syndrome,<sup>81</sup> Turner syndrome,<sup>109</sup> diffuse central nervous system venous abnormality,<sup>110</sup> and Hallermann–Streiff syndrome<sup>88</sup> (see [Table 59.2](#)). Small, in 1968, reported the combination of mental retardation, muscular dystrophy, and an exudative vasculopathy in four siblings.<sup>76</sup> Egerer and associates noted histologic evidence of rosettes characteristic of retinal dysplasia in a series of nine enucleated eyes carrying the diagnosis of Coats disease.<sup>98</sup> Fogle and colleagues noted an exudative vasculopathy with a clinical picture similar to that of Coats disease arising from abnormal choroidal vessels in both eyes of a patient with retinitis pigmentosa.<sup>100</sup> Despite these reports, no definite connection has been made between other systemic or ocular conditions and Coats disease.

## Treatment

Treatment for Coats disease depends on the stage of disease. Mild cases with only retinal telangiectasia (stage 1) should be documented with color fundus photography and wide-field fluorescein angiography and followed conservatively. If subretinal fluid or exudation develop, then intervention is necessary. For more advanced stages (2 through 4), treatment involves ablation with photocoagulation or cryotherapy to areas of telangiectatic vasculature and retinal nonperfusion. Surgical intervention to repair traction, hemorrhage, or rhegmatogenous retinal detachment is rarely necessary.

## Ablative Therapies – Laser Photocoagulation and Cryotherapy

In less severe cases of exudation due to Coats disease, with or without retinal detachment, argon or diode laser photocoagulation is the treatment of choice (Fig. 59.8).<sup>111-113</sup> Fluorescein angiographic guidance assists directed treatment of vascular leakage.<sup>67,114</sup> Most wavelengths of laser light are adequate for treatment, although those near the yellow portion of the spectrum have better absorption by blood in the target vascular channels and may be particularly useful if the vessels are in detached retina. Leaking lesions are treated directly with moderate to large (100–500  $\mu\text{m}$ , depending on size and location of the target lesions) applications of moderate-intensity light. Scatter photocoagulation to areas of extensive nonperfusion is of unproven value but could decrease the risk of later neovascularization. If lesions are too peripheral to be reached with the slit-lamp delivery system, the indirect ophthalmoscope-mounted laser, transscleral laser, or cryotherapy can be used.<sup>115</sup> These methods may be particularly useful in small children, who usually require general anesthesia for treatment. Of note, extensive laser photocoagulation can result in transient disruption of the blood–retinal barrier, paradoxically increasing retinal exudation. Several sessions of therapy, approximately every 3 months, are often necessary to produce complete resolution of exudation or detachment.<sup>60,111,116</sup> Complications of photocoagulation in Coats disease include inflammation, choroidal detachment, progressive exudation, creation of chorioretinal and vitreochoroidal

anastomoses, epiretinal membrane formation, sympathetic ophthalmia, rhegmatogenous retinal detachment, and hemorrhage.

**FIG. 59.8** Color fundus photographs from two patients demonstrating the effect of laser photocoagulation. Laser photocoagulation was used to treat focal areas of leakage in the peripheral retina with a modified scatter pattern to zones of capillary nonperfusion. Burns were 100–500  $\mu\text{m}$  and of moderate intensity applied through a fundus contact lens. (A) Montage color fundus photograph of a separate patient with stage 4 Coats disease. Note the extensive exudation. (B–E) Sequential color fundus photographs following treatment with laser photocoagulation; the exudation and retinal detachment were noted to be slowly improving. (F) Color fundus photograph of the left macula in a patient with stage 3A1 Coats disease. (G) Fluorescein angiogram of the same patient delineating areas of retinal nonperfusion and vascular abnormalities that are used to guide laser photocoagulation. (H) Montage color photograph of the same patient following treatment with laser photocoagulation. Note the laser scars in the far temporal periphery as well as the total resolution of retinal exudation. The visual acuity following treatment improved to 20/20.

Double freeze–thaw cryotherapy is also useful in ablating affected areas of the retina and is particularly helpful in cases where laser is ineffective, such as extensive subretinal exudation or retinal detachment. In some cases it may be necessary to drain subretinal fluid to obtain sufficient retinal vascular freezing. As with laser photocoagulation, many more advanced cases require multiple sessions.<sup>60</sup> To minimize side-effects in eyes with extensive vascular abnormalities, selective treatment with cryotherapy to two or fewer quadrants per session may be advised, as well as avoidance of the ciliary body. In some cases with advanced disease and imminent glaucoma, treatment of the entire four quadrants of the retina is necessary. Compared to laser, cryotherapy is associated with more inflammation and patient discomfort as well as potential complications, which include subcapsular cataract, proliferative vitreoretinopathy, and total retinal detachment.<sup>66</sup>

The use of photodynamic therapy in combination with intravitreal bevacizumab for adult Coats disease was reported in a single case report, with apparent success.<sup>117</sup>

## Pharmacologic Therapies

Intravitreal corticosteroids, including triamcinolone acetonide (IVTA) and sustained-release dexamethasone, are effective in reducing macular edema and subretinal exudation.<sup>118–121</sup> Othman and colleagues recently described their experience in 15 eyes treated with 4 mg IVTA in combination with traditional treatment modalities and followed for at least 1 year. All patients experienced an improvement in visual acuity, although 40% required cataract surgery and one patient required intraocular pressure-lowering drops.<sup>118</sup> IVTA has been combined with cryotherapy in cases of severe exudative detachments.<sup>122</sup>

Intravitreal anti-VEGF agents have been reported to be effective in reducing subretinal fluid and macular exudation in children with Coats if given alone<sup>123–127</sup> or in combination with IVTA,<sup>128</sup> laser photocoagulation, or cryotherapy.<sup>125,126,128–134</sup>

Intraocular VEGF levels are known to be substantially elevated in eyes with Coats disease, with dramatic decline following intravitreal anti-VEGF injection.<sup>135,136</sup> In a study of four eyes with

Coats disease, the intraocular VEGF levels were nearly 2400 pg/mL, compared to 15 pg/mL in five eyes with rhegmatogenous retinal detachment.<sup>136</sup> In one eye with stage 2B disease in that report, the intraocular VEGF level decreased from 1247 pg/mL to 20.4 pg/mL 1 month after a single injection of intravitreal bevacizumab, with a corresponding improvement in visual acuity. VEGF levels may be elevated secondary to retinal ischemia associated with the abnormal vasculature.

Although in most of the available reports anti-VEGF agents appeared to be well tolerated, the case numbers are small, with limited follow-up. There is some evidence that anti-VEGF injections may accelerate the formation of vitreous fibrosis.<sup>127,137</sup> In the largest published series to date of eight eyes, Ramasubramanian and Shields noted the development of vitreous fibrosis in four eyes after a mean of 1.75 injections and 5 months of follow-up. In three of these patients, this progressed to traction retinal detachment.<sup>137</sup> It is also important to note that anti-VEGF injections are not a definitive treatment regimen and may not reduce the overall treatment burden for patients. Ray et al. compared 10 patients who received anti-VEGF injections plus ablative treatments versus 10 patients who received ablative treatment alone and noted more treatment in the anti-VEGF group with no difference in the time to disease control. Notably, however, there were two treatment failures in the ablative group compared to none in the combined group.<sup>133</sup> It is important to consider that we have no data on the long-term consequences of repeated anti-VEGF injections in children. Larger studies with longer follow-up will be necessary to establish the safety of anti-VEGF in juvenile Coats disease.

In contrast, the safety profile of anti-VEGF injections in adults is well established, and several small studies have shown the efficacy of anti-VEGF agents in adult-onset Coats with macular involvement.<sup>138,139</sup>

## Surgery

Less invasive measures are usually effective in treating exudative retinal detachment with Coats disease;<sup>140</sup> however, eyes with advanced retinal detachment abutting the crystalline lens or those

with a rhegmatogenous component to the detachment may benefit from surgical repair.

Machemer and Williams reported improvement in the clinical course of selected cases of Coats disease with vitreous surgery consisting of removal of vitreal and preretinal membranes to eliminate traction detachment, combined with destruction of leaking vessels.<sup>141</sup> Other authors have advocated the use of vitrectomy with internal drainage of subretinal fluid to flatten the retina, before vasoablative procedures, and intraocular tamponade with gas or silicone oil.<sup>142-144</sup> Silodor and associates have used intraocular infusion, drainage of subretinal fluid, and cryotherapy with success in eyes with advanced bullous retinal detachment.<sup>145</sup> In their series of 13 children with blindness from Coats disease, six that were followed without surgery developed painful neovascular glaucoma necessitating enucleation and seven that were surgically repaired avoided glaucoma and the eyes remained cosmetically acceptable. When transscleral drainage of extensive subretinal fluid is necessary, a pediatric infusion cannula placed in the anterior chamber works well for maintaining the globe (Fig. 59.9).

**FIG. 59.9** In this eye of an 18-month-old boy with total exudative retinal detachment, anatomic stability was achieved by infusion into the anterior chamber, posterior drainage of subretinal fluid, and cryotherapy to 11 clock-hours of peripheral vascular anomalies.

Endstage cases associated with neovascular or angle closure glaucoma, or a blind painful eye may require enucleation.<sup>60,146</sup> Alternatively, eyes with neovascular glaucoma may respond to transscleral diode laser cyclophotocoagulation.<sup>147</sup>

## Outcomes

In a series of 103 eyes, published by Shields and associates in 2001, telangiectasia resolved completely (47%) or partially (53%) over a mean interval of 15 months following treatment.<sup>60</sup> Following treatment, inactive telangiectasia and old exudation were found in 45% of cases at 17 months.<sup>60</sup> Residual telangiectatic areas are often left untreated, especially if there is no fresh exudation or subretinal fluid. The goal of treatment is to close telangiectasia so that further leakage is halted. In 7% of cases by 10 years, recurrence of leakage from residual or new telangiectasia can occur.<sup>60</sup>

Anatomically, most cases (76%) stabilize or improve following treatment, with the minority (8%) progressively worsening.<sup>60</sup> Approximately 20% require enucleation for neovascular glaucoma or painful phthisis bulbi.<sup>60</sup> In the large series by Shields and colleagues on 150 patients, 117 individuals (124 eyes) were managed and followed for a median of 23 months and outcomes were determined. Management included observation in 22 eyes (18%), photocoagulation in 16 (13%), cryotherapy in 52 (42%), retinal detachment repair with drainage of subretinal fluid and cryotherapy or photocoagulation in 20 (17%), and enucleation in 14 (11%). Often multiple sessions were required. The median interval from initial treatment to complete resolution of telangiectasia was 10 months (range 2–123 months). Exudation resolved completely in 46 cases (45%) over a median of 12 months. Of the 88 eyes with retinal detachment prior to treatment, 50 (57%) had complete resolution of the detachment. Unfortunately, visual outcome with this condition is generally poor as foveal exudation and retinal detachment often destroy macular function. In that series, final visual acuity was 20/50 or better in 16%, 20/60 to 20/100 in 8%, 20/200 to finger counting in 29%, and hand motions to no light

perception in 47%.<sup>60</sup> Severe vision loss was due to persistent foveal exudation, retinal detachment, and/or subfoveal fibrosis. Risk factors predictive of poor visual outcome (20/200 or worse) included noncaucasian race, postequatorial ( $p=.01$ ), diffuse ( $p=.01$ ), or superior ( $p=.04$ ) location of telangiectasia and exudation, failed resolution of subretinal fluid after treatment ( $p=.02$ ), and presence of retinal macrocysts ( $p=.02$ ). Significant risk factors for enucleation included elevated intraocular pressure (greater than 22 mmHg;  $p<.001$ ) and iris neovascularization ( $p<.001$ ) at presentation.

Following resolution of exudation, extensive subretinal fibrosis and pigmentation, particularly in the fovea, can limit visual recovery. Intraocular surgical intervention carries the added risks of endophthalmitis, retinal tear formation, rhegmatogenous retinal detachment, and proliferative vitreoretinopathy.<sup>5,109,148-151</sup> Patients should be followed lifelong for recurrence (Fig. 59.10).<sup>60,152-154</sup>

**FIG. 59.10** This patient, previously treated successfully for Coats-type exudative retinopathy (see old scarring and fibrosis to the left of the photograph), has now developed a new adjacent area of vascular malformation and aneurysmal dilation, with a circinate lipid exudate.

In a landmark 1910 *Archives of Internal Medicine* article,<sup>1</sup> Dr James Herrick described “peculiar, elongated, sickle-shaped red blood corpuscles” from a peripheral blood smear of a Grenadian dental student with recurring medical illnesses. He reported the first written description of sickle-cell disease (SCD).<sup>1-3</sup> Linus Pauling and colleagues in 1949 were the first to implicate a defective hemoglobin molecule within the erythrocyte as the cause of the disease.<sup>4,5</sup>

The term “sickle-cell disease” encompasses the group of hemoglobinopathies characterized by intravascular hemolysis and by defective oxygen transport. In a normal red blood cell, two  $\alpha$ -globin subunits, two  $\beta$ -globin subunits, and a central heme molecule combine to form adult hemoglobin (Hb A). The  $\beta$ -globin gene, an oxygen transport gene, is found on the short arm of chromosome 11.<sup>6,7</sup> Hemoglobin S (Hb S) results from a single amino acid point mutation in which a valine molecule substitutes for a glutamic acid at the sixth position within the  $\beta$ -globin chain.

Hemoglobin C (Hb C) is caused by a glutamic acid to lysine change in the  $\beta$ -globin molecule.

SCD is transmitted through the autosomal recessive mode of inheritance. Two copies of Hb S may combine with one another (SS disease), or one copy of Hb S and another  $\beta$ -globin variant, such as Hb C, may combine (compound heterozygous SC disease).<sup>7</sup> Individuals with one copy of Hb A and one copy of Hb S are described as having the sickle-cell trait, the typically, but not invariably, symptom-free carrier state for SCD.  $\beta$ -thalassemia occurs when a reduced amount of  $\beta$ -globin is present. This condition is called beta-plus ( $\beta^+$ ) thalassemia, whereas the absence of  $\beta$ -globin is called beta-zero ( $\beta^0$ ). Either of these conditions may combine with Hb S, leading to a compound heterozygous state.<sup>7</sup>

## Prevalence

To date, SCD remains the most common inherited blood disorder, which occurs in 1/500 African American births.<sup>8-10</sup> Approximately 250,000 children are born worldwide with SCD each year.<sup>7</sup> SCD causes about 5% of deaths in children under 5 years in Africa, more than 9% of such deaths in West Africa, and up to 16% of under-5 deaths in individual West African countries.<sup>11</sup> Approximately 8% (or 1 in 12) of black Americans possess sickle-cell trait, which is usually not associated with increased mortality or morbidity (except in hyphema), and is thought to confer protection against malarial infection.<sup>10</sup> The hemoglobin concentration in sickle-cell trait is typically 35–40% Hb S and 55–60% Hb A.<sup>7</sup> Although sickle-cell trait subjects are generally asymptomatic, they may encounter systemic complications of SCD under conditions of extreme hypoxia.<sup>12</sup> Populations of African descent possess the highest frequency of Hb S. At-risk genotypes for SCD are also observed in people of Mediterranean, Caribbean, South and Central American, Arab, and East Indian descent.<sup>7</sup> HbSS disease occurs in approximately 0.15% of African descendants in North America.<sup>7,13</sup> Those with SS disease do not typically become symptomatic until after 6 months of age, when fetal hemoglobin (Hb F) is replaced with Hb S. These individuals have a decreased life expectancy, as they are prone to developing severe anemia and are highly

susceptible to recurrent infections.<sup>14</sup> Individuals with HbSC disease, the compound heterozygotes, typically exhibit 50% Hb S and 50% Hb C hemoglobin and typically have less systemic morbidity from the systemic complications of SCD, and have an approximately normal life expectancy.<sup>7</sup> Sickle  $\beta$ -thalassemia patients are typically encountered in central African and Mediterranean countries and normally have hemoglobin composition of 60–90% Hb S and 10–30% Hb F.<sup>7,15</sup>

## Genetic Modifiers

Phenotypic expression of SCD is quite variable, even among those with the same genotype. Environmental effects and multiple gene interactions are thought to be at play. Further, the ability of an individual to generate Hb F may lead to reduced disease severity. Different  $\beta$ -globin cluster haplotypes may result in different levels of Hb F.<sup>7,16</sup> Levels of Hb F have been shown to inversely correlate with the clinical manifestations of SCD.<sup>17</sup> The higher the Hb F, the milder the manifestations of sickle-cell disease. Hydroxyurea therapy works to increase the amount of Hb F in circulation in individuals with SCD.

## Pathophysiology

The interplay among abnormal erythrocytes and hypoxic, hyperosmolar, or acidotic conditions leads to the abnormal rheology and hemolysis that are characteristic of SCD. In Hb S, a strongly hydrophobic nonpolar valine takes the place of a polar strongly hydrophilic glutamic acid residue.<sup>5</sup> Upon deoxygenation in the microcirculation, hydrophobic residues within Hb S are exposed and associate with hydrophobic regions of adjacent molecules. This polymerization results in the generation of rigid fibers of Hb S, which damage the red blood cell membrane and cytoskeleton and cause the cell to assume an elongated sickle shape. This polymerization process is reversible as oxygenation increases, and the cell may resume its native more pliable discoid shape. However, the repeated cycle of sickling and unsickling of the red blood cell may lead to permanent damage to the erythrocyte

membrane, irreversible sickling, and hemolysis. The mean corpuscular hemoglobin concentration (MCHC) may be the most important factor contributing to the rate of Hb S polymerization.<sup>5</sup> The higher the MCHC, the more hemoglobin molecules that are available to participate in polymerization, and the closer these molecules are to one another, further promoting a favorable environment for Hb S polymerization.<sup>18,19</sup>

The erythrocyte's original state of oxygenation also impacts the extent and rate of polymerization.<sup>15,16</sup> An intrinsic property of the normal erythrocyte is the ability to deform easily in order to pass through capillaries with smaller diameters than its own. Decreased erythrocyte deformability and increased rigidity can cause increased capillary transit time, leading to deoxygenation and sickling. These events promote increased permeability of the cell membrane to potassium, sodium, and calcium cations, which leads to efflux of water from the cell, contraction of cellular volume, and resultant increase in Hb S concentration.<sup>5,19,20,21</sup>

In addition to mechanical obstruction of blood vessels by dense, sickled erythrocytes, these sickled erythrocytes display increased adhesion to matrix proteins of the vascular endothelium, such as laminin,<sup>22,23</sup> and thus cause direct damage to the endothelium. Integrin  $\alpha 4\beta 1$ , integrin-associated protein, sulfated glycolipid, lutheran protein, phosphatidylserine, band 3 protein, and CD36 are adhesion molecules expressed in sickled erythrocytes and have been implicated in the cellular adhesion and red blood cell aggregation.<sup>24-26</sup> Immature erythrocytes and reticulocytes increase in SCD following intravascular hemolysis. These cells also have increased adhesion molecules, such as integrin  $\alpha 4\beta 1$ ,<sup>27-29</sup> which promote pathologic adhesion to the vascular endothelium, specifically to vascular cell adhesion molecule-1 (VCAM-1). Direct activation of endothelial cells occurs in response to elevated circulating cytokines, such as tumor necrosis factor-alpha (TNF- $\alpha$ ) and interleukin-1 $\beta$  (IL-1 $\beta$ ),<sup>30,31</sup> which upregulate expression of endothelial adhesion molecules like intercellular adhesion molecule-1 (ICAM-1), VCAM-1, E-selectin, and P-selectin.<sup>32,33</sup>

Inflammation likely plays a role in the vaso-occlusive process in SCD. Luty and colleagues demonstrated retention of irreversibly sickled SS red cells and adherence of red cells in reticulocyte-rich

fractions in the retina and choroid of rat eyes under hypoxic conditions or following TNF- $\alpha$  stimulation.<sup>34-36</sup> TNF- $\alpha$  and IL-1 may contribute to vaso-occlusion by accelerating the production of adhesion molecules on the vascular endothelium and by activating polymorphonuclear leukocytes.<sup>30</sup> Additional evidence implicates inflammatory mediators in sickle-cell disease, as TNF- $\alpha$  and IL-1 have been shown to be upregulated in the sera of individuals with SCD at baseline.<sup>31,37,38</sup>

Nitric oxide (NO) is a potent vasodilator and regulator of vascular tone; it is derived from the vascular endothelial NO synthase. SCD has been associated with elevated reactive oxygen species, which scavenge NO and metabolize arginine, its precursor.<sup>7</sup> L-arginine as an oral supplement has been given to induce NO production in transgenic sickle-cell mice; therefore, oral arginine supplementation may be a potential therapy to improve vasodilation, thus facilitating blood flow in sickle-cell disease.<sup>38,39</sup>

Vascular endothelial growth factor (VEGF), which is upregulated by hypoxia, is present in the serum of SCD patients at baseline and is elevated during vaso-occlusive crises.<sup>40</sup> Elevated VEGF has been demonstrated in eyes with sickle-cell retinopathy.<sup>41,42</sup> VEGF has also been shown to increase levels of cell adhesion molecules, such as ICAM-1 and VCAM-1.<sup>43,44</sup> Angiopoietin-1 (Ang-1) and angiopoietin-2 (Ang-2) interact with the Tie-2 receptor on endothelial cells, regulating angiogenesis. Ang-1 is responsible for the maintenance and stabilization of mature blood vessels, while Ang-2 leads to vessel destabilization and dissociation of pericytes and is upregulated by hypoxia and VEGF.<sup>45</sup> Interaction among these proteins may be important in the pathophysiology of neovascularization in SCD.

## Systemic Manifestations

Over recent years, as the life expectancy of those affected by SCD has increased, so have the number of chronic complications that these individuals experience.<sup>12,46</sup> Sickling of the erythrocytes, with resultant intravascular hemolysis, thrombosis, ischemia, and tissue necrosis, causes a myriad of systemic complications, including cerebrovascular accident, acute chest syndrome, pulmonary

hypertension, splenic sequestration, priapism, osteonecrosis, cholelithiasis, pneumonia, leg ulcers, aplastic crisis, renal disease, need for recurrent transfusions, episodic, painful vaso-occlusive crises, and premature death.<sup>7</sup>

Severe visual impairment and blindness from complications of proliferative sickle-cell retinopathy (PSR) may also occur. For reasons that are as yet unclear, subjects with HbSC disease typically display less systemic morbidity from their hemoglobinopathy than do subjects with HbSS disease, but they have a higher likelihood of experiencing vasoproliferative retinal complications than their homozygous HbSS counterparts.<sup>47</sup> In one study, retinopathy was detected in 33% of patients with HbSC disease compared to 3% of patients with HbSS disease.<sup>37</sup>

Several theories have been proposed to explain this difference. One explanation could be that HbSS patients typically have a shorter life expectancy than HbSC patients and may not live long enough to manifest the retinal disease. Alternatively, the difference in retinopathy among sickle-cell genotypes may be due to the higher hematocrit and cell density, and the lower Hb F, of individuals with HbSC as compared to HbSS individuals.<sup>7</sup> The overall lower hematocrit in HbSS patients, and the resultant lowered viscosity of blood, may confer a relative protection from vaso-occlusion in the retinal circulation.<sup>48</sup> Another theory is that the retinal vaso-occlusions in SS disease may be so complete that no viable tissue remains to produce the growth factors necessary to mount a proliferative response. In HbSC disease, the vascular occlusions may be less complete, and they may occur in the setting of a chronic hypoxic, rather than a totally anoxic, state. HbSS patients are possibly more likely to have complete vascular occlusions, whereas HbSC patients may show a chronic state of incomplete vascular ischemia rather than complete vascular occlusions. Thus, in HbSC, a steady-state release of angiogenic growth factors from the remaining viable tissue may occur, leading to vasoproliferation.<sup>49</sup> Finally, Luty and colleagues showed that irreversibly sickled HbSS erythrocytes are easily trapped in retinal capillaries and precapillary arterioles in hypoxic conditions in a rat model.<sup>16,35</sup> HbSC cells, however, regardless of oxygen levels, were less easily trapped in the retinal microvasculature. When the

vascular endothelium was stimulated with cytokines, retention of HbSC cells did occur. The authors suggested that vaso-occlusion in HbSC disease may be the result of the complex interaction among cytokines, the fibrinolytic cascade, leukocyte interactions, and activation of the vascular endothelium with induction of adhesion molecules.<sup>13,35</sup> These data suggest that retention of sickled cells in the retina is not primarily mechanical (rigid cells retained in a small lumen) but rather is due to hypoxia-initiated cytokines and their receptors.

Alterations in potassium-chloride (K-Cl) cotransport have also been shown to be different in HbSC and HbSS, and this difference has been shown to be clinically significant.<sup>50</sup> One study demonstrated that K-Cl transport correlated with the formation of sickle cells, and K-Cl transport was higher in blood samples in HbSC patients. Increased K-Cl cotransport activity was also correlated with retinopathy.<sup>50</sup>

## Ophthalmic Clinical Features

### Retrobulbar and Orbital Involvement

Orbital involvement of SCD is uncommon, but is clinically important to recognize when it occurs. One study reported periorbital swelling during vaso-occlusive crisis.<sup>51</sup> Infarction of orbital bones and orbital hematomas occur and may lead to the orbital compression syndrome. These patients typically have lid edema, fever, facial pain, proptosis, restriction of motility, and resultant diplopia. These syndromes usually resolve with treatment of the underlying crisis, antibiotics, and steroids. Orbital involvement in SCD may cause sudden permanent unilateral loss of vision without detectable retinal arterial changes due to retrobulbar ischemic optic neuropathy.<sup>7,52</sup> Urgent decompression of the orbit may be required. Recurrent bilateral lacrimal gland swelling has also been reported.<sup>53</sup>

### Anterior Segment Involvement

Anterior segment involvement may be present in SCD. One

characteristic finding is the saccular and sausage-like or linear dilations of the smallest conjunctival vessels,<sup>54</sup> most easily seen with high magnification (Fig. 60.1). Paton described these comma-shaped and isolated linear capillary segments in the inferior bulbar conjunctival vessels and coined the term “conjunctival sign.” It is uncommon in those with high Hb F levels.<sup>55</sup> Local heat from the slit lamp induces vasodilation and causes normalization of these abnormalities,<sup>56,57</sup> whereas topical vasoconstricting drops increase the abnormal vascular pattern.<sup>58,59</sup> These conjunctival vascular changes vary with oxygenation status and are more prevalent in HbSS disease than in HbSC disease.<sup>55</sup> Biomicroscopic inspection shows constriction of these conjunctival vessels during painful crises, with normal blood flow returning on recovery.<sup>59</sup>

**FIG. 60.1** The bulbar conjunctiva of an HbSS patient demonstrates abnormal linear dilations (*black arrow*) that appear to be disconnected from the adjacent vascular network.

Segmental iris atrophy can be seen in individuals with SCD (Fig. 60.2).<sup>60,61</sup> Iris atrophy may result from sectoral ischemic necrosis involving radial iris arteries. Secondary neovascularization of the iris stroma has also been described and documented with intravenous fluorescein angiography. In one instance this neovascular frond resembled that classically seen as the “sea fan” in PSR.<sup>13,62</sup> Neovascular glaucoma rarely occurs.<sup>7,63</sup>

**FIG. 60.2** Atrophy and irregularity of the iris at the pupillary border are seen as a result of sectoral ischemic necrosis in a patient with sickle-cell disease.

Hyphema in a patient with SCD and in those with sickle-cell trait represents a sight-threatening emergency, as even modest elevations of intraocular pressure (IOP) have resulted in permanent loss of vision from retinal artery occlusion.<sup>63–66</sup> Sickled erythrocytes may clog the trabecular meshwork,<sup>62</sup> causing elevation in IOP. Although intensive medical management to lower IOP in SCD patients with hyphema is recommended, IOP-lowering medications must be used cautiously. Repetitive use of carbonic anhydrase inhibitors, for example, is contraindicated in SCD patients with hyphema, as some of these medications cause intracameral acidotic conditions that may worsen erythrocyte sickling. Early surgical intervention for IOP control should be considered, typically by paracentesis of the anterior chamber.<sup>67</sup> Intracameral tissue plasminogen activator may be a potentially useful agent in the treatment of large posttraumatic hyphema in some cases.<sup>68</sup> Hyperoxygenation of the patient may also be helpful.

## Posterior Segment Involvement

### Vitreoretinal Interface

The pathologic retinal neovascularization caused by retinal ischemia in SCD can result in loss of vision from vitreous hemorrhage.<sup>69,70</sup> Other abnormalities of the fundus have been described, such as peripheral retinal whitening. This has been described in 93% of HbSS patients,<sup>71</sup> 83% of HbSC patients,<sup>72</sup> and 82% of Hb S Thal patients.<sup>73</sup>

Flat, brown, ovoid lesions in the retinal periphery have also been noted in SCD and termed “dark without pressure.” The underlying choroid appears normal on ophthalmoscopy, and the corresponding fluorescein angiogram is also normal.<sup>13,74,75</sup>

## Optic Nerve

The optic nerve in patients with SCD may show dilated capillaries at the optic nerve head that appear as small red dots and represent precapillary arterioles plugged with sickled erythrocytes.<sup>13,58,71,76</sup>

These changes are not visually significant, because the vascular occlusions are transient. Optic disc neovascularization is rare, but has been reported in four HbSC patients<sup>13,77–80</sup> and one HbSS patient.<sup>13,71</sup>

## Macula

Though the hallmark of ocular SCD is the peripheral retinopathy, the macula is also susceptible to infarction from vaso-occlusive disease. The “macular depression sign” has been described as an oval depression of the bright foveal reflex as a result of macular thinning due to ischemic atrophy.<sup>81</sup> This finding is best detected using red-free illumination. The extent of macular vascular changes has not been shown to correlate with visual acuity. In one study, an enlarged foveal avascular zone (FAZ) was identified in patients with SCD on fluorescein angiography as compared to healthy, age-matched controls.<sup>82</sup> Within the SCD group, visual acuity did not correlate with FAZ size.

OCT provides in vivo images of abnormalities of macular morphology, even in asymptomatic patients.<sup>83</sup> Hoang and coworkers<sup>84</sup> described macular retinal thinning using spectral domain optical coherence tomography (SD-OCT), most notably in the deeper retinal layers in the central macula and parafoveal retina. Additionally, the authors noted “splaying,” or blunting of

the foveal contour on SD-OCT in asymptomatic SCD patients with areas of focal parafoveal thinning (Fig. 60.3). Paracentral acute middle maculopathy has also been described in SCD.<sup>85,86</sup> This condition may be seen in patients with unexplained acute vision loss and is diagnosed by hyperreflectivity of the parafoveal inner nuclear layer on SD-OCT. Another study also described thinning of the temporal macula in patients with PSR on SD-OCT and suggested that this finding should lead clinicians to perform peripheral wide-field angiography to evaluate the retinal periphery for ischemia.<sup>87</sup> Mathew and colleagues detected macular splaying on SD-OCT in 40% of patients and noted a higher prevalence of proliferative sickle-cell retinopathy in eyes of patients with areas of temporal macular thinning on SD-OCT. No significant differences in choroidal thickness were noted in eyes with and without retinal thinning.<sup>88</sup> Macular hole,<sup>89</sup> epiretinal membranes,<sup>90</sup> macular schisis,<sup>91</sup> and posterior pole neovascularization<sup>92</sup> have all been reported as complications of SCD (Fig. 60.4).

**FIG. 60.3** Spectral domain optical coherence tomography demonstrates “foveal splaying” (saucerization of the foveal pit) and focal thinning (*white arrow*) within the temporal foveal region in a patient with HbSS disease.

**FIG. 60.4** (A) An HbSC patient, with a history of PSR with a macular epiretinal membrane. (B) Development of vitreomacular traction (VMT) one month following supplemental scatter laser photocoagulation to the peripheral retina. (C) Release of the VMT 2 months following laser photocoagulation with return to normal foveal contour. Image quality is degraded because of vitreous hemorrhage.

## Angioid Streaks

Angioid streaks, associated with linear breaks in Bruch's membrane, have a well-documented association with SCD, occurring in 1–2% of patients.<sup>13,71,93</sup> These irregular, reddish subretinal bands are most commonly found in patients with the HbSS genotype.<sup>71,94</sup> The incidence of angioid streaks in these eyes increases with age.<sup>95</sup> Angioid streaks in SCD may occur as the result of hypoxia, inflammatory cytokine release, and tissue damage.<sup>7,96</sup> Heavy calcification and breaks in Bruch's membrane have been demonstrated in cadaver eyes of an HbSS patient with angioid streaks.<sup>97</sup> Angioid streaks in SCD usually have a benign course, and

resultant choroidal neovascularization (CNV) is rare in SCD patients.<sup>13</sup>

## Retinal Vasculature

Peripheral vascular tortuosity may be more commonly observed in HbSS patients.<sup>7</sup> One study reported increased retinal vascular tortuosity in 47% of HbSS patients and 32% of HbSC patients,<sup>98</sup> although another reported 11% with vascular tortuosity in both HbSS and HbSC patients.<sup>71,72</sup> This discrepancy could be due to an imprecise definition of vascular tortuosity.<sup>7</sup>

Retinal vascular occlusions frequently occur in the peripheral retina in patients with SCD, and peripheral retinal nonperfusion is a common finding. Arteriovenous anastomoses may occur (Fig. 60.5). “Silver-wiring” of retinal arterioles represents permanently occluded arterioles (Fig. 60.6).

**FIG. 60.5** Ultrawide-field fluorescein angiography demonstrates striking peripheral nonperfusion at the temporal border of the retina (*star*) with arteriovenous anastomoses (*arrow*).

**FIG. 60.6** Silver-wiring and occlusion of a peripheral retinal arteriole (*arrow*).

Depending on its location, vascular occlusion may cause temporary or permanent loss of vision, or no loss of vision at all. The cause of these occlusions may be multifactorial, potentially involving sickled erythrocytes attaching to vascular endothelium, or the activation of the coagulation cascade, with secondary intimal injury.<sup>2,99</sup> In the peripheral temporal retina, where vessels become markedly narrow, arteriolar occlusions are common. Although the occlusions clinically appear to be inside precapillary arterioles, the vaso-occlusions may actually start in the capillary bed downstream, where sickled erythrocytes have difficulty traversing the narrow lumens due to their nondeformability.

Vaso-occlusion arising from the posterior ciliary arterial circulation may potentially cause choroidal infarction in SCD. Histopathologic studies show impacted red blood cells, increased fibrin, and platelet fibrin thrombi in cases of choroidal occlusion.<sup>100,101</sup> CNV may rarely occur spontaneously<sup>102</sup> or result from high-energy laser burns.<sup>103</sup>

## **Nonproliferative Sickle Retinopathy**

### **Salmon Patch Hemorrhages**

Salmon patch lesions are pinkish-orange hemorrhages located between the retina and its internal limiting membrane (Fig. 60.7). They may arise from areas of bleeding into the retina adjacent to areas of nonperfusion and have been described as a “blowout” of an occluded arteriole.<sup>104,105</sup> Although the hemorrhage is initially red, it may turn a salmon color over time because of progressive hemolysis. The localized collection of blood may remain under the internal limiting membrane, travel into the subretinal space, or spread into the vitreous.<sup>13,104,105</sup>

**FIG. 60.7** A salmon patch hemorrhage results from “blowout” of blood from an occluded retinal arteriole.

## Iridescent Spots

If arteriolar occlusion causes retinal hemorrhage, a small schisis cavity may develop after the intraretinal portion of the hemorrhage resolves.<sup>13</sup> The cavity may contain hemosiderin-laden macrophages, which can appear as multiple refractile or iridescent spots (Fig. 60.8).

**FIG. 60.8** Iridescent spots (*arrow*) are shown within a retinoschisis cavity and may represent hemosiderin-laden macrophages.

## Black Sunbursts

Black sunbursts are flat, stellate, or round areas of hyperpigmentation and result when intraretinal hemorrhage tracks into the subretinal space (Fig. 60.9).<sup>104,106</sup> On histopathologic study, black sunbursts can show focal hypertrophy of the retinal pigment epithelium (RPE).<sup>104</sup> This “sunburst sign” may also represent localized choroidal ischemic damage to the overlying RPE.<sup>107</sup> Another hypothesis is that the black sunburst may be the RPE response to an area of underlying CNV.<sup>102,108</sup>

**FIG. 60.9** A small black sunburst (*arrow*) may represent focal hypertrophy or hyperplasia of the retinal pigment epithelium.

## Proliferative Sickle Retinopathy

A critical event in the development of PSR is the formation of the sea fan, so named for its close resemblance to the marine invertebrate *Gorgonia flabellum* (Fig. 60.10). Peripheral retinal arteriolar occlusions are the inciting events in sea fan formations. Occlusion of the vasculature causes release of growth factors, resulting in formation of these neovascular fronds. Complications of PSR are the major contributor to vision loss in SCD. Sea fans are predisposed to hemorrhage into the vitreous, and to cause vitreous membrane formation, tractional retinoschisis, and tractional or combined rhegmatogenous-tractional retinal detachment.<sup>48</sup> Sea fans often form at arteriovenous crossings and may have multiple feeding arterioles and draining venules (Fig. 60.11).<sup>109</sup>

**FIG. 60.10** Sea fan lesions are shown in the peripheral fundus in a patient with HbSC disease. The frond-like vascular structures are typically present at the border of perfused and nonperfused peripheral retina. (A) A 30° image shows details of a sea fan. (B) Ultrawide-field fluorescein angiography demonstrates bright hyperfluorescence of the sea fan lesions in another patient. (C) The later phase of the angiogram from the patient in (B) shows diffuse leakage from the neovascular fronds (*arrows*).

**FIG. 60.11** Flat-embedded ADPase retina from a 40-year-old HbSS subject. (A) A sea fan formation is shown with dark-field illumination of the retina en bloc before sectioning. This formation occurred at the crossing (*curved arrow*) of an artery (*a*) and vein (*v*) and had five connections to the arterial circulation and four connections to venous channels. (B) Higher magnification of the arteriovenous crossing. (C) Cross-section of the arteriovenous crossing shows the retina is very thin in this region at the border of perfused and

nonperfused retina. (Reproduced with permission from McLeod DS, Fukushima A, Goldberg MF, et al. Histopathologic features of neovascularization in sickle-cell retinopathy. *Am J Ophthalmol* 1997;124:455–72.)

In 1971, Goldberg devised the widely utilized classification system for PSR ([Table 60.1](#)).<sup>110</sup>

---

**TABLE 60.1**  
**Goldberg Classification of Proliferative Sickle-Cell Retinopathy**

---

Stage I	Peripheral arterial occlusions
Stage II	Peripheral arteriovenous anastomoses
Stage III	Neovascular and fibrous proliferations
Stage IV	Vitreous hemorrhage
Stage V	Retinal detachment

## Goldberg Stages

### Stage I

Stage I retinopathy is defined by peripheral vascular occlusion.<sup>58</sup> The peripheral retina may show multiple simultaneous arteriolar occlusions, and silver-wiring of the arterioles may be present. Vaso-occlusion occurs primarily in the peripheral temporal retina due to longer arteriovenous transit times (with deoxygenation), an increased number of occludable bifurcation sites, and decreased perfusion.

### Stage II

In this stage, vascular remodeling at the border of perfused and nonperfused retina occurs. Arteriovenous anastomoses form connections between occluded arterioles and adjacent terminal venules by way of preexisting capillaries ([Fig. 60.5](#)). The anastomoses do not leak on fluorescein angiography (FA), confirming that these early vascular lesions are derived from preexisting mature blood vessels with an intact blood–retinal barrier, as opposed to being truly neovascular.

### Stage III

Sea fan fronds are the hallmark of stage III PSR and are perhaps the

trademark lesion of sickle-cell retinopathy (Fig. 60.10). These lesions are most commonly found in the superotemporal retina, followed by the inferotemporal, superonasal, and inferonasal quadrants. Sea fans represent true neovascularization, and thus display diffuse leakage on fluorescein angiography (Fig. 60.10). Sea fan neovascularization causes chronic transudation into the vitreous, which in turn leads to vitreous degeneration and retinal traction, with possible vitreous hemorrhage and retinal detachment.<sup>13,48,58</sup>

Most sea fans are found at the border of perfused and nonperfused retina, and they grow toward the ora serrata.<sup>48,80</sup> Sea fan neovascular complexes often arise from the venous aspect of the arteriovenous anastomoses, and develop approximately 18 months following the formation of these arteriovenous connections<sup>13,48</sup> (Fig. 60.11). Chronic ischemia within the peripheral retina leads to an increase in angiogenic factors, such as VEGF and basic fibroblastic growth factor.<sup>13,41,100</sup> Pigment epithelial growth factor/VEGF balance may play a role in the angiogenesis of these lesions as well as the subsequent, spontaneous regression of some (but not all) neovascular complexes.<sup>42</sup>

Another potential mechanism for sea fan development has been proposed.<sup>101</sup> Arteriolar occlusive events may create hydrostatic back-pressure, causing extrusion of the upstream segment of the blocked vessel into the preretinal space. The rise in intraluminal pressure may cause expansion of the extruded vessel, with resultant stretching of the pericytes and endothelial cells. This process may stimulate endothelial cells, leading to endothelial cell proliferation<sup>111</sup> and subsequent neovascularization.<sup>101,112</sup>

Sea fans typically possess at least one feeding arteriole and one draining venule and are most commonly found at the sites of arteriovenous anastomoses and arteriovenous crossings.<sup>109,110</sup> A network of these lesions with multiple anastomoses may develop with multiple feeding and draining vessels, and they may form tractional vitreous bands.

## **Stage IV**

Vitreous hemorrhage represents Goldberg stage IV. Sea fans grow or are pulled into the vitreous chamber, and vitreous traction on the delicate neovascular fronds may cause bleeding into the vitreous.

Vitreous hemorrhage may be localized over the sea fan, and an individual may remain visually asymptomatic. However, dramatic, sudden loss of vision may occur as the hemorrhage disseminates into the vitreous. Vitreous hemorrhage occurs more commonly in HbSC than in HbSS.<sup>71,93,98</sup> The risk of recurrent vitreous hemorrhage also increases if an eye has more than 60° of circumferential retinal neovascularization, or if a patient initially presents with vitreous hemorrhage.<sup>113</sup> Chronic vitreous hemorrhage may give rise to fibroglial membranes and vitreous strands, which may produce traction and resultant retinal detachment.<sup>48,58</sup>

## **Stage V**

Presence of tractional and/or rhegmatogenous retinal detachment (TRD) defines Goldberg stage V (Fig. 60.12). TRD develops as the result of chronic vitreous hemorrhage or chronic transudation from neovascular tissue and resultant vitreous membrane formation. Retinal breaks may also occur due to localized retinal atrophy and thinning from chronic vaso-occlusion and ischemia.<sup>48</sup> Traction may also induce retinal breaks. In contrast to the TRD commonly seen in proliferative diabetic retinopathy, the TRD in SCD most commonly involves the peripheral retina as opposed to the posterior pole. Alternative classification schemes for PSR have been proposed, but are not widely utilized.<sup>114,115</sup>

**FIG. 60.12** A combined tractional-rhegmatogenous retinal detachment from sea fan neovascularization is demonstrated with bullous subretinal fluid throughout the macula in a patient with HbSC and PSR. (Reproduced with permission from Moshiri A, Ha NK, Ko FS, Scott AW. Bevacizumab presurgical treatment for proliferative sickle-cell retinopathy-related retinal detachment. *Retin Cases Brief Rep* 2013;7:204-5).

## Incidence/Prevalence

The incidence of PSR is higher in those individuals with HbSC disease and S- $\beta$  thalassemia than in individuals with HbSS disease. In one natural history study of SCD patients followed longitudinally over 20 years, prevalence of PSR was greater in those with HbSC disease, and by the ages of 24–26 years, PSR had occurred in 43% of subjects with HbSC disease and in only 14% of subjects with HbSS disease.<sup>116</sup>

## Risk Factors

Fox and colleagues described risk factors that increase an individual's likelihood of developing PSR.<sup>117</sup> In the HbSS genotype, high total hemoglobin in males and a low Hb F in both males and females were associated with the development of PSR. In the HbSC

genotype, increased mean cell volume and low Hb F increased the risk in men and women. High total hemoglobin and high MCHC caused a higher PSR risk of PSR in men with the HbSC genotype.<sup>7,117</sup>

## Natural History

Autoinfarction of the proliferative sickle lesions occurs frequently, and, as a result, spontaneous regression of PSR may occur in about 32% of eyes.<sup>116</sup> The mechanism of autoinfarction is not completely understood. This process may be due to chronic and repetitive vaso-occlusion within the vascular channels of the sea fan neovascular complexes. In a cohort of 120 patients with HbSS disease and 222 patients with HbSC disease followed for 10 years, loss of visual acuity occurred in 10% of untreated eyes.<sup>118</sup> Loss of vision most commonly resulted from PSR, specifically vitreous hemorrhage, TRD, and epiretinal membranes. Patients with nonproliferative disease had a lower incidence of loss of vision over the 10-year period than did their counterparts with PSR.<sup>118</sup>

## Ophthalmic Treatments

No intervention is indicated for small, flat, asymptomatic peripheral lesions, given the relatively low risk of spontaneous hemorrhage and the relatively high probability of autoinfarction.<sup>119,120a</sup> Treatment may be required in cases of rapid growth of a sea fan, presence of large, elevated sea fans, spontaneous hemorrhage, or bilateral proliferative disease.<sup>13</sup> The goal of intervention in these cases is to prevent the progression of stage III PSR to stages IV or V.

Scatter laser photocoagulation is the current mainstay of treatment in PSR (Fig. 60.13). The objective of scatter laser treatment is similar to that traditionally employed in the management of proliferative diabetic retinopathy, in which ischemic retina is ablated by laser photocoagulation, thus decreasing the stimulus for secretion of pathologic growth factors. Laser photocoagulation of ischemic retina may also help to decrease the overall oxygen requirement of the retina. Through laser destruction of ischemic,

damaged peripheral retina, intravascular oxygen may be shunted to healthier, more viable retinal tissue. Hypoxia inducible factor 1 alpha and VEGF are strongly expressed eyes with PSR in areas of avascular retina, areas anterior to the boundary between perfused and non perfused retina, and in posterior ischemic retina.<sup>120b</sup>

**FIG. 60.13** A sea fan lesion with localized hemorrhage is depicted on ultrawide-field fundus photography immediately after scatter laser treatment in a patient with HbSC disease.

Anti-VEGF agents have been successful in the management of PSR. Intravitreal bevacizumab has been reported to cause complete regression of retinal neovascularization and resolution of vitreous hemorrhage in eyes with PSR.<sup>121,122</sup> One group noted complete regression of neovascularization and resolution of vitreous hemorrhage after a single intravitreal ranibizumab injection in a patient with PSR, with no recurrence after 9 months of follow-up.<sup>123</sup> Intravitreal bevacizumab has also been used as a preoperative surgical adjunct for retinal detachment associated with proliferative sickle-cell retinopathy. Moshiri and our group observed that administering preoperative intravitreal bevacizumab caused regression of sea fan neovascularization, facilitating surgical dissection and removal of retinal traction bands, and decreased intraoperative bleeding (Fig. 60.12).<sup>124</sup> Further study is warranted to

assess the role of anti-VEGF therapy in PSR.

Vitreotomy may be considered for nonclearing vitreous hemorrhage, and may be indicated to improve visualization of retinal pathology to facilitate treatment such as photocoagulation. A possible therapeutic approach is combining vitrectomy with scatter laser photocoagulation, with consideration of an anti-VEGF injection in an eye with active PSR.

Exchange transfusion, erythropheresis, and hyperbaric oxygen have been utilized in the past to minimize complications from surgically induced anterior-segment ischemia. These methods showed no clear benefit and were associated with systemic complications.<sup>125</sup> Vitrectomy in an eye with PSR can be reasonably safe with today's modern vitrectomy techniques without these extra measures. The vitreoretinal surgeon should take special care to maximize perfusion in the eye by avoiding elevations in intraocular pressure (IOP) throughout the procedure and thereafter. In routine vitrectomy surgery, intraoperative bleeding is often managed by the surgeon's temporarily raising IOP by elevating the height of the infusion bottle until hemostasis is achieved. Eyes with PSR may be particularly sensitive to ischemic insult from even transient IOP elevations. It follows that measures to reduce the likelihood of intraoperative hemorrhage during vitrectomy surgery, such as pretreatment with intravitreal anti-VEGF, should be considered. It is also critical that the surgeon coordinate with the anesthesiologist to ensure that the patient is well oxygenated throughout and after the procedure.

Given the propensity for peripheral retinal breaks and other peripheral vitreoretinal pathology to develop, scleral buckling may be considered in SCD to relieve traction from peripheral vasoproliferative lesions. Though anterior segment ischemia is a feared complication of scleral buckling in eyes with sickle-cell retinopathy, scleral buckles have safely been utilized in sickle-cell retinal detachment surgery.<sup>126</sup>

Williamson and colleagues reported their experience with management of vitreoretinal complications of sickle-cell retinopathy.<sup>127</sup> A high rate of iatrogenic retinal tears was noted while peeling membranes from the atrophic, ischemic peripheral retina using delamination (i.e., tangential peeling of preretinal

fibrous tissue from the retinal surface). Therefore, these authors recommended segmentation (removal of anterior–posterior traction) techniques instead of delamination.

## Imaging

Selected imaging modalities facilitate diagnosis, monitoring, and assessment of responses to treatment in sickle-cell retinopathy. Indocyanine green angiography (ICGA) has been studied as a way to assess choroidal perfusion, but the utility of ICGA in sickle-cell retinopathy is unclear.<sup>128</sup> The use of ultrawide-field (UWF) imaging is helpful to detect and monitor peripheral lesions (Fig. 60.12). Wide field fundus photography and FA are best for detecting early retinal changes since the vaso-occlusions are in the far periphery, which many photographers can not visualize with standard cameras. FA remains the gold-standard imaging tool for assessment of retinal perfusion and neovascularization. A potential limitation of conventional FA is the difficulty in imaging the pathology of the far peripheral retina in some eyes with sickle retinopathy.<sup>114</sup> Accordingly, UWF imaging has become useful in the evaluation of the retinal periphery in such eyes. As previously mentioned, SD-OCT provides important details about foveal anatomy, which may aid in the diagnosis and management of sickle retinopathy,<sup>81,83–87</sup> even in asymptomatic patients.

A drawback of FA is that it is invasive and time-consuming, and lacks an ability to capture the peripapillary and deep capillary networks. OCT angiography (OCTA) is a nascent noninvasive imaging modality. Motion contrast is used to create detailed volumetric scans by which the retinal microvasculature is visualized. OCTA provides both structural and functional information regarding retinal blood flow.<sup>129</sup> Imaging studies have shown that patients with sickle-cell disease may suffer ischemia in the deep capillary networks, even with an apparently intact FAZ on FA (Figs. 60.14 and 60.15). Our group performed OCTA on consecutive patients with sickle-cell disease.<sup>130</sup> Five out of 10 eyes had retinal thinning identified on SD-OCT, each of which had corresponding loss of vascular density on OCTA. These OCTA images support the concept that nonperfusion of the deep capillary

plexus may be responsible for some of the areas of macular thinning seen on SD-OCT, as each patient with macular thinning had corresponding loss of vascular flow on OCTA that was more apparent in the deep plexus than in the superficial plexus.<sup>130</sup> OCTA may detect abnormalities present in the retinal microvasculature that may not be detected on FA (Fig. 60.14),<sup>129</sup> and though its utility is yet unclear, OCTA may, therefore, play a role in understanding retinal vascular pathology in patients with SCD.

**FIG. 60.14** Ultrawide-field fluorescein angiography of a patient with HbSS disease shows normal macular perfusion and very subtle peripheral nonperfusion in the temporal retinal periphery (*arrow*).

**FIG. 60.15** Optical coherence tomography angiography (OCTA) of the same patient from Fig. 60.14. (A) Fluorescein angiography shows an intact foveal avascular zone and normal macular perfusion. (B–D) OCTA shows mild capillary dropout in the superficial capillary layer (*white arrow*). (E–G) OCTA shows significant capillary dropout in the deep capillary plexus (*red arrow*).

# Health Maintenance and Retinopathy Screening

Large clinical trials providing guidelines for screening, monitoring, and management in order to minimize the complications of sickle-cell disease are limited. Expert consensus recommendations do exist for health maintenance,<sup>131</sup> including supportive management of painful sickle-cell crises (Table 60.2). Strong recommendations exist for referral of SCD patients to a retinal specialist beginning at about age 10 years for retinopathy screening, with reexamination in 1–2 years for those who have “normal” screening exams. However, although a “strong” recommendation is based on expert consensus, high-quality evidence-based data on which to base screening recommendations are lacking. Teleretinal screening has shown promise in diseases such as diabetic retinopathy and retinopathy of prematurity. Nonphysicians may acquire high-quality fundus images, which can then be transmitted to remote reading centers for interpretation by experts. Telemedicine may be a potential future strategy to determine which patients with SCD would benefit from referral for detailed ophthalmic examination.

**TABLE 60.2**

## Evidence-Based Recommendations for Health Maintenance in Sickle-Cell Disease

Evidence-Based Health Maintenance Recommendations for SCD <sup>a</sup>	Strength of Recommendation	Quality of Evidence
<b>PREVENTION OF INVASIVE PNEUMOCOCCAL INFECTION</b>		
Administer oral penicillin prophylaxis (125 mg for those aged <3 yr and 250 mg for those aged ≥3 yr) twice daily until age 5 yr in all children with HBSS	Strong	Moderate
Discontinue prophylactic penicillin in children with HbSS at age 5 yr unless they have had a splenectomy or invasive pneumococcal infection; ensure completion of pneumococcal vaccination series before discontinuation	Moderate	Moderate
Ensure that persons of all ages with SCD have been vaccinated against <i>Streptococcus pneumoniae</i>	Strong	Moderate
<b>IMMUNIZATIONS</b>		
Children aged 6–18 yr with functional or anatomic asplenia should receive 1 dose of PCV13 (conjugate 130-valent vaccine)	Consensus	Adapted <sup>b</sup>
Adults aged ≥19 yr who have not received pneumococcal vaccine but have functional or anatomic asplenia and who have not previously received PCV13 or PPSV23 (23-valent polysaccharide		

vaccine) should receive 1 dose of PCV13 first, followed by a dose of PPSV23 at least 8 wk later, with subsequent doses of PPSV23 to follow current PPSV23 recommendations for adults at high risk		
A second PPSV23 dose is recommended 5 yr after the first PPSV23 dose for persons ages 19–64 with functional or anatomic asplenia		
In addition, those who received PPSV23 before age 65 yr for any indication should receive another dose of the vaccine at age 65 yr or later if at least 5 yr have elapsed since their previous PPSV23 dose		
Adults aged ≥19 yr with previous PPSV23 vaccination and functional or anatomic asplenia who received ≥1 doses of PPSV23 should be given a PCV13 dose ≥1 yr after the last PPSV23 dose		
For those who require additional doses of PPSV23, the first doses should be given no sooner than 8 wk after PCV13 dose and at least 5 yr after the most recent dose of PPSV23		
Screening for hepatitis C: screen for HCV infection in persons at higher risk for infection (e.g., those with multiple transfusions) and offer 1-time screening for HCV infection to all adults born between 1945 and 1965	Consensus	Adapted <sup>c</sup>
Electrocardiogram screening: do not screen asymptomatic children or adults with SCD with electrocardiograms	Weak	Low
<b>SCREENING FOR RETINOPATHY</b>		
Refer to an ophthalmologist for a dilated eye examination to evaluate for retinopathy beginning at age 10 yr	Strong	Low
For persons having a normal dilated retinal examination, rescreen at 1- to 2-yr intervals	Consensus	Panel expertise <sup>d</sup>
<b>SCREENING FOR RISK OF STROKE USING NEUROIMAGING</b>		
In children with SCA, screen annually (beginning at age 2 yr and continuing until at least age 16 yr) with transcranial Doppler, according to the methods used in the STOP studies	Strong	Moderate
In children with conditional (170–199 cm/s) or elevated (≥200 cm/s) transcranial Doppler results, refer to a specialist with expertise in long-term transfusion therapy aimed at preventing stroke	Strong	High
In children with genotypes other than SCA (e.g., HbSβ*-thalassemia or HbSC), do not perform screening with transcranial Doppler	Strong	Low
In asymptomatic children with SCD, do not perform screening with MRI or CT	Moderate	Low
In asymptomatic adults with SCD, do not perform screening with neuroimaging (transcranial Doppler, MRI, or CT)	Moderate	Very low
Screening for pulmonary disease: do not screen asymptomatic children and adults with pulmonary function tests	Moderate	Low
Contraception, reproductive counseling and opioid use during pregnancy	Consensus	Adapted <sup>e</sup>

<sup>a</sup>The order of the recommendations was chosen to reflect the frequency with which they will likely need to be implemented. For example, immunization recommendations apply to all individuals with SCD, whereas pulmonary function assessment or contraceptive information may be needed for only a portion of those with SCD.

<sup>b</sup>Consensus adapted from 2014 recommendations of Advisory Committee on

Immunization Practices (ACIP).

<sup>c</sup>Consensus-adapted recommendations from the US Preventative Services Task Force (USPSTF). Box 1 contains criteria for consensus-adapted recommendations.<sup>131</sup>

<sup>d</sup>Box 1 contains criteria for panel expertise consensus.<sup>131</sup>

## Potential Therapeutic Options for the Future

SCD remains a devastating disease associated with multiorgan dysfunction and premature death. The only known curative therapy for sickle-cell disease is myeloablative conditioning and allo-stem cell therapy from HLA-matched sibling donors.<sup>132</sup> Treatment strategies that decrease Hb S and increase Hb F have been shown to decrease the systemic morbidity of SCD, in that higher Hb F may interfere with polymerization of Hb S. Agents to increase Hb F include hydroxyurea, omega-3 fatty acids, and erythropoietin. Hydroxyurea is the only approved oral medication for SCD.<sup>133</sup> The burden of Hb S cells may be reduced through transfusion or hemapheresis. Warfarin, heparin, and ticlopidine may also be utilized as adjunctive therapies in patients with SCD because these medicines work as antithrombotic agents. Additional future areas of investigation include hematopoietic stem cell transplantation, gene therapy, and autologous gene correction stem cell designs.<sup>7,133,134</sup>

## Introduction

Radiation retinopathy (RR) is a slowly progressive, delayed-onset occlusive microangiopathy of the retinal vasculature that occurs with variable latency after exposure of the retina to ionizing radiation. First described by Stallard in 1933,<sup>1</sup> the term encompasses all retinal vascular changes, including ischemic and proliferative RR (PRR) and radiation maculopathy. It is a potentially devastating sequela of exposure of the eye to any source of radiation, including local plaque radiation treatment (brachytherapy), external-beam radiation treatment (ERBT), proton beam radiation, helium ion radiotherapy, and gamma knife radiotherapy of the eye, ocular adnexa, orbit, and head and neck structures.<sup>2-6</sup> Radiotherapy offers an alternative to enucleation for patients with retinoblastoma, choroidal melanoma, and ocular metastases,<sup>7-9</sup> as well as life-saving treatment of orbital, sinus, and intracranial tumors. Since the Collaborative Ocular Melanoma Study showed similar survival rates after radiotherapy and enucleation, the shift towards globe-salvaging therapeutic strategies has increased the use of radiation and consequently increased its complications, with reports of the incidence of RR ranging from 3% to over 20%.<sup>10,11</sup> The current interest in use of radiation in the treatment of neovascular age-related macular degeneration (AMD) might further increase the risk of this complication.<sup>12-15</sup>

The risk of RR is related to characteristics of the radiation treatment itself, the presence of systemic disease, and exposure to radiation sensitizers such as chemotherapy. Fundoscopic findings can be highly variable, ranging from scattered retinal hemorrhages, microaneurysms, and cotton-wool spots to macular edema, large-vessel occlusion, extensive ischemic retinopathy and maculopathy, and consequent retinal and ocular neovascularization. Within the retina, the posterior pole is particularly sensitive to this pathology,<sup>16</sup> with grave implications for visual prognosis. Indeed, macular edema involving the fovea is a major source of visual morbidity in patients with radiation retinopathy. Further, RR has a long latency and may not be clinically detectable for 8 years or more.<sup>17</sup>

Although RR has a variable course, it is frequently fulminant, with a tendency for the vasculopathy to progressively decrease

vision by affecting the macular microvasculature. Further, the structural damage is often irreversible, particularly in cases with macular nonperfusion and ischemia.

## Etiology, Pathogenesis, and Histopathology

RR can be described as a progressive obliterative arteritis that initiates a characteristic pattern of degenerative and proliferative vascular changes and microvascular dysfunction. The therapeutic, tumoricidal effects of radiotherapy are generated both directly, via injury to the DNA of rapidly dividing cells, and indirectly, via the production of free radicals. However, these processes damage not only the tumor itself but also the vascular and interstitial support structures of healthy tissue. This induces an acute transudative as well as a slowly progressive occlusive vasculopathy.<sup>18</sup> The initial pathologic change, and the fundamental abnormality, is retinal vascular endothelial cell injury and loss<sup>18-21</sup> and associated inflammation,<sup>22</sup> which occur primarily in capillaries, followed by capillary closure, clearly visible with fluorescein angiography (FA),<sup>17,23-25</sup> leading to retinal ischemia, nerve tissue necrosis, and fibrovascular proliferation.<sup>16,21,24,26,27</sup>

The loss of capillary cellularity leads to the development of microaneurysms, and hemodynamic alterations produce fenestrated telangiectatic retinal vessels. Larger retinal vessels become involved later in the course of the retinopathy; diameter reduction of major retinal arteries and veins of up to 75% has been demonstrated in animal models.<sup>22</sup> Closure of blood vessels is the single most characteristic finding on FA, although other abnormalities, such as retinal angiomatous proliferation, have been described.<sup>28</sup> Ghost vessels are later visible ophthalmoscopically. Both central retinal artery occlusion<sup>29</sup> and interruption of the choroidal circulation<sup>30,31</sup> have been described as a consequence of high-dose irradiation. Choriocapillary hypoperfusion is detectable several months after treatment,<sup>31</sup> leading to choroidopathy and chorioretinal atrophy. The widespread vascular occlusion induces the production of vascular endothelial growth factor (VEGF),<sup>21</sup>

leading to neovascularization and increased vascular permeability, both of which result in vascular leakage and tissue edema.<sup>32</sup> Uveal effusion can also be present.<sup>33</sup>

The disappearance of choriocapillaris, retinal pigment epithelium (RPE), photoreceptors, and retinal nerve fibers, along with leukocyte invasion, has been demonstrated histologically.<sup>34</sup> Areas devoid of photoreceptor cells correspond with areas of pigment dispersion with reduced numbers of melanocytes. There is a thickening of arteriolar and capillary walls and endothelial cell loss. In contrast to diabetic retinopathy, in which pericytes are initially affected, RR exhibits an early loss of endothelial cells. However, pericytes can be affected in severely damaged capillaries.

Optical coherence tomography (OCT) demonstrates significant thinning of the inner plexiform, inner nuclear, and outer plexiform layers, suggesting that primary radiation-induced damage is initially confined to the inner layers of the retina.<sup>35</sup> However, secondary functional changes may occur in the outer retina.<sup>36</sup>

## Natural History and Clinical Features

RR displays clinical and angiographic features that are virtually identical to those seen in diabetic retinopathy.<sup>37</sup> This is unsurprising, as both radiation and diabetes primarily damage the retinal capillaries. Ophthalmoscopically, microaneurysms are the first to appear. They are near-universally present<sup>38</sup> and are closely followed by intraretinal hemorrhages, macular capillary dilation and nonperfusion, and nerve fiber layer infarcts (cotton-wool spots; [Figs. 61.1](#) and [61.2](#)).<sup>17</sup> Retinal edema, hard exudates, telangiectasia, and perivascular sheathing may follow in variable sequence and latency. Hard exudates have been found to be more prevalent after brachytherapy ([Fig. 61.3](#)), whereas retinal hemorrhages and microaneurysms are more commonly found after EBRT.<sup>16</sup> The telangiectatic-like vessels are a feature of established retinopathy and are likely to represent collateral vasculature at the edges of capillary occlusion.<sup>17</sup> Confluent areas of capillary closure lead to the development of large areas of retinal capillary nonperfusion.

**FIG. 61.1** A 32-year-old woman was treated with four cycles of rituximab and fractionated external-beam radiation therapy (20×2 Gy) for a non-Hodgkin lymphoma of the left maxillary sinus. Swelling of lids, ptosis, conjunctival redness, and dry-eye symptoms were the first ocular complications. Shortly thereafter, loss of visual acuity was noted due to radiation retinopathy and optic neuropathy with numerous cotton-wool spots, retinal hemorrhages, and pallor of the optic disc (A). Macular edema (B) as well as progressive capillary nonperfusion (C) were noted subsequently. A single intravitreal steroid injection was administered. Two years after radiotherapy, and 15 months after diagnosis of the radiation retinopathy, subhyaloidal and vitreous hemorrhages due to optic disc neovascularization and widespread retinal nonperfusion (D) were observed. Neither rubeosis iridis nor increased intraocular pressure was observed. However, final visual acuity was reduced to counting fingers.

**FIG. 61.2** A 63-year-old male noticed visual loss in his left eye 3 years after resection and subsequent radiotherapy (60 Gray in 2-Gray fractions) of a temporal anterior meningioma. At presentation, visual acuity was 20/40. Radiation retinopathy was diagnosed, with macular edema and numerous cotton-wool spots and hemorrhages in the posterior pole (A). Fluorescein angiography demonstrated capillary dropout (B) and leakage (C). Optical coherence tomography (OCT) showed marked cystoid edema (D). Four days after intravitreal bevacizumab injection, the edema had resolved, as demonstrated on Spectralis (E) and Cirrus (F) OCT. The radiation retinopathy remained mild during the 27 months follow-up, and visual acuity was 20/32 at last visit (G).

**FIG. 61.3** (A) Large mushroom-shaped choroidal melanoma before I<sup>125</sup> plaque radiotherapy. (B) Radiation retinopathy is documented 14 months after treatment with supramacular cotton-wool spots, exudative retinal detachment, and hard exudates threatening the macula.

The fluorescein angiographic hallmarks of the condition are the presence of severe retinal capillary nonperfusion, capillary dilation, and microaneurysms, frequently combined with macular edema or ischemia.<sup>16</sup> Central macular chorioretinal anastomosis has also been described.<sup>39</sup> Neovascularization may develop later (Fig. 61.1), and does so in approximately 32% of eyes with RR.<sup>40</sup> This development is referred to as proliferative radiation retinopathy (PRR), and its presence is ominous. Analogous to proliferative diabetic retinopathy, it suggests profound ischemia and carries a worse prognosis for long-term visual acuity. If left untreated, it can lead to neovascular glaucoma, vitreous hemorrhage, and traction retinal detachment caused by fibrovascular proliferation similar to that seen in diabetic retinopathy. However, in contrast to diabetic retinopathy and other retinal vasculopathies, neovascularization does not typically extend through the internal limiting membrane into the vitreous.<sup>21</sup> Nevertheless, vitreous hemorrhage can occur, and its presence is associated with a poor prognosis for both vision and globe salvage, as well as for ghost cell or neovascular glaucoma. It also impedes the clinician's ability to monitor the retinopathy and to employ laser photocoagulation to treat progression (Table 61.1).

---

**TABLE 61.1****Findings in 87 Eyes With Radiation Retinopathy**

---

Complication	Incidence
Macular ischemia	76%
Clinically significant macular edema	76%
Nonproliferative radiation retinopathy	68%
Radiation optic neuropathy	55%
Cataract	52%
Proliferative radiation retinopathy	32%
Vitreous hemorrhage	24%
Glaucoma	12%
Radiation keratopathy	10%
Traction retinal detachment	5%

Adapted from Kinyoun JL. Long-term visual acuity results of treated and untreated radiation retinopathy (an AOS thesis). *Trans Am Ophthalmol Soc* 2008;106:325–35.

## Classification

There is currently no standard method of classification for RR, although several methods have been developed. These can be categorized as clinical/ophthalmoscopic; fluorescein angiographic; or OCT-based. Finger and Kurli proposed a four-stage, prognosis-related classification that uses ophthalmoscopic and fluorescein angiographic findings to classify macular and extramacular changes.<sup>41</sup> In this system, Stage 1 includes extramacular ischemic changes; Stage 2 includes macular ischemic changes; Stage 3 indicates (extra)macula ischemic changes and the presence of macular edema and retinal neovascularization; and Stage 4 encompasses vitreous hemorrhage and at least 5 disc areas of retinal ischemia, whether macular or extramacular.

FA allows the clinician to determine the condition of the macula, allowing maculopathy to be subdivided into ischemic and nonischemic variants, which is of significant prognostic importance. FA also allows for the classification of macular edema, which is useful if grid or focal laser photocoagulation is to be administered. The Early Treatment Diabetic Retinopathy Study (ETDRS) definition of clinically significant macular edema has been applied to macular edema associated with radiation damage. In these cases, it is referred to as clinically significant radiation macular edema,

which follows the ETDRS definitions: retinal thickening within 500 mm of the fovea; edema-associated hard exudates within 500 mm of the fovea; and one or more zones of retinal thickening  $\geq 1$  disc area, any part of which is within 1 disc diameter of the fovea.<sup>42</sup>

As in the management of diabetic retinopathy, OCT is indispensable. Macular edema is visible on OCT approximately 5 months earlier than clinically detectable radiation maculopathy.<sup>43</sup> Horgan et al. proposed a five-point OCT-based grading scale based on standard reference OCT images: Grade 1 is extrafoveal, noncystoid edema; Grade 2 is extrafoveal cystoid edema; Grade 3 is foveolar noncystoid edema; Grade 4 is mild-to-moderate foveolar cystoid edema; and Grade 5 is severe foveolar cystoid edema.<sup>43</sup> This study demonstrated OCT evidence of macular edema as early as 4 months after plaque radiotherapy for uveal melanoma, with a peak incidence at 12–18 months, and that it is associated with significant vision loss.

The introduction of OCT-angiography (OCT-A) has allowed visualization of vascular changes prior to their detection on OCT. A recent study suggests that OCT-A can benefit diagnosis and follow-up of patients with RR, allowing earlier detection and more precise management.<sup>44</sup>

The classification of RR into proliferative (PRR) and nonproliferative (NPRR) subtypes is also of great prognostic importance. A retrospective study using Kaplan–Meier analysis reported a PRR rate of 5.8% at 5 years and 7% at 10 and 15 years in 3841 eyes treated with plaque radiotherapy for uveal melanoma.<sup>45</sup>

## Risk Factors

Risk factors for the development of RR can be divided into internal (inherent/patient) and external (iatrogenic) factors. The primary patient factor is concomitant vascular disease such as diabetes mellitus.<sup>46</sup> Since both diabetes and radiation primarily damage the retinal capillaries, this synergistic effect is to be expected, as the capillaries experience an early loss of pericytes due to diabetes and endothelial cell loss due to radiation. Destruction of these two cell types leaves little cellular structural support for capillaries and thus results in capillary closure, aneurysms, vessel leakage, and

hemorrhage. Concomitant diabetes mellitus is also a poor prognostic indicator for visual acuity, increasing the risk of visual loss by nearly 300%.<sup>47</sup> This is in part due to the association of diabetes mellitus with an increased incidence and severity of neovascular complications, including neovascular glaucoma<sup>48</sup> and radiation papillopathy<sup>49</sup> following radiotherapy.<sup>50</sup> Other vascular disorders predisposing to RR are arterial hypertension and coronary artery disease.<sup>51</sup> Tumor characteristics likely to lead to a worse prognosis include large tumors and close proximity to the macula and optic disc.<sup>52</sup> Multivariate analysis of a large retrospective study indicates three primary risk factors for proliferative RR after plaque radiotherapy for uveal melanoma: young age, diabetes mellitus, and shorter tumor distance to the optic disc.<sup>53</sup>

Chemotherapy, whether or not concurrent/concomitant with the radiation therapy, also increases the risk of RR,<sup>16,54</sup> as may pregnancy.<sup>55</sup> Chemotherapy increases the vulnerability of the retinal vasculature to radiation damage, possibly via an increase in oxygen-derived free radicals.<sup>26</sup> It also increases the risk of PRR, which carries a worse prognosis than NPRR.<sup>56</sup> The concomitant administration of chemotherapy increases the risk of visual complications,<sup>16,26,54,57-59</sup> potentiates the development of RR at lower radiation doses,<sup>16</sup> and may shorten the latent period between exposure and retinopathy.<sup>54,58,60</sup>

## Incidence and Dosimetry

The most important external or iatrogenic risk factors relate to the radiation itself. These are radiation type, treatment modality (external beam vs. brachytherapy or plaque), total radiation dose and the fractionation schedule of that dosage, the total elapsed time in the course of irradiation treatment, and errors in treatment technique and/or dosage calculations.<sup>59,61,62</sup>

## Radiation Type

If a large enough dose is applied, any type of radiation can result in retinopathy and its associated complications. RR is found in 87% of

patients after plaque radiotherapy for juxtapapillary melanomas, and radiation maculopathy in 89% after proton beam irradiation. However, neither of these radiation types is as highly associated with severe sight-limiting complications (such as rubeosis and neovascular glaucoma) as gamma knife treatment, which may lead to complete loss of vision in nearly 50%.<sup>5</sup>

## Treatment Modality

An important factor to be considered is the surveillance of patients whose eyes are exposed to EBRT. In contrast to patients treated with retinal plaques for choroidal melanoma, who are periodically evaluated by retinal specialists and ocular oncologists, patients treated with EBRT are less likely to be regularly evaluated with dilated ophthalmoscopic examinations several years after treatment. Considering the progressive pathophysiology and latency of RR, early posttreatment checkups might be insufficient, and subsequent delays in ophthalmic diagnosis and treatment can result in long-term macular edema leading to ischemia, fibrosis, and irreversible vision loss.

## Total Radiation Dose

The association between dose and RR is well established.<sup>29</sup> However, a precise threshold has been difficult to determine. The condition does not usually occur at total doses <45 Gy unless an additional risk factor such as diabetes is present.<sup>62,63</sup> In a study of 68 eyes that underwent EBRT for primary extracranial head and neck tumors, the dose–response curve for retinopathy was characterized by a dramatic increase in incidence between 45 and 55 Gy.<sup>63</sup> Nearly all patients receiving higher doses developed retinopathy. A more recent retrospective review suggests that the incidence can be significantly reduced by hyperfractionated (twice-daily doses of 1.1–1.2 Gy) EBRT.<sup>62</sup> However, above 70 Gy, the overall incidence of retinopathy approaches 40%.

## Fractionation Schedule

During EBRT, increased fraction size correlates with an increased

incidence of retinal complications.<sup>16,26,59,64,65</sup> A dose per fraction below 1.9 Gy/fraction has been shown to decrease the incidence of retinopathy.<sup>63</sup> This is referred to as hyperfractionation, which theoretically allows the retina enough time to repair single-strand DNA breaks before a second nearby insult can occur.<sup>62</sup> This reduces late toxicity to the retina. However, for brachytherapy, which is primarily used for the treatment of choroidal melanoma, fractionation is not possible, since the radiation is delivered continuously at a predetermined dose for a certain period of time.

## Volume of Retina Irradiated

The volume of retina irradiated has also been shown to be a significant predictor of retinopathy. Eyes receiving more than 50 Gy to greater than 60% of the retina have been shown to be more likely to develop RR.<sup>29</sup>

## Total Elapsed Time

The latency between radiotherapy and the onset of clinically significant retinopathy can range from 1 month to 15 years, but it most commonly occurs between 6 months and 3 years. High-dose, single-fraction treatment regimens are associated with a more rapid onset.<sup>66</sup>

## Differential Diagnosis and Diagnostic Evaluation

RR can occur many years after radiation therapy. Because of this potential delay, RR may not be recognized as the cause of visual loss. Further, due to the ophthalmoscopic and angiographic similarities, RR may be misdiagnosed as diabetic or hypertensive retinopathy. However, a dilated ophthalmic examination combined with a careful history, including questioning of the patient and a thorough review of the treatment records to determine whether the eyes were included in the field of radiation, will usually lead to the diagnosis. The diagnosis should be considered following cephalic radiation for any reason, including treatment for orbital

inflammatory disease such as thyroid disease<sup>67</sup> and orbital pseudotumor,<sup>68</sup> sinus malignancies, and periorbital cutaneous lesions. Two features of RR that distinguish it from diabetic retinopathy is the atrophy of the RPE sometimes seen after radiation treatment and the possibility of unilateral disease.

Bone marrow transplant retinopathy can mimic RR, and it can be very difficult to distinguish the two unless affected patients have a history of exposure to one (e.g., radiation) and not the other (e.g., bone marrow transplantation).<sup>69</sup> Other potential causes of the observed retinal abnormalities include multiple branch retinal artery occlusions, multiple retinal venous occlusive episodes, or retinal telangiectasia from other causes. Severe anemia, leukemia, and human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) must be excluded before the diagnosis of RR can be definitively made.

Although the diagnosis can usually be made clinically, further evaluation should be considered. Fluorescein and indocyanine green angiography can be useful to define the extent of retinal ischemia and vascular anomalies.<sup>70,71</sup> If macular pathology is suspected, OCT should be carried out to determine the degree of macular edema, since macular thickness on OCT correlates with visual acuity for up to 2 years after plaque treatment.<sup>43</sup>

## Prevention and Treatment

There is no widely accepted treatment protocol for RR. Treatment has until now been based on its clinical, histopathologic, and angiographic similarities with diabetic retinopathy and retinal vein occlusion, diseases for which large randomized controlled studies have already been successfully conducted.<sup>24,72,73</sup>

Retinal laser photocoagulation of the ischemic retina has been shown to be beneficial in the prevention of retinal and iris neovascularization.<sup>74,75</sup> The rationale is that the destruction of oxygen-consuming photoreceptor cells and RPE decreases the intraocular VEGF concentrations, thereby inhibiting active retinal neovascularization.<sup>76</sup> However, the visual acuity results of laser treatment have been disappointing. Attempts to improve visual acuity results following plaque brachytherapy have included

prophylactic treatment with sector laser photocoagulation and/or sub-Tenon triamcinolone injection and/or repeated intravitreal anti-VEGF injections.<sup>77,78</sup> In other conditions with established RR, anti-VEGF injection is currently the gold standard treatment of the macular edema and ischemic complications.

Finger et al. reported the use of laser photocoagulation to obliterate the ischemic zone caused by ophthalmic plaque brachytherapy.<sup>41</sup> They observed regression of early-stage RR in 64% of treated eyes and found that only 18.75% of the “high-risk” patients who were treated prophylactically with sector scatter laser later developed RR. Laser photocoagulation has also been used for the treatment of macular edema secondary to RR. Although macular ischemia is currently not treatable, the frequently associated macular edema may respond to photocoagulation. Hykin et al. reported a visual acuity improvement of at least one line on the Snellen chart in 42% of affected eyes at 6 months, although the difference between treated patients and controls was not significant at 12 and 24 months.<sup>79</sup>

Corticosteroids have both angiostatic and vascular antipermeability properties that have been harnessed in the treatment of neovascular AMD, diabetic retinopathy, and macular edema due to various conditions.<sup>80</sup> Intravitreal triamcinolone has been reported to be of both visual and anatomic benefit in the treatment of both radiation maculopathy<sup>81,82</sup> and optic neuropathy.<sup>83</sup> However, when compared with intravitreal injection, periocular triamcinolone is associated with lower rates of steroid-induced glaucoma,<sup>84</sup> cataracts, retinal detachment,<sup>84</sup> and endophthalmitis.<sup>85–87</sup> More recently, the beneficial effects of intravitreal dexamethasone 0.7-mg implants have been demonstrated.<sup>88–90</sup>

During the past several years, the focus has shifted to anti-VEGF agents for the treatment of intraocular neovascularization and vascular permeability. Finger et al. first reported the efficacy of intravitreal bevacizumab therapy for the treatment of radiation maculopathy and optic neuropathy.<sup>91</sup> This led to the regression of retinal edema, hemorrhages, exudates, and neovascularization after ophthalmic plaque radiation therapy. Since this early report, many reports have been published, suggesting the crucial role of intravitreal injection of both bevacizumab<sup>92</sup> and ranibizumab,<sup>93</sup> in

the treatment of radiation maculopathy<sup>94</sup> and optic neuropathy<sup>95</sup> due to plaque brachytherapy<sup>96</sup> and EBRT.<sup>97</sup> High-dose (2.0 mg) ranibizumab has also been successfully used in patients who were failing standard dose (0.5 mg) anti-VEGF therapy.<sup>98</sup> Anti-VEGF agents have also been used to treat the secondary complications of RR, namely neovascular glaucoma and exudative retinal detachment.<sup>99</sup> Whether it is most effective to administer anti-VEGF agents prophylactically or only upon development of pathology has not yet been conclusively determined. However, a small study by Gupta et al. suggested that patients with shorter duration of macular edema benefited more than those with long-standing retinal disease.<sup>94</sup> Further, the optimal administration schedule has not yet been determined.

Of course, prevention would be ideal. Reduced risk of human error in dosage calculations, improved shielding techniques, and increased surveillance of patients at risk for developing RR are desirable goals. Further, patients should be thoroughly informed of the possible consequences of radiation therapy, particularly in cases in which the treatment is being administered for nonlethal pathology such as Graves orbitopathy.

## Prognosis

The visual prognosis is largely dependent on the extent and location of capillary nonperfusion<sup>100</sup> as well as the presence of neovascularization. If the perifoveal capillary net is involved, the prognosis for central vision is grave, due to either retinal atrophy or persistent macular edema, as well as from neovascularization, which occurs at the interface of perfused and nonperfused retina, as well as on the optic nerve head. PRR, present in approximately one-third of eyes with RR, is likely to carry an inferior long-term visual prognosis (mean visual acuity 20/440) than the nonproliferative type (mean visual acuity 20/100), although this retrospective study had a very different follow-up duration for PRR (109 months) and NPRR (27 months).<sup>101</sup> The same study reported macular edema to be more common in PRR (85.7%) than in NPRR (71.2%). Shields et al. found predictors of poor visual acuity at long-term follow-up following plaque radiotherapy included patient age  $\geq 60$  years,

tumor base  $\geq 10$  mm, tumor thickness  $> 8$  mm, radiation dose to the tumor base of  $\geq 33, 300$  cGy, and increasing radiation dose to the optic disc.<sup>102</sup> Tumor location is also of great importance, with tumors located posterior to the equator at increased risk for radiation maculopathy and loss of central vision.<sup>103</sup>

## Conclusion

There are two quite distinct situations that should be considered by ophthalmologists treating patients at risk for RR. In the first situation, patients will have been treated with plaque brachytherapy. They may develop capillary nonperfusion in the retinal sector containing the plaque, as well as exudative lesions that can threaten the macula. Patients must thus be followed up closely and potentially treated prophylactically with sector laser if indicated. In these cases, the patients will likely be closely followed and the developing RR will be identified and managed shortly thereafter.

The second situation involves patients who will have been treated by nonophthalmologists for extraocular tumors with techniques besides brachytherapy. These patients are at great risk for remaining undiagnosed or diagnosed late because they are less likely to have been followed as closely as patients treated for intraocular disease. A nonophthalmologist is likely to take action only when the patient complains of visual loss, which often means that the retinopathy has progressed to an advanced stage. Moreover, many patients will only develop retinopathy years after the radiation therapy, long after they have been discharged from the care of the physician who administered the radiation. Indeed, an ophthalmologist may not be consulted until vision loss has been detected by patients.

The ophthalmologist must consider this diagnosis when confronted with a patient with retinovascular disease with cotton-wool spots, microaneurysms, exudative changes, and capillary dropout that looks like more common conditions, particularly diabetic retinopathy, but with a medical history that includes radiation therapy which may have damaged the posterior segment of the eye.

Direct Ocular Therapeutic Modalities

In 1963, Kearns and Hollenhorst<sup>1</sup> reported on the ocular symptoms and signs occurring secondary to severe carotid artery obstructive disease. They called the entity “venous stasis retinopathy” and noted that it occurred in approximately 5% of patients with severe carotid artery insufficiency or thrombosis. Some confusion has since arisen with this term because it has also been used to designate mild central retinal venous occlusion.<sup>2</sup> A number of additional alternative names have been proposed, including ischemic ocular inflammation,<sup>3</sup> ischemic oculopathy,<sup>4</sup> and the ocular ischemic syndrome.<sup>5,6</sup> Histopathologic examination of eyes with the entity generally does not reveal inflammation,<sup>7,8</sup> and therefore the descriptive term the present authors and Dr. Larry Magargal originated was the ocular ischemic syndrome.<sup>5,6</sup>

## **Demographics and Incidence**

The mean age of patients with the ocular ischemic syndrome (OIS) is about 65 years, with a range generally from the fifties to the eighties. No racial predilection has been identified, and males are affected more than females by a ratio of about 2 : 1. Either eye can

be affected, and in approximately 20% of patients, ocular involvement is bilateral.<sup>5</sup> The incidence of the disease has not been extensively studied, but from the work of Sturrock and Mueller<sup>9</sup> an annual estimate of 7.5 cases/million persons can be made. This number may be falsely low, since it is possible that a number of cases are misdiagnosed.

## Etiology

In general, a 90% or greater stenosis of the ipsilateral carotid arterial system is present in eyes with the OIS.<sup>5</sup> It has been shown that a 90% carotid stenosis reduces the ipsilateral central retinal artery perfusion pressure by about 50%.<sup>10,11</sup> The obstruction can occur within the common carotid or internal carotid artery. In about 50% of cases, the affected vessel is 100% occluded, while in 10% there is bilateral 100% carotid artery obstruction in association with collateral vessels.<sup>5</sup> Atherosclerotic obstructions are more common at arterial bifurcations.

Occasionally, obstruction of the ipsilateral ophthalmic artery can also be responsible.<sup>5,12,13</sup> Rarely, an isolated obstruction of the central retinal artery alone can mimic the dilated (but not tortuous) retinal veins and retinal hemorrhages seen in eyes with the OIS.<sup>14</sup>

Atherosclerosis within the carotid artery is the cause of the great majority of cases of the OIS.<sup>5</sup> Dissecting aneurysm of the carotid artery has been reported as a cause,<sup>15</sup> as has giant cell arteritis,<sup>16</sup> radiation damage,<sup>17</sup> Moyamoya syndrome,<sup>18</sup> melanoma of the optic disc,<sup>19</sup> and Takayasu arteritis.<sup>20</sup> Hypothetically, entities such as fibromuscular dysplasia,<sup>21</sup> Behçet disease,<sup>22</sup> trauma,<sup>23</sup> and other inflammatory entities that cause carotid artery obstruction could lead to the OIS. Increased levels of homocysteine and C-reactive protein have been associated with the OIS.<sup>24</sup>

## Symptoms

### Visual Loss

Greater than 90% of patients with the OIS relate a history of visual loss in the affected eye(s).<sup>5</sup> In two-thirds of cases, it occurs over a

period of weeks, but it is abrupt in approximately 12%. In this latter group, with sudden visual loss, there is often a cherry-red spot present on funduscopic examination (Fig. 62.1).

**FIG. 62.1** Cherry-red spot in the left eye of a 66-year-old man with rubeosis iridis, a 100% ipsilateral common carotid artery obstruction, and a history of rapid visual loss.

## Prolonged Light Recovery

Prolonged recovery following exposure to a bright light has been described in patients with severe carotid artery obstruction.<sup>25</sup>

Concurrent attenuation of the visual evoked response has also been observed in these cases after light exposure. The phenomenon has been attributed to ischemia of the macular retina. In cases of bilateral, severe carotid artery obstruction, the visual loss after exposure to bright light occurs in both eyes, mimicking occipital lobe ischemia due to vertebrobasilar disease.<sup>26</sup>

## Scintillating Scotomas

Dissection of the internal carotid artery has been reported to cause scintillating scotomas that resemble a migraine aura.<sup>27</sup> While these could theoretically be associated with the classic OIS, they have not been observed by the authors. Pulsating lights can be seen, however, in association with vertebrobasilar insufficiency.<sup>28</sup> In this latter instance, vertigo, syncope, and/or headache are often present. Photopsias secondary to the OIS are unusual.<sup>28</sup>

## Amaurosis Fugax

A history of amaurosis fugax is elicited in about 10–15% of OIS patients.<sup>5,29</sup> Amaurosis fugax, or fleeting loss of vision for seconds to minutes, is thought to most commonly be caused by emboli to the central retinal arterial system, although vasospasm may also play a role.<sup>30</sup> Although the majority of people with amaurosis fugax alone do not have the OIS, it can be an indicator of concomitant, ipsilateral carotid artery obstructive disease. About one-third of patients with amaurosis fugax have an ipsilateral carotid artery obstruction of 75% or greater.<sup>31</sup> Rarely, it has been associated with a stenosis of the ophthalmic artery.<sup>31</sup>

## Pain

Pain is present in the affected eye or orbital region in about 40% of cases,<sup>5</sup> and we refer to it as “ocular angina.” Most often, it is described as a dull ache. It can occur secondary to neovascular glaucoma, but in those cases in which the intraocular pressure is normal, the cause may be ischemia to the globe and/or ipsilateral dura.

## Signs

### Visual Acuity

The presenting visual acuities of patients with the OIS are bimodally distributed, with 43% of affected eyes having vision ranging from 20/20 to 20/50, and 37% having counting fingers or

worse vision.<sup>32</sup> Absence of light perception is generally not seen early but can develop in the later stages of the disease, usually secondary to neovascular glaucoma. Among all eyes with the OIS after one year of follow-up, including those with and without treatment, approximately 24% remain in the 20/20–20/50 group and 58% have counting fingers vision or worse. The visual prognosis is often poor unless carotid surgical intervention can be undertaken,<sup>33–35</sup> although we have seen one case of spontaneous resolution.

## External Collaterals

Prominent collateral vessels are occasionally seen on the forehead (Fig. 62.2). These vessels connect the external carotid system on one side of the head to that on the other. These vascular collaterals should not be mistaken for the enlarged tender vessels seen with giant cell arteritis, since temporal artery biopsy may shut down this important source of collateral blood flow to the brain.

**FIG. 62.2** Prominent collateral arteries from the right external carotid arterial system to the left external arterial system in a patient with a 100% common left carotid artery stenosis.

## Anterior Segment Changes

Neovascularization of the iris is encountered in approximately two-thirds of eyes with the OIS at the time of presentation<sup>5</sup> (Fig. 62.3). Nevertheless, only slightly over half of these eyes have or develop an increase in intraocular pressure, even if the anterior chamber angle is closed by fibrovascular tissue. Impaired ciliary body perfusion, with a subsequent decrease in aqueous production, likely accounts for this phenomenon.

**FIG. 62.3** Gonioscopy of neovascularization of the iris and angle in an eye with the ocular ischemic syndrome. A red arc of fibrovascular tissue is present, closing the anterior chamber angle.

Flare in the anterior chamber is usually present in eyes with rubeosis iridis (iris neovascularization). An anterior chamber cellular response is seen in almost one-fifth of eyes with the OIS,<sup>5</sup> but it rarely exceeds grade 2<sup>+</sup>, on a 0 to 4<sup>+</sup> range, as per the Schlaegel classification.<sup>36</sup> Keratic precipitates can be present but are typically small.

In unilateral cases, there is generally little difference between the degree of lens opacification in each eye. As the disease advances, however, cataractous lens changes can develop. In advanced cases, the lens may become mature.

## Posterior Segment Findings

The retinal arteries are usually narrowed, and the retinal veins are most often dilated, but not tortuous (Fig. 62.4). The venous dilation may be accompanied by beading, but usually not to the extent seen in eyes with marked preproliferative or proliferative diabetic retinopathy. Dilation of the veins is probably a nonspecific response to the ischemia from the inflow obstruction. Nevertheless, in some eyes both the retinal arteries and veins are narrowed. In contrast, eyes with central retinal vein obstruction usually also have dilated retinal veins, but they are typically tortuous.<sup>5</sup> The fact that the OIS occurs secondary to impaired inflow, while central retinal vein obstruction is usually associated with compromised outflow resulting from thrombus formation at or near the lamina cribrosa,<sup>37</sup> probably accounts for this difference.

**FIG. 62.4** (A) Narrowed, beaded retinal arteries and dilated, beaded, but not tortuous, retinal veins in an ocular ischemic syndrome eye. (B) Focal narrowing of the retinal arteries (*arrows*) in the right eye of a 55-year-old man with ocular ischemic syndrome and bilateral internal carotid artery obstructions. (Panel B

reproduced with permission from Brown GC, Magargal LE. The ocular ischemic syndrome. Clinical, fluorescein angiographic and carotid angiographic features. *Int Ophthalmol* 1988;11:239–51.)

Retinal hemorrhages are seen in about 80% of affected eyes. They are most commonly present in the midperiphery but can also extend into the posterior pole (Figs. 62.5 and 62.6 online). While

dot and blot hemorrhages are the most common variant, superficial retinal hemorrhages in the nerve fiber layer are occasionally seen. The hemorrhages probably arise secondary to leakage from the smaller retinal vessels, which have sustained endothelial damage as a result of the ischemia. Similar to the case with diabetic retinopathy, they may also result from the rupture of microaneurysms. In general, the hemorrhages seen with the OIS are less numerous than those accompanying central retinal vein obstruction. They are almost never confluent.

**FIG. 62.5** (A) Round retinal hemorrhages in the midperiphery of an eye with the ocular ischemic syndrome. (B) Histopathologic correlate of a retinal hemorrhage in an ocular ischemic syndrome eye demonstrates blood throughout the retina (hematoxylin and eosin,  $\times 60$ ). (C) Wide-angle photograph demonstrating retinal hemorrhages in the midperiphery in an eye with the ocular ischemic syndrome. (Panel B,

photograph courtesy of Dr. W. Richard Green.)

**FIG. 62.6** Right fundus of a 35-year-old man with a cherry-red spot, rubeosis iridis, and retinal hemorrhages in the macula. A 95% right internal carotid artery obstruction was present.

Microaneurysms are frequently observed outside the posterior pole, but can be seen in the macular region also. Hyperfluorescence with fluorescein angiography (Fig. 62.7) differentiates these abnormalities from hypofluorescent retinal hemorrhages. Retinal telangiectasia has also been described.<sup>38</sup>

**FIG. 62.7** (A) Ocular ischemic syndrome eye: fluorescein angiogram demonstrating numerous hyperfluorescent microaneurysms in the midperipheral retina. (B) Histopathologic correlation of a microaneurysm in an eye with the ocular ischemic syndrome discloses that the anomaly traverses the entire retina (periodic-acid Schiff,  $\times 60$ ). (Panel A reproduced with permission from Brown GC, Magargal LE. The ocular ischemic syndrome. Clinical, fluorescein angiographic and carotid angiographic features. *Int Ophthalmol* 1988;11:239–51. Panel B courtesy of Dr. W. Richard Green.)

Posterior segment neovascularization can occur at the optic disc or on the retina. Neovascularization of the disc (Fig. 62.8) is encountered in about 35% of eyes, while neovascularization of the retina is seen in about 8%.<sup>5</sup> Vitreous hemorrhage arising from traction upon the neovascularization by the vitreous gel has been reported to occur in 4% of eyes with the OIS in a retrospective study.<sup>5</sup> Rarely, the neovascularization can progress to severe preretinal fibrovascular proliferation (Fig. 62.9 online). Neovascularization of the retina (Fig. 62.10 online) is encountered in 8% of eyes with ocular ischemia. It is usually present concomitant with neovascularization of the disc.

**FIG. 62.8** (A) Neovascularization of the disc in an eye with the ocular ischemic syndrome. (B) Fluorescein angiogram of the eye in panel (A) reveals marked hyperfluorescence resulting from leakage of dye from new vessels. (Reproduced with permission from Brown GC, Magargal LE, Simeone FA, et al. Arterial obstruction and ocular neovascularization. *Ophthalmology* 1982;89:139–46. Copyright © 1982 American Academy of Ophthalmology.)

**FIG. 62.9** (A) Fibrovascular proliferation overlying the optic disc and causing retinal traction in an eye with the ocular ischemic syndrome. (B) Histopathology of an eye with ischemic retinopathy demonstrates a connection of neovascularization of the optic disc on

stretch (*arrow*) between the inferior disc and the superior vitreous gel filled with blood. Presumably, the intravitreal blood occurred as a result of rupture of the thin-walled vessels on stretch (hematoxylin and eosin,  $\times 60$ ). (Panel A reproduced with permission from Brown GC, Magargal LE. The ocular ischemic syndrome. Clinical, fluorescein angiographic and carotid angiographic features. *Int Ophthalmol* 1988;11:239–51.)

**FIG. 62.10** Neovascularization of the retina (*arrows*) with fluorescein angiography in a nondiabetic person affected by the ocular ischemic syndrome. Retinal capillary nonperfusion (*NP*) can be seen. (Reproduced with permission from Brown GC, Magargal LE, Simeone FA, et al. Arterial obstruction and ocular neovascularization. *Ophthalmology* 1982;89:139–46. Copyright © 1982 American Academy of Ophthalmology.)

A cherry-red spot is seen in approximately 12% of eyes with the OIS (see [Fig. 62.1](#)).<sup>5</sup> It can occur secondary to inner layer retinal ischemia from embolic obstruction of the central retinal artery, but may also develop when the intraocular pressure exceeds the perfusion pressure within the central retinal artery, particularly in

eyes with neovascular glaucoma.

Additional posterior segment signs<sup>5</sup> include cotton-wool spots (Fig. 62.11 online) in 6% of eyes, spontaneous retinal arterial pulsations in 4% (Fig. 62.12), and cholesterol emboli within the retinal arteries in 2%. In contrast to spontaneous retinal venous pulsations, which are a normal variant and located at the base of the large veins on the optic disc, the arterial pulsations are usually more pronounced and may extend a disc diameter or more out from the optic disc into the surrounding retina. Anterior ischemic optic neuropathy (Fig. 62.13) has also been reported in OIS eyes.<sup>39,40</sup> Acquired arteriovenous communications of the retina have been reported.<sup>41</sup>

**FIG. 62.12** Photographs taken several seconds apart in a fundus affected by the ocular ischemic syndrome. Closure of the retinal arteries can be seen on the right. **FIG. 62.11** Cotton-wool spots in the fundus of a man

with the ocular ischemic syndrome. Irregularly dilated retinal veins are also evident.

A list of the symptoms and anterior and posterior segment signs found with the ocular ischemic syndrome is shown in [Table 62.1](#).<sup>1-5,9</sup>

**TABLE 62.1**

**Symptoms and Anterior and Posterior Segment Signs Seen in Eyes With the Ocular Ischemic Syndrome**

	Prevalence
<b>OIS SYMPTOMS</b>	
Vision loss, typically gradual	90%
Periorbital pain (ocular angina)	49%
Amaurosis fugax	10–15%
Prolonged light recovery	Uncertain
<b>ANTERIOR SEGMENT SIGNS</b>	
Rubeosis iridis	67%
Neovascular glaucoma	35%
Uveitis (cells and flare)	18%
<b>POSTERIOR SEGMENT SIGNS</b>	
Narrowed retinal arteries	Most
Dilated retinal veins	Most
Retinal hemorrhages	80%
Neovascularization	37%
Optic disc	35%
Retina	8%
Cherry-red spot	12%
Cotton-wool spot(s)	6%
Spontaneous retinal arterial pulsations	4%
Vitreous hemorrhage	4%
Cholesterol emboli	2%
Ischemic optic neuropathy	2%

## Ancillary Studies

### Fluorescein Angiography

The intravenous fluorescein angiographic signs<sup>5</sup> associated with the ocular ischemic syndrome are listed in [Table 62.2](#).

---

**TABLE 62.2****Fluorescein Angiographic Signs Seen in Eyes With the Ocular Ischemic Syndrome**

---

Sign	Prevalence
Delayed and/or patchy choroidal filling	60% <sup>5</sup>
Prolonged retinal arteriovenous transit time	95% <sup>5</sup>
Retinal vascular staining	85% <sup>5</sup>
Macular edema	17% <sup>42</sup>
Other signs	
Retinal capillary nonperfusion	Common
Optic nerve head hyperfluorescence	If macular edema present
Microaneurysmal hyperfluorescence	Most cases

Delayed arm-to-choroid and arm-to-retina circulation times are frequently observed in the OIS. However, these measurements may be difficult to assess, since they depend upon whether the dye was injected in the antecubital fossa or hand, and also on the rate of injection. The observation of a well-demarcated, leading edge of fluorescein dye within a retinal artery after an intravenous injection is a distinctly unusual finding. It can be seen in eyes with the OIS, secondary to hypoperfusion (Fig. 62.14).

**FIG. 62.14** Fluorescein angiogram of an eye with the

ocular ischemic syndrome at 38 seconds after injection. A leading edge of the dye (*arrow*) is present within a retinal artery. (Reproduced with permission from Brown GC, Magargal LE, Simeone FA, et al. Arterial obstruction and ocular neovascularization. *Ophthalmology* 1982;89:139–46. Copyright © 1982 American Academy of Ophthalmology.)

Normally, the choroidal filling is completed within 5 seconds after the first appearance of dye. Sixty percent of eyes with the OIS demonstrate patchy and/or delayed choroidal filling (Fig. 62.15).<sup>5</sup> In some instances, the filling is delayed for a minute or longer. Although not the most sensitive sign, an abnormality in choroidal filling is the most specific fluorescein angiographic sign in ocular ischemic eyes.

**FIG. 62.15** (A) Fluorescein angiogram of an ocular ischemic syndrome eye at 44 seconds after injection shows patchy choroidal filling. A leading edge of dye (*arrow*) can again be seen within a retinal artery. (B) Histopathology of an ocular ischemic syndrome retina reveals a paucity of retinal ganglion cells, as well as cells in both the inner nuclear and outer nuclear layers, the latter the cell bodies for the rods and cones. These features occur secondary to panretinal ischemia from both retinal and choroidal hypoperfusion. The retinal pigment epithelial cells appear to be intact, correlating with the clinical picture that retinal pigment epithelial dropout and hyperplasia do not appear to be prominent

fundusoscopic features associated with the ocular ischemic syndrome (hematoxylin and eosin, ×60). (Panel A reproduced with permission from Brown GC, Magargal LE. The ocular ischemic syndrome. Clinical, fluorescein angiographic and carotid angiographic features. *Int Ophthalmol* 1988;11:239–51. Panel B courtesy of Dr. W. Richard Green.)

Prolongation of the retinal arteriovenous transit time is seen in 95% of eyes with the OIS (high sensitivity) but can also be seen in eyes with central retinal artery obstruction and central retinal vein obstruction (low specificity).<sup>5</sup> Normally, the major retinal veins in the temporal vascular arcade are completely filled within 10–11 seconds after the first appearance of dye within the corresponding retinal arteries. In extreme cases of the OIS, the retinal veins fail to fill throughout the study. Staining of the retinal vessels in the later phases of the study is seen in approximately 85% of eyes (Figs. 62.16 online and 62.17).<sup>5</sup> Both larger and smaller vessels can be involved, the arteries generally more so than the veins. Chronic hypoxic damage to endothelial cells may account for the staining. In contrast, staining of the retinal vessels is uncommon, with central retinal artery obstruction alone. With central retinal vein obstruction, the veins can demonstrate late staining, but the retinal arteries are generally not affected.

**FIG. 62.17** Prominent staining of the retinal arteries in the later phases of fluorescein angiography in an eye with the ocular ischemic syndrome.

**FIG. 62.16** Staining of the macular vessels in the ocular ischemic syndrome. (Reproduced with permission from Brown GC, Magargal LE. The ocular ischemic syndrome. Clinical, fluorescein angiographic and carotid angiographic features. *Int Ophthalmol* 1988;11:239–51.)

Macular leakage and edema evident on fluorescein angiography is seen in about one-sixth of eyes with the OIS<sup>42</sup> (Fig. 62.18). Hypoxia, and subsequent endothelial damage, within the smaller retinal vessels, as well as leakage from microaneurysms, may account for this phenomenon (Fig. 62.19). Dye accumulation may be mild or severe, and is usually associated with hyperfluorescence of the optic disc. The disc, however, is typically not swollen. Despite the prominent leakage with fluorescein angiography, the ophthalmoscopic cystic changes of macular edema are generally not as pronounced as those seen after ocular surgery or those associated with diabetic retinopathy.

**FIG. 62.18** (A) Left fundus of a 60-year-old woman with a 100% left internal carotid artery obstruction. The retinal veins are dilated, but not tortuous. (B) Fluorescein angiogram of the eye in panel (A) at more than 60 seconds after injection. A number of microaneurysms are present, and the optic disc is hyperfluorescent. (C) At several minutes after injection, prominent leakage of dye is evident. (Reproduced with permission from Brown GC. Macular edema in association with severe carotid artery obstruction. *Am J Ophthalmol* 1986;102:442; American Journal of Ophthalmology. Copyright © Ophthalmic Publishing Group.)

**FIG. 62.19** Peripheral fluorescein angiogram of the same eye shown in [Fig. 62.18](#). Many hyperfluorescent microaneurysms are seen, as is staining of the retinal vessels. (Reproduced with permission from Brown GC. Macular edema in association with severe carotid artery obstruction. *Am J Ophthalmol* 1986;102:442; American Journal of Ophthalmology. Copyright © Ophthalmic Publishing Group.)

Retinal capillary nonperfusion can be seen in some eyes ([Fig. 62.20](#) [online](#)). The histopathologically observed absence of endothelial cells and pericytes within the retinal capillaries most likely corresponds to the areas of nonperfusion seen with fluorescein angiography.<sup>7,8,43</sup>

**FIG. 62.20** (A) Fluorescein angiography reveals retinal capillary nonperfusion (NP) in an ocular ischemic syndrome eye. (B) Trypsin digest of the retinal vessels of an ocular ischemic syndrome eye reveals loss of both the endothelial cells and pericytes (hematoxylin and eosin,  $\times 200$ ). (Panel A reproduced with permission from Brown GC, Magargal LE. The ocular ischemic syndrome. Clinical, fluorescein angiographic and carotid angiographic features. *Int Ophthalmol.* 1988;11:239–51. Panel B courtesy of Dr. W. Richard Green.)

Bilateral, simultaneous, intravenous fluorescein angiography is a technique that has been reported to be helpful diagnostically in patients with a unilateral OIS.<sup>44</sup> However, the technique requires specialized equipment and is not generally available.

## Electroretinography

The electroretinogram typically discloses a diminution of the amplitude, or absence, of both the a- and b-waves in eyes with the OIS<sup>5,6</sup> (Fig. 62.21). The b-wave corresponds to activity of the Müller and/or bipolar cells, and therefore to inner layer retinal function, while the a-wave correlates with activity of the photoreceptors in the outer retina.<sup>45–47</sup> Therefore, with central retinal artery obstruction, in which there is essentially inner layer retinal ischemia, the b-wave amplitude is characteristically decreased. With the OIS there is both retinal vascular and choroidal compromise, leading to ischemia of the inner and outer retina, respectively. Thus, both the b-wave and a-waves are affected.

**FIG. 62.21** Electoretinogram from a 62-year-old woman with ocular ischemic syndrome and a severe left carotid artery stenosis. The tracing of the right eye (OD) is seen above, and that of the left eye (OS) is seen below. (A) The a- and the b-waves are markedly diminished in the left eye before endarterectomy. (B) After left endarterectomy the amplitudes of the a- and b-waves have increased in the left eye. The vision correspondingly improved from counting fingers to 20/70.

Reduction in the amplitude of the oscillatory potential of the b-wave has been noted in eyes with retinal ischemia secondary to carotid artery stenosis.<sup>47</sup> This can be seen in patients with proven carotid artery disease, even in the presence of a normal fluorescein angiogram.

## Carotid Artery Imaging

Carotid angiography typically discloses a 90% or greater obstruction of the ipsilateral internal or common carotid artery in persons with the OIS (Fig. 62.22).<sup>5</sup> Noninvasive tests, such as duplex ultrasonography and oculoplethysmography, have an accuracy of approximately between 88 and 95% in detecting carotid stenosis of 75% or greater.<sup>48-50</sup> Nonetheless, magnetic resonance angiography and imaging (MRA/MRI) are the gold standard in this arena, especially since MRI/MRA identifies the degree of occlusion, as well as intraplaque hemorrhage, plaque ulceration, plaque neovascularization, fibrous cap thickness, and a lipid-rich necrotic core. These factors seem to play a role in risk stratification in regard to plaque enlargement and rupture.<sup>51</sup> Computerized tomography angiography and imaging can very effectively delineate plaque and

the degree of obstruction, but is not as effective as magnetic imaging techniques for identifying plaque composition. Identification of plaque composition and prognosis is an area of great interest at this time.

**FIG. 62.22** Carotid angiography in a patient with bilateral ocular ischemic syndrome. (A) A marked stenosis is visible within the right internal carotid artery (*RIC*), as well as in the right external carotid artery (*REC*). (B) A 100% obstruction of the left common carotid artery (*LCC*) is present. (Reproduced with permission from Brown GC, Magargal LE. The ocular ischemic syndrome. Clinical, fluorescein angiographic and carotid angiographic features. *Int Ophthalmol* 1988;11:239–51.)

## Others

Visual evoked potentials have been used to study eyes with severe carotid artery stenosis. The recovery time of the amplitude of the major positive peak after photostress has been shown to improve in patients with severe stenosis after endarterectomy.<sup>52</sup>

Ophthalmodynamometry can be of benefit in detecting decreased ocular perfusion in cases of unilateral OIS.<sup>10,53</sup> In the absence of an ophthalmodynamometer, Kearns<sup>53</sup> has advocated light digital pressure on the upper lid of the affected eye during ophthalmoscopy. Retinal arterial pulsations can usually be readily induced in eyes with the OIS. This is generally not the case in eyes with central retinal vein obstruction, an entity that can be confused with the OIS.

Optical coherence tomography (OCT) has shown decreased thickness of the choroid in OIS eyes.<sup>54</sup> It is possible that future studies utilizing OCT angiography may disclose additional abnormalities in the setting of OIS.

## Systemic Associations

Diseases associated in one way or another with atherosclerosis are frequently seen in conjunction with the OIS. Systemic arterial hypertension has been reported in 73% of OIS patients, and concomitant diabetes mellitus has been observed in 56%.<sup>55</sup> In an age-matched historical control population from the Framingham Study,<sup>56</sup> the corresponding prevalences for systemic arterial hypertension and diabetes mellitus were 26% and 6%.

At the time of presentation, almost one-fifth of patients relate a history of having peripheral vascular disease for which previous bypass surgery was required.<sup>55</sup> The stroke rate for patients for people with the OIS is approximately 4% per year.<sup>55</sup>

A rare but serious cause of OIS is giant cell arteritis.<sup>57</sup> This condition has been reported to cause bilateral loss of vision, which may occur despite treatment with steroids.<sup>58</sup>

Mortality data<sup>55</sup> have shown that the 5-year death rate for patients with the OIS is 40%. The leading cause of death is cardiovascular disease, which accounts for about two-thirds of

cases. Stroke is the second leading cause of death. Thus, most patients with the OIS should be considered for cardiac evaluation, in addition to a carotid artery workup. It is also important to note that Mizener et al.<sup>59</sup> noted that in 69% of their patients, the OIS was the first clinical manifestation of carotid occlusive disease, a fact that only further underscores the importance of timely systemic evaluation in these patients.

## Differential Diagnosis

The entities that are most commonly confused with the ocular ischemic syndrome include mild central retinal vein obstruction and diabetic retinopathy. Features that differentiate these abnormalities are listed in Table 62.3. In contrast to the OIS, the veins in eyes with mild, or nonischemic, central retinal vein obstruction are often dilated and tortuous. Additionally, it is difficult with light digital pressure on the lid to induce retinal arterial pulsations in eyes with central retinal vein obstruction. Not so with the OIS. While both entities usually have a prolonged retinal arteriovenous transit time, choroidal filling defects and prominent retinal arterial staining are usually absent on fluorescein angiography in eyes with central retinal vein obstruction.

**TABLE 62.3**

**Features That Differentiate the Ocular Ischemic Syndrome, Central Retinal Vein Obstruction, and Diabetic Retinopathy**

Clinical Features	OIS	CRVO	Diabetic Retinopathy
Laterality	80% unilateral	Usually unilateral	Bilateral
Age	50s–80s	50s–80s	Variable
Fundus signs			
Venous status	Dilated (not tortuous), beaded	Dilated and tortuous	Dilated and beaded
Hemorrhages	Peripheral, dot, and blot	Nerve fiber layer, posterior pole	Posterior pole, dot, and blot
Microaneurysms	In midperiphery	Variable	Present in posterior pole
Exudate	Absent	Rare	Common
Optic disc	Normal	Swollen	Affected in papillopathy
Retinal arterial perfusion pressure	Decreased	Normal	Normal

Fluorescein angiography			
Choroidal filling	Delayed, patchy	Normal	Normal
Arteriovenous transit time	Prolonged	Prolonged	May be prolonged
Late retinal vessel staining	Arterial	Venous	Usually absent

CRVO, central retinal vein obstruction; OIS, ocular ischemic syndrome.

Diabetic retinopathy can exist concomitantly with the OIS. The presence of hard exudate in the posterior pole usually suggests diabetic retinopathy, rather than the OIS.<sup>5</sup> As is the case with central retinal vein obstruction, choroidal filling defects and retinal arterial staining are generally absent on fluorescein angiography in eyes with diabetic retinopathy.

In some cases of diabetic retinopathy, the OIS can exacerbate the proliferative changes. It has not been definitively proven that carotid stenosis is protective against the development of proliferative diabetic retinopathy.<sup>60</sup>

## Treatment

With regard to vision, the natural course of the ocular ischemic syndrome is uncertain. Nonetheless, most eyes with the fully developed entity probably have a poor long-term outcome. When iris neovascularization is present, well over 90% of eyes become legally blind within a year of discovery.<sup>32</sup>

## Total Carotid Artery Obstruction

When a carotid artery is 100% obstructed, endarterectomy is usually ineffective since a thrombus often propagates distally to the next major vessel. In these cases, extracranial to intracranial bypass surgery, usually from the superficial temporal artery to the middle cerebral artery, has been attempted to alleviate the obstruction.

Although reports suggest that this procedure can be of benefit initially in salvaging vision in eyes with the OIS,<sup>61-66</sup> we found the visual prognosis at one year after the surgery to be universally poor, despite the fact that 20% of patients had visual improvement within the first 3 months of surgery.<sup>32</sup> Additionally, the procedure has not been shown in a large randomized study to be of benefit in

preventing the risk of ischemic stroke.<sup>67</sup>

That said, some authors have offered objective support of improvement in perfusion following endarterectomy. Costa et al.<sup>68</sup> were able to demonstrate increased mean peak systolic flow velocities and end diastolic velocities in the orbital vessels following surgery, with a significant reduction of the mean resistance indices in the central retinal and posterior ciliary arteries.<sup>7</sup>

Kawaguchi et al.<sup>69</sup> evaluated the effects of superficial temporal to middle cerebral artery (STA–MCA) bypass in a series of patients with the OIS. These authors compared a number of clinical parameters including carotid Doppler flow imaging in 32 patients who received STA–MCA as compared to nine patients with OIS who did not have STA–MCA. Prior to surgery all 32 patients had reversal of flow in their ophthalmic arteries. The mean peak systolic flow improved to 0.15 m/s at 3 months as compared to –0.26 at baseline. In addition, whereas all patients had reversal of flow in the ophthalmic artery preoperatively, 56% developed antegrade flow at the 3-month period. In the final analysis, 47% had visual improvement following surgery.

## Less-Than-Total Carotid Artery Obstruction

Although there are no randomized studies that compare the natural history of the disease to the course after carotid endarterectomy, this surgery may also stabilize or improve vision in the eyes of patients who undergo successful endarterectomy prior to the development of iris neovascularization.<sup>32,70</sup> Notwithstanding, the visual results associated with this treatment are fair at best. In the series of Sivalingam et al.,<sup>32</sup> at the end of one year 7% of eyes with the OIS that underwent endarterectomy had visual improvement, 33% were unchanged, and 60% had worse vision. Among the 60 total OIS eyes in the group, an endarterectomy was performed for only three without iris neovascularization. At the end of one-year follow-up the vision was better in one, stable in one, and worse in the third. Endarterectomy appears to rarely cause regression of iris neovascularization in eyes with the OIS.<sup>71</sup>

More recent data demonstrated that carotid revascularization

surgery results in improved retinal blood in 80% of cases, although the long-term visual implications are unclear.<sup>72</sup> Stenting can also be undertaken in select cases to successfully restore blood flow within the carotid artery.<sup>73,74</sup> Rarely, bilateral external carotid obstruction can cause the OIS.<sup>75</sup> In this instance, external carotid endarterectomy can be considered. In cases of the OIS with ipsilateral internal carotid and external carotid obstructions, it would seem that reversal of both would yield the best ocular prognosis, but this is not known with certainty at the current time.

It should be noted that eyes with the OIS will occasionally develop a severe increase in intraocular pressure after ipsilateral carotid endarterectomy.<sup>76,77</sup> This is most likely to occur in eyes with iris neovascularization and anterior chamber angle compromise from fibrovascular tissue formation. Although aqueous outflow is impaired in such eyes, ciliary body perfusion and aqueous humor formation are also decreased secondary to the carotid stenosis. When the carotid obstruction is suddenly reversed, ciliary body perfusion and aqueous humor formation increase, but the outflow obstruction in the anterior chamber angle is still present. Thus, the intraocular pressure rises dramatically. Ciliary body destructive procedures or glaucoma filtering surgery may be required in these cases.

## Carotid Endarterectomy in General

Several large randomized studies have been published concerning the indications for carotid endarterectomy in general.<sup>78-81</sup> Carotid endarterectomy has been proven to be efficacious in both symptomatic patients with high-grade (70–99%) symptomatic carotid stenosis,<sup>79</sup> and in asymptomatic patients with greater than (or equal to) 60% stenosis.<sup>80</sup> Specifically, the investigators of the North American Symptomatic Carotid Endarterectomy Trial<sup>79</sup> noted a 17% absolute risk reduction from 26% to 9% in the cumulative 2-year risk of ipsilateral stroke, and a 10% absolute risk reduction in fatal ipsilateral stroke when those randomized to endarterectomy were compared to those who were treated medically. The European Carotid Surgery Trialists' Collaborative Group<sup>78</sup> also were able to demonstrate a similar treatment effect of

carotid endarterectomy for patients with 70–99% stenosis (sixfold reduction in 3-year risk of ipsilateral stroke), but also found that in the 0–29% stenosis group, the early risks of surgery (2.3% died or had a disabling stroke within 30 days of surgery) outweighed the 3-year benefit when compared to medical therapy. The investigators of the Asymptomatic Carotid Atherosclerosis Study<sup>65</sup> were able to demonstrate an aggregate risk reduction of 53% in the incidence of death or stroke, when those randomized to surgery were compared to those who received medical treatment. Asymptomatic patients with carotid artery stenosis of 60% or greater reduction in diameter were eligible to benefit.

A Cochrane Database Systematic Review<sup>82</sup> incorporating 35,000 years of patient follow-up recently demonstrated that carotid surgery: (1) increased the 5-year risk of ipsilateral ischemic stroke in patients with less than 30% stenosis ( $n = 1746$ , absolute risk reduction (ARR)  $-2.2\%$ ,  $p=.05$ ); (2) had no significant effect in patients with 30–49% stenosis ( $n=1429$ , ARR  $3.2\%$ ,  $p=.6$ ), was of marginal benefit in patients with 50–69% stenosis ( $n=1549$ , ARR  $4.6\%$ ,  $p=.04$ ), and was highly beneficial in patients with 70% to 99% stenosis ( $n=1095$ , ARR  $16.0\%$ ,  $p<.001$ ). Accordingly, any patient with the OIS and severe carotid artery stenosis should be evaluated for carotid endarterectomy or stenting.<sup>74</sup> The implications of plaque composition and surgery should become clearer with time.<sup>51</sup>

## Medical Therapy

Since atherosclerosis is, by far, the most common cause of the OIS, medical therapy should be directed toward treating atherogenic disease by controlling risk factors such as systemic arterial hypertension, smoking, diabetes mellitus, and hyperlipidemia. Of considerable importance is the fact that high-dose (40 mg per os daily) rosuvastatin therapy<sup>83,84</sup> and high-dose (80 mg per os daily) atorvastatin therapy<sup>84</sup> have been shown to decrease the volume of coronary artery atherosclerotic lesions, an event likely generalizable to atherosclerosis elsewhere in the body. Since cardiac disease is the leading cause of death associated with the OIS, evaluation by a cardiologist should be considered.<sup>55</sup>

## Direct Ocular Therapeutic Modalities

Full scatter panretinal laser photocoagulation has been advocated for ocular ischemic eyes with iris neovascularization and/or posterior segment neovascularization.<sup>70,85,86</sup> This generally consists of 1500–2000 500  $\mu\text{m}$  burns with the argon green laser. Unlike the situation when iris neovascularization occurs secondary to diabetic retinopathy, in which there is regression in a majority of cases with full scatter panretinal photocoagulation, approximately 36% of OIS eyes will demonstrate regression of the iris neovascularization after full scatter treatment. If the anterior chamber angle is completely closed by fibrovascular tissue and there is no posterior segment neovascularization, panretinal photocoagulation is probably not indicated unless a glaucoma filtering procedure is being considered, as higher success rates of filtration surgery have been reported when PRP has been performed.<sup>87</sup>

While there is little in the reported literature regarding the management of macular edema secondary to this condition, Klais and Spaide reported excellent clinical resolution of fluid and dramatic improvement in vision in a patient treated with intravitreal triamcinolone acetonide.<sup>88</sup> Intravitreal bevacizumab has been used for the treatment of the iris neovascularization and macular edema associated with the OIS.<sup>89</sup> Nonetheless, intravitreal bevacizumab has been shown to cause vision loss due to a circulatory disturbance in OIS eyes.<sup>90</sup> Any intraocular injection into an OIS eye could raise the intraocular pressure to above that in the choroidal and central retinal arterial circulations, both of which have similar perfusion pressures. Thus, such eyes should be monitored very carefully after injection, with a consideration of anterior chamber paracentesis if these circulations appear shut down (very narrowed retinal arteries, a pale optic disc, and a lightened fundus).

# Coagulopathies

*Sandra Liakopoulos, Florian M.A. Heussen, SriniVas R. Sadda*

## **Introduction**

### **General Considerations**

Disseminated Intravascular Coagulation

Thrombotic Thrombocytopenic Purpura and  
Primary Immune Thrombocytopenia

HELLP Syndrome

### **Ophthalmic Involvement**

### **Conclusion**

## **Introduction**

A variety of hereditary as well as acquired diseases belong to the group of coagulopathies – diseases that affect the blood clotting system, causing hypercoagulability and susceptibility to bleeding. Important coagulopathies include disseminated intravascular coagulation (DIC), primary immune thrombocytopenia (ITP, also known as idiopathic thrombocytopenic purpura), thrombotic thrombocytopenic purpura (TTP), and the HELLP syndrome (hemolytic anemia (H), elevated liver enzymes (EL), and low platelet count (LP)). Since coagulopathies are multiorgan disease processes, ocular involvement may occur and show characteristic

changes that should be recognized by ophthalmologists and retina specialists.

## General Considerations

### Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is often described as a secondary disease process typically associated with other disease entities.<sup>1</sup> The presence of DIC increases the risk of mortality beyond that associated with the primary disease.<sup>2</sup> A cascading activation of both procoagulants and fibrinolysis leads to simultaneous, uncontrolled hemorrhages and diffuse thrombosis of small and large vessels affecting virtually all mucocutaneous tissues and various organs, ultimately resulting in end-organ failure (see [Box 63.1](#)). As such, DIC is regarded as one of the most common causes of death. But not all presentations of DIC are lethal; it may also manifest as low-grade disease with a chronic or compensated

#### **Box 63.1**

### Clinical Manifestations of Disseminated Intravascular Coagulation

#### Hemorrhagic Events

- Petechiae
- Purpura
- Hemorrhagic bullae
- Hematoma
- Wound bleeding

#### Peripheral Thrombotic Events

- Acral cyanosis
- Gangrene

## Central/Organ Dysfunction

- Fever
- Hypotension
- Acidosis
- Proteinuria
- Hypoxia
- CNS dysfunction

Triggering events for DIC are manifold and range from trauma to malignancies, septicemia, obstetric complications, cardiovascular disease, inflammatory disorders, and renal disease, only to name a few. Whether DIC will pursue a fulminant or compensated course is loosely related to the disease entity with which it is associated. Chronic conditions such as cardiovascular disease, autoimmune diseases, or hematologic disorders tend to be associated with a low-grade DIC, whereas more acutely presenting entities such as crush injuries are more likely to trigger a fulminant DIC with poor prognosis. Furthermore, DIC is not restricted to a particular age range and may occur in neonates as well as elderly individuals.

The currently established theory of pathogenesis is an initial activation of the coagulation cascade following inflammation or damage to tissue and vascular endothelial cells.<sup>3</sup> Fibrin formation leads to microvascular or macrovascular thrombosis. Soon thereafter, fibrinolysis is upregulated and the consumption of platelets in the obstructed microcirculation causes a systemic thrombocytopenia (cell count  $<100 \times 10^9/L$ ), thereby generating an environment of simultaneous clotting and extrusion of hemorrhages. Despite a common pathophysiologic pathway, clinical manifestations of the disease may vary widely (see [Box 63.1](#)), complicating diagnosis and treatment management.

The onset of DIC is usually marked by fever, shock, acidosis and, more specifically, widespread hemorrhaging, acral cyanosis, gangrene, and end-organ failure. Bleeding from more than three

unrelated sites at once and a recent medical history compatible with known causes of DIC can direct the clinician towards the diagnosis. Definite diagnosis is heavily based on positive laboratory test results for platelet count, D-dimer (fibrin degradation product or FDP), antithrombin-III, protein C, prothrombin time, partial thromboplastin time, and fibrinogen.<sup>4</sup>

Treatment of DIC is difficult and should primarily address the underlying cause. DIC spontaneously resolves in many cases when the underlying causative disorder is effectively treated; however, removal of its cause does not necessarily alleviate the process in all cases. Replacement treatment such as frozen plasma transfusion or infusion of antithrombin-III, fibrinogen, and platelet-concentrates can help to limit hemorrhages. If features of thrombosis predominate, anticoagulant treatment may be required. Activated protein C has been suggested to treat this condition;<sup>5</sup> however, most recent studies did not show any advantage over placebo, and thus this agent has been removed from the market and relevant guidelines have been revised.<sup>6,7</sup> A new promising adjunctive agent that is currently under evaluation is human soluble thrombomodulin.<sup>6,8</sup> Thrombin binds to this molecule, which will then convert protein C into active protein C.

## **Thrombotic Thrombocytopenic Purpura and Primary Immune Thrombocytopenia**

Thrombotic thrombocytopenic purpura (TTP) is a severe thrombotic microangiopathy caused by platelet adhesion and aggregation mediated by endothelial cell-attached ultra-large von Willebrand factor multimers (ULvWF). The underlying cause is a congenital or acquired (autoimmune) deficiency of the von Willebrand factor-cleaving protease ADAMTS-13<sup>9</sup> TTP is more frequent in young female adults than in males or older individuals. Most presentations of the disease are idiopathic, although familial and secondary TTP have been described. Pregnancy, treatment with certain drugs (clopidogrel, cyclosporine, tacrolimus), and malignancies are associated with a higher incidence of TTP. Of note, systemic (not intravitreal) treatment with bevacizumab, a monoclonal antibody to VEGF that is commonly used intravitreally

for management of ocular neovascular disorders, can induce a TTP-like microangiopathy.<sup>10</sup>

TTP is accompanied by profound thrombocytopenia, erythrocyte fragmentation, and increased serum levels of lactate dehydrogenase (LDH).<sup>11</sup> Partial vessel occlusion by platelet-rich thrombi may result in organ ischemia. Clinically, TTP manifests with fever, renal failure, neurologic symptoms, purpura, and signs of hemolytic anemia. There is often a prodromal phase that may consist of headache, dizziness, nausea, and abdominal pain, presumably caused by microinfarction of the viscera. Though there are chronic smoldering patterns of the disease, an acute and fulminant course is not uncommon and, if left untreated, can be lethal. In some cases, ocular manifestations as described below may present as the first signs of the disease; thus, prompt referral to a hematologist may be life-saving.<sup>12</sup> Plasmapheresis is the principal treatment for this condition and can be supplemented by immunosuppressive therapy (corticosteroids and rituximab), although relapses are generally the rule.<sup>13</sup>

Although primary immune thrombocytopenia (ITP, also known as idiopathic thrombocytopenic purpura) also features thrombocytopenia and purpura, the underlying pathophysiology is distinctly different from TTP. ITP is an acquired autoimmune disorder characterized by isolated thrombocytopenia often occurring in the absence of any identifiable precipitants.<sup>14,15</sup> Current concepts in the pathogenesis of thrombocytopenia in ITP include immunologic destruction of platelets and impaired platelet production.<sup>14</sup> Fortunately, ITP is self-limiting in most cases and responds well to treatment with corticosteroids, intravenous immunoglobulin (IVIg), anti-D immunoglobulin (anti-D), rituximab, or the thrombopoietin-receptor agonists (TPO-RAs). Splenectomy may be considered in selected cases for children and adolescents with chronic or persistent ITP who have significant or persistent bleeding, and lack of responsiveness or intolerance of other therapies.<sup>15</sup> Rarely, the extremely low platelet counts seen in ITP can cause severe, life-threatening complications.

## HELLP Syndrome

The incidence of the HELLP syndrome (toxemia of pregnancy) is reported as being between 0.2 and 0.6% of all pregnancies.<sup>16</sup> “HELLP” is an abbreviation of the three main features of the syndrom: hemolytic anemia (H), elevated liver enzymes (EL), and low platelet count (LP). While being regarded as a microangiopathy much like TTP, it can also convert into a fulminant DIC in 20% of cases. The mortality rate is around 1.1% with adequate management, yet other serious complications such as abruptio placentae (16%), acute renal failure (7.7%), or pulmonary edema (6%) can occur more frequently.<sup>17</sup>

## Ophthalmic Involvement

Although there are many differences regarding the underlying etiology or management of the various coagulopathies discussed in this chapter, they all may present with similar ophthalmic manifestations (see Figs. 63.1–63.3). The precise frequency of ocular complications, however, is unknown, as many cases may remain unrecognized due to the life-threatening nature of those systemic diseases. Relatively few reports are available regarding ocular complications of DIC as most cases are diagnosed and reported after the patients have died.<sup>18</sup> By comparison, many more reports can be found in the literature describing ophthalmic findings in TTP, ITP, or HELLP syndrome.<sup>19-37</sup> Some groups have reported that ocular signs and symptoms occur in up to 14% of patients with TTP.<sup>22</sup>

**FIG. 63.1** A 75-year-old woman presented with a recent diagnosis of primary immune thrombocytopenia (ITP) and acute blurring of vision in her left eye with a visual acuity of 20/60. (A) Red-free photograph of the left eye illustrates a few scattered intraretinal hemorrhages in all quadrants with blurring of the inferior disc margin and loss of the foveal reflex. (B) Late-phase fluorescein angiogram demonstrates leakage from parafoveal capillaries with accumulation of dye in cystoid spaces as well as disc hyperfluorescence and focal staining of some vessels. (C) Spectral domain optical coherence tomography (SD-OCT) B-scan through the foveal center shows cystoid macular edema involving multiple retinal layers. (D) SD-OCT B-scan 2 weeks following treatment with a single injection of intravitreal ranibizumab 0.5 mg. Note significant reduction in edema.

**FIG. 63.2** Young Latino female with HELLP syndrome (toxemia of pregnancy). (A,B) Severe serous retinal detachments involving the macula as well as the

periphery and Elschnig spots can be seen in both eyes on color fundus photography. (C,D) Early phase and (E,F) late phase fluorescein angiogram demonstrates multiple areas of leakage originating from the choroid.

(G,H) During follow-up, resolution of fluid and hemorrhages was noted, though pigment epithelial alterations were still evident. (Images courtesy of David Sarraf, Stein Eye Institute, University of California - Los Angeles.)

**FIG. 63.3** Forty-five-year-old female with suspected disseminated intravascular coagulation (DIC) after

arteriovenous shunt surgery due to kidney transplant failure. (A) Color fundus photography illustrates many retinal hemorrhages. (B) Early and (C) late phase fluorescein angiogram demonstrates only mild leakage from smaller retinal vessels with disc hyperfluorescence and some late-appearing hyperfluorescence at the level of the choroid (especially superiorly). (D) Spectral domain optical coherence tomography (OCT) shows severe accumulation of intra- and subretinal fluid. One month later, there was spontaneous resolution of the fluid on OCT, though alterations at the level of the ellipsoid zone were still observed (E).

The hypercoagulable state in these individuals typically leads to choriocapillaris occlusion by fibrin-platelet clots, whereas subcutaneous or subconjunctival,<sup>23</sup> choroidal, retinal, or vitreous hemorrhages<sup>19,21,24</sup> are thought to be indicative of thrombocytopenia and anemia. A patchy delay in filling of the choroidal vessels on fluorescein angiography can be an early sign of ophthalmic complications. Pathophysiologically, microthrombi in the choriocapillaris cause localized ischemic injury to the retinal pigment epithelium (RPE), resulting in a dysfunction of the outer blood–retinal barrier as well as a decreased ability of the RPE to transport fluid out of the subretinal space.<sup>25</sup> Fluid extravasation from choroidal vessels can then pass through small disruptions of the RPE, extending into the subretinal space and manifesting as serous retinal detachments.<sup>26</sup> Intraretinal, subretinal, and sub-RPE fluid accumulations have been reported.<sup>12,33–35</sup> Fluid accumulation may resolve spontaneously when systemic conditions improve; however, macular pigmentary changes may persist after resolution of fluid. Intravitreal anti-VEGF therapy has been tried, but the benefits are uncertain (Fig. 63.1).

Hemorrhage in the posterior segment may vary from subclinical small intraretinal dot hemorrhages to widespread sub-RPE, subretinal, or intravitreal hemorrhage resulting in dramatic decrease in vision.<sup>19,21,24</sup> Some groups have reported large tears of the RPE leading to acute vision loss.<sup>27</sup> Choroidal hemorrhage seems to be more specific and has rarely been described in conditions other than the coagulopathic disorders described in this chapter.

Cotton-wool spots, typically located around the optic disc, are generally related to a secondary cause such as hypertension or other systemic disease.<sup>28</sup> Whereas the decrease in vision from fluid accumulation and hemorrhage may recover following resolution and resorption,<sup>20</sup> visual impairment due to choroidal infarction is frequently permanent.<sup>29</sup>

The preferential localization of fibrin-formation and occlusion in the choroidal bed at the posterior pole has not yet been fully explained. Cogan proposed the hypothesis that a sudden deceleration of the blood flow between the short posterior ciliary arteries and the choriocapillaris sinusoids greatly facilitates clot precipitation in this region.<sup>18</sup> Involvement of the retinal vasculature has been rarely reported, with findings including impaired retinal circulation, retinal artery or retinal vein occlusion, and purtscher-like retinopathy.<sup>30,36-38</sup> In these cases, the authors have speculated that the underlying diseases may have been the cause of the retinal vascular changes instead of a direct effect of DIC. More recently, ultra-widefield fluorescein angiography revealed the presence of peripheral retinal vascular leakage in a patient with HELLP syndrom.<sup>35</sup> Lin et al. concluded that in addition to a choroidal etiology for the serous retinal detachment, breakdown of the blood-retinal barrier manifest in retinal vasculature may have also contributed to the observed findings.<sup>35</sup>

There are also reports describing ocular involvement of DIC and TTP in neonates.<sup>39</sup> Common causes of mechanisms in this setting include placenta previa, sepsis, trauma, hepatocellular failure, or infant respiratory distress syndrome (IRDS). The ocular fundi show extensive hemorrhages in the retina or the vitreous, usually with concomitant focal retinal detachments. In selected neonatal cases, anterior segment manifestations were also observed with hyphema, thrombi in the iris and the ciliary body, and subconjunctival hemorrhage.<sup>40</sup>

Ocular manifestations of toxemia of pregnancy are discussed in detail in [Chapter 95](#) (Pregnancy-related diseases). As the HELLP syndrome may be associated with DIC, all of the above-mentioned complications may occur in this condition. Additionally, hypertensive retinal vascular changes are not uncommon. Mere presence of serous retinal detachments should not be used as an

indicator of DIC, as these may also occur in pregnancy independent of the presence or absence of DIC and pregnancy-associated hypertension.<sup>31,32</sup>

## Conclusion

DIC and related coagulopathies generally exhibit very similar ocular manifestations, which include widespread retinal or vitreous hemorrhage, subretinal or intraretinal fluid accumulation, and choroidal infarction. The anterior segment is rarely involved in these disease processes. While visual loss related to these conditions is usually not the chief driver in the treatment of the underlying potentially life-threatening systemic diseases, ocular findings may be the initial presentation that enables the diagnosis of these disorders.

**Retinopathy of Prematurity**

**Retinal Detachment**

**Other Pediatric Retinal Vascular Diseases**

**Newborn Screening for Retinal Disease**

## Retinopathy of Prematurity

Retinopathy of prematurity (ROP) is a disease affecting the retinas of premature infants. Its key pathologic feature, local ischemia with subsequent retinal neovascularization, has common features with other proliferative disorders such as diabetic and sickle-cell retinopathy. ROP is unique in that the vascular disease is found only in infants with incompletely vascularized retinas. The spectrum of ROP disease ranges from mild cases without visual sequelae to advanced cases with bilateral irreversible blindness.

## Historical Perspective

### Early History

ROP was first described in 1942<sup>1,2</sup> and quickly became recognized as the primary cause of childhood blindness throughout the developed world.<sup>3</sup> Terry's original reports designated the condition retrolental fibroplasia (RLF), based on his impression that it involved a proliferation of the embryonic hyaloid system, but Owens and Owens<sup>4</sup> found that the hyaloid system was normal at birth and that RLF developed postnatally. As the pathogenesis and clinical manifestations became better understood, the term "retinopathy of prematurity" was adopted.

The discovery of the relationship between supplementary oxygen and ROP in the 1950s<sup>5-9</sup> led to rigid curtailment of oxygen supplementation in the nursery, and a dramatic decrease in ROP incidence followed. Unfortunately, this had an adverse effect on infant morbidity and mortality (e.g., respiratory distress syndrome, cerebral palsy, neurologic disorders).<sup>10-12</sup>

## **Retinopathy of Prematurity and Contemporary Nursery Practices**

By the early 1970s, arterial blood gas analysis had come into general use, and the oxygen requirements of premature infants with respiratory distress syndrome were better documented.<sup>13</sup> This enabled pediatricians to titrate the incubator oxygen concentration to more nearly meet the individual premature infant's oxygen needs.

Modern transcutaneous oxygen monitoring and continuous pulse oximetry have provided additional noninvasive tools, allowing neonatologists to monitor babies in real time more closely. These have stimulated studies, including large multicenter oxygen restriction trials, which have found that lower target oxygen saturation levels (e.g., 85–89%) correlate with significantly improved rates of severe ROP but are also associated with increased mortality rates.<sup>14-16</sup> At this time, general consensus regarding target oxygen saturation levels that balance ROP risk and mortality has not been reached.

With improvements in neonatology practice, more of the smallest premature infants are now surviving. Eight percent of low-birthweight infants survived in 1950, but with ventilators, surfactant, intravenous nutrition, and other gains in knowledge,

survival has risen to 37–72%.<sup>17–19</sup> Clearly, infants are surviving today with more immature retinal vasculature and therefore higher ROP risk. For this reason, and because of common pathophysiology with other proliferative vascular diseases such as diabetic retinopathy, there has been mounting interest in ROP.<sup>20–22</sup>

## The Role of Oxygen

### Clinical Findings

Results of controlled nursery studies<sup>5,8</sup> that suggested supplementary oxygen to be the principal cause of ROP in the epidemic of the early 1950s were confirmed, and the role of prolonged oxygen was documented in a collaborative randomized controlled trial.<sup>9</sup>

Since that time, attempts to delineate the critical blood oxygen levels producing ROP have not resulted in definitive conclusions. In a prospective study of 589 infants monitored by intermittent blood gas measurements, and where clinical goals were to avoid elevated arterial oxygen, the occurrence of ROP was not related to arterial oxygen levels.<sup>23</sup> Only the duration of oxygen exposure was a risk factor. Somewhat unexpectedly, continuous transcutaneous monitoring of blood oxygen levels was found in one study to be of no more value than intermittent monitoring in preventing visual disability.<sup>24</sup>

Recent studies, including large multicenter oxygen restriction trials, have found that lower target oxygen saturation levels (e.g., 85–89%) correlate with significantly improved rates of severe ROP, but are associated with increased mortality rates.<sup>14–16</sup> At this time, a consensus about optimal target oxygen saturation levels has not been reached.

### Experimental Findings

In the early 1950s the laboratory kitten model, which produced lesions resembling the early stages of human ROP, was used extensively because it demonstrated selective response to oxygen by the immature retinal vessels.<sup>6,7</sup> In the full-term newborn kitten, the immature retinal vascularization is comparable to that of a human fetus at 6 months' gestation, thus providing the unique

opportunity to study the response to oxygen of the immature retina, albeit in a full-term, healthy animal.<sup>3</sup> When hyperoxia studies were extended to other animal models, such as the young mouse and puppy,<sup>6</sup> the general concept of oxygen toxicity to immature retinal vessels was reinforced.

Investigators<sup>26,27</sup> have pointed out the histologic differences in the retinas of these animal models from the human but were unable to explain why progression to retinal detachment did not occur. It is noteworthy that McLeod et al. reported the production of intravitreal neovascularization with traction retinal folds in young dogs exposed to hyperoxia.<sup>28</sup> These findings add to the potential application of the canine model to investigate these stages of ROP (Figs. 64.1 and 64.2 online<sup>Ⓞ</sup>).

**FIG. 64.1** (A) Ophthalmoscopic examination of a 45-day-old dog exposed to 100% oxygen for the first 4 days of life disclosed a 2-mm-wide area of retinal neovascularization (*arrow*) extending from the disc to the temporal midperiphery. Two similar structures are present at the 2- and 5-o'clock positions. (B) Area of temporal retinal neovascularization (*arrow*) indicated by arrow in A shows mild folds in the retina (*arrowheads*) (periodic acid–Schiff and hematoxylin,  $\times 50$ ).

**FIG. 64.2** (A) Gross appearance of the areas of neovascularization extending temporally and two smaller areas in the same 45-day-old dog shown in Fig. 64.1. A denser 2 × 0.5-mm area is present inferior nasally (*arrow*). (B) Area from A (marked by *arrow*) discloses retinal neovascularization (*arrow*) attached to the apex of a retinal fold (periodic acid–Schiff and hematoxylin, ×125).

The hyperoxic animal models demonstrated that only the incompletely vascularized retina was susceptible to oxygen's adverse effect, and that the more immature the vascularization, the greater the pathologic response to oxygen.<sup>29</sup> These findings supported the clinical observation that the infant with a less mature retina has greater ROP susceptibility, and that the infant with a fully vascularized retina has no risk. Accordingly, the temporal retina, the last part to vascularize, remains susceptible to ROP the longest (Fig. 64.3 online).

**FIG. 64.3** Schematic diagram of retinal vessel development in humans. At 4 months' gestation, vessels grow from the disc to reach the ora serrata nasally at 8 months and the ora temporally shortly after term. The vascularization of the newborn kitten corresponds to the  $6\frac{1}{2}$ -month-gestation human fetus. *N*, nasal retina; *T*, temporal retina; numbers refer to months' gestational age.

## Mechanism of Oxygen's Effects on the Immature Retina

### Primary Stage of Retinal Vasoconstriction and Vascular Occlusion

The primary effect of elevated blood oxygen in any retina is vasoconstriction, which, if sustained, is followed by some degree of vascular closure. In young kittens, initial vasoconstriction occurs within several minutes after oxygen exposure. Vascular caliber is reduced by approximately 50% initially, but then rebounds to its original dimensions. Continued oxygen exposure results in gradual vasospasm during the next 4–6 hours, until the vessels are approximately 80% constricted.<sup>30</sup> At this stage, constriction is still reversible. However, if significantly elevated arterial oxygen partial pressure levels persist for an additional period (e.g., 10–15 hours), some immature peripheral vessels are permanently occluded.<sup>7,23</sup>

This occlusion progresses as the duration of hyperoxia increases, and local vascular obliteration is complete after 2–3 days of exposure. In the dog, after 4 days of exposure to hyperoxia, most capillaries are lost and only major blood vessels survive.<sup>31</sup>

Electron microscopic observations demonstrate selective hyperoxic injury to the endothelial cells of the most immature vessels, without obvious changes in the neuronal elements of the retina.<sup>32</sup>

## **Secondary Stage of Retinal Neovascularization**

After removal of the laboratory animal to ambient air following sustained hyperoxia, marked endothelial proliferation arises from the residual vascular complexes adjacent to retinal capillaries ablated during hyperoxia (Fig. 64.4 online<sup>Ⓞ</sup>). This can be demonstrated on fluorescein angiography (Fig. 64.5). Nodules of proliferating endothelial cells canalize to form new vessels that not only grow within the retina but also erupt through the internal limiting membrane to grow on its surface, similar to the neovascularization in other proliferative retinopathies (Figs. 64.6–64.9). In the dog and cat, the initial preretinal neovascular formations are like angioblastic masses with few lumens (formations sometimes called “popcorn”), which mature into neovascular formations that include vessels invested with pericytes.<sup>33,34</sup> Although the neovascularization may be extensive, this is generally the maximum response to oxygen in the kitten model and is followed by progressive vascular remodeling and involution of abnormalities. The preretinal neovascularization in

the dog persists and can develop into tented membranes that create traction retinal folds in the retina (Figs. 64.1 and 64.2 online).<sup>28</sup> The mouse and rat preretinal neovascular formations, however, will regress after 5 days.<sup>30-37</sup> Although regression is rapid and spontaneous in mice, the mouse model has been useful in evaluating topical<sup>38</sup> and systemic drugs,<sup>39,40</sup> experimental gene therapy strategies,<sup>41,42</sup> and endogenous inhibitors like pigment epithelial growth factor.<sup>43</sup>

**FIG. 64.5** (A) Fluorescein angiogram of a young kitten with oxygen-induced retinal neovascularization (*arrows*); midtransit phase of angiogram. (B) Late phase of angiogram of young kitten in (A). Note dye leakage from neovascularization (*arrows*).

**FIG. 64.6** Cross-section of the eye of a 21-day-old mouse exposed to hyperoxia. Normal capillary is seen just posterior to the area of vascular closure (*short arrow*); an endothelial nodule proliferating from the most anterior part of the vascularized retina is erupting through the internal limiting membrane (*long arrow*). Oxygen exerts an important effect on the remodeling of the original primitive capillary network that develops in the retina.<sup>44</sup> Capillaries regress from areas of higher oxygen concentration and grow toward areas of lower oxygen. Penn et al.<sup>45</sup> used experimentally alternating periods of high and low oxygen in the rat pup model to produce a more proliferative form of retinopathy. Pierce and colleagues<sup>21</sup> used hyperoxia and hypoxia in a mouse pup model to demonstrate the correlation of vascular endothelial growth factor (VEGF) protein production with periods of low oxygen and its disappearance during oxygenation.

## Pathogenesis

### Normal Retinal Vasculogenesis

It is appropriate to review normal retinal vascular development as background for understanding ROP pathogenesis. Michaelson<sup>33</sup> originally suggested that retinal capillaries arise by budding from preexistent arteries and veins that originate from the hyaloid vessels at the optic nerve head. Cogan<sup>34</sup> proposed a similar mechanism, except for the hypothesis of budding of solid endothelial cords from hyaloid vessels. Ashton<sup>37</sup> suggested that mesenchyme, the blood vessel precursor, grows from the optic disc through the nerve fiber layer to the periphery of the retina. Mesenchymal precursors have recently been observed far in advance of formed blood vessels in human fetal retinas.<sup>46</sup> On the posterior edge of the advancing mesenchyme, a “chicken-wire” meshwork of capillaries develops and undergoes absorption and remodeling to produce mature retinal arteries and veins that are surrounded by the capillary meshwork.<sup>37,44</sup> Variations in capillary development may be species-specific. However, across all species studied to date, VEGF appears to be a key factor guiding vascular growth, which most closely fits the identity of Michaelson's proposed “factor X.”<sup>33</sup> In the kitten, Chan-Ling and Stone demonstrated the role of astrocytes leading to growth of the capillary network.<sup>47-49</sup> Provis et al.<sup>50</sup> demonstrated the expression of VEGF message in the predicted location in the developing normal human retina, just anterior to the developing vessels (Fig. 64.10).

**FIG. 64.10** Vascular endothelial growth factor (VEGF) mRNA expression in the human fetal retina. Bright (*H*) and dark-field (*G*) views of the retina in cross-section from a 20-week gestation human fetus. In dark-field illumination the retinal pigment epithelium is prominent. Note the greater differentiation of the retinal layers in the section to the right (temporal) of the optic disc. The vascular layer lies superficially, VEGF mRNA expression being limited to the most distal portion of that vasculature (*G*), indicated in the light-field image (*H*) by asterisks. (Reproduced with permission from Provis JM, Leech J, Diaz CM, et al. Development of the human retinal vasculature – cellular relations and VEGF expression. *Exp Eye Res* 1997;65:555–68.)

Fig. 64.11 shows the normal rate of progression of the retinal vessels into the far retinal periphery in human premature infants without ROP according to their postconceptional age (gestational age at birth plus chronologic age). More than 80% of prematurely born infants have been observed to develop this relatively mature retinal vasculature by the time they reach full term.

**FIG. 64.11** Cumulative proportion of infants with no retinopathy of prematurity whose vessels end in zone III, by postconceptional age. (With permission from Palmer EA, Flynn JT, Hardy RJ, et al. Incidence and early course of retinopathy of prematurity. *Ophthalmology* 1991;98:1628–40.)

## Pathogenesis of Retinopathy of Prematurity

Initial changes in the developing vessels are described above, and historically this was believed to be an injury initiated by “excess” oxygen. Alon et al. demonstrated that hyperoxia caused downregulation of VEGF and death of endothelial cells, suggesting that VEGF is an endothelial survival factor.<sup>51</sup> In the time that follows closure of these growing vessels, the differentiating retina becomes increasingly ischemic and hypoxic and VEGF is upregulated,<sup>52,53</sup> driving the neovascularization.<sup>48</sup>

Theoretically, the provision of increased oxygen should downregulate the release of such growth factor(s) and permit neovascularization to remodel and regress in an orderly fashion. Szewczyk<sup>54</sup> proposed this and treated infants with significant ROP by returning them to oxygen. With no controls, it is difficult to know from his report if this success was simply due to spontaneous involution of ROP. This hypothesis was tested in the kitten model of oxygen-induced retinopathy. Systemic mild hypoxia was found to worsen the retinopathy,<sup>55</sup> whereas mild hyperoxia improved it.<sup>56</sup>

With National Institutes of Health sponsorship, the multicenter Supplemental Therapeutic Oxygen for Prethreshold ROP (STOP-ROP) trial, chaired by Dale L. Phelps, found that, once the ROP was established, raising the oxygen saturation mildly did not harm the ROP, but neither was it of clear benefit.<sup>57</sup>

The clinical and histopathologic observations of Flynn and coworkers<sup>58–62</sup> led them to postulate the following sequence of events in human ROP pathogenesis:

1. Endothelial injury occurs where it has just differentiated from mesenchyme to form the primitive capillary meshwork. This is reminiscent of animal studies in which a short duration of hyperoxia resulted in capillary damage limited to the most recently differentiated vascular complexes (see [Fig. 64.4A](#) online<sup>Ⓞ</sup>). It is currently believed that environmental factors other than oxygen also are involved. For example, Brooks and associates found that nitric oxide may contribute to the vaso-obliterative stage of ROP,<sup>63</sup> while Alon et al. found that reduced VEGF may result in death of endothelial cells<sup>51</sup> because of its role as a survival factor.
2. After this injury to the vascular endothelium, the mesenchyme and mature arteries and veins survive and merge via the few remaining vascular channels to form a mesenchymal arteriovenous shunt which replaces the destroyed or damaged capillary bed.
3. The mesenchymal arteriovenous shunt is located at the demarcation between the avascular and vascularized retina. It consists of a nest of primitive mesenchymal and maturing endothelial cells that are fed by mature arteries and veins. No capillaries are found in the region of the shunt. Flynn<sup>60</sup> suggested that this structure represents the pathognomonic lesion of acute ROP.

Flynn described a dormant period after the injury (days to months), during which retinal findings are relatively stable. The tissues comprising the shunt may thicken, and the gray-white initial color of the structure turns from pink to salmon to red. He stated: “during this period when vasculogenic activity resumes in the retina, the fate of the eye is decided.”<sup>60</sup> Flynn pointed out that when

the cells inside the shunt divide and differentiate into normal capillary endothelium, they form primitive endothelial tubes that send forth a brush border of capillaries that grows anteriorly into the avascular retina. This represents ROP involution, which he observed to occur in more than 90% of cases at this early stage. In progressive disease, however, the primitive cells inside the shunt proliferate and erupt through the internal limiting membrane, growing on the surface of the retina and into the vitreous body. Flynn stated: "it is this lack of differentiation and destructive proliferation of cells and their invasion into spaces and tissues where they do not belong that is the chief event in the process of membrane proliferation leading to traction detachment."<sup>60</sup>

Foos<sup>64-66</sup> suggested a pathogenesis of ROP based on examination of histopathologic material. He used the terms "vanguard" and "rearguard" to describe cellular components of the developing retina. The vanguard (anterior) component contains spindle-shaped cells thought to be glia, which play a role in nourishing the immature retina during development.<sup>67</sup> The rearguard contains primitive endothelial cells. As the retina matures, the endothelial cells aggregate into cords that, according to Foos,<sup>66</sup> subsequently lumenize and become the primordial capillaries of the retina. It is from the rearguard and primitive endothelial cells that neovascularization of ROP develops (Figs. 64.12 and 64.13). Foos noted that, as the developing vasculature reaches its most anterior extent and matures, the spindle cells of the vanguard disappear. The work of Chan-Ling et al.,<sup>46</sup> McLeod et al.,<sup>68</sup> and Provis et al.<sup>50</sup> showed that spindle cells are endothelial precursors and, in fetal human and neonatal dog retina,<sup>68</sup> the precursors organize and differentiate to form the initial retinal vasculature.<sup>46</sup>

**FIG. 64.12** Retinopathy of prematurity, stage 2, in a 27-week stillborn infant, showing a meridional section through the retinal ridge, with a thick layer of spindle cells that tapers anteriorly (to the right), representing the proliferative vanguard zone. Nodule of proliferating endothelial cells is seen in the rearguard zone. *R*, rearguard zone; *V*, vanguard zone. (Reproduced with permission from Foos RY. Retinopathy of prematurity – pathologic correlation of clinical stages. *Retina* 1987;7:260–76.)

## International Classification

The international classification of ROP divided the retina into three anteroposterior zones and describes the extent of disease by the 30° meridians (clock-hours) involved (Fig. 64.14). Retinal changes are divided into stages of severity, based on descriptive and photographic standards.<sup>69</sup>

**FIG. 64.14** Schematic diagram of a right eye, showing zones of the retina and clock-hours used to describe the location and extent of retinopathy of prematurity.

## Zones of Involved Retina

Each of the three zones of the retina is centered on the optic disc (Fig. 64.14). Zone I includes the posterior pole and is defined as a circle, centered on the disc, whose radius is twice the distance from the disc to the center of the macula. It subtends an arc of about 60° (Fig. 64.15). Zone II extends from the peripheral border of zone I to a concentric circle tangential to the nasal ora serrata. Temporally, this boundary corresponds approximately to the anatomic equator. Once the nasal vessels have reached the ora serrata, zone III is the

remaining temporal crescent of retina anterior to zone II. Zone III, which is the farthest from the disc, is the last zone to become vascularized. It is clinically important to continue classifying ROP as zone II if there remains any active ROP or immature vessels in the nasal retina.

**FIG. 64.15** Zone 1 grid overlaid on a montage of RetCam photos: black dot represents foveal center. Radius of circle is twice the distance from the disc to the fovea. This illustration demonstrates how retinopathy of prematurity may involve both zones I and II in the same eye.

Although the definition of the different zones is fairly explicit, the actual diagnosis at the bedside can be subjective, especially with respect to zone I. Because the fovea remains poorly defined in premature infants, the center of the macula is an estimation. Work by Chiang et al. showed that when 10 experts reviewed digital fundus images, there was disagreement regarding which examinations displayed zone I ROP in 33% of the cases.<sup>70</sup>

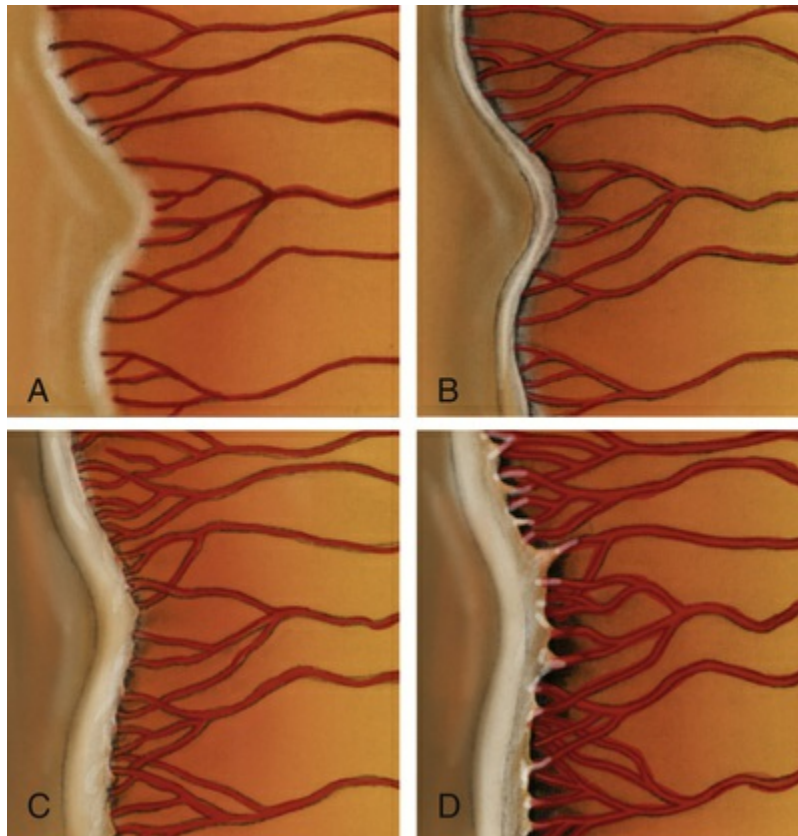

## Extent of Retinopathy of Prematurity

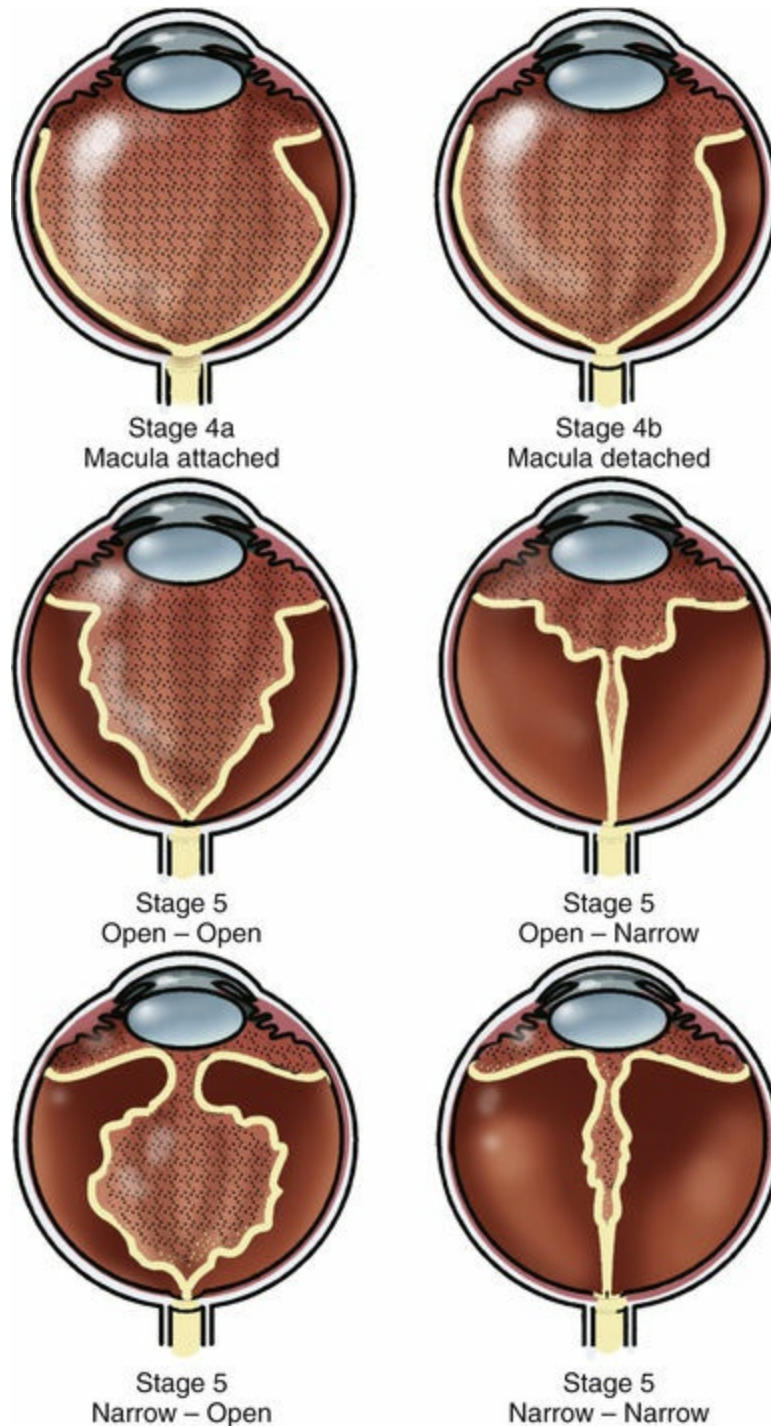

The extent of the ROP changes is described according to the twelve 30° sectors involved, labeled as hours of the clock (see [Fig. 64.14](#)): the nasal side of the right eye is at 3:00, and the nasal side of the left eye is at 9:00.

## Staging

Abnormal peripheral changes are divided into three stages, which may progress to retinal detachment (stages 4–5) ([Figs. 64.16](#) and [64.17](#)).

**FIG. 64.16** Diagrams modified from color photographs of the international classification of retinopathy of prematurity. Vascularized, more mature retina is seen to the right and avascular retina to the left. (A) The demarcation line of stage 1. (B) The characteristic ridge of stage 2 is noted. (C) Extraretinal fibrovascular proliferative tissue of “mild” stage 3. (D) “Moderate” proliferation of extraretinal fibrovascular tissue from the ridge in more advanced stage 3. **FIG. 64.17** Retinopathy of prematurity detachment configurations. Top two, stage 4a and b detachments; bottom four, stage 5. (Courtesy of Rand Spencer, MD.)

## Stage 1: Demarcation Line

Stage 1 is characterized by the presence of a demarcation line, the first ophthalmoscopic sign of ROP (Fig. 64.16A). This represents a structure separating the anterior, avascular retina from the posterior, vascularized retina. It appears flat and white, and lies within the plane of the retina. Abnormal branching or arcading of vessels leads up to the line. Stage 1 is relatively evanescent, generally either progressing to stage 2 or involuting to normal vascularization within several weeks. According to Garner,<sup>71</sup> the stage 1 demarcation line morphologically comprises two relatively distinct zones. The more anterior vanguard zone is formed by a mass of spindle-shaped cells, which are the progenitors of the differentiated vascular endothelium. As such, it corresponds to the primitive mesenchyme (spindle cells) seen in normal fetal development but with a considerable increase in the number of cells. It is this hyperplasia, involving both thickening and widening, that makes the demarcation line visible.<sup>71</sup>

## Stage 2: Ridge

In stage 2, the demarcation line has grown into a ridge with height and width, which extends centripetally within the globe (Fig. 64.16B). The ridge may be white or pink and, rarely, vessels may even leave the surface of the retina to enter it. Small tufts of new vessels ("popcorn" lesions) may be seen located posterior to the ridge structure but not attached to it. The absence of fibrovascular growth from the surface of the ridge separates this stage from stage 3. According to Garner, the stage 2 retinal ridge results from the proliferation of endothelial cells "with some evidence of organization into recognizable vascular channels."<sup>71</sup> Flynn et al.<sup>61</sup> demonstrated that in this stage these channels leak fluorescein on angiographic examination.

## Stage 3: Ridge With Extraretinal Fibrovascular Proliferation

Stage 3 is characterized by the addition of extraretinal, fibrovascular tissue proliferating from the former ridge (Figs. 64.16C–D). This proliferating tissue is localized continuous with the posterior and

interior aspect of the ridge, causing a ragged appearance of the ridge as proliferation increases into the vitreous. As in stage 2, vessels may leave the surface of the retina to enter the ridge and could be mistaken for retinoschisis or even detachment. The presence of elevated retinal vessels coursing from the retinal surface to the height of the ridge does not alone constitute a retinal detachment;<sup>69</sup> however, this may signify presence of vitreous traction. According to Foos,<sup>66</sup> the stage 3 “extraretinal vascularization” may appear placoid, polypoid, or pedunculated on histologic examination. The placoid pattern is the most common and also the most important because it correlates with subsequent development of retinal detachment. Foos demonstrated that these extraretinal vessels are apparently derived from proliferating endothelial cells and not from the vasoformative mesenchymal “spindle” cells based on his factor VIII preparations. He also observed significant sychysis and condensation of the vitreous body in stage 3. Foos suggested that a condensation of the vitreous body over the ridge is related to depolymerization of hyaluronic acid and collapse of the collagenous framework into optically visible structures.<sup>66</sup>

### **“Plus” and “Pre-Plus” Disease.**

Plus disease signifies a more florid form of ROP. Increasing dilation and tortuosity of the retinal vessels, iris vascular engorgement, pupillary rigidity, and vitreous haze indicate progressive vascular incompetence. When vascular changes are so marked that the posterior veins are enlarged and the arterioles tortuous, this represents plus disease, and a plus sign is added to the ROP stage number. This finding is a key sign of worse prognosis.<sup>72</sup> A published standard photograph selected by expert consensus, which has been used in four multicenter clinical trials and represents the minimum arteriolar tortuosity and venous dilation required for plus disease, is shown in [Fig. 64.18A](#). There has been increasing recognition of a spectrum of retinal vascular abnormalities in ROP. In 2005, the revised international classification defined an intermediate “pre-plus” categorization as abnormal arteriolar tortuosity and venous dilation of the posterior pole, which is insufficient for diagnosis of plus disease.<sup>73</sup> Studies

have shown that up to 70% of patients with pre-plus ROP will go on to require laser treatment.<sup>74</sup> Studies have shown that the diagnosis of plus disease may be subjective and qualitative, even among experts, and future definitions may be based on more quantitative measures.<sup>75-77</sup>

**FIG. 64.18** Plus disease examples. (A) Fundus photograph of minimum dilation and tortuosity of retinal vessels considered as plus disease in National Institutes of Health studies of retinopathy of prematurity. (B) Fundus appearance of an extremely severe degree of posterior pole plus disease in an eye that soon developed total retinal detachment. (Panel A reproduced with permission from Cryotherapy for Retinopathy of Prematurity Cooperative Group. Multicenter trial of cryotherapy for retinopathy of prematurity: preliminary results. *Arch Ophthalmol* 1988;106:471-9. Panel B courtesy of Ophthalmic Photography, Oregon Health & Science University, Portland.)

### Zone I Retinopathy of Prematurity.

ROP located in zone I can be dangerously deceptive, in that the proliferation signifying stage 3 can appear spread out “flat” on the retina posterior to the ridge, rather than elevated.<sup>36</sup> In severe plus disease cases inside zone I, centripetal proliferation from the ridge may occur virtually simultaneously with detachment of the retina. Flynn and Chan-Ling examined the distinction between vasculogenesis (de novo formation of new vessels by transformation of vascular precursor cells) and angiogenesis (budding from existing vessels) with regard to the distinction of zone I and zone II ROP. They proposed that zone I ROP correlates

with vasculogenesis and is therefore less sensitive to treatment by laser or cryotherapy because the disease mechanism is not VEGF-mediated. They proposed that zone II ROP correlates with angiogenesis, is mediated by hypoxia-induced VEGF-165, and is therefore more sensitive to treatment by laser or cryotherapy.<sup>78</sup>

### **Aggressive Posterior Retinopathy of Prematurity.**

The 2005 revised international classification of ROP designated an uncommon, severe form of disease as “aggressive posterior ROP.” This rapidly progressive disease variant had been previously termed “rush disease” and is characterized by its location in zone I or posterior zone II, ill-defined nature of the peripheral retinopathy, and prominent plus disease out of proportion to the peripheral findings.<sup>73</sup> This diagnosis can be made by a single examination without serial evaluation and may not progress through the class stages 1–3. In fact, the peripheral disease may appear as a flat area of neovascularization at the junction of vascular and avascular retina.

## **Classification of Retinal Detachment**

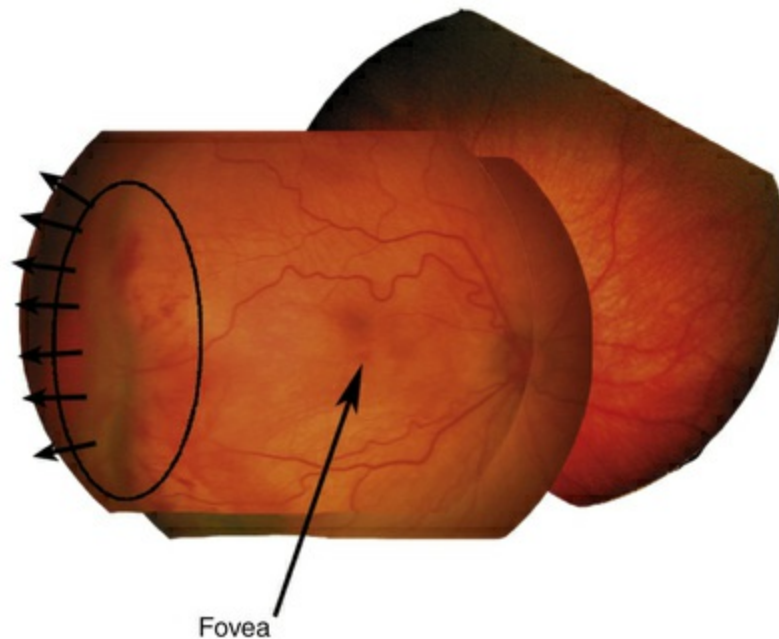

In 1987, ophthalmologists and pathologists established a second international committee, which expanded the original 1984 international classification to describe the morphology, location, and extent of retinal detachment (Fig. 64.17).<sup>79</sup> This classification was based on an understanding of the development of severe ROP gained from surgical experience<sup>80</sup> and pathology.<sup>66</sup> Stage 4 (subtotal) retinal detachment is usually tractional elevation added to findings in stage 3, although there may also be exudative effusion from adjacent active stage 3 neovascularization.

### **Stage 4A: Extrafoveal Retinal Detachment**

Typically this is a concave traction detachment in the peripheral retina without involvement of the central macula (Fig. 64.19). Generally, these detachments are located at the sites of extraretinal fibrovascular proliferation with associated vitreous traction. Elevation may start in any zone where there was stage 3 disease that incompletely involuted following ablative treatment with laser

photocoagulation or cryotherapy, and they may become circumferential. They may extend for 360° in the periphery without elevation of the macula, or they may be segmental, occupying only a portion of the periphery. The prognosis anatomically and visually is relatively good in the absence of posterior extension.

**FIG. 64.19** Stage 4A retinopathy of prematurity (ROP). Fundus photo montage of right eye showing elevation of retina posterior to incompletely regressed stage 3 ROP with vitreous traction (*arrows*). Oval approximates area of retinal detachment.

### **Stage 4B: Partial Retinal Detachment Including the Fovea**

This can follow extension of stage 4A, or may appear as a fold from the disc through zone I to zones II and III ([Fig. 64.20](#)). Once a stage 4 detachment involves the fovea, the prognosis for recovery of good visual acuity is poor.

**FIG. 64.20** Stage 4B retinopathy of prematurity (ROP). Fundus photo montage of right eye showing elevation of retina posterior to fibrotic ridge of incompletely regressed stage 3 ROP. Arrows away from ridge indicate vectors of vitreous traction elevating ridge and adjacent retina, including the macula. Oval outline approximates area of retinal detachment.

### **Stage 5: Total Retinal Detachment**

This is virtually always funnel-shaped. The classification of stage 5 detachments divides the funnel into an anterior and a posterior part (Fig. 64.17). When open both anteriorly and posteriorly, the detachment has a concave configuration and extends to the optic disc. An alternative configuration is one in which the funnel is narrow both anteriorly and posteriorly, and the detached retina is located just behind the lens. A third, less common type is one in which the funnel is open anteriorly but narrowed posteriorly. Least common is a funnel that is narrow anteriorly and open posteriorly.

### **Other Factors Related to Retinal Detachment**

The classification of retinal detachment in ROP focuses attention on certain physical findings in stages 4 and 5:

1. Appearance of the retrolenticular space. This space may be occupied by heavily vascularized translucent tissue, which represents disease activity. As the disease subsides, the tissue occupying this space becomes white, with a scarcity of blood vessels. This is the appearance that gave rise to the original term "retrolental fibroplasia."

2. Peripheral trough. The presence of a peripheral red reflex in combination with apparent narrow funnel stage 5 retinal detachment indicates the presence of attached or shallowly detached avascular, stretched, and nonfunctioning peripheral retina.

3. Anterior segment. In more severe cases of ROP, the anterior segment may become involved as follows:

a) Shallow anterior chamber and corneal edema. A relatively shallow anterior chamber may be a normal early finding in a premature infant's eye; however, when a progressively shallow anterior chamber develops along with a retinal detachment in ROP, it has serious implications. Some cases progress to acute angle closure glaucoma or to a flat chamber and corneal decompensation. (See later section on [glaucoma](#).)

b) Iris abnormalities. Posterior synechiae, iris atrophy, and ectropion uveae are common formations in eyes with stage 4 or 5 ROP. Particularly in eyes with stage 5 disease, the iris may become rigid and the pupil difficult to dilate because of adhesions to the anterior lens capsule and persistence of the pupillary membrane with retention of its vascular network. Rarely, the pupil can seclude, leading to

iris bombé and angle closure. (See later section on [glaucoma](#).)

4. Other tissues. Subretinal blood and exudate may be identifiable by ultrasonography or optical coherence tomography, but it may be difficult to distinguish one from another. Subretinal fibrotic membranes may be present but usually are recognized only during surgery.

## Involution of Retinopathy of Prematurity

Involution of ROP typically begins after 38 weeks' postconceptional/postmenstrual age and may be characterized by a downgrading of staging and/or growth of retinal vessels into a more peripheral zone.<sup>81</sup>

## Regressed ROP: Retinal Detachment, Strabismus, and Amblyopia

Although active ROP usually involutes without progressing to retinal detachment, cicatricial sequelae can remain even in those cases.<sup>82,83</sup> The relatively stable state of the eye after retinopathy has run its course is referred to as regressed ROP. In [Box 64.1](#) the residual changes have been classified into those affecting the retinal periphery and those affecting the posterior fundus. Retinal [Box 64.1](#) changes may be mistaken for side-effects of treatment.<sup>84</sup>

### Regressed Retinopathy of Prematurity

#### Peripheral Changes

##### Vascular

Failure to vascularize peripheral retina

Abnormal, nondichotomous branching of retinal vessels

Vascular arcades with circumferential interconnection

Telangiectatic vessels

## **Retinal**

Pigmentary changes

Vitreoretinal interface changes

Thin retina

Peripheral folds

Vitreous membranes with or without attachment to retina

Lattice-like degeneration

Retinal breaks

Traction or rhegmatogenous retinal detachment

## **Posterior Changes**

### **Vascular**

Vascular tortuosity

Straightening of blood vessels in temporal arcade

Abnormal narrowing or widening in the angle of insertion of major temporal arcade

### **Retinal**

Pigmentary changes

Distortion and ectopia of macula

Stretching and folding of retina in macular region  
leading to periphery

Vitreoretinal interface changes

Vitreous membrane

Dragging of retina over disc

The most serious complications of regressed ROP are late development of retinal detachment and angle closure glaucoma. At almost any age after the neonatal period, but especially several years after birth, retinal detachment remains a risk in eyes with sequelae from ROP. Eyes with high myopia, peripheral retinal pigmentary changes or lattice-like degeneration, vitreoretinal interface changes, vitreous condensation, and stretching and folding of the retina are at special risk of developing retinal breaks and detachment. Eyes with partial retinal detachment present at about 3 months after threshold retinopathy remain at risk for progression of the detachment.<sup>85</sup> Overall visual outcomes for 61 eyes studied were poor: only six eyes had better than 20/200 visual acuity.<sup>85</sup> These patients and their parents should be alert to the symptoms of retinal detachment as soon as the child is old enough to appreciate and report them.

Patients with regressed ROP are at risk for developing strabismus and amblyopia.<sup>86-90</sup> In the Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) study, 200 (6.6%) of 3030 infants who had weighed <1251 g at birth were strabismic at the 3-month examination. Presence of ROP was found to be a significant predictor of strabismus at 3 months. Subgroup analysis determined that the risk for strabismus increased as the zone of ROP became more posterior and the stage more severe.<sup>91</sup> Regular examinations and attention to refractive, visual, and extraocular muscle status are indicated for all infants who have had ROP until about age 18 months, and thereafter as clinically indicated.

In the multicenter Early Treatment for ROP (ETROP) study, the prevalence of strabismus at 6 months corrected age was 20% among

infants with high-risk prethreshold ROP and 10% among infants with low-risk prethreshold ROP. At 9 months corrected age, 30% of infants with high-risk prethreshold ROP had strabismus, and risk factors associated with development of strabismus included abnormal fixation behavior, presence of amblyopia, and outborn birth status (i.e., birth outside a study-affiliated hospital).<sup>92</sup> Overall, ophthalmologists should be aware of significant variability in ocular alignment early in life among infants with a history of severe ROP.

## History of Prematurity

In patients with a history of prematurity, particularly when there is significant myopia dating back to early childhood, careful examination is recommended to rule out any evidence of regressed ROP. This should be done regardless of the presenting age of the patient. Particular attention should be given to the temporal periphery of the retina in view of its relatively greater potential effects on macular vision.

## Ocular Findings of Regressed Retinopathy of Prematurity

### Myopia

In the CRYO-ROP study, 20% of infants with birthweight <1251 g were found to develop myopia in the first 2 years of life. The lower the birthweight, the higher the chance of myopia. Among infants with ROP, the incidence of myopia increased in direct relationship to the severity of ROP. For example, in patients who developed zone II, stage 3 ROP (without plus disease), 44–45% were myopic at 12 and 24 months postterm. In contrast, infants of this same birthweight group who never developed ROP had a 13% incidence of myopia.<sup>93</sup>

In the ETROP study, infants treated for high-risk prethreshold ROP were found to have 58% prevalence of myopia (defined as spherical equivalent  $\geq 0.25$  D) at age 6 months postterm, 68% prevalence of myopia at 9 months postterm, and little change thereafter until 3 years postnatal age. The prevalence of high

myopia increased steadily between ages 6 months and 3 years. There was little difference in prevalence of myopia or high myopia between eyes with zone I versus zone II ROP, or between eyes with plus disease versus without plus disease. However, prevalence of myopia and high myopia was higher in eyes with retinal residual of ROP such as straightened temporal vessels or macular heterotopia.<sup>94</sup> The exact mechanism of the myopia remains unclear. Fletcher and Brandon<sup>95</sup> suggested that it might be due to an elongation of the globe, alteration of the lens or the corneal curvature, or a combination of these factors.

### **Other Refractive and Binocular Defects**

Astigmatism and anisometropia are relatively common in patients with regressed ROP. In the CRYO-ROP study, 2518 infants born weighing <1251 g were refracted at 12 months postterm, and 3.3% had anisometropia. Of the 1548 who had ROP of some degree, 4.8% had anisometropia.<sup>93</sup> In the ETROP study, 401 infants with prethreshold ROP in one or both eyes were randomized to early treatment (laser photocoagulation at high-risk prethreshold ROP) versus conventional treatment only if threshold ROP developed. All infants were refracted at 6 and 9 months correct age, and at 2 and 3 years postnatal age. The prevalence of astigmatism was similar at each test age in the early treatment and conventional management groups. For both groups, there was an increase in prevalence of astigmatism (defined as >1.00 D) from 32% at 6 months to 42% at 3 years.<sup>96</sup>

Approximately 20% of ROP cases are asymmetric at the time they reach threshold for treatment, and this asymmetry may well contribute to anisometropia. Amblyopia, nystagmus, and strabismus are also common after ROP has regressed.<sup>86,87,91,97</sup> Taken together, these findings highlight the importance of follow-up ophthalmology examinations in infants with a history of severe ROP.

### **Lens and Corneal Changes**

At the 12-month examination of the CRYO-ROP study, there was an overall incidence of cataract of 0.3% in the natural history population. The incidence of cataract among eyes with a history of

zone I ROP or zone II stage 3+ ROP was approximately 2.5%.<sup>98</sup> At the final 6-year examination of the ETROP study, cataract or aphakia was found in 4.9% of early-treated eyes and in 7.2% of conventionally managed eyes in 271 children with symmetric ROP.<sup>99</sup> Kushner<sup>97</sup> pointed out that early development of cataract may seriously compromise vision in the presence of retinal abnormalities. Results can be satisfactory from cataract surgery in adults with a history of ROP.<sup>100</sup> Patients with ROP also have an increased risk of developing irregularities of corneal curvature, band keratopathy, and acute hydrops.<sup>72</sup>

## Glaucoma in Retinopathy of Prematurity

Patients with retinopathy can develop acute or subacute glaucoma later in life. In the ETROP Study, 1.67% of enrolled eyes went on to develop glaucoma during the first six years of life. This was associated with a shallow chamber and stage 4B or worse retinal detachments.<sup>101</sup> This complication, which does not always look typical of iris bombé, may occur at any time: in the nursery, shortly after discharge, and throughout childhood. Where feasible, parents should be instructed to recognize the appearance of corneal haze and episcleral injection, and to seek ophthalmic consultation for these concerns. A trial of topical steroids and cycloplegic agents is recommended in suitable cases of glaucoma in the setting of ocular damage from ROP,<sup>102</sup> and further glaucoma management may be required.

## Angle Closure Glaucoma in Regressed Retinopathy of Prematurity

Eyes with regressed ROP are at increased risk of developing acute angle closure glaucoma, even in adulthood.<sup>103,104</sup> Kushner<sup>102</sup> pointed out that certain patients with mild degrees of regressed ROP have a predilection for developing ciliary block glaucoma. Because these forms of glaucoma may be treatable by surgery in selected cases, ophthalmologists and patients should be aware of these potential complications, their associated signs and symptoms, and their management.

## Differential Diagnosis

Although the differential diagnosis in a premature infant in a neonatal intensive care unit (NICU) is almost exclusively limited to ROP, there are several conditions that can mimic ROP out of that context in older children. Familial exudative retinopathy, incontinentia pigmenti (IP), and Norrie disease can all present with peripheral ischemic retina resulting in a traction retinal detachment secondary to retinal neovascularization. ROP can be excluded in these cases if there is no history of prematurity. Retinoblastoma can simulate a retinal detachment, although it is exudative and has a convex as opposed to concave surface. The tumors associated with exudative detachments are typically quite large and would be seen on ultrasound. Persistent fetal vasculature (PFV) can have a similar appearance to ROP, but is usually unilateral. Coats disease is also generally unilateral and has substantial lipid exudates which are not typically seen in ROP.

## Risk Factors

In general, prematurity, low birthweight, a complex hospital course, and prolonged supplemental oxygen are today's established risk factors for the development of ROP.<sup>10,73,105,106</sup> Supplemental oxygen given for a period of weeks, without specific indication, was abundantly documented to be a major cause of ROP during the epidemic of the 1950s but is no longer the predominant factor in cases of ROP seen since the mid-1970s. Now, neonatal advances have resulted in improved survival rates of extremely low-birthweight children. The risk of developing treatment-requiring ROP is higher in this group, with as many as 25% of children born at 750 g or less developing plus disease.<sup>107</sup>

The role of blood carbon dioxide levels in the development of ROP is controversial. Bauer and Widmayer,<sup>108</sup> following Flower's observation<sup>109</sup> that carbon dioxide enhanced the oxygen-induced retinal changes in Beagles, conducted a retrospective analysis of infants with low birthweights. They reported that higher arterial carbon dioxide values were the most important variable in separating those infants of equal gestation who developed ROP from those without disease. Biglan et al.<sup>110</sup> and Brown et al.<sup>105,111</sup>

failed to confirm this association and, indeed, found that infants with “scarring retinopathy of prematurity” had lower carbon dioxide blood levels. It is likely that this parameter, like many others, is associated with an unstable clinical course – as is ROP – but not necessarily linked with it causally.

Numerous other neonatal health factors have been reported to be associated with ROP, including cyanosis, apnea, mechanical ventilation, intraventricular hemorrhages, seizures, transfusions, septicemia, in utero hypoxia, anemia, patent ductus arteriosus, and vitamin E deficiency.<sup>13,25,89,106,108–117</sup> These associations require further investigation to identify causal relationships. In the CRYO-ROP natural history cohort of 4099 infants born weighing less than 1251 g, significant additional factors were identified, including white race, multiple birth, and being transported elsewhere for intensive care. Once ROP develops, greater risk is associated with ROP located in zone I, the presence of plus disease, the severity of stage, and the extent of circumferential involvement.<sup>118,119</sup> The risk factors studied during the CRYO-ROP study were consolidated into a mathematical model that can predict the risk of an unfavorable outcome for a particular eye that reaches prethreshold severity.<sup>120</sup>

## Examination Procedures in the Nursery

### General Aspects and Timing of the Examination

The nursery surveillance carried out in the CRYO-ROP study produced definitive information concerning the early course of ROP. The “natural history” portion of this study recorded data from 4099 infants born weighing less than 1251 g. The study showed that ROP occurs on a schedule according to the infant's corrected age (postmenstrual age since mother's last menstrual period, or postconceptional age), rather than the time since birth, the so-called chronologic age (Fig. 64.21).<sup>118</sup> For infants in the birthweight category studied, it was found that those who develop stage 1 ROP (and no worse) do so at a median of 34.3 postmenstrual weeks. The median time for onset of stage 2 ROP that progresses no further is 35.4 weeks, and 95% of these cases have onset at 32 weeks or later. For patients with eyes that reached the treatment randomization “threshold” severity of stage 3+ ROP (at least five

contiguous or eight interrupted clock-hours in zones I or II), the threshold was reached at a median of 36.9 weeks (90% of cases were in the range of 33.6–42.0 weeks) (Table 64.1).

**FIG. 64.21** (A) Distribution of onset of prethreshold retinopathy of prematurity (ROP) by chronologic age and by birthweight. (B) Comparable data for threshold ROP. (C) Prethreshold data by postconceptional age, for comparison with A (by chronologic age). (D) Threshold data by postconceptional age, for comparison with B (by chronologic age). ## **Screening Guidelines**

Because ROP can progress to blindness during the first 3 months of life<sup>121</sup> and treatment is available to arrest it in many cases, a protocol has been recommended for examining the eyes of premature infants during that time span to detect the onset of advancing ROP and specifically the development of prethreshold ROP defined as ROP of less severity than the threshold severity in the CRYO-ROP trial: specifically as any ROP in zone I, or zone II ROP of stage 2+ or stage 3 with or without plus disease. The current recommendations from the American Academies of Ophthalmology and Pediatrics are that children born at 30 weeks or less, or at less than 1500 g, should be screened for ROP. Specifically those born at a gestational age of 27 weeks or less should have their first examination at 31 weeks and children born from 28 to 32 weeks should have their first examination 4 weeks after birth. The subsequent examination schedule is determined by findings on the initial examination, as discussed at the end of this chapter.<sup>122</sup> If the infant reaches 45 weeks' gestational age without developing prethreshold ROP or worse, the risk of visual loss from ROP is minimal.<sup>76</sup> It should also be noted that these are data from the United States and the natural history of ROP may be different in other parts of the world.

## **Side-Effects of the Examination**

Very-low-birthweight infants, while they are still in a precarious general condition, must be managed with care. The stress of an indirect ophthalmoscopic examination is necessary whenever the risk of treatable disease capable of progressing to blindness exists or when information is needed to assist in the general medical evaluation.<sup>123</sup> Screening programs must be designed around the consideration that the procedure may be stressful for the infant.

## **Techniques of Eye Examination**

Eye examinations should be performed at the request of, or with the

approval of, an attending neonatologist. Pupils may be effectively dilated in most infants with Cyclomydril eye drops (cyclopentolate 0.2% and phenylephrine 1%), with the excess drops immediately blotted from the lids to minimize systemic side-effects such as hypertension and intestinal ileus.<sup>123</sup> The examination is performed about 25–30 minutes later using a binocular indirect ophthalmoscope and condensing lens. More heavily pigmented infants sometimes fail to respond adequately to the mydriatic drops, in which case 0.5% cyclopentolate or 1% tropicamide, or both, and 2.5% phenylephrine may be substituted and instilled twice. Most examiners generally use a lid speculum, and there are now a variety of designs suitable for premature infants (e.g., Barraquer, Sauer, Alfonso specula). The infant's hands should be physically restrained, and a nurse ordinarily assists with the examination. As a precaution against viral or chlamydial transfer, the lid speculum must be sterile for each infant and the examination lens should be wiped with an alcohol sponge between cases whenever it has touched the infant's face. The universal precaution of wearing gloves during examination is recommended.

In general, ROP severe enough to cause serious concern will be visible far enough posteriorly in the fundus to bring it into view without scleral indentation. However, to determine the final maturity of retinal vascularization requires either serial examinations past full term or, preferably, examination of the nasal retina to the ends of the growing vessels to determine whether vascularization has advanced into zone III.<sup>79,118</sup> For this far-nasal peripheral retinal examination, scleral indentation or eye positioning is generally needed. An aluminum-wired Calgiswab nasopharyngeal culture swab can be used as an inexpensive, sterile, and relatively gentle tool for this. The tip can be bent to any desired angle, even to resemble a fine muscle hook. Scleral depressors designed for infant examinations (e.g., Flynn depressor) are also commercially available. For scleral depression, topical anesthetic, such as proparacaine, is typically used. It is recommended that a member of the nursery staff be present during the entire examination to monitor the infant's airway, vital signs, and behavior and to deal with apnea or other adverse reactions that may occur.

## Informing the Patient's Family

Often ROP becomes severe just as the infant is achieving medical stability, making it especially difficult on parents who have already experienced much anxiety. The ophthalmologist or neonatologist should keep families informed of the results of eye examinations. The ophthalmologist should contact the parents at the time it is first realized that the ROP is becoming severe, for example, when it develops in zone I or when zone II ROP reaches stage 3. If the parents are kept apprised of the eye condition as it develops, it may soften the emotional impact if the ROP ultimately causes vision damage, and it helps pave the way for discussion of possible surgical intervention.

## Prophylaxis and Therapy

### The Role of Vitamin E

Vitamin E was considered as a potential agent to prevent ROP due to its antioxidant properties. It was evaluated by Johnson et al.<sup>124,125</sup> with subsequent controlled clinical trials having tested the role of large doses of vitamin E.<sup>126-133</sup> The results were equivocal and a report from the Institute of Medicine published in 1986 concluded: "Vitamin E as prophylaxis for retinopathy of prematurity was subject to a detailed analysis. This committee found no conclusive evidence either of benefit or harm from vitamin E administration. Risks from vitamin E appear to be minimal for premature infants provided that doses are kept moderate to achieve a blood level no higher than 3 mg/dl."<sup>134</sup> Currently, there is no formal recommendation on the use of vitamin E in the management of ROP.

### The Role of Light

Historically there has been interest in a possible relationship between light and ROP. In his original descriptions of RLF, Terry<sup>135</sup> considered premature exposure of the eye to light as an important etiologic possibility.

Before the importance of the role of inspired oxygen levels was recognized in ROP, two studies addressed the question of the effect

of light. In the late 1940s, Hepner et al.<sup>136</sup> patched the eyes of five premature infants from birth until they weighed 2000 g. They found that four of the five infants developed ROP, and they concluded that light was not a factor in its development. In 1952, Locke and Reese<sup>137</sup> reported on a series of 22 premature infants (birthweight less than 2000 g) in which they had patched one eye of each baby. Both found that there was no difference in the incidence of ROP between the patched eyes and the unpatched eyes.<sup>136,137</sup>

To examine the relationship between light exposure and ROP more definitively, a feasibility trial of light-reducing goggles (LIGHT-ROP study), chaired by James D. Reynolds, was sponsored by the National Eye Institute in 1995 at three nurseries in the United States. Half of 409 infants with birthweights of less than 1250 g were randomly selected either to wear goggles containing 97% near-neutral density filters until 31 weeks' postconceptional age or to undergo no extraordinary light reduction. The study concluded that there is no clinically important effect of light on the occurrence or severity of ROP.<sup>138</sup> Neither the American Academy of Ophthalmology nor the American Academy of Pediatrics has made any recommendations about restricting ambient light from the eyes of premature infants.

## **Cryotherapy**

From 1968, reports suggested that ablative treatment of the peripheral retina of premature infants with ROP may ameliorate the course of the disease. Those early reports suggested that photocoagulation<sup>139,140</sup> or cryotherapy<sup>141,142</sup> may accomplish this goal. Throughout the early 1980s, studies produced conflicting results and opinions regarding the efficacy and role of cryotherapy for severe ROP.<sup>143-148</sup> The need for a large-scale clinical trial was apparent.

### **The Multicenter Trial of Cryotherapy.**

The CRYO-ROP study was organized in 1985 under the chairmanship of Earl A. Palmer. Supported by the National Eye Institute, the study began enrolling premature infants weighing 1250 g or less at birth in 1986. Infants eligible for the cryotherapy trial had stage 3 ROP, involving five or more clock-hours of retina

posterior to zone III in the presence of a standardized plus disease.<sup>69,107</sup> The results of the CRYO-ROP study were evaluated through a masked comparison by fundus photographs of the incidence of objectively visible macular fold, retinal detachment, or retrolental mass in the eyes that received cryotherapy, with those eyes not receiving it.<sup>149</sup> Cryotherapy was found to reduce the listed unfavorable fundus outcomes over the serial examination visits. At the 10-year outcome assessment, unfavorable fundus outcomes were present in 27% of treated eyes versus 48% of control eyes, and visual acuity was 20/200 or worse in 44% of treated eyes versus 62% of control eyes.<sup>149</sup>

## Current Concepts in Management of Retinopathy of Prematurity

### Treatment Techniques

#### Cryotherapy – Special Considerations.

The average number of individual freezes used in the CRYO-ROP study was 50. As with other forms of eye surgery, a number of factors are considered in determining the method of analgesia or anesthesia, including the physical arrangement of the nursery, proximity to operating or procedure rooms, experience of the anesthesiologist, current medical stability of the infant, “track record” of the infant in tolerating previous stressful procedures, experience of the cryosurgeon, and posterior extent of retinopathy.

#### Laser – Special Considerations.

During the early 1990s laser ablation gained acceptance as an alternative to cryotherapy. In general, ophthalmologists have found that the LIO delivery system is technically easier than cryotherapy and creates fewer postoperative sequelae, such as inflammation and swelling. Furthermore, it seemed apparent that the outcomes of treatment of threshold disease in zone I and posterior zone II were superior to cryotherapy, and at least equivalent to cryotherapy results for zone II disease.<sup>150-159</sup>

When LIO delivery systems became available around 1990, the only laser offered was an argon photocoagulator (488–532 nm).

Subsequently, the diode laser (810 nm) photocoagulator was introduced. Although circumstances may require taking patients to the operating suite for ROP laser therapy, it can also be done in the NICU, with the patient under local anesthesia and with or without the aid of conscious sedation. Subsequently, large spot laser indirect headsets became available which offered threefold increase in area covered by an individual spot.

A technique of laser treatment in the NICU is to place the infant swaddled in a blanket in an open warmer. Mydriatic drops are instilled, and treatment is performed with the aid of a neonatal nurse. A neonatologist must always be available in the nursery should resuscitation be necessary. A heart rate monitor, apnea monitor, and pulse oximeter are used throughout the procedure. Topical anesthesia is instilled in the eye(s) to be treated, and a lid speculum is placed. Lidocaine 2% is injected subconjunctivally in each quadrant (0.25–0.3 ml) for local anesthesia. Approximately 10 minutes is allowed for the anesthetic to take effect. Treatment is then begun with the LIO delivery system, generally with a 28-D-condensing lens. Appropriate laser safety precautions must be taken for the protection of all personnel involved.

Photocoagulation burns are distributed in a confluent pattern to minimize skip areas. The objective of the treatment is to apply burns throughout the entire peripheral nonvascularized retina. Treatment is generally started at the anterior edge of the vascularized retina and applied out to the ora serrata utilizing a Calgiswab or similar instrument for eye positioning and scleral depression. Initial settings for the diode laser are a power of 0.2 W and a pulse duration of 0.3–0.4 seconds. This power setting is usually subthreshold for photocoagulation, and power is titrated up until a yellowish-gray reaction is observed in the retina. The power and/or pulse duration often needs to be varied from one area to another in the avascular retina.

The total number of laser applications necessary to treat a given eye will depend primarily on the size of the avascular zone in the eye. In the authors' experience, if the ROP is in mid to peripheral zone II, then 1000 laser spots may be sufficient to cover the entire nonvascularized retina. However, if the eye to be treated has vessel growth only in zone I, then it is not unusual to apply 1500–3000

laser spots for adequate coverage. Laser is usually performed during a single session in the event there is a postlaser hyphema or vitreous hemorrhage that would prevent subsequent treatment. However, circumstances such as reduced visibility or patient distress may necessitate more than one treatment session. Occasionally, inadvertently skipped areas near the ROP ridge require supplementary laser treatment, in the absence of involution.

## The Early Treatment for Retinopathy of Prematurity Trial

In 1999, the National Eye Institute funded a clinical trial, under the chairmanship of William V. Good, to study optimal ROP treatment indications. In this trial, called the ETROP study, eyes were randomized to early peripheral retinal ablation or conventional management (observation until threshold criteria developed) once they achieved a high-risk level of prethreshold ROP. The ETROP study showed a significant benefit of earlier treatment intervention as measured by visual acuity outcome at a corrected age of 9 months and in the structural outcome of the retina at corrected ages of 6 and 9 months.<sup>160</sup> In the selected high-risk eyes that were studied, unfavorable acuity results were reduced by earlier treatment intervention to 14.5%, from 19.5% in the conventionally treated control group ( $p=.01$ ). Unfavorable structural outcomes were reduced from 15.6% in the control group to 9.1% in the early treatment eyes ( $p<.001$ ).

The ETROP study results, published in December 2003, produced a new clinical algorithm as a guide for treatment intervention in eyes with severe ROP.<sup>160</sup> Prompt treatment is indicated for eyes with type 1 ROP, and continued serial observations without treatment are recommended for eyes with type 2 ROP, as shown in [Table 64.2](#). The ETROP group cautions that plus disease should involve at least two quadrants (usually six or more clock-hour segments) with dilation and tortuosity of the posterior retinal blood vessels as they exit the optic nerve, meeting the published standard ([Fig. 64.18A](#)).

---

### TABLE 64.2

## The ETROP Indications for Treatment

---

Type 1 ROP (“New Threshold”)	Type 2 ROP
Administer peripheral ablation treatment	Wait and watch for progression
Zone II: Plus disease with stage 2 or 3	Zone II: Stage 3 without plus disease
Zone I: Plus disease with stage 1, 2, or 3 Stage 3 without plus disease	Zone I: Stage 1 or 2 without plus disease

ETROP, Early Treatment for ROP; ROP, retinopathy of prematurity.

At the final study outcome examinations performed at age 6 years, unfavorable visual acuity outcomes in eyes with type 1 ROP were reduced by early treatment to 25.1% from 32.8% in the conventionally treated control group ( $p=.02$ ). Interestingly, unfavorable visual acuity outcomes in eyes with type 2 ROP increased in the early treatment group to 23.6% from 19.4% in the conventionally treated group, although this difference was not statistically significant ( $p=.37$ ).<sup>99</sup>

## Retinal Detachment

There is a need for randomized trials of treatment approaches for retinal detachment from ROP. Current clinical thinking about the treatment of retinal detachment from ROP is discussed in [Chapter 118](#) (Surgical management of retinopathy of prematurity).

## The ETROP Study: Better Outcomes, Changing Clinical Strategy

In the ETROP trial, only 66% of the high-risk eyes selected at random to be treated conventionally went on to receive laser therapy (cryotherapy was rarely used). Secondary analysis of the large database produced a simplified revision of the indications for treatment, which was a great practical improvement over the computer-generated algorithm used to select the research subjects for the study<sup>120</sup> ([Table 64.2](#)).

Some of the advantages of an earlier treatment policy may be lost if newborn eye examinations do not occur, as in the ETROP study. Careful reading of the methods used in the trial<sup>161</sup> reveals a real

impact on an intensive care unit's policy for serial ROP examinations. Therefore, consider the following schedule for infants who do not meet criteria for treatment:<sup>122</sup>

- 1-week or less follow-up for type 2 ROP (Table 64.2):
  - Zone II stage 3 and no plus
  - Zone I stage 1 or 2 and no plus
- 1–2-week follow-up:
  - Zone II, no plus, stage 2
  - Zone I, immature, no ROP
  - Zone I, regressing ROP
- 2-week follow-up:
  - Zone II, no plus, stage 1
  - Zone II, regressing ROP
- 2–3-week follow-up:
  - Zone III, no plus, stage 1 or 2
  - Zone II, immature, no ROP
  - Zone III, regressing ROP.

Favorable signs, with respect to progression or involution of ROP, include attainment of postmenstrual age of 45 weeks without developing at least type 2 (as defined above) ROP, and either the completion of full retinal vascularization or progression of retinal

vascularization into zone III without previous zone II ROP.<sup>76</sup>

## Anti-VEGF Therapy for Posterior Retinopathy of Prematurity

There have been numerous trials demonstrating the benefits of bevacizumab in adult patients suffering from choroidal neovascular membranes in the setting of wet age-related macular degeneration. Based on this experience, many investigators have been interested in using a similar approach for the treatment of aggressive ROP. A number of recent case series have reported that intravitreal injections of anti-VEGF antibodies (e.g., bevacizumab) are a very promising approach for the treatment of aggressive ROP, with the possibility of easier administration and improved preservation of peripheral retina compared to laser.<sup>162-167</sup> The BEAT-ROP study was a prospective multicenter trial which included 150 infants with bilateral stage 3+ disease in zone I or posterior zone II were randomized to intravitreal bevacizumab (0.625 mg) versus conventional laser treatment. This showed that infants treated with bevacizumab for stage 3+ disease in zone I had significantly fewer disease recurrences and better structural outcomes at 54 weeks' postmenstrual age, although there was no difference for infants with ROP in posterior zone II.<sup>168</sup> Specifically, 6% of the children with zone 1 treatment-requiring ROP needed additional therapy. In contrast, 42% of the eyes treated with laser required additional therapy. It should be noted that in the ETROP study the unfavorable structural outcome was only 29.6% for zone I with stage 3 and/or plus and 22.2% for zone II with plus and no stage 3.

Although there is the possibility of improved treatment efficacy with bevacizumab, ROP recurrences have been reported several months postinjection.<sup>168</sup> Unlike laser treatment, where the regression is often durable and permanent, the potential for recurrence after bevacizumab injection emphasizes the need for prolonged follow-up examinations. In the BEAT-ROP study the recurrences often occurred many months after initial injection with a mean onset of 16 weeks post injection.<sup>168</sup> This places a special burden on both the family and the screening physician to continue frequent follow-up often beyond 50 weeks of gestational age. Early

reports of recurrence from Hu et al. identified children who had initial response to bevacizumab treatment but then recurred aggressively and in some cases went on to stage 4 or 5 detachments.<sup>169</sup> This emphasized the need for close follow-up especially for those children who remained in zone I or posterior zone II despite advancing gestational age. More recently, ranibizumab has been used as initial monotherapy with most reporting an initial response similar to that seen with bevacizumab.<sup>170</sup> With increasing use, some centers report much higher recurrence rates after ranibizumab with some as high as 83% within 6 weeks of injection.<sup>170,171</sup>

Until ROP can be prevented, it behooves physicians caring for premature infants to detect treatment-requiring cases through coordinated and timely methods. Neonatologists, ophthalmologists, discharge coordinators, and ROP coordinators must collaborate in adhering to local policies developed to benefit these infants.

## Other Pediatric Retinal Vascular Diseases

### Coats Disease

Coats disease arises from abnormal telangiectatic retinal vessels that result in profuse leakage, leading to retinal edema and exudative detachments. It was originally described in 1908 by George Coats, who noted that patients with this condition had unilateral telangiectatic vessels with associated lipid deposits.<sup>172</sup> Interestingly, none of the patients described in the original paper were children, and it was not until subsequent observations that its incidence in the pediatric population was appreciated.

Children often present initially with leukocoria. This is increasingly identified by parents who notice a glow in the setting of a flash photograph, which results from either an exudative detachment or subfoveal lipid exudate as a consequence of distant telangiectasias in the peripheral retina. The differential diagnosis includes retinoblastoma, familial exudative retinopathy, and PFV. In those cases where there are only telangiectatic vessels and subretinal lipid deposits, the diagnosis is relatively straightforward,

especially if wide-angle fluorescein angiography is performed (Fig. 64.22). In those cases where there is a prominent exudative detachment, discriminating between retinoblastoma and Coats disease can be challenging. One useful feature is the color of the subretinal material: an exudative detachment from retinoblastoma will often have tumor visible underneath the retina with a whitish color and a mayonnaise-like appearance. In contrast, the subretinal material in Coats disease will often appear more yellow-green with a mustard-like appearance. In addition, an eye with retinoblastoma will often have a substantial dome-shaped mass on ultrasound. The presence of telangiectatic vessels, however, is not limited to Coats disease, and many exudative detachments from retinoblastoma will have similar vessels.

**FIG. 64.22** Coats disease. (A) Macular exudate in a child with Coats disease. (B) Telangiectatic vessels are seen in the temporal periphery. (C) Fluorescein angiography reveals capillary dropout and vascular dilation.

In 2001, Shields et al. proposed a classification system based on response to treatment. Stage 1 eyes have telangiectasias only. Stage 2 eyes have in addition exudation in either extrafoveal (2a) or subfoveal (2b) locations. Stage 3 eyes have an exudative detachment that is subtotal (3a) or total (3b). Of the stage 3a eyes, if it involves the fovea, then it is stage 3a1, and if it remains outside the fovea, it is stage 3a2. Stage 4 is a detachment with glaucoma, and stage 5 is endstage disease.<sup>173</sup>

The primary treatment of Coats disease involves laser photocoagulation directly to telangiectatic vessels. It is helpful to have wide-angle fluorescein angiography to identify the full extent of the disease. By using a green 532-nm frequency-doubled yttrium aluminum garnet (YAG) laser indirect, it is possible to coagulate the vessels even in areas where the retina is fully detached.<sup>174</sup> This often requires multiple treatment sessions under anesthesia over successive months. In more recalcitrant cases, subretinal fluid drainage can help expose more retina that may be hidden anteriorly due to the extent of the detachment. In severe cases, vitrectomy with external drainage may be necessary. Prior to considering any invasive treatment, retinoblastoma must be clearly ruled out.

Bevacizumab has been used by some centers with the rationale that it may decrease the vascular permeability and amount of subretinal fluid.<sup>175</sup> Recent work by Ray et al. showed that in a retrospective review, bevacizumab in conjunction with conventional laser therapy did not impact overall resolution of the disease.<sup>176</sup> In addition, Ramasubramanian et al. showed that of the eight patients who received injections, half developed vitreous fibrosis with some developing traction detachments requiring vitrectomy.<sup>177</sup> In the absence of randomized trials, the benefit of bevacizumab for Coats disease remains unclear.

Little is known regarding the etiology of Coats disease. There is no clear hereditary component, and it is rarely bilateral. Although there is a mild sex predisposition toward males and it can be more common in the Asian population, there is little else that would point to an underlying cause. Interestingly, although there is often widespread ischemia due to capillary dropout, there is rarely any retinal neovascularization or vitreous hemorrhage. This is despite the high rate of neovascular glaucoma in advanced cases.

## Persistent Fetal Vasculature

Originally labeled as persistent hyperplastic primary vitreous (PHPV), PFV is a result of incomplete regression of the vascular primary vitreous leaving a stalk of fibrovascular tissue extending from the optic nerve to the posterior lens capsule.<sup>178</sup> This often leads to a white opaque membrane behind the lens, resulting in dense amblyopia. The ciliary processes are often drawn towards the center and are associated with some degree of microphthalmia. The retina around the optic nerve can be drawn up into the stalk and in some cases can involve the entire length of the stalk, making surgical amputation of the stalk a risk.

There are a number of conditions that can present with a traction detachment, including familial exudative vitreoretinopathy (FEVR), Norrie disease, incontinentia pigmenti, and retinoblastoma. PFV is almost always unilateral and can be distinguished from the hereditary conditions based on bilaterality. Also the implantation of the stalk is generally to the central posterior lens capsule, whereas in FEVR, Norrie, and incontinentia pigmenti, there is not a stalk but rather a fold that usually runs to the temporal ora serrata. Eyes with retinoblastoma are rarely microphthalmic and will have a mass with possible calcifications on ultrasound.

Treatment for PFV can vary from observation to surgical amputation of the stalk. In some cases, the stalk is mild and the macula can be visualized. If the retina is intact and there are macular structures, a surgical approach to clear the visual axis can be helpful. In some cases, the posterior plaque is quite dense and upon removal the stalk ends up being less severe with relatively normal retinal architecture. Some have advocated surgical treatment in the setting of significantly deformed retina, even when the vision is at light perception. Amputation of the stalk is thought in these cases to prevent phthisis and allow for continued eye growth.<sup>179</sup>

Little is known about the pathogenesis of PFV. The primary vitreous undergoes a well-described programmed involution, and in patients with PFV, it is believed that this process is altered. Recent work suggests that astrocytes may play a role in altering how this process happens and may prevent the hyaloid artery from undergoing a macrophage-mediated involution.<sup>180</sup>

## Incontinentia Pigmenti

Previously called Bloch–Sulzberger syndrome, after the two dermatologists who first recognized the condition, IP is an X-linked dominant disease with ocular, central nervous system, dermatologic, and dental abnormalities. It is associated with a mutation in the *NEMO* gene located on Xq28. The resulting protein regulates the activity of NF- $\kappa$ B, increasing a cell's sensitivity to apoptotic signals and resulting in increase endothelial cell death.<sup>181</sup>

Ocular findings include retinal ischemia with neovascularization that can lead to vitreous hemorrhage and traction detachment. The differential diagnosis based solely on the ocular findings includes ROP, FEVR, and Norrie disease. However, unlike these diseases, the ischemia in IP does not mimic a developmental vascular pattern with distinct areas of vascularized retina posteriorly and avascular retina anteriorly. Instead, the peripheral ischemia is often accompanied by ischemia in posterior vascularized retina and in some cases the macula as well (Fig. 64.23A). Usually, the diagnosis of IP is made soon after birth based on the presence of the skin blisters (Fig. 64.23B). Approximately one in three children with IP have obvious retinal abnormalities on examination, and one in four have traction retinal detachments.<sup>182</sup>

**FIG. 64.23** Incontinentia pigmenti (IP). (A) Widespread retinal ischemia both peripherally and in the macula. (B) Skin pustules in a newborn with IP.

Ocular management for IP includes regular examinations, including those done under anesthesia. Some have recommended

monthly examinations from birth to 4 months of age and then every 3 months until the patient is 1 year old. Examinations can then be performed every 6 months until 3 years of age and then every 6 months after that. Fluorescein angiography can be helpful in identifying the area and extent of ischemia. The managing physician should be careful about the presence of any ischemia, since this potentially can be progressive and may result in neovascularization and subsequent detachment. Eyes at risk for traction detachments can be treated with laser to ischemic areas.

## **Familial Exudative Vitreoretinopathy and Norrie Disease**

FEVR and Norrie disease are both conditions that may result from genetic mutations affecting the Wnt pathway. They can present with similar retinal findings. These mutations result in incomplete development of the retinal vessels similar to what is seen in ROP. Patients can have peripheral avascular retina, neovascular membranes, and traction retinal detachments. In addition to the retinal findings, Norrie disease, which is X-linked recessive, can also be associated with hearing loss and mental retardation. The differential diagnosis for both includes ROP, PFV/PHPV, and IP.

Management of any patient where FEVR or Norrie disease is being considered should include careful examination under anesthesia and, when possible, fluorescein angiography. Both conditions can have an asymmetric presentation and can mimic PFV. In these cases the presumed unaffected eye may have subtle fundoscopic abnormalities that can be overlooked in an outpatient clinic setting and even under anesthesia. Wide-angle fluorescein angiography can provide a very definitive assessment of the vasculature in both eyes and may demonstrate premature termination of the peripheral vessels and subclinical neovascularization. In eyes with ischemia and neovascularization but no detachment, laser photocoagulation to the avascular retina can induce regression and prevent a detachment. When traction retinal detachment is present, some have advocated vitrectomy to release stress on the retina and ciliary body to reduce the likelihood of hypotony and maintain light perception vision when present.<sup>183</sup>

In the case of FEVR, the mutation occurs in the *FZD4* gene that encodes the frizzled-4 receptor. This receptor binds Wnt ligands 3, 5a, and 8a as well as Norrin and triggers the translocation of  $\beta$ -catenin to the nucleus where it can activate transcription of genes involved in cell proliferation. In Norrie disease, the mutation occurs in the *NDP* gene that produces norrin, a secreted protein that can bind frizzled-4.<sup>184,185</sup> Recently, another gene, *TSPAN12*, was found to facilitate norrin binding to frizzled-4 and loss of *TSPAN12* was found in some patients with FEVR.<sup>186</sup> There is currently ongoing investigation as to whether mutations in these genes may also increase the risk of developing aggressive ROP.

## Newborn Screening for Retinal Disease

With the exception of ROP, pediatric retinal disease is often diagnosed very late and is usually initially detected by the parents. A large study by Abramson et al. showed that 80% of the time, parents were the first to identify leukocoria in children with retinoblastoma while the pediatrician was the initial source of diagnosis in only 8% of the cases.<sup>187</sup> This raises the argument of using photoscreening for early detection of pediatric retinal diseases before the condition becomes symptomatic. A large prospective study by Li et al. of digital fundus exams of 3573 newborn children showed that 0.5% of had retinal pathologies and that an additional 6% had macular hemorrhages.<sup>188</sup>

Although the instrument used (RetCam, Clarity MSI) in this study was appropriate in a newborn nursery setting, it would be impractical to perform in an outpatient pediatric examination office. More recently, several smartphone-based applications have been developed to assess nonverbal children for amblyopia, as well as cataracts and retinal diseases.<sup>189</sup> Although still in the early stages of evaluation, these platforms have the potential to reduce the time to diagnosis for retinal diseases with the hope that earlier detection will lead to a reduction in visual loss in this vulnerable population.

**Future Directions**

## **Limitations of Traditional Care**

Traditional screening for retinopathy of prematurity (ROP) involves indirect ophthalmoscopy at the neonatal intensive care unit (NICU)

bedside. Although this has been effective at identifying infants with severe treatment-requiring disease,<sup>1-3</sup> there are important limitations. Ophthalmoscopic examinations are logistically difficult and require significant travel time and coordination. Findings are documented using hand-drawn sketches, which are subjective and qualitative (Fig. 65.1). There may be variability in diagnosis of critical features such as zone I and plus disease,<sup>4,5</sup> and there is enormous medicolegal liability. Surveys have found that the number of retinal specialists and pediatric ophthalmologists willing to manage ROP is decreasing for these reasons.<sup>6</sup> Meanwhile, more infants are at risk for disease because of increasing premature birth rates and improved neonatal survival throughout the world.

**FIG. 65.1** Documentation of traditional indirect ophthalmoscopy using annotated examination template. Limitations include subjective and qualitative documentation, and difficulty identifying change during serial examinations.

## Telemedicine as an Emerging Approach

Telemedicine is an emerging approach with potential to improve

the quality, delivery, and cost of care. This may be particularly important in areas with limited accessibility to care. In this approach, clinical data and images are captured from the infant's eyes by trained personnel in the NICU. Data are transmitted for review by a remote ophthalmologist, who communicates management recommendations. Examples of wide-angle images taken with a commercially available camera (RetCam; Clarity Medical Systems, Pleasanton, CA) are shown in Fig. 65.2. It has been shown that trained neonatal nurses can capture high-quality retinal images,<sup>7,8</sup> and that imaging may cause less physiologic stress to infants than ophthalmoscopy with scleral depression.<sup>9</sup>

**FIG. 65.2** Examples of ROP images captured by a trained neonatal nurse during routine screening using a wide-angle camera (RetCam; Clarity Medical Systems, Pleasanton, CA). Images demonstrate retinas with (A) no ROP, (B) type 2 ROP based on the presence of stage 3 disease in zone II, and (C) type 1 treatment-requiring ROP based on the presence of plus disease as well as posterior stage 3 disease.

In a telemedicine approach, the availability of archived retinal images would provide other advantages. Infant photographs could be directly compared to reference images,<sup>1</sup> and may be transmitted securely to experts for second opinions. Images provide objective documentation of clinical findings, improve recognition of disease progression, enhance communication, and create infrastructure for education and research.<sup>10</sup>

## Evaluation Studies

### Accuracy

Diagnostic accuracy of telemedicine for ROP has been evaluated since the late 1990s. Virtually all studies have used wide-angle digital images captured by a neonatal nurse, ophthalmologist, or ophthalmic photographer. Although these studies have varied in design and outcome measure, most have compared the diagnostic performance of telemedicine to a reference standard of dilated ophthalmoscopy. Schwartz et al. (19 eyes from 10 infants) examined accuracy of telemedicine in a selected group of infants at 30–32 weeks postmenstrual age (PMA), all of whom had moderate or severe ROP. The sensitivity and specificity of telemedicine for detecting prethreshold or worse ROP were 89% and 100%, respectively.<sup>11</sup>

Since then, research has involved larger and broader cohorts of consecutively-enrolled infants. For diagnosis of any ROP, studies have demonstrated sensitivity of 46–97% and specificity of 49–100% compared to a reference standard of indirect ophthalmoscopy<sup>7,12,13</sup> (Table 65.1). Generally, lower accuracy has been found while examining infants at lower PMA, and when detecting presence of mild ROP (e.g., stage 1). This is presumably because younger infants have milder disease with more subtle diagnostic features, and because it may be technically more difficult to image smaller eyes with increased media opacities.<sup>14</sup>

**TABLE 65.1**

**Diagnostic Accuracy of Telescreening for Detection of Any ROP Using Images Captured by Wide-Angle Camera<sup>a</sup>**

Study	Outcome Measures	Sensitivity/Specificity
Roth et al., 2001 <sup>13</sup>	Any ROP	0.82/0.94
Yen et al., 2002 <sup>14</sup>	Any ROP at 32–34 wk PMA	0.46/1.00
	Any ROP at 38–40 wk PMA	0.76/1.00
Chiang et al., 2006 <sup>12</sup>	Any ROP	0.82–0.86/0.49–0.96
Shah et al., 2006 <sup>15</sup>	Any ROP	0.86/0.92

<sup>a</sup>RetCam; Clarity Medical Systems, Pleasanton, CA. For definition of “clinically significant ROP”, see text. Reference standard was standard indirect ophthalmoscopy.

CA, chronologic age; PMA, postmenstrual age; ROP, retinopathy of prematurity; wk, weeks.

Other studies have examined the accuracy of telemedicine for detecting clinically significant ROP (Table 65.2). Ells et al. (371 exams from 36 infants) found sensitivity 100% and specificity 96% for diagnosis of “referral-warranted ROP”<sup>\*</sup> during serial examinations throughout an infant's hospital course.<sup>17</sup> Wu et al. (serial exams from 43 infants) performed telemedicine screening for prethreshold or worse ROP and found sensitivity 100% and specificity 98%.<sup>18</sup> Chiang et al. (163 exams from 64 infants) reported sensitivity 72–83% and specificity 90–99% for detection of type 2 or worse ROP, and sensitivity 85–90% and specificity 95–97% for detection of treatment-requiring ROP.<sup>12</sup> The multicenter prospective Photo-ROP Study (300 exams from 51 infants) found sensitivity 92% and specificity 37% for detection of “clinically significant ROP”<sup>†</sup> during weekly examinations throughout an infant's hospital course.<sup>19</sup>

**TABLE 65.2**

**Diagnostic Accuracy of Telescreening for Detection of Clinically Significant ROP Using Images Captured by Wide-Angle Camera<sup>a</sup>**

Study	Outcome Measures	Sensitivity/Specificity

<sup>a</sup>RetCam; Clarity Medical Systems, Pleasanton, CA. For definition of “clinically significant ROP,” see text. Reference standard was standard indirect ophthalmoscopy.

CA, chronologic age; NA, not applicable; PMA, postmenstrual age; ROP, retinopathy of prematurity; wk, weeks.

In a prospective study, Chiang et al. (248 exams from 67 infants) examined the effect of PMA and disease severity on telemedicine accuracy. At 31–33 weeks PMA, the sensitivity and specificity was 71–86% and 93–97%, respectively, for detection of type 2 or worse ROP, and the specificity for detection of treatment-requiring ROP was 94–100%. At 35–37 weeks PMA, sensitivity and specificity were 91–97% and 98–100%, respectively, for detection of any ROP, 100–100% and 85–94%, respectively, for detection of type 2 or worse ROP, and 100–100% and 81–94%, respectively, for detection of treatment-requiring ROP.<sup>7</sup> The finding of higher accuracy in older infants was in agreement with previous studies.<sup>14</sup>

Dhaliwal et al. (245 exams from 81 infants) conducted a masked, double-observer prospective longitudinal cohort study. Two pediatric ophthalmologists were randomized to perform examinations using either telemedicine or ophthalmoscopy.

Absolute agreement between ophthalmoscopy and telemedicine was 96% for detection of stage 3, and 97% for detection of plus disease.<sup>16</sup> Dai et al. (422 exams from 108 infants) conducted a study in which all infants received telemedicine imaging and ophthalmoscopy by a pediatric ophthalmologist. Images were reviewed independently by a masked grader. Using ophthalmoscopy as the reference standard, sensitivity of telemedicine for detecting treatment-requiring ROP (i.e., type 1 or worse) was 100% and specificity was 98%. The positive predictive value of telemedicine for detecting treatment-requiring ROP was 86%, and the negative predictive value was 100%.<sup>21</sup>

Scott et al. compared the accuracy of telemedicine vs. ophthalmoscopy using a study design in which these two methods were performed by the *same* experts in 67 consecutive infants. There was absolute intragrader agreement of 86% (178/206 eyes) and kappa 0.66–0.85 between ophthalmoscopy and telemedicine. Among the 14% (28/206 eyes) intra-expert discrepancies, some cases

provided photographic evidence that ophthalmoscopy failed to recognize mild ROP that was detected by telemedicine. There were also discrepancies involving presence of zone I and plus disease, in which telemedicine may have provided theoretic advantages by allowing examiners to review their diagnoses or make more exact measurements of anatomic landmarks.<sup>23</sup>

The multicenter e-ROP study (5520 exams analyzed from 1257 infants) implemented a system in which images were captured by trained nonphysician imagers and interpreted by trained nonphysician graders. When comparing the image-set grading of each eye to indirect ophthalmoscopy as a reference standard, the sensitivity for detecting “referral-warranted ROP”<sup>\*</sup> was 82% and specificity was 90%. When both eyes of an infant were considered, the sensitivity was 90% and specificity was 87%.<sup>22</sup>

## Image Quality

Several studies have examined the quality of images captured by nurses, ophthalmic photographers, or ophthalmologists. Ells et al. found that wide-angle images were captured successfully in 96% of examinations, and that 94% of image sets could be graded remotely.<sup>17</sup> Wu et al. found that 79% of initial retinal images and 78% of repeated images were acceptable.<sup>18</sup> The Photo-ROP cooperative group found that 92% of image sets were acceptable.<sup>19</sup> Chiang et al. reported that telemedicine graders reported an “unknown” diagnosis because of inadequate image quality or insufficient retinal coverage in 0–41% of exams at 31–33 weeks PMA and in 0–7% of exams at 35–37 weeks PMA.<sup>7</sup> Lorenz et al. reported that, among 6460 telemedicine imaging sessions conducted at five NICUs over a six-year period, nearly 98% were of adequate quality.<sup>20</sup> Heavy fundus pigmentation, corneal and vitreous haze, smaller palpebral fissures, and limited dilation may be associated with decreased image quality.<sup>7,12,15,18</sup> Quinn et al. reported in a multicenter study that among 5520 image sets captured by nonphysician study-certified personnel, 91% of images were of adequate quality, 6% were of poor quality, and 3% were missing.<sup>22</sup>

## Cost-Effectiveness, Speed, and Satisfaction

Economic and practical factors must be considered for long-term viability of telemedicine systems. Two studies have compared cost-effectiveness of telemedicine versus ophthalmoscopy for ROP management. One study, performed in the United States, found that telemedicine is more cost-effective than traditional ophthalmoscopy (\$3193 per quality-adjusted life year [QALY] compared to \$5617/QALY).<sup>24</sup> The second study, performed in the United Kingdom, modeled five possible strategies for ROP surveillance using telemedicine and ophthalmoscopy, and found that telemedicine using image capture and grading by visiting nurses (£175 per infant examined) and telemedicine using image capture by visiting nurses and image grading by remote ophthalmologists (£201/infant examined) were more cost-effective than traditional ophthalmoscopy at the NICU bedside (£321/infant examined).<sup>25</sup>

Other studies have examined logistical factors such as examination time and acceptability to patients. Richter et al. found that telemedicine examinations required significantly less physician time than ophthalmoscopy (1.02–1.75 minutes per telemedicine exam versus 4.17–6.63 minutes per ophthalmoscopic exam).<sup>26</sup> Lee et al. developed and validated a survey instrument to assess attitudes toward digital imaging and telemedicine by parents, and found high acceptance of these technologies. Families did, however, report that face-to-face contact with physicians was important.<sup>27</sup>

## Evaluation of Operational ROP Telemedicine Programs

Real-world telemedicine programs have been implemented in several centers, typically relying on trained neonatal technicians or nurses to capture images and transfer data for interpretation by remote ophthalmologists. Infants identified with clinically significant disease are either examined locally by an ophthalmologist or transferred for further evaluation.

A telemedicine program involving five German NICUs has been operational since 2001. In this program all premature infants at risk

for ROP are screened with imaging and also examined by local ophthalmologists. All suspected treatment-requiring ROP stages were detected with 100% sensitivity, and the overall positive predictive value for treatment-requiring ROP was 88.2% after 6460 examinations in 1222 infants.<sup>20</sup>

A similar program involving six NICUs, in which nurses are trained to capture serial images, has been used for routine telemedicine management at Stanford University since 2005.<sup>8</sup> Infants felt to have referral-warranted (i.e., type 2 or worse) or treatment-requiring (i.e., type 1 or worse) ROP were referred for complete ophthalmoscopic evaluation. Within one week of NICU discharge, all infants in this program received a mandatory ophthalmoscopic examination by the same retinal specialist. The sensitivity of telemedicine for identifying referral-warranted and treatment-requiring ROP was reported to be 100%, the positive predictive value of telemedicine for identifying treatment-requiring ROP was 96%, and the negative predictive value was 100%. No known cases of treatment-requiring ROP were missed, and there were no adverse anatomic outcomes.<sup>8</sup>

Weaver and Murdock reported a real-world telemedicine system in rural Montana, in which 582 telemedicine exams were performed on 137 infants from 2007 to 2011. Infants with referral-warranted ROP (defined as type 2 or worse; zone II, stage 2 with pre-plus disease, or poorly imaged eyes) were transferred within 24 hours. Thirteen infants were transferred for referral-warranted ROP, of whom 9 ultimately required laser treatment. Prompt transfer of all infants was feasible, and there were no poor anatomic outcomes during the study period.<sup>28</sup>

Vinekar et al. implemented a public-private partnership program in India, which has provided telemedicine ROP screening by nonphysicians, which may become a model for outreach screening in middle-income countries. During a 77-month period, 20,214 imaging sessions were captured from 7106 infants at 36 rural centers.<sup>29</sup>

## **Barriers and Challenges**

Despite technologic advances to support telemedicine for ROP

management, its widespread adoption has been limited by factors such as medical licensure and lack of consistent insurance coverage and reimbursement policies. The level of diagnostic accuracy required for implementation of real-world ROP telemedicine systems is unclear, given concerns about medicolegal liability. Furthermore, it is difficult to rigorously assess accuracy because there may be variability in the reference standard of indirect ophthalmoscopy. Capturing images with sufficient diagnostic quality may not always be practical, particularly in the peripheral retinas of younger infants, warranting reevaluation either by repeat imaging or ophthalmoscopy. Finally, implementation of telemedicine for ROP requires approval of physicians and financial investments for new equipment and information technologies.

## Future Directions

Telemedicine has potential benefits for ROP management, education, and research. Studies have demonstrated that it has very high accuracy for detection of clinically significant ROP. Attention should be given to training protocols and to the assignment of roles and responsibilities for neonatology and ophthalmology personnel. Rules must be defined for cases in which image quality is inadequate, and when digital imaging is impractical because of systemic illness, infection contact precautions, or other reasons. Development of image capture protocols will help standardize the process of ROP telemedicine diagnosis. Reading software, which helps optimize workflow and mitigate risk, should be accessible for ophthalmologists and hospitals.<sup>30</sup> The success from operational programs suggests this is practical, but maintenance of sustainable ROP telemedicine programs will require generalizable solutions to these challenges.

## Introduction

Age-related macular degeneration (AMD) is a complex disease with genetic and environmental etiology and is the leading cause of irreversible blindness.<sup>1,2</sup> AMD is estimated to affect more than 8 million individuals in the United States. The advanced form of the disease impacts more than 1.75 million individuals,<sup>1</sup> adversely affecting quality of life and activities of daily living, and causing many individuals to lose their independence in their retirement years. Despite the introduction of new therapies for prevention and treatment of AMD, the prevalence of AMD is expected to increase by 97% by the year 2050.<sup>3</sup>

Although some treatments are available for AMD, including

specific nutritional intake and dietary supplements for dry AMD<sup>4-12</sup> and anti-VEGF therapies for neovascular disease (NV),<sup>13-15</sup> preventive measures are needed to reduce the burden of this disease. Smoking is the most consistently identified modifiable risk factor.<sup>16,17</sup> Obesity may also affect AMD incidence and progression to advanced disease.<sup>18</sup> There has also been great progress in identifying the genetic variants that impact AMD risk.<sup>19-36</sup> The knowledge of genetic risk variants for the disease coupled with knowledge of nongenetic risk factors has improved the ability to predict which patients will develop advanced forms of this disease.<sup>2</sup> Although much progress has been made over the past two decades, identifying the causes and mechanisms underlying AMD remains a challenge.

## Classification

It is important for investigators to standardize definitions of a disease and its subtypes in order to enhance comparability and to promote collaborative efforts. Toward this goal, an international classification and grading system for AMD was recommended, although it is not universally applied.<sup>37</sup> In this system, drusen and RPE irregularities are called age-related maculopathy and only geographic atrophy (GA) and NV are called AMD. Clinical manifestations of AMD can be subcategorized according to the specific type of AMD.<sup>10,38</sup> For example, the Age-Related Eye Disease Study (AREDS) has a 4-step scale that combines noncentral GA into stage 3 and both central GA and NV into one stage, 4. Individuals with visual loss presumed to be due to AMD are also classified as stage 4. The Clinical Age-Related Maculopathy Staging system (CARMS) separates GA and NV into two distinct subtypes and classifies individuals solely on their phenotype.<sup>38</sup> Both central and noncentral GA are classified as stage 4, and NV is classified as stage 5. The CARMS system has been useful for clinical management and genetic epidemiologic research and has been used in numerous studies.<sup>9,18,27,28-36,39,40</sup> More detailed systems have been used in some of the population-based studies described below,<sup>41,42</sup> and an updated classification developed under the auspices of the Beckman Initiative for Macular Research may be useful for future

studies.<sup>43</sup> New subcategories of AMD will evolve as genetic and epidemiologic studies provide further insight into disease pathogenesis.

## Incidence and Prevalence

Population-based studies have provided information on the prevalence of AMD within the United States, and include the National Health and Nutrition Examination Survey (NHANES),<sup>44,45</sup> the Framingham Eye Study (FES),<sup>46</sup> the Chesapeake Bay Watermen Study,<sup>41</sup> the Beaver Dam Eye Study (BDES),<sup>47</sup> the Baltimore Eye Survey,<sup>48</sup> and the Salisbury Eye Evaluation Project.<sup>49</sup> Population-based studies outside the United States include the Rotterdam Study in the Netherlands,<sup>50</sup> the Blue Mountains Eye Study (BMES) in Australia,<sup>51</sup> and the Barbados Eye Study.<sup>52</sup> Prevalence is quite variable for all types of AMD due to differences in definitions of AMD, but rates are more consistent for “advanced AMD.”

The total prevalence of AMD in the United States was estimated in 2004 using pooled findings from seven large population-based studies both inside and outside the United States and applying those prevalence rates to the US population.<sup>1</sup> This meta-analysis by the Eye Diseases Prevalence Group calculated the overall prevalence of NV and/or GA to be 1.47% of the US population aged 40 years or older. The most recent NHANES, conducted from 2005 to 2008, sampled approximately 5500 persons.<sup>45</sup> The total prevalence of any AMD in this civilian noninstitutionalized US population aged 40 years or older was 6.5%, and 809,000 persons in the United States were estimated to have late AMD.<sup>45</sup>

Studies conducted outside the United States have found similar or lower rates of AMD. In the Rotterdam Study, the prevalence of AMD was observed to be slightly lower compared with the BDES in Wisconsin.<sup>50</sup> In the BMES in Australia, the authors also found lower prevalence of all lesions related to AMD in each age stratum.<sup>51</sup> Methodologic differences between studies may exist, but the lower prevalence rates found in these countries may also reflect genetic or environmental differences compared with the US population.

A few studies have been done to evaluate the incidence of AMD. The FES used the age-specific prevalence data to estimate 5-year

incidence rates of AMD, according to the definition of AMD in that study. These estimates were 2.5%, 6.7%, and 10.8% for individuals who were 65, 70, and 75 years of age, respectively.<sup>53</sup> The BDES found that the 5-year cumulative incidence of early AMD increased from 3.9% in individuals aged 43–54 years to 22.8% in persons 75 years and older. The overall 5-year incidence of late AMD was 0.9%. Persons 75 years of age or older had a 5.4% incidence rate of late AMD. The Visual Impairment Project of Melbourne, Australia, found the overall 5-year incidence of AMD to be 0.49%.<sup>54</sup> The overall incidence of early AMD was 17.3% in this population of participants 40 years and older. As with the BDES, incidence of AMD increased with age – up to 6.3% for people aged 80 years and older at baseline. The Barbados Eye Study described a 5.2% 4-year incidence of early macular changes in a black population, with an extremely low incidence of exudative AMD, which may be attributable in part to differences in the racial/ethnic composition of this population<sup>55</sup> (discussed below in the “[Race/ethnicity](#)” section).

## Quality of Life

The psychologic costs associated with AMD underscore the growing importance of this disease on the expanding older adult population. For this reason it is important to incorporate a functional component into studies of AMD. An early study found that patients with visual loss resulting from AMD often report this disease as their worst medical problem and have a diminished quality of life.<sup>56</sup> Similarly, in one study of wellbeing, patients with AMD had comparable scores to patients with chronic obstructive pulmonary disease and acquired immunodeficiency syndrome (AIDS); the poor quality of life in patients with AMD was related to greater emotional distress, worse self-reported general health, and greater difficulty carrying out daily activities.<sup>57</sup> More recently, the National Eye Institute Visual Function Questionnaire and the Macular Disease Dependent Quality of Life Questionnaire have been used in AMD studies.<sup>58,59</sup>

## Sociodemographic Risk Factors

## Age

All studies demonstrate that the prevalence, incidence, and progression of all forms of AMD rise steeply with increasing age. There was a 17-fold increased risk of AMD comparing the oldest to the youngest age group in the Framingham Study.<sup>46</sup> In the Watermen Study, the prevalence of moderate to advanced AMD doubled with each decade after age 60.<sup>41</sup> In the BDES, approximately 30% of individuals 75 years of age or older had early AMD; of the remainder, 23% developed early AMD within 5 years.<sup>47,60</sup> By age 75 years and older in that study, 7.1% had late AMD, compared with 0.1% in the age group 43–54 years and 0.6% among persons aged 55–64 years. Pooled data in a prevalence paper showed similar rates, with dramatic increases in rates for both men and women over age 80.<sup>1</sup>

## Gender

Several studies<sup>1,46,47,50</sup> have shown no overall difference in the frequency of AMD between men and women, after controlling for age. However, in NHANES III, men, regardless of race and age, had a lower prevalence of AMD than women.<sup>44</sup> Incidence rates in the Beaver Dam population also suggest a gender difference. After adjusting for age, women aged 75 years or older had approximately twice the incidence of early AMD compared to men.<sup>60</sup> A study using reported incidence of exudative AMD in the United States among Medicare beneficiaries supported the Beaver Dam results.<sup>61</sup> In the BMES, there were consistent, although not significant, gender differences in prevalence for most AMD lesions, with women having higher rates for soft, indistinct drusen, but not for retinal pigmentary abnormalities.<sup>51</sup> A case–control study in AREDS also found women had a higher risk for intermediate drusen.<sup>62</sup> Residual confounding by age in the broad age category “75 and older” may partially explain the differences between studies as there are more women than men in that age group. Additional research is needed to assess these associations.

## Race/Ethnicity

Ophthalmologists observe visual loss caused by NV less frequently among US ethnic minority groups compared with Caucasians. In the Baltimore Eye Survey, AMD accounted for 30% of bilateral blindness among whites and for 0% among African Americans.<sup>63</sup> Data from a population-based study of blacks in Barbados, West Indies,<sup>52,55</sup> revealed that incidence of AMD and signs of AMD changes occurred commonly but at a lower frequency than in predominantly white populations in other studies. Hispanics also have a lower prevalence of advanced AMD compared to non-Hispanics. Late-stage AMD was significantly less frequent among Hispanics vs. non-Hispanic whites in the BDES (odds ratio [OR] 0.07; 95% confidence interval (CI) 0.01–0.49).<sup>64</sup> The Los Angeles Latino Eye Study indicates Latinos have a relatively high rate of early AMD but not late AMD.<sup>65</sup> Among persons aged 40–79 years, the age-specific prevalence of late AMD in Asians was comparable with that reported from white populations, but early AMD signs were less common among Asians.<sup>66</sup> It is also important to consider that approximately half of Asian patients with AMD may actually have the polypoidal variant of AMD, which may respond differently to therapies for standard management of NV.<sup>67</sup> These variations suggest that both race and ethnicity are important determinants of AMD.

## Socioeconomic Status

Lower levels of education and lower income have been shown to be related to increased morbidity and mortality from a number of diseases,<sup>68</sup> and there are mixed findings for AMD. The Eye Disease Case Control Study (EDCCS), a National Eye Institute-sponsored multicenter study, was designed to study risk factors for several types of maculopathy, including NV.<sup>69</sup> Persons with higher levels of education had a slightly reduced risk of NV, but the association did not remain statistically significant after adjustment for other risk factors.<sup>69</sup> Education was also inversely related to AMD in case–control and prospective studies based on the AREDS population even in multivariate analyses.<sup>62,70</sup> Similarly, a more recent study in Singapore found that lower education level was associated with a significantly higher prevalence of early AMD, when controlling for

age, cardiovascular risk factors, and cigarette smoking, although no association was found with income.<sup>71</sup> In the BDES, no association was found between maculopathy and education, income, employment status, or marital status.<sup>72</sup> Furthermore, no association was found in the FES,<sup>46</sup> although different definitions of AMD were used in this report, compared with the more recent studies. It is possible that education is a surrogate marker for other behaviors and lifestyles that are related to AMD, and it is important to consider this variable in analyses of AMD risk factors.

## Ocular Risk Factors

Several studies have shown an association between AMD and hyperopia, which has been supported by meta-analyses of these results.<sup>73,74</sup> The results of some studies, including the BMES, suggest that the association may only apply to early AMD.<sup>74,75</sup> A potential limitation is the clinical setting in which they were conducted. As ophthalmology practices tend to contain a disproportionate number of myopic patients, controls selected from such practices tend to have a higher prevalence of myopia than the general population. However, two population-based studies that reduce this bias, the BMES and Rotterdam Study, have also demonstrated similar results.<sup>75,76</sup> This association, therefore, might implicate structural and mechanical differences that render some eyes predisposed to maculopathy.<sup>77</sup>

Consistent with the association between AMD and hyperopic refractive error, the EDCCS demonstrated that eyes with larger cup-to-disc ratios had a reduced risk of exudative AMD. This effect persisted even after multivariate modeling,<sup>69</sup> adjusting for known and potential confounding factors. While this association has been demonstrated in another population-based study in India,<sup>78</sup> whether this finding is meaningful in terms of the mechanisms associated with the development of AMD awaits further study.

Higher levels of ocular melanin may be protective against light-induced oxidative damage to the retina, as melanin can act as a free radical scavenger and may have an antiangiogenesis function. To date, the literature is inconclusive about the relationship between iris color and AMD. Darker irides have been found to be protective

in some studies but not in others.<sup>79</sup> Differences between studies may be partly related to the use of different definitions of disease, different number and types of other factors evaluated simultaneously, and residual confounding by ethnicity in some studies.

Data regarding the relationship between cataracts and AMD are also inconsistent. FES investigators found no relationship,<sup>80</sup> whereas data from the NHANES did support a relationship between AMD and lens opacities.<sup>81</sup> In the BDES, in which photographs of the lens and macula were graded, nuclear sclerosis was associated with increased odds of early AMD (OR 1.96; 95% CI 1.3–3.0) but not of late AMD. Neither cortical nor posterior subcapsular cataracts were related to AMD.<sup>82</sup> A case–control study of 1844 cases and 1844 controls indicated that lens opacities or cataract surgery were associated with an increased risk of AMD.<sup>83</sup>

Although AMD-affected individuals reported better visual function and quality of life after cataract surgery,<sup>84</sup> a history of cataract surgery has been found to be associated with an increased risk for advanced AMD in some studies.<sup>85,86</sup> Investigators have postulated that this association might arise because the cataractous lens can block damaging ultraviolet light. Inflammatory changes after cataract surgery may also cause progression from early to late AMD. In the BDES, previous cataract surgery at baseline was associated with a statistically significant increased risk for progression of AMD (OR 2.7) and for development of late AMD (OR 2.8; 95% CI 1.03–7.6).<sup>87</sup> A more recent analysis from the BDES examining this question over a 20-year interval supports this association for late AMD,<sup>88</sup> however, in other recent prospective studies, including the large AREDS study cohort, there was no evidence to support a higher rate of progression of AMD in patients who underwent cataract surgery.<sup>89,90</sup>

## Behavioral and Lifestyle Factors

### Smoking

The preponderance of epidemiologic evidence indicates a strong positive association between both wet and dry AMD and smoking.

Seddon et al. in a prospective cohort study reported that women in the Nurses' Health Study who currently smoked 25 or more cigarettes per day had a relative risk (RR) of 2.4 (95% CI 1.4–4), and women who were past smokers had an RR of 2.0 (95% CI 1.2–3.4) for developing incident AMD compared with women who never smoked.<sup>16</sup> There was a dose–response relationship between AMD and pack-years of smoking, and risk remained elevated for many years after smoking cessation. Results were consistent for various definitions of AMD, including non-exudative and exudative AMD, with different levels of visual loss, and for different definitions of smoking. It was estimated that 29% of the AMD cases in that study could be attributable to smoking.<sup>16</sup> These results were supported by a study among men participating in the Physicians' Health Study.<sup>91</sup> Several other studies have also shown an increased risk of AMD among smokers.<sup>62,92–95</sup> Smoking is an important, independent, modifiable risk factor for AMD.

Mechanisms by which smoking may increase the risk of developing AMD include its adverse effect on blood lipids by decreasing levels of high-density lipoprotein (HDL) and increasing platelet aggregability and fibrinogen, increasing oxidative stress and lipid peroxidation, and reducing plasma levels of antioxidants.<sup>16</sup> In animal models, nicotine has been shown to increase the size and severity of experimental NV, suggesting that non-neuronal nicotinic receptors may also play a part in the effect of smoking on advanced AMD.<sup>96</sup> Smoking is independently associated with AMD even after adjusting for the genes complement factor H (*CFH*) Y402H or *ARMS2/HTRA1* genotypes<sup>97–99</sup> (see “[Genetic factors](#)” below).

## Diet

Diets high in antioxidant-rich fruits and vegetables are related to a lower risk of AMD. The first study launched to evaluate diet and AMD, the Dietary Intake Study ancillary to the EDCCS, showed an inverse association between exudative AMD and dietary intake of carotenoids.<sup>5</sup> In that study reported in 1994, a diet rich in green leafy vegetables containing the carotenoids lutein and zeaxanthin was associated with a reduction in the risk of exudative AMD, and

they are also associated with macular pigment.<sup>100–102</sup> Intake of 6 mg of lutein per day was significantly associated with a 43% reduction in risk of AMD.<sup>17</sup> A prospective double-masked study involving lutein and antioxidant supplementation in a group of 90 individuals showed that visual function was improved with 10 mg of lutein or a lutein/antioxidant formula.<sup>103</sup> In a British study of 380 men and women, lower plasma levels of zeaxanthin were also found to be associated with an increased risk of AMD.<sup>104</sup> A prospective follow-up study has shown that fruit intake is inversely associated with exudative AMD. Participants who consumed three or more servings of fresh fruit per day have a RR of 0.64 (95% CI 0.44–0.93) compared to those who consumed less than 1.5 servings per day.<sup>4</sup> Evidence regarding the beneficial effect of lutein on risk of AMD was also supported by analyses of diet data from AREDS.<sup>105</sup>

The role of antioxidant vitamins in the pathogenesis of AMD has received a great deal of attention. Antioxidants, including vitamin C (ascorbic acid), vitamin E (alpha-tocopherol), and the carotenoids (including alpha-carotene, beta-carotene, cryptoxanthin, lutein, and zeaxanthin), may be relevant to AMD as a result of their physiologic functions and the location of some of these nutrients in the retina. Trace minerals such as zinc, selenium, copper, and manganese may also be involved in antioxidant functions of the retina. Antioxidants could prevent oxidative damage to the retina, which could in turn prevent development of AMD.<sup>5,106</sup> Damage to retinal photoreceptor cells could be caused by photo-oxidation or by free radical-induced lipid peroxidation,<sup>107,108</sup> leading to impaired function of the RPE and eventually to degeneration involving the macula. The deposit of oxidized compounds in healthy tissue may result in cell death because they are indigestible by cellular enzymes.<sup>108,109</sup> Antioxidants may scavenge, decompose, or reduce the formation of harmful compounds. These early studies evaluating dietary impact on the pathogenesis of AMD provided background for subsequent clinical trials investigating the impact of dietary supplementation on the disease course in dry AMD.

An association between dietary fat intake, omega-3 fatty acids, and AMD was first reported in 1994 and published in 2001.<sup>7,8</sup> This association was primarily due to vegetable fat rather than animal fat. An inverse, protective association was found for higher

consumption of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) omega-3 fatty acids in the multivariate model.<sup>8</sup> Associations were also shown between risk of AMD and total fat, vegetable, monounsaturated, and polyunsaturated fats as well as linoleic acid.<sup>8</sup> These relationships were strengthened in a prospective longitudinal study of progression to advanced forms of AMD in an independent cohort.<sup>9</sup> A high intake of fish and omega-3 fatty acids reduced this risk when linoleic acid intake was low.<sup>9,18</sup> Later studies using data from the Women's Health Initiative, the Women's Health Study, and Australia confirmed that regular consumption of omega-3 fatty acids and fish were beneficial and they were associated with significantly decreased risk of early AMD.<sup>110–112</sup> Nuts have also been shown to decrease the risk of AMD progression.<sup>9</sup> In the BDES, individuals with greater saturated fat and cholesterol intake also had increased risk for early AMD.<sup>113</sup> Analyses of dietary data from AREDS support the previous observations of a beneficial effect of higher intake of omega-3 fatty acids.<sup>114</sup> One a study using data from this population suggested that not only can a higher intake of omega-3 fatty acids reduce the risk of GA, but the relationship may also be modified by genetic susceptibility.<sup>115</sup>

## Dietary Supplements

The AREDS confirmed that antioxidant and zinc supplementation can decrease the risk of AMD progression and vision loss.<sup>10</sup> This study included a double-blind clinical trial in 11 centers around the United States, randomly assigning 3640 participants to take daily oral supplements of antioxidants, zinc, antioxidants and zinc, or placebo. Both zinc alone and antioxidants and zinc together significantly reduced the odds of developing advanced AMD in participants with intermediate signs of AMD (see [Chapter 68, Age-related macular degeneration: Non-neovascular early AMD, intermediate AMD, and geographic atrophy](#)) in at least one eye. The zinc supplement included zinc (80 mg) as zinc oxide and copper (2 mg) as cupric oxide; the antioxidant supplement included vitamin C (500 mg), vitamin E (400 IU), and beta-carotene (15 mg).

The AREDS2 expanded on the use of antioxidant vitamins for the

prevention of AMD progression.<sup>11</sup> The primary goal of AREDS2 was to evaluate the efficacy and safety of supplements containing lutein plus zeaxanthin and/or omega-3 fatty acids in reducing the risk of developing advanced AMD, as suggested in previous observational studies of dietary intake as described above. The use of much lower doses of zinc than the original AREDS formulation and the omission of beta-carotene was also investigated. Notably, the dietary study published in 1994 showed a benefit of dietary lutein and zeaxanthin but no benefit of dietary beta-carotene on risk of developing NV.<sup>5</sup> AREDS2 enrolled 4203 participants, aged 50–85 years, who were considered at risk of developing advanced AMD. Participants were randomized to placebo, lutein/zeaxanthin (10 mg/2 mg), omega-3 fatty acids DHA (350 mg) and EPA (650 mg), or lutein/zeaxanthin and DHA/EPA, in addition to taking the original first-generation AREDS supplements described above. A second randomization was performed in approximately three-quarters (72%) of participants to investigate the effect of eliminating beta-carotene and reducing the zinc level from 80 mg in the original AREDS supplement to 25 mg.

In the initial analysis, additional supplementation with lutein/zeaxanthin and/or DHA/EPA was not shown to reduce the risk of progression to advanced AMD.<sup>11</sup> However, secondary analyses showed that lutein/zeaxanthin could be helpful in reducing the risk of AMD progression, particularly in patients with bilateral large drusen at baseline.<sup>12</sup> The overall results of the secondary analyses and the potential increased lung cancer risk in current and former smokers taking beta-carotene supplements led to the recommendation of supplementing with lutein/zeaxanthin rather than beta-carotene. Comparison of low-dose zinc supplementation to the higher dose in the original AREDS formulation did not reveal a statistically significant difference. While AREDS2 provided valuable information, several issues have been raised including the generalizability of the study results to a less well-nourished population, the complex randomization design, the lack of a true placebo group, and the relatively short duration of the trial.

## Alcohol Intake

Studies that have examined the relationship between AMD and alcohol consumption yield mixed results. In the EDCCS, no significant relationship between alcohol intake and exudative AMD was noted in univariate analyses,<sup>69</sup> but an inverse association could not be ruled out in multivariate analyses. A study using data from the Nurses' Health Study found no significant relationship between moderate alcohol consumption and risk of AMD; however, there was a modestly increased risk of early, dry AMD in drinkers consuming 30 g/d or more of alcohol.<sup>116</sup> In a case–control study using NHANES I data, moderate wine consumption was associated with a decreased risk of developing AMD, although the analysis did not control for the potential confounding effects of smoking.<sup>117</sup> The BDES found heavy drinkers were more likely to develop late AMD,<sup>93</sup> whereas the BMES found an increased risk of early AMD only in current spirits drinkers.<sup>118</sup> A prospective cohort study using data from the Melbourne Collaborative Cohort Study showed that drinking more than 20 g of alcohol per day was associated with an approximately 20% increase in the odds of early AMD, but did not replicate these findings for late AMD.<sup>119</sup> The evidence to date does not provide consistent support that alcohol intake has a large effect on the development of AMD.

## Obesity and Physical Activity

There is an association between progression to advanced stages of AMD and overall obesity, abdominal adiposity, and higher waist–hip ratio AMD.<sup>18</sup> Early stages of AMD have been associated with body mass index.<sup>120–125</sup> In a prospective cohort study of AMD progression, 261 individuals with some sign of nonadvanced AMD in at least one eye and a body mass index (BMI) between 25 and 29 had a RR of 2.32 (95% CI 1.32–4.07) for progression to advanced AMD when compared to those with a BMI of less than 25.<sup>18</sup> Those with a BMI of 30 or higher had a RR of 2.35 (95% CI 1.27–4.34) compared to the lowest category (BMI <25), after controlling for other factors. Similarly, increased waist circumference and higher waist-to-hip ratio were associated with increased risk of AMD progression. In the BMES, obesity was associated with higher incidence of AMD during the 10-year follow-up,<sup>124</sup> and the BDES

showed a similar association of increased risk of early AMD with increasing measures of obesity.<sup>125</sup> Vigorous physical activity three times a week reduced the risk of AMD progression by 25% compared to no physical activity.<sup>18</sup> Obesity and physical activity are modifiable factors that may alter an individual's risk of AMD and progression over time to advanced stages of the disease. In one study, the susceptibility to advanced AMD associated with *CFH* Y402H was modified by BMI, and both higher BMI and current and past smoking increased risk of advanced AMD within the same genotype category<sup>97</sup> (see “Genetic factors” below).

## Sunlight Exposure

Literature to date regarding the association between sunlight exposure and AMD is conflicting. Overall, the data do not support a strong association between ultraviolet radiation exposure and risk of AMD, although a small effect cannot be excluded. In the BDES,<sup>126</sup> increased time spent outdoors in the summer was associated with a twofold increased risk of advanced AMD. The 5-year<sup>127</sup> and 10-year<sup>128</sup> incidence of early AMD in the BDES confirmed this association, although the 10-year incidence study showed few significant associations between environmental light and incidence and progression of early AMD. The EDCCS<sup>69</sup> and the Pathologies Oculaires Liées à l'Age (POLA) study in France<sup>129</sup> showed no significant association between advanced AMD and sunlight exposure. Sensitivity to sunburn may also be a risk factor. An Australian case–control study noted an association between sun-sensitive skin and risk of neovascular AMD.<sup>130</sup> The European Eye Study found no association between overall sunlight exposure and neovascular or early AMD; however, a subgroup analysis suggested a positive association between lifetime sunlight exposure and NV among individuals in the quartile of lowest antioxidant level intake (vitamin C, zeaxanthin, vitamin E, and dietary zinc).<sup>131</sup> Conflicting results from these studies exemplify the difficulties encountered when studying this complex exposure. These difficulties include challenges in measuring short-term and lifetime exposure and the effect of potential confounding variables, such as sun sensitivity and sun avoidance behaviors or even dietary

composition. Furthermore, studies have evaluated different populations with different stages of AMD and people with varying intensity of exposures.

## Medications

The use of certain medications may be associated with AMD, although studies yield mixed results. Some studies have shown borderline statistically significant associations between increased risk of early AMD with use of antihypertensive medication, especially beta blockers.<sup>132</sup> Other studies have shown a decreased rate of NV among AMD patients taking aspirin, but the results have been inconsistent.<sup>133</sup> Similarly, a possible protective association between statins and AMD has been investigated in numerous studies with varied findings.<sup>134</sup> The use of statins may be associated with decreased NV due to their antiinflammatory and antioxidant properties.<sup>135</sup> Increased levels of C-reactive protein in patients with AMD underscore the role of inflammation in the pathophysiology of the disease,<sup>136</sup> and it may be the antiinflammatory effects of statins that affect risk, rather than the cholesterol-lowering effect of the medication. The potential link between anticholesterol medications is more intriguing given the finding that the lipase C (*LIPC*) gene, a gene that influences high-density lipoprotein (HDL) level, and other genes involved in cholesterol pathways, including cholesteryl ester transfer protein (*CETP*), are associated with AMD.<sup>30,31</sup>

## Cardiovascular-Related Factors

### Cardiovascular Diseases

It is important to study possible cardiovascular risk factors not only to understand the etiology of AMD, but also because anti-VEGF therapies may have cardiovascular risk. Some studies have suggested an association between AMD and clinical manifestations of cardiovascular disease (CVD). These studies suggested that many of the same risk factors for CVD were also associated with AMD. It was hypothesized that the pathogenesis of these two

disease spectrums may share causal pathways, and this could be helpful in identifying susceptible individuals who may benefit most from disease prevention measures as well as related mechanisms.<sup>137</sup>

The presence of atherosclerotic lesions, determined by ultrasound, was examined in relation to risk of macular degeneration in a large population-based study conducted in the Netherlands.<sup>138</sup> Results obtained from this cross-sectional study showed a 4.5-fold increased risk of late AMD (defined as GA or NV) associated with plaques in the carotid bifurcation, and a twofold increased risk associated with plaques in the common carotid artery. Lower-extremity arterial disease (as measured by the ratio of the systolic blood pressure [SBP] level of the ankle to the SBP of the arm) was also associated with a 2.5-times increased risk of AMD.

In addition, a case-control study found a relationship between AMD and a history of one or more CVDs.<sup>139</sup> The NHANES I study reported a positive association between AMD and cerebrovascular disease, but positive associations with other vascular diseases did not reach statistical significance.<sup>140</sup> A Finnish study reported a significant correlation between occurrence of AMD and the severity of retinal arteriosclerosis;<sup>141</sup> however, other studies found that individuals who reported a history of cardiovascular disease did not have a significantly greater risk of AMD.<sup>69,92,142,143</sup> At the same time, many CVD risk factors are associated with AMD.<sup>2,137</sup>

## Blood Pressure and Hypertension

The role of blood pressure in the etiology of AMD remains unclear. There was a small and consistent statistically significant relationship between AMD and systemic hypertension in three cross-sectional population-based studies.<sup>140,144,145</sup> The BDES reported that SBP was associated with incidence of RPE depigmentation,<sup>146</sup> 10-year incidence of advanced AMD lesions, and progression of AMD.<sup>135</sup> That study has also shown that arteriovenous nicking, a retinal vascular characteristic associated with hypertension, is associated with an increased incidence of AMD.<sup>147</sup> The Rotterdam Study also showed a relationship between elevated SBP and incidence of AMD.<sup>148</sup> In the Macular Photocoagulation Study, there

was an associated between hypertension and increased incidence of exudative AMD in the fellow eye of individuals with exudative AMD in one eye at baseline (RR 1.7; 95% CI 1.2–2.4).<sup>149</sup> In another case–control study, dry AMD was not associated with hypertension, but exudative AMD was significantly associated with both hypertension and antihypertensive medication use.<sup>132</sup> Other cross-sectional<sup>92,138,150</sup> and case–control studies,<sup>69</sup> as well as a prospective study<sup>142</sup> did not show an increased risk of AMD associated with current hypertension or systolic or diastolic blood pressure. Overall evidence suggests a possible mild to moderate association between elevated blood pressure and AMD. Assessment of this relationship could be enhanced by evaluating the duration of hypertension and its effects on onset and progression of maculopathy in large study populations with a sufficient number of participants with advanced stages of AMD.

## Cholesterol Levels

There is some evidence linking cholesterol level to AMD, but results are not consistent. The EDCCS reported a statistically significant fourfold increased risk of exudative AMD associated with the highest serum cholesterol level (>4.88 mmol/L) and twofold increased risk in the middle-cholesterol-level group, compared with the lowest-cholesterol-level group, controlling for other factors.<sup>69</sup> A positive association was found between risk of AMD and increasing HDL levels in the population-based POLA study,<sup>121</sup> the Rotterdam Study,<sup>151</sup> and the EPIC–Norfolk Eye Study.<sup>152</sup> A case–control study showed that higher HDL cholesterol levels tended to reduce the risk of AMD.<sup>153</sup> The BDES found that early AMD was related to low total serum cholesterol levels in women and men older than 75. Furthermore, men with early AMD had higher HDL and lower total cholesterol-to-HDL ratios.<sup>92,146</sup> A small, not significant increased risk of wet AMD was seen with increasing triglyceride level in the EDCCS.<sup>69</sup> This trend was not seen in the Rotterdam Study<sup>142</sup> or the BDES<sup>97</sup> but both studies had small numbers of exudative AMD cases.

The genes involved in the HDL cholesterol pathway that have been associated with AMD have had discordant effects between the

HDL-increasing alleles and the protective or risk effects for AMD. An HDL-raising allele of the *LIPC* gene was associated with a reduced risk of AMD, whereas an HDL-increasing allele of *CETP* increased risk for AMD.<sup>30,31</sup> Furthermore, mean HDL level was lower in advanced AMD cases compared with controls in one study, and this association was independent of the *LIPC* genotype.<sup>153</sup> In turn, *LIPC* genotype was associated with advanced AMD independent of HDL level and other factors including dietary lutein, smoking, BMI, and other AMD-related genetic variants.<sup>154</sup> The mechanisms through which genetic variants in the HDL cholesterol pathway exert their effect on AMD risk require further investigation.

In summary, serum cholesterol levels may be related to exudative AMD, but there is a more consistent relationship with dietary fat intake (see section on “Diet”). The mechanisms through which variants in HDL-related genes affect AMD risk is not simply through their influence on serum HDL level. Dissection of the mechanisms by which HDL mediates AMD risk may illuminate additional treatment strategies. This possible association with cholesterol intake may indicate a relationship with atherosclerosis.<sup>137</sup>

## Diabetes

Many studies have investigated the relationship between diabetes and AMD, and most have found no significant relationships. Only a few studies suggested a possible positive association.<sup>155</sup> One difficulty related to these studies is the uncertainty of diagnosing AMD in the presence of diabetic retinopathy involving the macula. In addition, many studies of AMD exclude persons with diabetic retinopathy. This could result in attenuated relationships between AMD and diabetes in published studies.

## Hormonal and Reproductive Factors

There is evidence to support a small protective effect of hormone therapy on AMD,<sup>156,157</sup> but associations with pregnancies<sup>158</sup> or menopause<sup>158,159</sup> are more mixed. The EDCCS showed a marked

decrease in the risk of NV among postmenopausal women who used estrogen therapy,<sup>69</sup> as did a cross-sectional study.<sup>156</sup> No relationship was found in the BDES between years of estrogen therapy and exudative AMD (OR 0.9 [per 1 year of therapy]; 95% CI 0.8–1.1) or any of the less severe forms of AMD among women,<sup>158</sup> however, this study had limited power to detect a potential effect of estrogen therapy on advanced AMD. Some studies,<sup>160,161</sup> including the BMES,<sup>159</sup> reported no relationship between AMD and hormone replacement therapy or early menopause. However, the BMES did describe a small but significant decrease in risk of early AMD with increasing number of years between menarche and menopause. A study of 799 female participants found a protective association between estrogen therapy, either hormone replacement therapy or birth control pills, and NV.<sup>162</sup> The Women's Health Initiative Sight Exam study demonstrated a protective association between combined estrogen and progestin hormone therapy and NV as well as soft drusen, but not early-stage AMD.<sup>163</sup> The evidence is sparse with varying results, but a protective effect of estrogen on AMD is possible.

## Inflammatory Factors

Studies have suggested that inflammation plays a role in the pathogenesis of drusen and AMD.<sup>136,137,164–166</sup> Examination of tissue samples has shown that “cellular debris” from RPE cells becomes trapped in the RPE basal lamina and Bruch's membrane, potentially causing a chronic inflammatory response that could prompt drusen formation.<sup>164</sup> Drusen contain proteins that are associated with chronic and acute inflammatory responses<sup>165</sup> and other age-related diseases, including amyloid P component and complement proteins.<sup>166</sup> Inflammation is also associated with angiogenesis, and may play a role in the neovascularization seen in the advanced exudative form of AMD.

A study of 930 individuals showed that serum levels of the systemic inflammatory marker, high sensitivity C-reactive protein, are significantly elevated in individuals with advanced AMD.<sup>136</sup> This study showed that, after adjusting for variables including age, gender, BMI, and smoking, the OR for AMD comparing the highest

and lowest quartiles of C-reactive protein was 1.65 (95% CI 1.07–2.55,  $p$  for trend = .02). Higher levels of high-sensitivity CRP and single nucleotide polymorphisms (SNPs) in the *CFH* and *ARMS2* genes were found to be independently associated with greater risk of AMD within most genotype groups.<sup>167</sup> These elevated levels suggest that reducing inflammation may slow the progression of AMD. Some studies raise the possibility that medications with anti-inflammatory properties, such as statins<sup>134</sup> and triamcinolone,<sup>168</sup> may be beneficial.

The existence of multiple, complement-related AMD risk alleles has provided further support for the inflammatory pathogenesis theory for AMD and sheds light on the role of uncontrolled alternative complement pathway activation in this disease (see “[Genetic factors](#)” below). *CFH* inhibits the alternative complement pathway by blocking formation of and accelerating the decay of alternative pathway C3 convertases; it also serves as a cofactor for the Factor-1-mediated cleavage and inactivation of C3b.<sup>169</sup> The *CFH* Y402H variant is within the *CFH* binding site for heparin and C-reactive protein. Binding to these sites increases the affinity of factor H (FH) for C3b, which in turn increases the ability of FH to inhibit complement's effects.<sup>170</sup>

As a result of the complement-related genetic discoveries, various complement-modulating agents are currently in clinical trials for the treatment of AMD.<sup>171</sup> Systemic administration of the anti-C5 antibody, eculizumab, was investigated for geographic atrophy and the phase II study failed to show efficacy of this therapeutic agent.<sup>172</sup> Other agents in various phases of clinical trials include intravitreal compstatin/POT-4 (C3 inhibitor), intravitreal ARC1905 (a C5 inhibitor), and intravitreal lampalizumab (an antibody against Complement Factor D).

## Genetic Factors

AMD is a complex, polygenic disease in which multiple common genetic variants each add a small to moderate amount of increased risk, while rare variants have higher risk, and all contribute to disease in addition to environmental factors.<sup>2,173</sup> The risk of developing the disease is threefold higher in people who have a

family member with AMD than in those without an affected first-degree relative.<sup>174,175</sup> Since 2005, several genetic variants have been consistently associated with AMD, including common and rare variants in the *CFH* gene and variants in several other genes in the alternative complement cascade,<sup>27,33,176,177,178</sup> including Factor B (*BF*)/Complement Component 2 (*C2*),<sup>26,27</sup> Complement Component 3 (*C3*),<sup>28</sup> and Complement Factor I (*CFI*).<sup>29</sup> Rare genotypic variants in the *CFH* gene, such as the R1210C rare variant, are associated with higher risk of disease, extensive drusen accumulation and earlier onset of advanced disease.<sup>40,177</sup>

Several genes not involved in the complement cascade have also been implicated as AMD risk factors. Variation in the *ARMS2/HTRA1* locus on chromosome 10 has been convincingly associated with AMD with an effect size similar to or greater than that of *CFH*.<sup>23-25,179</sup> The function of this gene is not completely elucidated, but there is evidence that it confers a somewhat greater risk for wet AMD compared to GA.<sup>33,35</sup> *LIPC* and tissue inhibitor of metalloproteinase 3 (*TIMP3*) were associated with AMD in two large genome-wide association studies.<sup>30,31</sup> *LIPC* is involved in HDL cholesterol metabolism and *TIMP3* is implicated in a Mendelian, early-onset form of macular degeneration, Sorsby fundus dystrophy.<sup>180</sup> More recently, new variants near the collagen type X alpha 1 precursor/fyn related kinase (*COL10A1/FRK*) genes and in *VEGFA* were discovered to be associated with advanced AMD,<sup>34</sup> supporting the association noted with the gene *COL8A1*<sup>30,34</sup> and emphasizing the importance of extracellular matrix biology and angiogenesis in AMD. The genetic variants discovered to date explain about half of the classical sibling risk of AMD, and commercial genetic testing for some AMD risk variants is currently available. Knowledge of genetic variation at risk loci increases the ability to predict AMD progression above and beyond knowledge of demographics, ocular factors, smoking history, and BMI.<sup>176,178,181-183</sup> Although there is not yet a consensus on how genetic testing should be integrated into clinical practice, genotyping may become a useful tool for identifying individuals who have a higher risk for disease onset and progression. These patients may benefit from more intense monitoring and/or preventive treatment strategies, and may help with designing

clinical trials.<sup>176,178,181–183</sup>

## Pharmacogenetics

Pharmacogenetic studies have explored the association of the *CFH* and/or *ARMS2/HTRA1* polymorphisms with patients' responses to anti-VEGF therapy and antioxidant supplementations. One retrospective cohort study found that patients with the *CFH* Y204H CC genotype had worse visual outcomes with intravitreal bevacizumab than did those with the *CFH* TC and TT genotypes; they found no pharmacogenetic relationship with *ARMS2/HTRA1*.<sup>184</sup> This relationship between *CFH* genotype and poorer visual acuity outcomes with intravitreal bevacizumab was corroborated by a prospective study.<sup>185</sup> Another retrospective study evaluating only the *CFH* locus found that patients who were homozygous for the Y402H risk allele have a 37% significantly higher risk of requiring additional intravitreal ranibizumab injections.<sup>186</sup> There were no significant treatment interactions with *ARMS2/HTRA1*. A recent study, that evaluated more AMD genes as well as nongenetic factors as predictors of response to anti-VEGF treatment, showed significant improvement in visual acuity after one year for the low-risk *CFH* genotypes and among subjects with a low *CFH* risk score.<sup>187</sup> In analyses of data derived from two large clinical trials comparing anti-VEGF treatments, no significant differences regarding genotypes were reported.<sup>188,189</sup>

Results from pharmacogenetic analyses to assess whether genetic susceptibility may influence response to antioxidant/mineral supplements have been conflicting. In a retrospective analysis of the AREDS data, an interaction between *CFH* Y402H genotype and supplementation with antioxidants plus zinc and zinc alone was observed.<sup>181,190</sup> Two studies using data from the AREDS study established risk prediction models for progression to AMD and showed a benefit of antioxidant-mineral supplementation for *CFH* homozygous low-risk genotypes but little benefit for the *CFH* homozygous risk genotype.<sup>181,182</sup> These studies did not identify any interactions between antioxidant/mineral supplements and other genetic variants. Further studies suggested that certain genotypic subgroups had neutral or even unfavorable responses to AREDS

supplements, and some genotypic subgroups had a greater reduction in disease progression rate with zinc only or antioxidants only, compared with the combined AREDS formulation.<sup>191,192</sup> However, a separate analysis of a subgroup of the same data suggested that there is no interaction between genotype and response to AREDS supplements.<sup>193,194</sup> Differences in definitions and sample sizes for subgroups and analytic methods may explain some of the variation in the results. Another study using a larger AREDS cohort and applying a different analysis found no beneficial AREDS treatment effect among subjects with the *CFH* high risk genotype, and a significant interaction was observed for the NV subtype.<sup>195</sup> On the other hand, the higher risk genotype group for *ARMS2* appeared to benefit more from the supplements, with a significant interaction.<sup>195</sup> There is currently no formal recommendation for genetic testing in determining the appropriateness of antioxidant/mineral supplementation.

## Conclusion

AMD is a multifactorial disease that affects a large proportion of the population. Research to date has yielded some preventive measures and a few effective treatments for the advanced exudative form of the disease, and there are ongoing studies investigating possible therapeutics for advanced dry AMD. Several factors that could modify individual risk have been identified, including smoking, dietary intake of omega-3 fatty acids, green leafy vegetables, and fruit with antioxidants including lutein and zeaxanthin, as well as exercise and maintaining a healthy overall and abdominal weight. Studies have shown mixed effects of sunlight exposure, medication use, and alcohol intake. The understanding of the genetic architecture of AMD has increased significantly over the past decade and those pathways underscore the roles of inflammation, immune mechanisms, HDL cholesterol metabolism, angiogenesis, and dysfunction of extracellular matrix proteins, in the etiology of this disease. A combination of these genetic and nongenetic factors can predict rates of progression to advanced AMD subtypes over time. Ongoing studies of therapies targeting these mechanisms of disease may potentially change treatment paradigms for the

advanced forms of the disease, and may reduce rates of transition to stages of AMD that cause visual loss among high-risk individuals.

### **Balance of Tissue Change In Early AMD**

## Introduction

Age-related macular degeneration (AMD) can be divided into early and late stages. In early disease, visual acuity is good, and in the fundus, focal deposits, called drusen, are seen in Bruch's membrane. The distribution and size of drusen varies from one patient to another, although their attributes are highly concordant between eyes of an individual implying that their morphology reflects the risk factors of disease in that individual. There may also be pigmentary changes at the level of the retinal pigment epithelium (RPE).

The three forms of late AMD cause loss of central vision. With few exceptions<sup>1</sup> the most common form is choroidal neovascularization (CNV), in which blood vessels grow inwards from the choroid into or through Bruch's membrane. Detachment of the retinal pigment epithelium (PED), in which there is accumulation of fluid between the RPE and Bruch's membrane, is relatively uncommon. In geographic atrophy (GA) there is well-defined loss of RPE and photoreceptor cells.

It is generally considered that GA is the default pathway of the disease process of early AMD, and that CNV occurs as a reactive event during the evolution of early changes. The treatment of CNV is well established and is described elsewhere in this book. If the default pathway of early AMD to GA is correct, it would be expected that GA would follow at some stage following successful treatment of CNV, and there is evidence to support this conclusion.<sup>2,3</sup> There is no well-recognized treatment whereby the disease mechanisms inducing transition from early AMD to GA can be modified.

The structures involved in the early AMD are the photoreceptor cells in the outer retina, the RPE, Bruch's membrane, and the capillary bed in the inner choroid (choriocapillaris). In early AMD changes occur in all these tissues throughout the eye, although they are most marked at the macula that subserves central vision in which there is a high density of cones. The changes in each of these

tissues represent a potential target for treatment based on the current understanding of the relevant pathogenic mechanisms. In this chapter changes in each tissue will be described and the logic of the various therapeutic approaches will be discussed.

## Structural Changes

### Choroid

In the young, the choroidal capillary bed is formed of a sinusoidal complex in which the capillary bed is fenestrated and lacks tight junctions. It is believed that the nature of the choriocapillaris is determined largely by the constitutive expression of vascular endothelial growth factor (VEGF) outwards by the RPE toward the choroid.<sup>4-8</sup> In one morphometric study it was found that the density of the choriocapillaris decreases with age in eyes without AMD<sup>9</sup> and choroidal casts have shown that the capillary bed may become tubular.<sup>10</sup> With advanced AMD, loss or narrowing of the choriocapillaris may become more marked.<sup>11-16</sup>

A clue as to possible clinical detection of change in the choriocapillaris came from studies of Sorsby fundus dystrophy, a monogenic disorder characterized by major thickening of Bruch's membrane and a prolonged choroidal filling phase on fluorescein angiography.<sup>17</sup> It was thought that the diffusely thickened Bruch's membrane represented a barrier to diffusion of VEGF towards the choroid resulting in changes in the capillary bed to a tubular state and with loss of fenestrae such that acquisition of fluorescence of the inner choroid is irregular and delayed.<sup>18,19</sup> This angiographic sign has also been identified in patients with AMD.<sup>20</sup> It is not known whether this sign indicates only change in circulation, or if slow egress of dye into the extravascular space is due largely to loss of fenestrae; poor diffusion through lipid-laden tissues may also contribute to this angiographic abnormality. The potential significance of this clinical sign has been established by demonstrating discrete areas of scotopic threshold elevation of up to 3.4 log units and slow dark adaptation, which corresponded closely to regions of choroidal perfusion abnormality.<sup>21,22</sup> Loss of photopic function was less marked. Subsequent studies have also

shown that the recovery from bleaching is prolonged<sup>23</sup> and the functional loss has an impact on daily tasks.<sup>24</sup>

## Therapeutic Implications

It is most likely that modification of the choroid in AMD is a response to alteration of neighboring tissues rather representing an intrinsic change, although the consequent reduction of metabolic supply to the outer retina may play a contributory role in the generating of disease. However, the possibility that choroidal changes occur independently of changes in other tissues cannot be excluded. This is not seen as a good target for therapy currently.

## Bruch's Membrane

A direct relationship between aging and thickness of Bruch's membrane has been established both by electron and light microscopy,<sup>25,26</sup> and in one study the correlation coefficients ( $R^2$ ) were only 0.57 and 0.32, respectively, with great variation in the elderly.<sup>27</sup> Thus about half of the change in thickness must be explained by factors other than age, such as genetic or environmental influences. In AMD the thickening is greater than with aging alone due to accumulation of material internal to the inner collagenous layer that has been termed the basal laminar deposit.<sup>28</sup>

Several studies on the nature of the deposits have been undertaken. Consequent upon discussion of the pathogenesis of PEDs, it was hypothesized that reduction of the hydraulic conductivity of Bruch's membrane would hamper movement of water towards the choroid, thus causing it to accumulate in the sub-RPE space.<sup>29</sup> This demands that Bruch's membrane contains a high lipid content that would increase the resistance of fluid flow. A series of investigations followed to test this hypothesis and support was derived from both histopathologic, biochemical, biophysical, and clinical observations. A study of frozen tissue undertaken using histochemical staining on human eyes with an age range between 1 and 95 years showed accumulation of lipids with age that varied greatly both in the quantity and form of lipids in the elderly.<sup>30</sup> Some eyes stained for neutral lipids alone, some stained predominantly

for phospholipids, and others stained equally for both neutral lipids and phospholipids. To confirm these conclusions, material extracted by universal lipid solvents from tissue of eye-bank fresh eyes was analyzed by thin layer and gas chromatography.<sup>31,32</sup> After separation, the chemical species were identified by mass spectroscopy, which included fatty acids, cholesterol esters, triglycerides, and phospholipids. This study confirmed the conclusion that the quantity of total lipid in Bruch's membrane increases with age. Little or no lipid was extracted from specimens from donors younger than 50 years of age. In specimens from donors older than 50 years, the increase was exponential. Eyes from donors over the age of 60 years showed wide variation of total lipid extracted from donors of similar age, and that the ratio of phospholipids to neutral fats was different from one specimen to another. The ratio of neutral lipids to phospholipids did not correlate with the total quantity of lipid. The finding that the major lipid species were phospholipids and fatty acids rather than cholesterol and cholesterol esters, and that only 50% of the phospholipids was phosphatidylcholine, led to the conclusion that the lipids were of a cellular (presumably RPE) rather than plasma origin.<sup>32</sup> Curcio and coworkers, using different extraction methods, reported that cholesterol and cholesterol esters were the major lipids rather than phospholipids.<sup>33</sup> As in the previous study, however, it was concluded that the lipids were of RPE origin on the basis of the nature of the cholesterol. Unlike atheroma, there was little free cholesterol.

Finally, measurements of hydraulic conductivity of Bruch's membrane showed that it becomes reduced with age,<sup>34,35</sup> and after the age of 50 years there is a close direct linear relationship between resistance of fluid flow and lipid content.

Clinical observations were sought to support the concept that the biochemical content as well as thickness of Bruch's membrane influenced subsequent clinical behavior. It was hypothesized that drusen that are hyperfluorescent on fluorescein angiography must be hydrophilic allowing free diffusion of water-soluble sodium fluorescein into the abnormal deposit and that there would be binding of dye to polar molecules. By contrast, if the drusen were hypofluorescent it would imply that they are hydrophobic due to

the presence of neutral lipids. This conclusion was supported by histologic observations in which it was shown that *in vitro* binding of sodium fluorescein correlated well with the biochemical contents of drusen as shown by histochemistry.<sup>36</sup> Drusen rich in neutral lipids did not bind fluorescein, whereas those with little lipid content bound fluorescein strongly.

It would be predicted that the highest resistance to water flow and diffusion in Bruch's membrane would be found in eyes destined to suffer tears of the detached RPE, in which there is sufficient tangential stress in the detached tissues to cause them to rupture. The slow accumulation of fluorescein in the sub-RPE space in those destined to tear supports this concept. The determination that a tear in one eye implied high risk of a similar event occurring in the fellow eye<sup>37</sup> provided the opportunity to test the concept further. A comparison was made of the drusen in the fellow eye of a tear with those of the fellow eye of one with visual loss due to subretinal neovascularization. It was shown that the drusen were larger, more confluent, and less fluorescent on angiography in the former group than in the latter.<sup>38</sup> Thus, there is good reason to believe that thickening and lipid accumulation in Bruch's membrane would hamper movement of metabolites and water between the RPE and choroid.

There is considerable lipid trafficking through Bruch's membrane, and lipids are believed to accumulate as they fail to pass freely through a thickened Bruch's membrane. This demands that Bruch's membrane becomes thicker as a prerequisite for this lipid accumulation. Analysis has been undertaken of proteins in aging Bruch's membrane since this is likely to initiate the thickening. Recent studies have shown that several of the proteins associated with the immune system, such as C3, C5b-C9, and complement factor H (CFH), are present in high quantity in Bruch's membrane in AMD.<sup>39</sup> These observations serve to underline the potential significance of a disordered immune system to AMD. However, unlike inflammation elsewhere there is no infiltration by inflammatory cells in the absence of CNV. Beta-amyloid has also been identified.<sup>40</sup> In the inner part of Bruch's membrane there are high levels of vitronectin.<sup>41-43</sup> The origin of the proteins is in doubt given that there is RPE expression of some of the constituents

although a major contribution may come from plasma. Furthermore, there is no certainty as to the mechanisms causing accumulation and stabilization of the proteins. The state of the proteins is unknown, but circumstantial evidence suggests that they are oligomerized<sup>44</sup> and that oligomerization may be generated by high levels of zinc or other metallic ions. In Bruch's membrane the levels of zinc are very high.<sup>45</sup> The levels of bioavailable zinc are many times that necessary to cause oligomerization of CFH in vitro, and oligomerization occurs at even lower levels if CFH is mixed with C3.<sup>46</sup> Thus the proteins may not have the biological properties of the monomers. Withdrawal of zinc reverses the polarization.

A recent report describes the presence of spherules of hydroxyapatite round cholesterol-rich cores in Bruch's membrane that may be an additional factor inducing protein accumulation.<sup>47</sup> These spherules had been described previously, but their nature had not been established. It has been shown that these spherules become covered by proteins that may be different from one spherule to another, and it was argued that these spherules may act as an initiator of oligomerization.

Further insight into the possible mechanisms of accumulation of material in Bruch's membrane was derived from observation in the CFH<sup>-/-</sup> mouse.<sup>48</sup> It is acknowledged that a gene knockout is not necessarily homologous with a polymorphism, that the immune system in mouse is dissimilar from human and mouse does not have a macula. However, if reduction of CFH activity is important, as has been concluded from genetic studies, the observations may help in understanding AMD. In this mouse there is thickening of the renal glomerulus basement membrane, but surprisingly, Bruch's membrane was thinner than in age-matched mice. This implies that dysregulation of the immune system alone may not explain thickening of Bruch's membrane and that the presence of the CFH protein itself may be important to the process.

## **Therapeutic Implications**

If thickening of Bruch's membrane and impedance of metabolic exchange and fluid movement is important to the pathogenesis of AMD, several therapeutic approaches might be considered. Reduction of the availability of the constituent proteins may slow

the disease process, such as might be achieved with the chronic use of antiinflammatory agents. Once thickening is established, mobilizing lipids or breaking down the oligomers may be achieved with the use of antibodies or possibly zinc buffers, as has been suggested in Alzheimer's disease.<sup>49</sup> There might be potential risks in rapid generation of monomers.<sup>50</sup> Alternatively, the lipids might be mobilized. All these approaches would increase hydraulic conductivity and improve metabolic exchange between the RPE and choriocapillaris. In addition, it may induce an increase in choroidal circulation and in the density of fenestrae.

## The Retinal Pigment Epithelium

Accumulation of residual bodies that fluoresce can be used as an index of age change in the RPE. A quadratic relationship exists in donor eyes between age, and both autofluorescence and residual body quantity as measured by autofluorescence imaging as seen by light microscopy and electron microscopy, respectively.<sup>27</sup> The slowing of accumulation in the elderly was not surprising since the population of photoreceptors decreases in late life.<sup>51</sup> The relationship between age and autofluorescence, however, is not close, with an adjusted  $R^2$  of only 0.45, and for residual bodies the  $R^2$  was 0.50,<sup>27</sup> reflecting the wide variation in the eyes from elderly donors. Thus 50% of the variation in either autofluorescence or residual bodies is not explained by aging, the suspicion being that genetic or environmental factors would play a role in determining the variance. Most surprising was the relationship between autofluorescence and residual body volume. The relationship was direct, which would have been expected since it is from the residual bodies that the autofluorescence is derived. However, the  $R^2$  was only 0.26. In retrospect, the variation between specimens should not have been surprising since only a small proportion of the material in residual bodies fluoresces, and this proportion may be influenced by circumstances such as vitamin A content in diet. If rodents are given a diet low in vitamin A the residual bodies do not fluoresce, whereas in littermates given a diet high in vitamin A the residual content of the RPE is similar but they fluoresce brightly.<sup>52</sup> From this observation it might be concluded that those with high

autofluorescence levels had a diet high in vitamin A.

The clinical relevance of these findings is underlined by the ability now to image RPE autofluorescence *in vivo* through the efforts of Fitzke and von Rückmann.<sup>53</sup> This was achieved initially using a confocal scanning laser ophthalmoscope with an excitation wavelength of 488 nm. Emission is recorded above 514 nm by inserting a barrier filter. The evidence that the signal originates from lipofuscin in the RPE is derived from the work of Delori and coworkers.<sup>54</sup> The spectral nature of the signal is characteristic of lipofuscin and is derived from internal to the choroid and external to the neurosensory retina. It has been shown that in early AMD the distribution of autofluorescence varies from one patient to another. In about half of eyes with early AMD, autofluorescence is homogeneous, whereas in the remainder, diffusely irregular or focally increased autofluorescence is seen.<sup>55,56</sup> Drusen do not appear to explain the differences, since apart from serogranular drusen at the fovea, drusen in AMD do not influence autofluorescence significantly. It has been shown that in bilateral early AMD the pattern of autofluorescence is symmetric, implying that the autofluorescence characteristics reflect the form of disease in an individual that may be determined by the genetic or environmental influences. In patients with unilateral visual loss from AMD, focal increased autofluorescence in the good eye is associated with GA in the other eye and predicts the development of GA in the good eye.<sup>56</sup> This impression was reinforced by the observation that if a high level of autofluorescence is found around the perimeter of GA, this area becomes atrophic within one year,<sup>57</sup> whereas cases without marginal hyperautofluorescence tend not to have progression of their GA.

The underlying molecular mechanisms by which changes in the RPE result in the development of GA have been subject to debate. It has been argued that the cytoplasmic volume occupied by the residual bodies may interfere with cell metabolism.<sup>58</sup> It has been shown that lipofuscin is a free radical generator and that may cause cell damage.<sup>59</sup> In addition, there is evidence for toxic effects of individual lipofuscin compounds. A2-E, a Schiff-base product of retinaldehyde and ethanolamine, has surfactant-like properties on biomembranes that have been shown in one study to increase

intralysosomal pH by inhibition of the ATP-dependent lysosomal proton pump that in turn would inhibit activity of lysosomal hydrolases.<sup>60</sup> Furthermore, A2-E has been shown to cause leakage of lysosomes in vitro.<sup>61</sup> Release of lysosomal content may cause further RPE cell dysfunction and cell death. Another study failed to confirm a rise in lysosomal pH, possibly because lower quantities of lipofuscin were used, but it did show that lipid degradation was reduced.<sup>62</sup> Thus, both studies imply that lipofuscin reduces the activity of phagolysosomal enzymes.

The possible consequences of reduced RPE lysosomal degradation have been investigated in vivo. Interference with degradation of lysosomes was achieved in 11-week-old Sprague-Dawley rats by injection of 5  $\mu$ L of a lysosomal protease inhibitor, E-64 (2.22  $\mu$ M), intravitreally.<sup>63</sup> A single injection of E-64 caused a transient accumulation of phagolysosome-like inclusion bodies in the RPE. Furthermore, two or three injections on alternate days caused greater accumulation of these inclusions associated with changes in intracellular organelles such as loss of smooth endoplasmic reticulum and of RPE cell conformation. This was accompanied by shortening and loss of photoreceptor outer segments without prior dysmorphic changes, photoreceptor loss, reduction of fenestrae in the choroidal capillaries, and invasion of Bruch's membrane by fibroblasts and pericytes. Intravitreal injection of vehicle for comparison induced no such structural changes.

It was considered likely that the changes in the RPE reflected reduced metabolism of lipids and reduction of basolateral VEGF expression caused the loss of fenestrae. The shortening and loss of the outer segments was thought to be due to impaired morphogenesis of disc membranes rather than a direct effect of E-64 on photoreceptor cells, because there was no vesiculation of disc membranes. The shortening of the OS could be explained by the lack of available lipids due to the inability of the RPE to break down and recycle the contents of the phagosome. The findings imply greater dependence upon the availability of products of phagosomal degradation for OS renewal than was previously considered, and that acquisition of plasma-derived material is insufficient to sustain this process fully. The ability of the RPE to

recycle lipids has been well illustrated.<sup>64,65</sup> The observed changes in rats are similar in many respects to age changes in RPE, photoreceptor, and choroid in humans, although there are major differences between such an acute experiment and the consequences of lifelong metabolic activity, and species differences between rat and human.

Thus, both experimental evidence and clinical observations illustrate a potential pathogenetic mechanism of GA and explain the association of GA with focal increased autofluorescence if the latter is witness to the inability to recycle phagosomal contents.

Another potential intriguing consequence of the presence of lipofuscin is the demonstration that photodegradation products of the fluorophore induce the complement cascade that may be relevant to Bruch's membrane thickening.<sup>66</sup>

Measurement of visual function over areas of increased autofluorescence showed loss of scotopic function that was much greater than photopic, and that the loss was as great as 3.5 log units.<sup>67</sup> The question as to whether the loss is due to cell loss or cell dysfunction was not addressed.

In addition it has been shown that RPE mitochondrial damage is severe in some eyes from elderly donors,<sup>68,69</sup> although the relevance of this finding to RPE and photoreceptor cell loss has not been investigated to date.

## **Therapeutic Implications**

If increased lipofuscin is important to genesis of GA, it would argue against dietary supplementation with vitamin A or its precursors. Efforts are now underway to reduce the accumulation of lipofuscin therapeutically by restricting the availability of vitamin A to the retina. Initial results have shown the potential benefits of this approach in the ABCA4 knockout mouse<sup>70,71</sup> and trials in humans have been initiated.<sup>72</sup> Agents that increase lysosomal activity or lower phagolysosomal pH might also be effective. On theoretic grounds light restriction might also be helpful. In addition illumination with near infrared light may improve mitochondrial function that would address the RPE deficit in those in whom this is a problem.<sup>73</sup>

## Outer Retina

Relative to other structures there has been little attention paid to physical changes in the neurosensory-retina in AMD. This is surprising since in early histologic studies it was concluded that photoreceptor cell loss occurs progressively in early AMD, although it was thought that this may occur as a consequence of RPE dysfunction.<sup>74,75</sup> Considerable evidence exists to support the conclusion that photoreceptor loss occurs early in the course of disease in some and that disease mechanisms internal to the RPE are important in early AMD.

Three papers report findings from ocular coherence tomography in patients with GA.<sup>76-78</sup> Areas of the fundus beyond the edge of atrophy in which the retina appeared unexceptional by ophthalmoscopy were imaged to determine the thickness of the photoreceptor layer. In some subjects there was an abrupt change from the lack of photoreceptor cells in the area of atrophy, to a normal thickness outer nuclear layer. However, in others there was evidence of major photoreceptor loss for a considerable distance beyond the edge of GA.

Several studies have been undertaken on functional attributes in early AMD. All report that there is a major loss of scotopic sensitivity and less profound loss of photopic sensitivity in a proportion.<sup>21,23,67,79-88</sup> In none of these studies was the question addressed as whether the loss was due to photoreceptor loss or photoreceptor dysfunction.

Observations in the CFH knockout mouse may also be relevant to photoreceptor cell loss in AMD.<sup>48</sup> It had been shown that visual function was reduced when compared with age-matched mice despite the lack of expected Bruch's membrane thickening. In these mice, the photoreceptor outer segments were dysmorphic and there was increased C3 expression in the outer retina. The relevance of C3 to outer segment morphology or of disease mechanism inducing high levels of C3 is unknown. As a result of these observations it was concluded that the consequences of the high-risk CFH polymorphism might not be restricted to its influence upon Bruch's membrane. Of possible relevance is that RPE expression of CFH in vitro appears to be apically into the outer retina rather than through the basolateral domain into the choroid.<sup>89</sup> These observations raise

the possibility that there is a role played by the immune system in photoreceptor health, and that disturbance of the immune system may cause demise of photoreceptor cells that is unrelated to changes in Bruch's membrane or the RPE. It is also of interest that some have failed to reproduce the findings in the knockout mouse. There is a suspicion that the changes may not occur in a pathogen-free animal house.

Further evidence of a pathogenetic component of AMD internal to the RPE was originally described in 1990 as an irregular appearance on blue light reflection.<sup>90</sup> It is believed that this is associated with deposits internal to the RPE termed reticular pseudodrusen.<sup>91</sup> The material has not been fully characterized but is stated not to be lipid-rich, and to contain cholesterol but not cholesterol esters; in these respects they differ from deposits external to the RPE.<sup>92</sup>

A recent histopathologic study has been undertaken on donor eyes with GA<sup>93</sup> examining the same question as had been addressed with optical coherence tomography (OCT). It was shown that for a considerable distance beyond the edge of GA there was major photoreceptor loss in a majority of eyes (Figs. 67.1 and 67.2). The only photoreceptors were cones, there were no outer segments, and a few cones had inner segments. In addition, in three donor eyes with early AMD the outer nuclear layer was reduced to 2–3 layers. As a consequence it was concluded that the visual loss in early AMD is due to photoreceptor loss at least in part. In addition, measuring the area of GA is not a good measure of photoreceptor survival.

**FIG. 67.1** Light micrograph of a 70-year-old donor with geographic atrophy (GA) showing that photoreceptor cells are restricted to a few cones with inner segments

only beyond the edge of GA (*arrow*) (A). Over a distance of 1400  $\mu\text{m}$  only cones with few inner segments are seen (B). There is little Bruch's membrane thickening, the choriocapillaris is well perfused throughout, and the RPE is unexceptional physically.

**FIG. 67.2** Light micrograph of a 78-year-old female donor in whom geographic atrophy (GA) had been diagnosed. Some distance from the edge of GA, there is marked loss of photoreceptor cells, Bruch's membrane is very thick due largely to the presence basal laminar deposits, and the choriocapillaris is not perfused.

## Therapeutic Implications

Preservation of the photoreceptor cells might be best achieved by improving RPE function by reduction of accumulation of lipofuscin that may be achieved through manipulation of bisretinoid formation in the photoreceptor outer segment. Restriction of vitamin A availability presumably would achieve this end. Neuroprotective agents might be of benefit as has been hypothesized in the treatment of glaucoma.<sup>94</sup> Such an approach might slow or prevent photoreceptor cell loss, and this has been attempted with the use of a slow-release device that uses cells embedded in a matrix that express ciliary neurotrophic factor (CNTF).<sup>95</sup> There is early indication that this may be successful in the

management of retinitis pigmentosa.<sup>96</sup> The relevance of the immune system to retinal health and immune dysfunction to generation of AMD are unknown but may represent a target for therapy in future.

## Balance of Tissue Change in Early AMD

In the histopathology study,<sup>93</sup> great variation was shown in changes in the various tissues involved in AMD pathogenesis (Figs. 67.1 and 67.2). When a comparison was made between autofluorescence derived from the RPE and basal laminar thickness, an inverse relationship was found between the two. This is understandable since thickening of Bruch's membrane would represent a barrier to diffusion from choroid to the RPE and restrict availability of vitamin-A to the retina, although other explanations may account for this. It was also the case that some of the eyes examined had profound photoreceptor cells loss without manifest physical change in either Bruch's membrane or the RPE (Fig. 67.1). This implies that in some cases photoreceptor loss may occur due disease mechanisms internal to the RPE.

## Conclusion

In age-related macular degeneration, changes occur in the choroid, Bruch's membrane, the RPE, and outer retina. Both genetic and environmental influences have been identified as conferring risk of disease and presumably initiate disease through their cumulative effect. However, there is doubt as to tissues primarily affected by these factors. It is clear that the balance of changes in the various tissues varies from one case to another, which is not surprising given that the factors conferring risk vary from one case to another. Thus in some individuals Bruch's membrane thickening may be the most threatening change, whereas it may be the RPE alterations in others. It is also possible that photoreceptor loss may not be due to structural or functional change of either the RPE or Bruch's membrane in some cases but is a consequence of an abnormality

limited to the outer retina. If correct, therapy directed to one aspect of the disorder should be reserved to those in whom the specific tissue is the primary threat to photoreceptor survival. To achieve this goal it would be necessary to have knowledge of changes in the various tissues involved. If it is shown that the phenotype correlates well with genetic risk variants, genetic testing may be used to select cases for a specific therapeutic approach.

The photoreceptor population could be assessed using imaging such as OCT, or visualization of the photoreceptor cells with adaptive optics. The same objective could be achieved using psychophysics means such as visual field recording, microperimetry, or fine matrix mapping. Assessment of the concentration of bleachable rhodopsin using reflectometry might be the most effective method of determining the population of viable photoreceptor cells.<sup>97,98</sup> Whatever testing device is used, it would be important to assess the scotopic, as well as the photopic, system. The health of the RPE might be assessed by measuring absolute levels of autofluorescence. Such measurements are aided by the use of an internal standard in the imaging device.<sup>99</sup> An external standard would be ideal, although it is not clear how this could be achieved. There is some doubt as to whether or not the thickness of Bruch's membrane could be measured *in vivo*, but it is likely that the state of the choroid is determined by access of VEGF expressed outward by the RPE. Thus choroidal thickness and choriocapillaris flow would be influenced by the biophysical properties of Bruch's membrane. Both these have been measured recently, although variation in normal subjects has yet to be fully established. Characterization of disease in this way would be important in selecting patients for a specific therapeutic approach and in monitoring the response to treatment. Without segregation of cases on the basis of phenotype, effective treatment of a component may not be evident in treatment trials since the treatment would only be appropriate to a proportion of cases recruited to the trial. It is true that the tissues are metabolically interdependent and modulation of age change in one tissue may have secondary benefits on its neighbors.

Some treatments may modify progress of disease in a large proportion of cases. The main purpose of any treatment is

preservation of function such that neuroprotection may be appropriate whatever the nature of disease. Similarly, modulation of the immune system may be of benefit in a wide range of AMD although systemic treatment may not influence complement-induced changes internal to the RPE.

The presence of drusen has been used to recruit patients to all the clinical studies to date. This ignores diffuse thickening of Bruch's membrane, abnormal autofluorescence from the RPE, and photoreceptor loss. In particular, reticular pseudodrusen, which is undoubtedly a part of AMD, may occur in the absence of drusen such that this form of disease would be underrepresented in studies. Recently, a functional study of subjects over the age of 60 years with normal ocular fundi revealed abnormal recovery from bleach in a proportion of subjects.<sup>100</sup> Whether or not they are manifesting AMD is open to debate, but if OCT shows photoreceptor loss, it would be reasonable to conclude that they do so. Thus studies of AMD are incomplete, and it would be good to see the entry criteria being enlarged in future research projects.

#### **Prognosis and Management of Non-Neovascular AMD**

## **Introduction**

Age-related macular degeneration (AMD) has been the leading cause of legal blindness in patients aged 65 and over,<sup>1</sup> and in 2010 it remained the most common overall cause of blindness in the developed world.<sup>2</sup> Using data from the 2000 census, it has been estimated that in the United States more than 8 million people have specific AMD features that put them at risk for progression to advanced AMD and vision loss.<sup>3,4</sup> Over a 5-year period about 1.3 million of these individuals are predicted to develop the advanced forms of AMD, namely neovascular (NVAMD) or foveal geographic atrophy (FGA).<sup>3</sup> The relative contribution of AMD to the prevalence of visual impairment and blindness in the developed world continues to rise as a direct result of the increasing percentage of elderly persons in the United States and other industrialized countries and due to the improved management of other eye diseases.<sup>2,4-6</sup> Hundreds of thousands of people aged 75 and over in the United States are anticipated to join the pool of people at increased risk of developing advanced AMD over subsequent 5-year periods.<sup>7</sup> Without new treatments or prevention strategies, rates of vision impairment associated with AMD are expected to rise further. By 2020, it has been estimated that 196 million people worldwide will be affected by AMD, increasing to 288 million people by 2040.<sup>8</sup>

Prevalence estimates for the proportion of cases of late AMD due to NVAMD compared to geographic atrophy (GA) (considering GA in any posterior pole location) among Western populations range from almost a 1 : 1 ratio to a 2 : 1 ratio.<sup>4-6</sup> In contrast to earlier studies,<sup>4,9</sup> the most recent comprehensive meta-analysis of population-based data among individuals of European ancestry did not find age-specific differences in the prevalence of NVAMD compared to GA.<sup>10</sup> Prevalence of late AMD (NVAMD or GA) roughly quadruples with each decade beyond age 50.<sup>10</sup> As an example, the predicted prevalence of late AMD rises from 5.2% (95% confidence interval [CI] 3.8–7.1%) to 13.2% (95% CI 9.5–17.6%) for people age  $\geq 60$  years as compared to those  $\geq 80$  years.<sup>10</sup>

Within the past 10 years novel and improved treatments for the neovascular form of advanced AMD have been adopted throughout the developed world. As such, in the years ahead, the percentage of AMD patients with vision impairment or legal blindness associated

with neovascular AMD is anticipated to decline substantially.<sup>11,12</sup> This effect has already been reported in several recent small population studies citing declining rates of individuals registered as blind from AMD, coinciding with the widespread clinical use of intravitreal anti-vascular endothelial growth factor (VEGF) therapy to manage NVAMD.<sup>13-15</sup> However, despite our current best treatments, due to aging populations, the overall burden of vision loss from both NVAMD and non-neovascular AMD (NNVAMD) is expected to increase.<sup>5,6</sup> The same therapeutic progress has not been made for management of advanced non-neovascular AMD (NNVAMD), namely FGA or GA (located anywhere within the posterior pole). As such, the importance of the later forms of NNVAMD, also known as atrophic AMD, as a leading cause of vision impairment is expected to increase.

A major step toward a better understanding of AMD was taken when Gass<sup>16</sup> clarified that drusen, senile macular degeneration, and senile disciform macular degeneration represented a single disease. Since this time, there has been a lack of consensus regarding terminology used to define AMD and different classification systems have been proposed.<sup>17-20</sup> In 1995, the International Age-Related Maculopathy Study Group devised a classification and grading system for standardizing the terminology and grading used in epidemiologic studies.<sup>18</sup> This classification system has been widely employed and uses the term age-related maculopathy (ARM) for the earlier changes that are presently associated with AMD (drusen and retinal pigment epithelial abnormalities other than GA) and reserves the term AMD for NVAMD or any GA. More recent clinical studies such as the Age-Related Eye Disease Study (AREDS) considered all of these clinical manifestations to be various stages of AMD, omitting the term ARM, while classifying NVAMD and FGA as the advanced forms of AMD. More recent efforts to standardize terminology and classification of AMD have continued in order to assist clinicians and researchers in managing this disease.<sup>19,20</sup> In these more contemporary classification systems, there is early, intermediate, and late AMD. "Late" AMD encompasses NVAMD and GA, that is GA found anywhere within two disc diameters of the foveal center ("any" GA),<sup>19,20</sup> in contrast to the terminology used in AREDS, which restricted inclusion of GA

to FGA when describing advanced AMD.<sup>17</sup>

This chapter is devoted to description of the clinical and histopathologic changes that can occur in the aging macula, which range from what is considered normal aging to the development of more significant drusen and retinal pigment epithelium (RPE) changes that may impair visual function and are considered risk factors for the development of either form of advanced AMD, as well as descriptions of advanced non-neovascular AMD itself. In addition this chapter focuses on the clinical management of this spectrum of macular pathology. Neovascular AMD will be the subject of another chapter ([Chapter 69](#), Neovascular (exudative or “wet”) age-related macular degeneration). The term *AMD* will be used to describe alterations that are considered pathologic and distinct from normal aging and that confer risk for the development of late AMD. The term *non-neovascular AMD* (NNVAMD) encompasses any AMD feature(s) in the absence of choroidal neovascularization (CNV) or its sequelae, and the term “dry” AMD will be avoided as it has been variably used to describe any AMD feature in the absence of choroidal neovascularization, has been used as a synonym for GA specifically,<sup>18</sup> or has been used to describe atrophic appearing disciform scars.

## Normal Aging of the Macula

One of the difficulties in establishing a classification system for AMD is separating the manifestations of normal aging from those of disease. Aging is a fundamental biologic phenomenon that occurs even in the absence of disease, each cell having a genetically programmed lifespan. Tissues that are comprised of cell types that do not undergo renewal with mitotic division, such as those in the central nervous system and the retina, are more likely to demonstrate changes with age.

## Macular Examination Findings

With age there is loss of the foveal and foveolar reflexes. This may be due to disappearance of cells from the inner retinal layers, shallowing of the walls of the foveal pit, and enlargement of the

capillary-free zone.<sup>21</sup> A few small, hard drusen are practically ubiquitous among people of all ages.<sup>22-26</sup> Irregularity of the RPE pigmentation may give rise to a fine granularity in the macula, and the fundus commonly demonstrates a tigroid background. This senile tigroid fundus (Fig. 68.3A) is increasingly apparent with advancing age but remains compatible with normal vision. It is unrelated to skin pigmentation and differs from the tigroid fundus in youth in that the choroidal vessels become visible beneath the macula as part of aging. Commonly there is a peripapillary halo of RPE atrophy in which the exposed vessels may be sheathed and the intervascular spaces appear pale. A lower number of perifoveal arterioles and venules have also been reported.<sup>27</sup>

## Histopathologic and Compositional Changes of the Aging Macula

The RPE, Bruch's membrane, and choriocapillaris have integrated functions to provide support for the photoreceptors. Prior to aging (Fig. 68.1A), there is a large number of photoreceptors, the RPE is a monolayer of single cells, Bruch's membrane is not thickened, and the choroid consists of three layers of vessels. As each of these tissues has at one time been regarded as primarily at fault in fostering the development of AMD, it is necessary to consider the changes developing in these structures during life in the absence of AMD (Fig. 68.1B).

**FIG. 68.1** Diagram depicting the ultrastructural features of aging and the evolution of age-related macular degeneration (AMD). Bruch's membrane (BrM) is defined as an inner and outer collagenous zone (ICZ and OCZ) separated by an elastic layer (EL) but excluding the basement membranes of the retinal pigment epithelium (RPE BM) and choriocapillaris. The principal distinguishing feature of each stage is the quantity and type of basal laminar deposit (BlamD)

present at the base of the RPE. (A) Young. The BlamD is absent. Mitochondria lie at the base of the cell. The pigment granules comprise elliptical melanin granules in the apical part of the cell and the incompletely degraded products of phagolysosomal digestion, or lipofuscin, toward the base. (B) Aged. Patches of the early, or striated, type of BlamD appear on the inner aspect of the RPE basement membrane, where the basal infoldings of the cells are reduced. Also, fewer apical microvilli are present. Elongated rod outer segments attest to impaired phagocytosis. Progressive accumulation of lipofuscin causes the RPE cells to enlarge. Coated membrane-bound bodies (CMBB) accumulate in Bruch's membrane and, together with an increase in fibrous long-spacing collagen (*FLSC*), cause thickening of the OCZ. (C) Early histologic changes seen in AMD. The early type of BlamD now forms a continuous layer. Membranous debris in the form of coiled lipid membranes is found (1) at the apex of the RPE as subretinal drusenoid deposits, where there is more distortion of outer segments; (2) at the base of the RPE interspersed among the strands of BlamD, where it may form basal mounds; (3) as a layer between the RPE basement membrane and the ICZ (basal linear deposit (BlinD)), where it may build up into soft drusen; and (4) within the collagenous zones. Coated membrane-bound bodies and fibrous long-spacing collagen accumulating in Bruch's membrane can be seen in the intercapillary pillars extending to the level of the outer surface of the choroidal capillaries. (D) More advanced changes in AMD. A thick layer of late BlamD is present, predominantly of the amorphous type. Being a later development, the amorphous layer lies on the internal aspect of the early type and appears to be formed in waves. The retinal pigment cells are engorged with lipofuscin and become rounder, with loss of both apical microvilli and basal infoldings. Cell fallout occurs, and necrotic portions of cells containing membrane-bound granules are liberated into the subretinal space. The photoreceptor outer segments disappear, leaving stunted cone inner segments. The membranous debris disappears, resulting in "empty spaces" between the strands of early BlamD internal to the basement membrane and

the regression of any soft drusen present external to the basement membrane. The choroidal capillaries undergo atrophy.

## **Photoreceptors and Ganglion Cells**

Cone density and number at the foveal center does not significantly change during the first eight decades of life,<sup>28-30</sup> which argues against foveal cone vulnerability during normal aging. A significant loss of foveal cones may occur beyond age 90, but this loss variably occurs.<sup>31</sup> In contrast to the stability of foveal cone density with age, age-related loss of centrally located and peripheral rods, equatorial cones, and ganglion cells has been described to be common.<sup>28,30</sup> With aging, rod and cone outer segments become disorganized and convoluted, possibly as an expression of impaired phagocytosis by the RPE.<sup>28,32</sup> This may lead to the accumulation of outer-segment material external to the apical surface of the RPE<sup>31</sup> and lipofuscin deposition within cone inner segments.<sup>33,34</sup> Loss of rods generally begins between the second and fourth decades of life with continued, but potentially slower rate of loss noted, with each successive decade.<sup>30</sup> The centrally located ganglion cell layer shows a similar rate of cell loss with age such that the rod and ganglion cell layer densities maintain a constant ratio.<sup>28,30</sup> The pattern of the central photoreceptor mosaic appears unchanged with age as the remaining rods enlarge to occupy space vacated by the rod loss.<sup>28</sup> It is unknown whether the age-associated central rod loss is due to a primary defect within the rods themselves or whether it is due to RPE dysfunction that affects renewal of rod and not cone outer segments.<sup>28</sup>

## **Retinal Pigment Epithelium**

Throughout life, each RPE cell is responsible for a diurnal cycle of engulfing photoreceptor outer segments that have been shed; the rod outer segments being digested by day and the cone outer segments by night.<sup>35</sup> Over a lifetime, this represents a heavy burden as 10–15% of rod outer segments are phagocytized each day.<sup>36</sup> Rod outer segments have a unique composition of approximately 50% phospholipid and 50% protein with most of the protein being

rhodopsin.<sup>37</sup> Damage to photoreceptor outer segment molecules, namely peroxidation of phospholipid molecules that comprise the outer-segment membranes and free-radical damage to rhodopsin and other outer-segment proteins, may occur as a result of free-radical chain reactions initiated by radiation, light, or oxygen metabolism.<sup>38,39</sup> After phagocytosis by the RPE, the lysosomal degradation enzymes may fail to “recognize” these abnormal molecules, causing molecular degradation to fail with accumulation of lipofuscin in the RPE lysosomes. Over time the RPE accumulates lipofuscin granules.<sup>38,39</sup> Free radicals may also damage the RPE cells' own molecules, and there is evidence that enzymatic inactivation may occur within aged RPE cells. Such inactivation has been demonstrated with cathepsin D, the main lysosomal protease responsible for rhodopsin degradation.<sup>40</sup> In addition to processing shed photoreceptor outer segments, the RPE must also remove material that accumulates from the death of individual photoreceptors and RPE cells. Finally, as the RPE is a nondividing tissue, autophagy, the process by which cells degrade dysfunctional cellular components, also may lead to further accumulation of lipofuscin within the RPE.

Accumulation of lipofuscin in the RPE has been demonstrated to increase with age, with the largest accumulation occurring in the second decade of life followed by progressive accumulation at a slower rate throughout the remainder of life.<sup>38,41</sup> With age, and more prominently in the macula than in the periphery, the RPE also shows an increase in melanolysosomes and melanolipofuscin granules.<sup>41</sup> These complex granules are thought to be melanin granules undergoing repair or degradation.<sup>41</sup> Due to the increase in lipofuscin granules, melanolysosomes, and melanolipofuscin with age, the volume of RPE cytoplasm not occupied by pigments decreases with age.<sup>41</sup> This may reduce RPE cell function and lead to cell death.<sup>29</sup>

In addition to the accumulation of pigmented granules, other morphologic changes occur within the RPE with age. The normal, young RPE is composed of a single layer of hexagonal cells of equal size and degree of pigmentation.<sup>42</sup> With advancing age, increased pleomorphism is noted with regards to cell size, shape, and pigmentation.<sup>42</sup> RPE cells in the macula are also noted to become

taller and narrower with aging.<sup>42</sup> Prominent histologic changes may also occur with aging at the base, or underside, of the RPE cell in the absence of any clinical findings to suggest AMD.<sup>43,44</sup> These changes include loss of basal infoldings and early, patchy deposition of material termed basal laminar deposits (BlamD), termed “basal linear deposits” in the older literature, which lie anterior to the basement membrane of the RPE and posterior to the basal surface of the RPE (Fig. 68.1B).<sup>43,44</sup> Pathologic progressive accumulation of these BlamD is discussed in the section below under “Pathologic changes seen in NNVAMD” (see footnote regarding nomenclature in this section below).

In addition, RPE cell number decreases with age, particularly in the peripheral retina.<sup>29,30,45</sup> There is less consistent data on age-related macular RPE cell loss.<sup>29-31,41,45</sup> The ratio of foveal photoreceptors to RPE cells remains stable with age,<sup>30,31</sup> with an approximated average cone-to-RPE ratio of 24 : 1.

## **Bruch's Membrane**

Although anatomists regard Bruch's membrane as a five-layered structure, alterations are more readily understood by simplifying Bruch's membrane, essentially excluding the basement membranes of the RPE and choriocapillaris, as proposed by Gass.<sup>46</sup> Bruch's membrane can then be thought of as a 3-layer, sheet-like condensation of the innermost portion of the choroidal stroma that consists of an inner (ICZ) and outer collagenous zone (OCZ) separated by an elastic layer. A linear relationship exists between age and thickness of these three internal layers within Bruch's membrane,<sup>44,47-49</sup> with an average thickness of 2  $\mu\text{m}$  in the first decade of life increasing to 4.7  $\mu\text{m}$  by the 10th decade.<sup>48</sup> Changes to the ICZ account for a small proportion of the age-related increased thickness to Bruch's membrane, with a majority of the increased thickness occurring within the OCZ,<sup>49</sup> while no significant change in thickness occurs in the elastic layer.<sup>47</sup> The normal age-related changes that occur within Bruch's membrane can be identified early in life with transmission electron microscopy (TEM)<sup>47,49,50</sup> and through biochemical assays<sup>51-53</sup> prior to becoming visible with light microscopy.<sup>43</sup>

Three types of changes that contribute to this age-related Bruch's

membrane thickening have been described on TEM within the collagen and elastic layers. These changes include the deposition of coated, membrane-bound bodies; the deposition of collagen that appears as banded material; and the formation of mineralized deposits.<sup>44,47-50,54-56</sup> In addition, with normal aging, the presence of a small number of drusen can also be identified by light microscopy or TEM between the ICZ and the basement membrane of the RPE.<sup>43,44,50,54</sup> These drusen, as they relate to normal aging, will be described later in this section.

### **Coated, Membrane-Bound Bodies.**

The majority of the normal age-related thickening of Bruch's membrane is due to accumulation of rounded, coated, membrane-bound bodies<sup>49</sup> (Figs. 68.1B and 68.2). This material may result from the shedding of unwanted RPE basal cytoplasm through the basement membrane of the RPE.<sup>49,50</sup> These membrane-bound bodies have been identified in the process of spilling their contents of coated vesicles and granular material into Bruch's membrane.<sup>49</sup> Membrane-bound bodies have been identified in first and second decades of life within the ICZ,<sup>49,50</sup> while absent within the first 2 years of life.<sup>47,49</sup> Membrane-bound bodies subsequently occur, even in greater amounts, in the OCZ.<sup>49,50</sup> In a study of 68 eyes, among the 20 eyes from donors, aged 20–60, 90% had this type of deposit in Bruch's membrane specimens from the macula in both the ICZ and OCZ; the remaining few in this age range did not have these deposits in either location. Each of the 38 eyes older than 60 years had this type of change in both the ICZ and OCZ, with more prominent changes in the OCZ compared to younger eyes. Only 2 of the 10 eyes from donors younger than 20 (aged 17 and 18) had these types of deposits, one in the ICZ only and the other in the ICZ and OCZ.<sup>50</sup>

**FIG. 68.2** Electron micrograph (x1800) shows accumulation of debris in Bruch's membrane. The patient was 62 years of age and had 20/20 vision; however, this process can be detected as early as the second decade. Coated membrane-bound bodies (*short arrow*) are apparently trapped between the basement membrane of the retinal pigment epithelium (RPE) (*long arrow*) and the inner collagenous zone (entrapment sites). Others lie in the outer collagenous layer (*yellow arrows*). Some have ruptured, releasing vesicular and granular material and fragments of the coated membrane. (Courtesy of MC Killingsworth.)

## Collagen.

A general increase in collagen deposition occurs within both the ICZ<sup>47</sup> and OCZ. The 64-nanometer (nm) banded fibers are found in increasing numbers within both of these layers with age and are believed to be fibrillar type I collagen.<sup>51</sup> Clumps of fibrous long-spacing collagen with band periodicity ranging from 100 to 133 nm also accumulate.<sup>47,49,51,57</sup> The molecular composition of the long spacing collagen is uncertain, but it appears similar to banded

material that is also present in BlamD.<sup>43,44,50</sup> These longer spaced collagen deposits are found primarily in the OCZ or embedded in the basement membrane of the choriocapillaris<sup>47,57</sup> (Fig. 68.1B). These deposits have been found as early as age 19, and their prevalence progressively increases with age<sup>57</sup> such that they are present in all eyes age 40 and older.<sup>49</sup> There is a significant linear decline in Bruch's membrane solubility with age, and this may be due to increase in collagen crosslinking.<sup>51</sup> Other components that have been identified in Bruch's membrane with age by biochemical or by immunoelectron microscopy (EM) analysis include collagen types III, IV, and V, fibronectin, chondroitin sulfate, dermatan sulfate, and proteoglycans.<sup>51,55</sup>

### **Mineralized Deposits.**

Mineralized deposits accumulate less frequently than the above changes<sup>47,49,50</sup> and have been described as fine granules on collagen fibers in the ICZ in younger eyes. However, they are more commonly seen in the elastic layer in eyes from middle-aged persons.<sup>47,49,50</sup>

Other than the thickening of Bruch's membrane, described above, the most significant other histologic findings in Bruch's membrane, visible by light microscopy, do not become evident until the fifth decade.<sup>43</sup> These changes are comprised of hyalinization and patchy basophilia.<sup>43</sup> With increasing age, diffuse deposition of hyalinized material occurs in the collagenous zones and can also extend down the intercapillary pillars,<sup>43</sup> the spaces between the capillaries of the choriocapillaris. Using special stains with light microscopy calcium deposits may be noted within Bruch's membrane in about 60% of eyes over age 30.<sup>43,44</sup>

As determined both biochemically and with light and electron microscopic study, the lipid content of Bruch's membrane also increases after the fourth decade.<sup>52,53,56</sup> Lipid increases exponentially with age<sup>52</sup> and consists largely of phospholipids, triglycerides, fatty acids, and free cholesterol.<sup>52,53</sup> The lack of cholesterol ester in Bruch's membrane indicates that the source of lipid in Bruch's membrane is likely independent of the bloodstream.<sup>52</sup> Likewise, peroxidized lipids in Bruch's membrane increase exponentially with age.<sup>58</sup> The peroxidized lipids are derived from long-chain

polyunsaturated fatty acids, particularly docosahexaenoic acid (DHA) and linolenic acid, which are polyunsaturated fatty acids found in photoreceptor outer segments.<sup>58</sup> Lipid peroxides have been shown to induce neovascularization of the retina and choroid by inducing expression of a cascade of angiogenic cytokines.<sup>59,60</sup>

The presence of small, hard drusen are common in eyes with normal gross fundus appearance.<sup>43,44</sup> These appear mostly as hyalinized globular material between the ICZ and RPE basement membrane on light microscopy,<sup>43</sup> and they frequently contain calcium in eyes from older individuals (beyond age 60).<sup>44,54</sup> Ultrastructurally, the smallest ones are composed of material resembling cytoplasm or of cell fragments with organelles, including mitochondria and coated vesicles, and are present as early as the fourth decade of life.<sup>54</sup> Small drusen that are somewhat larger (spanning the width of 2–4 RPE cells) in young eyes contain fine granular particles, many “bent fibers,” and masses of basophilic material, resembling nucleoplasm.<sup>54</sup>

The structural and ultrastructural changes described in Bruch's membrane above may be expected to decrease the rate at which fluid can pass through Bruch's membrane. Hydraulic conductivity is the measurement of the bulk flow of fluid through a test membrane in response to applied pressure. Studies have shown a decrease in hydraulic conductivity through Bruch's membrane with age. The decrease in conductivity is greatest in the first four decades of life,<sup>61,62</sup> and then it continues to decline at a slower rate with increasing age. This raises questions about the mechanisms through which this decline occurs as the linear increase in thickness of Bruch's membrane<sup>48</sup> and the exponential increase in lipid with advancing age<sup>52</sup> would suggest that the rate of loss of hydraulic conductivity would more closely parallel these changes.

Using excimer laser to produce ultrathin shavings of Bruch's membrane, the greatest resistance to water flow through Bruch's membrane throughout life resides within the ICZ.<sup>62</sup> Serial ultrathin sections have led to estimates of the porosity at sequential levels of Bruch's membrane and have confirmed that the ICZ has the lowest porosity. Calculations based on the pore radii and length further confirm that the ICZ also has the lowest flow rate. This, too, is at odds with histologic studies, noted above, that show that greater

increases in thickening of Bruch's membrane occur in the OCZ. Clearly, further studies are required, as only a limited number of younger eyes have been examined. Reductions in permeability of Bruch's membrane with age, brought about through structural and/or biochemical changes, may in turn compromise RPE structure and function.

## Choroid

Progressive histologic changes are also noted to occur in the choroid with age. Comparing the macula of normal eyes in the first and 10th decades of life, the density of the choroidal capillaries decreases in a linear fashion by 45%, the diameter of the choriocapillaris decreases by 34%, and average choroidal thickness decreases from 200  $\mu\text{m}$  to 80  $\mu\text{m}$ .<sup>48</sup> The reduction in choriocapillaris permits the larger choroidal vessels to be seen more readily on clinical examination, accounting for the senile tigroid fundus (Fig. 68.3A).

**FIG. 68.3** Evolution of retinal pigment epithelium abnormalities developing into geographic atrophy over 16 years (continues in Fig. 68.38). (A) At age 68, the

patient has a normal left fundus with senile tigroid pattern (vision 20/15). (B) At age 73, small drusen-like dots are present centrally,  $\leq 63 \mu\text{m}$  in size (vision 20/20). (C) At age 77, a ring of pigment clumps developed around the foveal center. (D) At age 79, pigment clumping around fixation has increased; vision is still 20/20. The choroidal vascular pattern has become more prominent in the fovea consistent with nongeographic atrophy. (Reproduced from Sarks JP, Sarks SH, Killingsworth M. Evolution of geographic atrophy of the retinal pigment epithelium. *Eye* 1988; 2:552–577.)

## Age-Related Macular Changes as Seen on Fundus Imaging

The structural changes noted with normal aging, as described in the previous sections, do correlate with observations made on clinical imaging performed in living persons. Fluorescein angiography demonstrates an increase in the area occupied by the foveal avascular zone (FAZ) with age; mean area of the FAZ is estimated at  $0.53 \text{ mm}^2$  among individuals younger than 40 years as compared with  $0.61 \text{ mm}^2$  for individuals over age 40.<sup>21</sup> Studies using blue-field stimulation<sup>63</sup> and scanning laser Doppler flowmetry<sup>64</sup> have also shown a decrease in blood flow in the retinal macular capillaries of older individuals. Each of these observations may correlate with loss of centrally located ganglion cells that occur with age.

Enhanced-depth imaging optical coherence tomography (EDI-OCT) of the choroid (performed with spectral domain OCT (SD-OCT) and 1050-nm wavelength light source) corroborates the histologic findings of decreased density of macular choroidal capillaries and decreased choroidal thickness that occurs with age. Despite significant variability of choroidal thickness measurements among normal individuals, the mean central subfield thickness measurements of the choroid decrease by about  $2 \mu\text{m}$  per year of age among subjects between the ages of 20 and 68.<sup>65</sup> A larger study that included patients between age 50 and 93 reported an annual decrease in central choroidal thickness of  $4 \mu\text{m}$  for each successive year.<sup>66</sup> Enface swept-source OCT images in individuals age 24–66

years has confirmed age-related thinning of the choroid and specifically the choriocapillaris, with no significant change in the deeper layers of the choroid.<sup>67</sup> As might be anticipated, choroidal blood flow also decreases with age among normal subjects as assessed by laser Doppler flowmetry.<sup>68</sup> Indocyanine green angiography (ICGA) shows age-related alterations in filling patterns. Young subjects demonstrate early arteriolar filling in the fovea with rapid expansion peripherally within fine, tortuous, and multibranching arterioles, whereas in older subjects the choroidal arterioles are more sparse, thicker, straighter, and have fewer branches<sup>69</sup> (Fig. 68.4).

**FIG. 68.4** The initial arterial filling pattern during indocyanine green angiography of normal subjects. (A–D) 22-year-old man. The arteriolar filling begins in the subfoveal region in radial fashion toward the peripheral fundus. The dye fills rapidly, and the arterioles run in a fine, tortuous, and multibranching

fashion throughout the time course. The vertical watershed zone through the optic disc is clearly observed (*arrow*). (E–H) 62-year-old man. The choroidal arterioles are scanty in the posterior fundus. The vessels are thickened and run a straight course with reduced branching. The watershed zone is blurred. (Reproduced with permission from Ito YN, Mori K, Young-Duvall J, et al. Aging changes of the choroidal dye filling pattern in indocyanine green angiography of normal subjects. *Retina*. 2001;21(3):237–42.)

Fundus autofluorescence imaging (FAF) also corroborates histologic findings associated with aging. Lipofuscin is the predominant fluorophore responsible for in vivo FAF, and quantification of in vivo FAF demonstrates an age-related increase in macular FAF that would be expected based on the increased accumulation of lipofuscin within the RPE with age.<sup>70</sup>

## Pathology of Non-Neovascular AMD

A clinical diagnosis of AMD is appropriate when extensive small drusen<sup>17</sup> or any medium or large-sized druse or drusen,<sup>19</sup> with or without RPE abnormalities, are found during examination of the posterior pole. The clinical parameters describing drusen size and extent (area involved) and presence of pigmentary abnormalities are critical as they are the strongest predictors of progression to the late stages of AMD.<sup>71,72</sup> Studies evaluating the histopathology of aged eyes, including those with AMD, have typically failed to focus on the gross fundus appearance to describe the size and extent of drusen. In addition, drusen components are often lost during tissue processing. Therefore, separate histopathologic definitions of AMD have been described<sup>43,73–75</sup> that are difficult to correlate to clinical grading scales that focus largely on the extent of drusen. Histopathologic studies are critical to advance our understanding of the disease processes, while clinical studies provide more limited information about mechanisms of the disease processes but are essential to the understanding of clinical disease evolution. It is challenging to correlate clinical findings with those seen histopathologically, as some of the best described histopathologic features of AMD, such as pathologic basal deposits (described

below), are not visible with ophthalmoscopy and presently do not have correlate findings with in vivo retinal imaging of the posterior pole. The advent of high-resolution OCT, which provides images with resolution that is analogous to histologic cross-sections, has improved our ability to correlate clinical findings to the well-described histologic findings that occur in AMD. However, at present there is limited availability of histologic specimens from eyes that were imaged in vivo with these instruments to provide direct clinical (OCT)-pathologic comparisons. This section describes the range of histopathologic alterations that are found in eyes with NNVAMD and summarizes our best current understanding of the clinical exam features and retinal imaging correlates of these various findings.

## **Histologic Alterations of Non-Neovascular AMD that May Not Be Apparent on Ophthalmoscopy**

### **Basal Deposits\* and Membranous Debris**

On histopathologic examination, degeneration of the RPE<sup>74</sup> along with the presence of membranous debris, basal linear deposits (BlinD), and extensive basal laminar deposits (BlamD) (the latter two are collectively referred to as basal deposits)<sup>43,75,77</sup> are the hallmarks of AMD. BlamD are located between the RPE cells and the basement membrane of the RPE, and BlinD form external to the basement membrane of the RPE and internal to Bruch's membrane<sup>76</sup> (Figs. 68.1C–D). Neither deposit is visible in the fundus on examination, and TEM is needed to definitively differentiate one from the other.<sup>78</sup> Along with membranous debris, these basal deposits, as defined in this paragraph, are described in greater detail below.

### **Basal Laminar Deposits: Early and Late Forms.**

Basal laminar deposits (BlamD) lie posterior to the RPE, between the RPE cell plasma membrane and the basement membrane of the cell (see Figs. 68.1C–D and 68.5–68.9). This is in contrast to drusen, which lie external to the basement membrane of the RPE. BlamD

can be demonstrated consistently by the seventh decade<sup>43</sup> but has been found even in the fifth decade.<sup>44</sup> Initially the deposit occurs in a patchy distribution anterior to thickened or basophilic segments of Bruch's membrane, anterior to intercapillary pillars, or anterior to small drusen.<sup>43</sup> The deposit can be classified histologically as class 1 (occurring in small, solitary patches), class 2 (a thin continuous layer on a histologic section), or class 3 (a thick layer, at least half the height of the RPE cell).<sup>44</sup> As noted in the "Normal aging" section above, this deposit can be a part of normal aging, but only class I deposits are consistent with normal aging, whereas class 2 and 3 deposits are strongly associated with the presence of AMD, by clinical or by histopathologic definitions.<sup>43,44,75,77</sup>

**FIG. 68.5** (A) Section through the macula of a 79-year-old man. Fundus appeared normal, and vision was 20/30. Early form of basal laminar deposit is seen as continuous, blue-staining layer beneath the retinal pigment epithelium. Unstained spaces (*right arrow*) would correspond to membranous debris on electron microscopy. *Arrow* at left indicates area magnified in panel B ( $\times 75$ ). (B) Basal laminar deposit is most developed over a thicker segment of Bruch's membrane. Hyalinization of Bruch's membrane extends down intercapillary pillars (picro-Mallory stain;

×500). (Reproduced with permission from Sarks SH. Aging and degeneration in the macular region: a clinico-pathological study. Br J Ophthalmol 1976;60:324–41.)

**FIG. 68.6** Electron micrograph illustrating diffuse basal laminar deposit (BlamD) and diffuse basal linear deposit (BlinD) that develop in age-related macular degeneration, corresponding to Fig. 68.1C. Horizontal *yellow arrows* indicate the basal plasma membrane of the retinal pigment epithelium (RPE). Early-type BlamD (*BlamD*) projects inward from the RPE basement membrane (*white arrows*) and comprises mainly banded material resembling fibrous long-spacing collagen. Coiled membranes with a bilayered structure of lipids lie among the clumps of BlamD and appear to pass through the basement membrane to lie between it and the inner collagenous zone (*ICZ*) as a component of BlinD, as well as filtering into the membrane itself. Identifiable structures within Bruch's membrane include fragments of coated membrane (*CM*) and fibrous long-

spacing collagen (*FLSC*). *CC*, choriocapillaris.  
(x11,780.) (Reproduced with permission from Killingsworth MC, Sarks JP,  
Sarks SH. Macrophages related to Bruch's membrane in age-related macular  
degeneration. *Eye* 1990; 4:613–621.)

**FIG. 68.7** Same eye as in [Figs. 68.3](#) and [68.38](#).  
Section passes through the temporal margin of the  
area of geographic atrophy. (A) Photoreceptors  
become fewer and outer segments wider and stunted  
as they approach the edge. Vacuolated appearance  
under the retinal pigment epithelium (RPE) is due to  
disappearance of membranous debris. Collections of  
membranous debris can be seen on the internal  
(apical) surface of RPE (*arrow*), possibly due to failure  
of phagocytosis (x150). (B) Hyperpigmented edge  
noted clinically corresponds to a double layer of RPE,  
the inner layer representing necrotic hyperpigmented  
cells in the process of being eliminated. Late  
amorphous form of basal laminar deposit (BlamD) lies  
internal to striated form and has a multilaminar  
appearance, suggesting formation in successive  
waves according to the level of RPE (see [Fig. 68.1D](#)).  
Photoreceptors disappear, and external limiting  
membrane terminates on BlamD (methylene blue and  
basic fuchsin; x500). (Reproduced with permission from Sarks JP, Sarks

SH, Killingsworth M. Evolution of geographic atrophy of the retinal pigment

**FIG. 68.8** (A) Incipient atrophy, showing an unusually thick layer of late BlamD. This material is hyalinized and periodic acid–Schiff-positive; on electron microscopy it would have a corresponding amorphous appearance. The retinal pigment epithelium forms a very attenuated layer over the surface and seems about to disappear (periodic acid–Schiff;  $\times 45$ ). (B) Parafoveal area from the same eye shows the different deposits. The two forms of the BlamD are seen: the blue-staining, early form (*long arrow*) and, on its inner surface, nodular collections of the late hyalinized form (*arrowheads*). External to the BlamD lie two typical drusen; beneath the *short arrow at left* is a small hard druse; beneath the two *short arrows at right* is a soft druse (picro-Mallory stain;  $\times 500$ ). (Reproduced with permission from Sarks SH. Aging and degeneration in the macular region: a clinicopathological study. Br J Ophthalmol 1976;60:324–41.)

**FIG. 68.9** Grades of retinal pigment epithelium (RPE) morphology in late age-related macular degeneration (AMD). Submicrometer epoxy resin sections were stained with toluidine blue. Epithelial RPE and RPE morphologies with epithelial components (A,B,D,E,G,I,J); nonepithelial (noncontinuous) morphologies (C,F); atrophic RPE (H,K). (A) “Nonuniform” RPE: slightly “Nonuniform” morphology and pigmentation with small patches of early basal laminar deposit (BLamD). (B) “Very Nonuniform” RPE: more nonuniformity in shape and pigmentation; melanosomes within apical processes (*pink arrowhead*). Subretinal drusenoid deposits (SDD) localize to RPE apical aspect. (C) “Dissociated” RPE: individual RPE cells with or without nuclei in atrophic area, adherent to early BlamD. Some RPE granules are translocated among HFL fibers. (D) “Shedding”

RPE: basal translocation of shed RPE fragments into a thick continuous layer of BlamD (late and early forms shown by large and small *yellow arrowheads*, respectively); BlinD (*black arrowheads*). (E) “Intraretinal” RPE: anterior migration through ELM. Epithelial component remains atop BlamD (bottom), which in turn overlies an artifactually empty soft druse. Photoreceptors have degenerated. Retina is artifactually detached. (F) Cells “entombed” by a subretinal scar(s) together with nonpigmented cells. Persistent BlamD divides subretinal fibrocellular scar in the subretinal space from fibrovascular scar (*fv.s*) in sub-RPE space. This histologic phenotype occurs only in neovascular AMD and is therefore not describe further in the text. (G) “Sloughed” RPE: release of spherical cells into the subretinal space; the epithelial component overlies BlamD (blue) and BlinD (gray). (H) “Atrophy with BlamD”: absent RPE and persistent BlamD. Photoreceptors have atrophied. ELM delimits endstage outer retinal tubulation. (I) “Bilaminar”: double layers of epithelial RPE (delimited by *dotted line*) adherent to BlamD. (J) “Vacuolated” RPE: cells with a single large vacuole delimited apically by extremely effaced cytoplasm. (K) “Atrophy without BlamD”: absent RPE, absent BlamD. Photoreceptors have atrophied. *Yellow arrowheads*, BlamD; *red arrowheads*, calcification in BrM; *green arrowheads*, ELM. *HFL*, Henle fiber layer; *INL*, inner nuclear layer.

The deposit has two different appearances that are termed “early” and “late” BlamD. The early form is seen in normal aging as well as in eyes with early or late stages of AMD, while the late form is present with increasing frequency in eyes with late AMD manifestations (GA and CNV).<sup>43,75</sup> Early BlamD appear on light microscopy as pale-staining eosinophilic material that stains blue with picro-Mallory and shows faint anteroposterior striations (Fig. 68.5). In contrast, the light microscopic appearance of late BlamD is a thick, hyalinized layer that stains red with picro-Mallory, similar

to hyalinized Bruch's membrane, and is more periodic acid–Schiff-positive than the earlier, banded form (Figs. 68.7 and 68.8). Being a later development, it forms a distinct layer on the anterior surface of the earlier form (Figs. 68.2D, 68.7 and 68.8) and may approximate the thickness of the normal RPE, occasionally displaying nodular elevations on its internal surface<sup>43,75,78</sup> (Fig. 68.8).

With electron microscopy the BlamD is seen to consist of three phenotypes: fibrillar, polymerized, and amorphous. The fibrillar and polymerized phenotypes are present in early BlamD, and the fibrillar form may only be detected as irregular nodules lying on the anterior surface of the original RPE basement membrane. The polymerized form resembles the fibrous long-spacing collagen seen within Bruch's membrane and is also found in the cornea, trabecular meshwork, and other tissues in the body with aging.<sup>57</sup> It projects anteriorly from the original RPE basement membrane<sup>79</sup> (Fig. 68.6) and accounts for the striations, or bush-like appearance, seen histologically in the early forms. The amorphous form of the BlamD is seen in late BlamD. It has a flocculent appearance and consists mainly of amorphous material that forms anterior to early BlamD<sup>75</sup> (Figs. 68.7 and 68.8). It is often associated with attenuation of the overlying RPE (see Fig. 68.10).

**FIG. 68.10** Example of regressing druse in an area of geographic atrophy. The druse is covered by late, amorphous BlamD (*short arrow*) and has dystrophic calcification. A clinically unsuspected small vessel passes through a gap in Bruch's membrane beneath

the druse (*long arrow*). A layer of fibrous tissue (F) lies on the anterior surface of Bruch's membrane. (Methylene blue and basic fuchsin, x240.) (Reproduced from Sarks JP, Sarks SH, Killingsworth M. Evolution of geographic atrophy of the retinal pigment epithelium. *Eye* 1988; 2:552–577.)

The similarity of the BlamD to basement membrane and its proximity to rough endoplasmic reticulum at the base of the RPE cells suggest that it is a secretory product of the RPE.<sup>79,80</sup> It reacts with antibodies against type IV collagen, heparan sulfate proteoglycans, and laminin,<sup>80</sup> but the BlamD is biochemically distinct from the RPE basement membrane, and a faulty, degradative process rather than enhanced synthesis may account for its accumulation in aged maculas.<sup>50,55</sup>

On examination, BlamD have not been identified in the fundus with any certainty, but the histopathologic presence of late BlamD may be presumed when significant pigment alterations are present on clinical examination.<sup>75</sup>

### **Basal Linear Deposits.**

Basal linear deposits (BlinD) form a thin layer between the RPE basement membrane and the ICZ of Bruch's membrane (Fig. 68.6, see Fig. 68.9D). These deposits are difficult to distinguish with light microscopy; however, they are well visualized with TEM. BlinD can become continuous with soft drusen, soft drusen may form within this layer (discussed in a later section)<sup>75–77,81</sup> (see Fig. 68.11) and the deposit itself is sometimes referred to as diffuse drusen.<sup>77,78</sup> These deposits are comprised largely of membranous debris while the other major component of BlinD are non-membrane-bound electron-lucent droplets.<sup>77</sup> The BlinD appear to disturb the normal attachment of the RPE to Bruch's membrane, creating a cleavage plane, in which RPE detachments may develop due to blood or serous fluid and into which early choroidal new vessels may grow.<sup>82</sup>

**FIG. 68.11** Semithin section showing medium-sized soft drusen from the left eye of the patient illustrated in [Fig. 68.22](#). Since these deposits are focal accentuations of a continuous layer of debris, their margins are ill defined and they readily become confluent. It is into this plane that choroidal new vessels grow; a neovascular membrane was present nearby. Drusen appear empty or very finely granular at this magnification. The arrow points to a small basal mound of similar appearance, lying above the druse. Higher magnification is shown in [Fig. 68.27](#) (methylene blue and basic fuchsin, x240). (Reproduced from Sarks JP, Sarks SH, Killingsworth MC. Evolution of soft drusen in age-related macular degeneration. *Eye* 1994;8:269–283.)

### Membranous Debris.

Membranous debris is identified with TEM and accumulates in three locations in eyes with AMD: anterior to the RPE basement membrane (along with BlamD) ([Fig. 68.12](#)), immediately posterior to the RPE basement membrane (as a component of BlinD and within soft drusen that develop in this plane), and in the subretinal space at the apex of the RPE (see [Fig. 68.13](#)).<sup>73,75</sup> When samples are processed to preserve lipid, membranous debris does not resemble surrounding cells or vesicles as it is composed of solid lipid particles rather than having an aqueous interior.<sup>83</sup>

**FIG. 68.12** Basal mound lying internal to retinal pigment epithelium (RPE) basement membrane.

Electron micrograph shows buildup of coiled membranous debris separating the grossly abnormal RPE from its basement membrane. These collections are referred to as “basal mounds” and may account for the drusen-like dots noted clinically. Only a very thin layer of membranous debris lies external to the basement membrane (*arrows*), so there are no soft drusen ( $\times 1680$ ). (Courtesy of M.C. Killingsworth.)

**FIG. 68.13** Disposition and ultrastructure of subretinal drusenoid deposits and soft drusen. Sections were postfixed by the osmium-tannic acid-paraphenylenediamine method for neutral lipid and sectioned at 1  $\mu\text{m}$  for staining with toluidine blue (A) or sectioned for transmission electron microscopy (B,C). (A) Adjacent subretinal drusenoid deposit (at left) and soft druse (at right) that is attached to the retinal pigment epithelium. The subretinal drusenoid deposit is well formed, with overlying photoreceptors that are deflected or shortened. It includes an apical cap of material, distinct from outer segments in both staining density and size. The soft druse has partial contents that bind little stain. Both retinal pigment epithelia underlying the deposit and overlying the druse are minimally disturbed. Scale bar: 25  $\mu\text{m}$ . ON, outer nuclear layer. (B,C) The interior of the subretinal drusenoid deposit has complex membranous whorls with neutral lipid interiors dispersed throughout a ground substance with globular proteins (*arrows*). In

contrast, the soft druse has membranous debris of simpler shapes, mostly spheres, and heterogeneous sizes. Much of the druse contents are missing, consistent with the known physical fragility of these lesions. Globular proteins present in (B) are absent in (C). Scale bar: 1  $\mu\text{m}$ . *Arrowheads* indicate retinal pigment epithelium basal lamina. (Reproduced with permission from Spaide RF, Curcio CA. Drusen characterization with multimodal imaging. *Retina*. 2010;30(9):1441-54.)

When membranous debris is present anterior to the RPE basement membrane, it is in conjunction with continuous early or late BlamD. It is not found in this tissue plane in the absence of BlamD<sup>74,75</sup> (Fig. 68.6). In this particular location the membranous debris forms layers and then basal mounds internal to the RPE basement membrane (Figs. 68.1C and 68.12). Membranous debris in this location is not demonstrated well in conventional light microscopic histologic sections, since the mounds manifest only as small, unstained spaces within the BlamD (Fig. 68.14). As the mounds of membranous debris associated with BlamD enlarge and fuse, the RPE overlying it shows more derangement and cell dropout.<sup>75</sup>

**FIG. 68.14** Section through the macula of an 83-year-old man in whom pigment changes were evident clinically. Stretches of attenuated, hypopigmented retinal pigment epithelium (RPE) alternate with clumps from which hyperpigmented cells are shed into the

subretinal space. Basal laminar deposit is thicker and comprises both early and late forms. Small, unstained patches beneath the RPE would correspond to mounds of membranous debris on electron microscopy ( $\times 525$ ). (Reproduced with permission from Sarks SH. Aging and degeneration in the macular region: a clinico-pathological study. *Br J Ophthalmol* 1976;60:324–41.)

Membranous debris posterior to the RPE basement are a major component of BlinD (discussed above), and membranous debris in the subretinal space has been correlated with the clinical appearance of subretinal drusenoid deposits (reticular pseudodrusen), which are described further below.<sup>73,84</sup>

### **Significance of Basal Deposits and Membranous Debris.**

By light microscopy, the finding of continuous BlamD is regarded as the hallmark of AMD. However, by TEM, it is membranous debris that correlates more closely with clinical signs of AMD. In particular, increased accumulations are associated with late stage AMD.<sup>75,77</sup> This association had been noted by Sarks and coworkers<sup>75,81</sup> and was studied in a more formal way by Curcio and Millican.<sup>77</sup> In the latter study, TEM findings from eyes with and without AMD based on histopathologic evidence of drusen and RPE changes were evaluated to determine the sensitivity and specificity of various TEM features for diagnosing AMD. Identification of BlinD or large drusen (both features consisting of membranous debris external to the RPE basement membrane) had a specificity of 0.73 and a sensitivity of 0.9 for an AMD diagnosis, whereas continuous BlamD with membranous debris had a specificity of 0.68 and sensitivity of 0.7. The specificity of BlinD and continuous BlamD was similar, meaning that most eyes with either feature had AMD; however, the lower sensitivity of continuous BlamD as compared to BlinD means that many eyes with AMD do not have continuous BlamD while they are likely to have BlinD. When any BlamD, as opposed to continuous BlamD, was evaluated, sensitivity increased but specificity decreased, meaning that most eyes with AMD had some BlamD, but many eyes with BlamD do not necessarily have typical clinical features of AMD.<sup>77</sup> This is consistent with the concept that some BlamD is consistent with

normal aging and the presence of any form of membranous debris (within BlinD, within large drusen, associated with BlamD) signifies the pathologic state of AMD.

## **Retinal Pigment Epithelium and Photoreceptors**

During normal aging, lipofuscin and complex melanolipofuscin granules accumulate in RPE cells and the cells become pleomorphic in size, shape, and degree of pigmentation. Pathologic changes within the RPE that have been described in AMD include the continued accumulation of these materials while the cells enlarge and lose their regular shape.<sup>75</sup> The posterior or basal surface of the cells shows loss of the basal infoldings and a consequent reduction in surface area. The RPE becomes increasingly separated from its basement membrane by thickening of the BlamD and more membranous debris.<sup>75</sup> Occasional cells undergo lipoidal degeneration or become vacuolated.<sup>75,85,86</sup> Finally, the hyperpigmented cells resulting from this phagocytic overload round off and lose all but a few apical microvilli.<sup>75</sup> This may indicate a loss of their ability to phagocytose.<sup>75</sup> Lipofuscin becomes packed into large degenerate retinal pigment cells or membrane-bound bodies and can be shed into the subretinal or sub-RPE space (Fig. 68.1D; see Figs. 68.9G–E and 68.14).<sup>75</sup>

The changes described above may appear visible on macular examination as small focal areas of hyper- or hypopigmentation. Focal hyperpigmentation correlates histologically with localized areas of RPE cell hypertrophy, which may be accompanied by clumps of hyperpigmented cells in the sub-RPE space, the subretinal space (see Fig. 68.14), and migrating to the outer nuclear layer (ONL) of the neurosensory retina.<sup>75,86</sup> Using SD-OCT<sup>87</sup> and ultrahigh resolution (UHR) OCT,<sup>88,89</sup> moderate to intense hyperreflective deposits have been demonstrated, in vivo, within these various planes. These findings have corresponded to foci of hyperpigmentation on clinical examination or on fundus photographs. It is common for eyes with drusen to have these intraretinal deposits recognized on histopathology or OCT directly anterior to the drusen, primarily in the subretinal space or ONL, but migration can occur into more anterior retinal layers.<sup>43,86,88</sup> Focal hypopigmentation correlates with attenuated, depigmented RPE

cells surrounding the hyperpigmented cells.<sup>78</sup>

Based on histologic examination of RPE cells from eyes with various stages of AMD, Sarks, et al. proposed the following sequence of events occur for the evolution of progressive RPE atrophy.<sup>75</sup> When a RPE cell dies, the products are phagocytosed by its neighbors. These cells in turn become filled with lipofuscin and round off, losing their ability to phagocytose. As the dead cells are discarded, nearby viable cells migrate and increase in surface area. This results in thinned, hypopigmented cells adjacent to focal hyperpigmentation. Finally, neighboring cells can no longer stretch to fill the gap and atrophy results. Hyperpigmentation therefore precedes hypopigmentation, and this in turn is the prelude to the development of patches of atrophy.<sup>75</sup>

Progressive derangement of the RPE is accompanied by dropout of photoreceptors, with a reduction in the number of nuclei in the ONL. The inner segments tend to become shorter and more bulbous, and the outer segments may terminate in collections of membranes over the apical surface of the RPE<sup>75</sup> (Fig. 68.7). More advanced progressive changes that occur in the RPE and photoreceptors in eyes with GA are discussed further in a later section on this topic.

## **Bruch's Membrane and Choroid**

In eyes with AMD, hyalinization and densification of Bruch's membrane extends posteriorly along the intercapillary pillars and may even surround the choriocapillaris<sup>43</sup> (Fig. 68.5, see Fig. 68.9). Some segments of Bruch's membrane thin, and small breaks within it develop.<sup>79</sup> Non-membrane-bound electron-lucent droplets of the type found in BlinD can also be identified in the ICZ and OCZ.<sup>77</sup>

The density of veins in the macular choroid is significantly reduced.<sup>74</sup> Away from regions of atrophy, the percent vascular area of the choriocapillaris and diameter of capillaries are not significantly different compared to control eyes.<sup>90</sup> However, fewer fenestrations per capillary are noted in eyes with GA compared to control eyes even in regions with overlying intact RPE.<sup>90</sup>

In addition to the structural changes identified within the choroid and Bruch's membrane, macrophages, giant cells, fibroblasts, and occasional lymphocytes are found in proximity to the outer surface

of Bruch's membrane in the space formerly occupied by the choroidal capillaries.<sup>79,91</sup> This chronic, low-grade inflammatory reaction, which possibly develops in response to the membranous debris liberated by degenerating RPE, is often found in the choroid near breaks in Bruch's membrane<sup>79,92</sup> and may be a link in the chain of events leading to CNV and progressive atrophy.

## Drusen

As noted above, the clinical hallmark of AMD is the presence of at least one medium-size druse<sup>19</sup> or extensive small drusen,<sup>17</sup> with or without RPE abnormalities. The spectrum of drusen, how drusen evolve, and the histopathologic and imaging characteristics of drusen will be detailed in this section. Descriptions of clinical grading systems for AMD that highlight drusen features and the prognostic implications of these variables are discussed further in the section on management of NNVAMD.

## Drusen Characteristics Identified With Ophthalmoscopy or Fundus Photography

Drusen can be described in terms of size, color, morphology,<sup>81,93</sup> and extent. Drusen size is estimated by comparing the shortest diameter of a druse to the width of a major retinal vein as it crosses the edge of the optic disc.<sup>72,94</sup> At this location the retinal vein has an approximate diameter of 125  $\mu\text{m}$ . Drusen are labeled *small* when they are less than half the width of the reference vein (<63  $\mu\text{m}$ ), *medium or intermediate* when judged at least equal to half the vein width but less than the full width (63  $\mu\text{m}$  to <125  $\mu\text{m}$ ), and *large* when they are at least as big as the full retinal vein width ( $\geq 125$   $\mu\text{m}$ ). For research studies, more precise estimates of drusen size are made by overlaying circles of known diameter to fundus images and selecting the smallest circle diameter that contains the shortest drusen diameter within it (Fig. 68.15) or by using digital software to measure individual drusen diameter on digital fundus images.<sup>95</sup> Drusen color varies from white, to pale yellow, to bright yellow. Concentrating on the morphology of drusen, both its borders and its central substance, drusen can be broadly divided into hard and

soft categories, with soft drusen being further subdivided into soft indistinct or soft distinct based on further characterization of the sharpness of the drusen borders.<sup>17</sup> Soft drusen are generally medium size or larger and have an amorphous appearance centrally and along the border. Viewed stereoscopically they appear to have an inherent thickness. Soft drusen may converge or become confluent with one another and demonstrate heterogeneity in size and shape. Hard drusen tend to be small and have a sharp or distinct appearance throughout the deposit, and they tend to exist individually from one another. As drusen size and morphology are highly correlated with one another, current drusen descriptions have largely shifted to inclusion of size alone, as this can be derived with more objectivity than describing drusen morphology.

**FIG. 68.15** Standard circles C0, C1, C2, C3, and C4 that are used to grade the size of specified lesions. They are reduced on a transparent sheet to range from 1/24 to 1/3 disc diameter, thereby representing 63  $\mu\text{m}$ , 125  $\mu\text{m}$ , 175  $\mu\text{m}$ , 250  $\mu\text{m}$ , and 500  $\mu\text{m}$ , respectively.

Circle C0 is used to differentiate small from medium drusen, circle C1 is used to differentiate medium from large drusen, and circle C2 indicates the minimum area on which to base a definition of geographic atrophy. The diagonal lines facilitate locating the central point and estimating size of lesions. (Reproduced with permission from Bird AC, Bressler NB, Bressler SB, et al. An international classification and grading system for age-related maculopathy and age-related macular degeneration. *Surv Ophthalmol* 1995;39:367–374.)

The extent or severity of macular involvement may be assessed by noting drusen number or the total macular area occupied by drusen.<sup>17,71,93</sup> Drusen number may be simpler to categorize on clinical exam than mentally sweeping all drusen into an area and estimating the size of the area occupied by the “condensed” drusen. Drusen number may be described as *minimal* or *nonextensive* under the following conditions: when there are fewer than five and the largest druse present is small; when there are fewer than 20 and the most advanced druse present is soft, indistinct, and extensive soft distinct drusen are not present; or when there are fewer than 65 soft distinct drusen in the absence of extensive soft indistinct drusen on macular examination. Moderate or extensive drusen are present when the number of drusen within these drusen subtypes is exceeded. Area occupied by drusen is largely reserved for research purposes, as it requires study of fundus photographs with the assistance of templates that depict a spectrum of area sizes to estimate the total drusen area. Alternatively, software programs for use with human operators or automated programs may be used to identify and outline each druse present within the macula on digital color images of the fundus<sup>95</sup> or from OCT images<sup>96</sup> and then sum these areas to derive total macular area occupied by drusen. The total area occupied by drusen is the single most important prognostic feature for AMD worsening and is discussed in the section on management of NNVAMD.

Different patterns of age-related drusen distribution have been reported.<sup>97</sup> The superior and temporal quadrants of the posterior pole are typically associated with the largest area of soft indistinct drusen involvement. However, after adjusting for the differences in absolute area mapped by the nine subfields illustrated in the

ETDRS 6 mm diameter grid (Fig. 68.16), it is the central subfield that has the highest percent area occupied by drusen.<sup>97</sup> Subretinal drusenoid deposits (reticular drusen) are most commonly found in the superior and temporal subfields and are sparser centrally.<sup>73,98</sup> Comparisons between the two eyes of an individual with bilateral NNVAMD may demonstrate a fair degree of symmetry in drusen number, type, and distribution.<sup>97,99</sup>

**FIG. 68.16** Standard grid for classification of age-related macular degeneration. For a 30° fundus camera the diameters of the central, middle, and outer circles are 1000  $\mu\text{m}$ , 3000  $\mu\text{m}$ , and 6000  $\mu\text{m}$ , respectively. These circles represent the central, inner, and outer subfields. The diagonal lines help to center the grid on the macula. (Reproduced with permission from Klein R, Davis MD, Magli YL, et al. The Wisconsin age-related maculopathy grading system. *Ophthalmology* 1991;98:1128–34.)

Drusen may have a life cycle, as drusen number may increase or decrease over time while size and morphology can also evolve. Some drusen may grow larger in diameter, taller in height, and coalesce while others may spontaneously regress. Drusen regression is characterized by reduction in yellow color, decrease in thickness, greater definition of drusen borders, potential appearance of glistening calcification, and the emergence of RPE

atrophy or depigmentation (see Fig. 68.17).<sup>81,100,101</sup> This is discussed further later in this section.

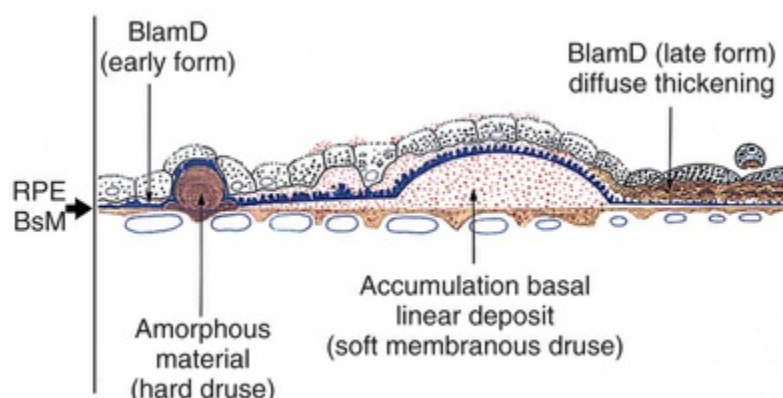

**FIG. 68.17** Images of the right eye of a 76-year-old Caucasian woman with non-neovascular age-related macular degeneration (AMD) in the right eye and neovascular AMD in the left eye. Images show calcified drusen and multifocal, fovea-sparing geographic atrophy (GA) in the right eye in various stages of regression of drusen and progression of GA. (A) Color fundus photograph, (B) near infrared reflectance (NIR) image from Zeiss Cirrus spectral domain optical coherence tomography (SD-OCT), (C) high resolution SD-OCT scan through area shown as dashed blue line on color photography and as solid blue line on NIR image. *Blue arrowheads* show regressing calcified druse with developing GA. On OCT image, retinal pigment epithelium, ellipsoid layer, and external limiting membrane (ELM) overlying this druse is not visible. Highly reflective material is present. *Green arrowhead* shows regressed, calcified druse within area of GA (area of GA is between *yellow*

arrows). *Red arrowheads* show large druse with no apparent calcification on color photographs and examination. On SD-OCT imaging, this druse has internal hyper- and hyporeflective characteristics. Overlying ellipsoid layer and ELM is intact. *White arrows* denote a small focus of GA surrounding a regressed calcified druse. Extent of GA is more evident on NIR image compared to color photographs. This region is not captured in the SD-OCT B-scan image that is shown.

## Clinicopathologic Characteristics of Drusen

Typical age-related drusen are deposits of extracellular material, which lie between the basement membrane of the RPE cells and the ICZ of Bruch's membrane (Fig. 68.18), the same tissue plane in which BlinD are found.<sup>81</sup> The clinical description of drusen mentioned at the beginning of this section pertains to the ophthalmoscopic appearance at a fixed point in time. Different histologic classification systems for drusen have been described,<sup>76,78,81,102</sup> with some relying solely on ultrastructural classification of the drusen,<sup>102</sup> others combining clinicopathologic correlations and more global assessments of the histologic features of the maculas,<sup>76,78</sup> and others combining historical changes on clinical exam and imaging with histopathologic assessment.<sup>81</sup> As these studies each have their own focus and different methods, it has been difficult to unify these classification systems.<sup>102</sup> Furthermore, there is relatively scant information describing drusen composition and structure and a relatively limited number of eyes that have been available for direct clinicopathologic correlation. In addition, the contents of soft drusen are easily lost during histopathologic processing, and thus all the constituents of these drusen may not have been identified. Discordance between the descriptions of ultrastructure of drusen and assumptions about drusen composition based on clinical descriptions also exists. For example, drusen of each of the four ultrastructural phenotypes described by Hageman could occur clinically in a range of drusen sizes that would appear small to large with ophthalmoscopy.<sup>102</sup> As clinically apparent small drusen correlate with hard morphology

and large drusen correlate with soft morphology, it would follow that the different ultrastructural phenotypes may exist in both hard and soft appearance on clinical exam. One can argue that any existing classification system may not be widely generalizable to clinical findings. Additionally, while limited clinicopathologic correlation studies focusing on drusen exist in this era of modern retinal imaging,<sup>103</sup> no studies have tried to relate the histologic description of drusen from older publications to observations made with FAF and SD-OCT images. Therefore, in the following sections, these prior classification schemes may be referenced, but the distinction, especially between differing soft drusen types under these classification systems,<sup>76,78,81</sup> will be deemphasized in this discussion.

**FIG. 68.18** Diagram showing the relationship to the retinal pigment epithelium (RPE) basement membrane (BsM) of the deposits accumulating under the RPE during the evolution of age-related macular degeneration. The basal lamina deposit (BlamD) lies internal to the BsM, and typical drusen lie external. The BlamD exists in an early, striated form (shown in blue) and late amorphous form (shown in brown). Membrane coils are found both internal to the BsM, as mounds at the base of the RPE, and external to the BsM, as the BlinD, where it may form soft, membranous drusen. Hard drusen consist predominantly of amorphous material.

## Small, Hard Drusen

Small, hard drusen are not visible in the fundus until they have a diameter of 30–50  $\mu\text{m}$ , equivalent to the width of two to three RPE cells. They are difficult to see in lightly pigmented fundi, but use of red-free light may facilitate identification. Small, hard drusen may first be noted within 1500  $\mu\text{m}$  of the fovea,<sup>97</sup> but when numerous they are most common on the temporal side of the fovea. They tend to occur in clusters. Another common pattern for this type of drusen is a wide band outside the vascular arcades that continues nasal to the disc, with sparing of the posterior pole. Toward the equator they assume a linear arrangement in relation to a polygonal pattern of hyperpigmented lines, giving rise to reticular (honeycomb) degeneration of the pigment epithelium.

By following a number of patients with small, hard drusen over time, Sarkis and coworkers described the process by which these drusen may fuse to form large drusen, which they termed “pseudosoft” drusen. Initially small, hard drusen that form in a cluster may remain as discrete deposits on ophthalmoscopy, even if they appear to touch one another. As the drusen become more closely packed, the cluster morphs into a single larger deposit that clinically appears soft; however, the small drusen can usually still be made out in red-free light<sup>81</sup> (Fig. 68.19). These fused drusen are up to 250  $\mu\text{m}$  in diameter, depending on the number of drusen in the cluster. If sufficiently elevated, they may tent up the RPE and retina, which may cause a reddish halo around the base of the deposit<sup>81</sup> (Fig. 68.20). These clusters of fused, small, hard drusen can be found in middle age. Some of these drusen slowly regress over many years leaving a focal patch of RPE atrophy or GA (Fig. 68.20). This cycle may be completed in younger persons before the BlinD and membranous debris characteristic of AMD have developed. As such these cluster-derived large drusen can occur independently of the intermediate or advanced stages of AMD.

**FIG. 68.19** Soft, cluster-derived drusen (pseudosoft drusen). Right fundus of a 50-year-old man with 20/20 vision (A). Groups of mainly small, hard drusen associated with hyperpigmentation are seen at the fovea. Large, soft, confluent drusen appear to be located temporal to the fovea, but in red-free light (C), and particularly on fluorescein angiography (B), the soft drusen can be seen to consist of closely packed clusters of small, hard drusen.

**FIG. 68.20** Patient illustrating large pseudosoft druse with halo around base, apparently derived from a fused cluster of small, hard drusen. Photographs trace the regression of the druse over 9 years. The druse was located just superior to the foveal center and vision remained unaffected. (A) At age 48, the druse is surrounded by a red halo. (B) At age 52, the druse appears whiter, and pigment stippling is present over the surface. (C) At age 54, the halo fades as the druse becomes shallower and clumps of hyperpigmentation are preceding the formation of a patch of geographic atrophy (GA). (D) At age 57, the drusen material is resorbing and a patch of GA is emerging. This appearance may be called incipient GA. (Reproduced from Sarks SH. Drusen patterns predisposing to geographic atrophy of the retinal pigment epithelium. *Aust J Ophthalmol* 1982;10:91–97.)

## Large, Soft Drusen

For drusen that they considered to be associated with AMD, Sarks et al. made the distinction between larger, more distinct soft-appearing drusen that they termed “granular soft” drusen (Fig. 68.21) and paler, shallower medium-size drusen with more indistinct borders that they termed “soft membranous” drusen<sup>81</sup> (Fig. 68.22). This nomenclature was based on clinicopathologic data

(detailed below) from a limited number of eyes with these features that had been followed for many years. The former are about 250  $\mu\text{m}$  in diameter and have a yellow, solid appearance, their confluence resulting in crescentic or sinuous shapes (Fig. 68.21). The latter are usually smaller than 250  $\mu\text{m}$ , most commonly 63–175  $\mu\text{m}$  in diameter. Their margins are usually indistinct, and they readily become confluent (Fig. 68.22). They described these drusen as common in eyes with intermediate or advanced AMD.<sup>81</sup>

**FIG. 68.21** Soft drusen of granular structure. Numerous soft, yellow drusen of solid appearance in the right eye of a 72-year-old man. Confluence of soft drusen results in a sinuous pattern. Patient died 3 years later, and corresponding histopathology (see Fig. 68.26) demonstrated a granular structure derived from broken down small, hard drusen. (Reproduced with permission from Sarks SH. Drusen and their relationship to senile macular degeneration. *Aust J Ophthalmol* 1980; 8:117–130.)

**FIG. 68.22** Color photograph of the right eye of a 71-year-old man showing soft, indistinct drusen composed of membranous debris. This eye developed a hemorrhagic disciform lesion shortly before the patient died at age 75. The left eye had similar drusen and also proved to contain an early active neovascular membrane. The morphology of the drusen in the left eye is illustrated in [Figs. 68.11](#), [68.27](#), and [68.28](#).

(Reproduced with permission from Sarks JP, Sarks SH, Killingsworth MC.

Evolution of soft drusen in age-related macular degeneration. *Eye* 1994;8:269–283.)

Soft drusen that are larger than 250  $\mu\text{m}$ , but more so those larger than 500  $\mu\text{m}$ , may have an accumulation of serous fluid, may be translucent on retroillumination, and may be referred to as drusenoid PEDs<sup>104–107</sup> ([Figs. 68.23](#) and [68.24](#)). A fluid component is presumed due to their appearance on retroillumination and their sometimes rapid resolution following laser photocoagulation performed at the border of the drusenoid PED.<sup>108</sup> These drusen were described as a separate clinicopathologic category by Sarks et al.,<sup>81</sup> but they likely represent a continuum of progression from other drusen types. They appear to evolve from progressive confluence of existing soft drusen often retaining a scalloped

outline representing the borders of the original individual druse before they merged.<sup>81,107</sup> They often grow to larger than one disc diameter (DD) (2.54 mm<sup>2</sup>) in size with one prospective study showing an average size of 4.19 mm<sup>2</sup> at initial presentation with 14 of 16 drusenoid PEDs larger than 1 DD.<sup>105</sup> In another retrospective report one-third of the 61 drusenoid PEDs were greater than 1 DD at the presenting visit.<sup>107</sup> Drusenoid PEDs have variable elevation or thickening but tend to be shallower than serous PEDs and have less variable topography than fibrovascular PEDs. Drusenoid PEDs may enlarge over time, both in height and extent, and ultimately regress, with or without the development of NGA and GA. As overlying hyperpigmentation and hypopigmentation develop, often in the form of a radiating pigment figure, the contents become whiter and more inspissated. Once heavy pigment clumping has appeared, the drusenoid PED generally begins to collapse and may be replaced by GA<sup>75,104</sup> (Fig. 68.23). Relative to other types of PEDs, drusenoid PEDs have unique ophthalmoscopic and angiographic features (described below).

**FIG. 68.23** Development of geographic atrophy following the collapse of a drusenoid pigment epithelial detachment (PED). (A) Left eye of a 65-year-old woman with a drusenoid PED that had been observed

to develop from the confluence of soft drusen. Clumps of focal hyperpigmentation developed on the surface of the PED (vision 20/50). Choroidal neovascularization (CNV) was never identified on fluorescein angiography (FA), rather the PED was brightly fluorescent. (B) Three years later the PED had collapsed, with an area of geographic atrophy replacing much of the same area. Many of the surrounding soft drusen have spontaneously resolved as well, many without overt signs of nongeographic atrophy in their place.

**FIG. 68.24** Patient showing evolution of clusters of small, hard drusen into larger, soft, confluent drusen (*arrows*), presumably due to the addition of serous fluid. Fluorescein angiograms of the right eye of a man

at age 55 (A), 58 (B), and 61 (C). The drusen farthest from the fovea remain discrete. In the inner macula they form clusters in which the individual drusen are more difficult to distinguish owing to confluence and breakdown. The more central clusters have become completely homogeneous on fluorescein angiography.

(D) Red-free photograph at age 61 shows corresponding clinical picture. Homogenized clusters have a soft, yellow appearance. Visual acuity remained 20/20, although the patient had been aware of some deterioration.

All drusen types may in time disappear,<sup>7,26,109</sup> but this does not necessarily signify a return to a more normal state, since areas of drusen may be replaced by other subtle or more severe manifestations of AMD. When drusen fade some eyes appear “improved,” but whether this is associated with a decreased risk of the late stages of AMD remains to be seen. It is doubtful that the RPE remains unaffected at these locations as fluorescein angiography (FA) may show increased transmission of fluorescence where drusen have faded.

Drusen often begin to regress in conjunction with failure of overlying RPE, frequently assuming a whiter and harder appearance as the contents of the druse become inspissated (see [Fig. 68.20](#)). Hyperpigmentation and hypopigmentation often develop over the surface of the druse. Later the margins become irregular and foci of calcification may appear, especially after the age of 60 years. Ultimately the drusen fade and may leave multifocal patches of nongeographic atrophy (NGA) and GA that reflect their original distribution. Glistening calcium deposits may remain in these atrophic areas for many years ([Fig. 68.17](#)).

## Histopathology of Drusen

### **Small, Hard (Hyalinized, Nodular) Drusen**

Small, hard drusen histologically are focal globular deposits of hyalinized material along the inner aspect of Bruch's membrane with staining properties similar to hyalinized Bruch's membrane (see [Fig. 68.8](#)).<sup>81</sup> They have also been called nodular drusen.<sup>78</sup> Histopathologic specimens have shown that within an area of

clinically apparent hard drusen clusters there are often numerous intervening drusen too small (“microdrusen”) to be seen on clinical examination.<sup>81</sup> This is the predominant drusen type found in postmortem specimens from younger persons, and they are ubiquitous, present in 83% of donors between age 36 and 94 (mean 67 years).<sup>110</sup> Certain changes in Bruch's membrane may precede formation of these drusen.<sup>111</sup> In eyes with only a few drusen, small, hyalinized plaques of densification in Bruch's membrane are observed, sometimes with extensions into the OCZ and even on to the anterior surface of the choroid.

These drusen have an amorphous appearance on electron microscopy (Fig. 68.25).<sup>81</sup> Another early change, seen only by electron microscopy, is that of coated membrane-bound bodies, both ruptured and intact (see Fig. 68.2), that are trapped between the basement membrane of the RPE and the inner collagenous zone (entrapment sites) as well as in the OCZ.<sup>111</sup> Entrapment sites are found in specimens from all ages and probably indicate a normal aging phenomenon.

**FIG. 68.25** Electron micrograph shows a parafoveal cluster of small, hard drusen measuring 250  $\mu\text{m}$  in diameter with the drusen touching and fusing. Larger drusen inside the cluster are breaking down into globules of hyaline material, leaving small, hyalinized drusen around the perimeter. The smallest drusen would not be seen clinically, but they can be assumed to be present around the larger, visible drusen. Retinal pigment epithelium over the larger drusen is thinned. Fundus had shown only a few drusen clusters. Vision was 20/20 2 years before death at age 81; lens

opacities and dementia precluded further documentation. The cluster would appear as a single deposit, and fluorescein angiography (not performed) would be expected to demonstrate brightly staining, small drusen around a more homogeneous center (methylene blue and basic fuchsin,  $\times 290$ ).

In eyes with many small, hard drusen the Bruch's membrane findings noted above become more extensive. Hyalinized drusen form anterior to these changes, and as they grow they become hemispherical or almost globular. When small, hard drusen grow larger than about  $63\ \mu\text{m}$ , the amorphous contents become less compact and paler-staining, a process that begins in the posterior part of the druse. On electron microscopy, greater electron density is noted at the borders and less in the center.<sup>81</sup> Microdrusen, or rounded elevations  $2\ \mu\text{m}$  in diameter, and composed of very dense amorphous material, may be seen in the intervening space between drusen.<sup>81</sup> Single hard drusen rarely exceed  $125\ \mu\text{m}$ , and further enlargement is the result of the fusion of several drusen, which have been termed "cluster-derived drusen."<sup>81</sup> As the RPE anterior to the drusen degenerates, the contents of the drusen become increasingly dispersed (Fig. 68.25) or, especially in older patients, coarsely granular (Fig. 68.26). Softening of the margins of hard drusen correlates with spreading of the base of the druse along Bruch's membrane (Figs. 68.25 and 68.26).

**FIG. 68.26** Semithin section through edge of fovea (*F*) of eye shown in Fig. 68.21 demonstrates confluence of three soft drusen. Drusen have a granular structure, comprising variably sized globules of amorphous material, some membrane-bound. This material may be derived from the breakdown of small hard drusen,

several of which were still present around the edge of these drusen. Note that, as the contents break down, drusen tend to lose sharp margins and nodular surface elevations present in fused clusters (see [Figs. 68.8](#) and [68.18](#)). The fellow eye demonstrated similar drusen, but many were regressing (methylene blue and basic fuchsin,  $\times 115$ ). (Reproduced with permission from Sarks JP, Sarks SH, Killingsworth MC. Evolution of soft drusen in age-related macular degeneration. *Eye* 1994;8:269–83.)

In addition to the above findings, note there is an alternate hypothesis as to the generation of hard drusen, which is that some hard drusen are actually lipoidal degeneration of RPE cells.<sup>78,85</sup>

## Soft Drusen

While distinct clinicopathologic categories of soft drusen have been described, these drusen types may differ only in their relative proportion of component material. Granular soft drusen have a coarsely granular structure on transmission electron microscopy ([Fig. 68.26](#)), consisting of membrane-bound globules of amorphous material, small membrane fragments, and other cellular debris. The presence of microdrusen and the proximity of some of these drusen to hyalinized (hard) drusen ([Fig. 68.25](#)) may indicate that the granular contents represent, in part, cluster-derived drusen in which the original hard drusen have broken down. In fact, it is the drusen in the center of a hard derived drusen cluster that appear to be initially affected ([Fig. 68.25](#)), as small, hard drusen may remain identifiable around the perimeter of the cluster. The detection of this heterogeneous composition, either on FA ([Fig. 68.24](#)) or in histologic sections, led to the designation semisolid.<sup>112</sup> A thin layer of this granular material would appear to resemble the soft drusen described by Green<sup>76,78</sup> as localized detachment of the RPE and BlamD deposit, in an eye with diffuse BlamD ([Fig. 68.26](#)).

Other drusen contain mostly membranous debris and can be thought of as localized accumulations of the same or similar material to that of which BlinD are comprised. Sarks et al. termed these “membranous” drusen, and Green referred to them either as “localized detachment of RPE and basal linear material in an eye with diffuse BlamD and BlinD” or a “localized detachment due to

localized accumulation of basal linear material in an eye with diffuse BlamD but not diffuse BlinD.” As such Green created two categories from what Sarks described as “membranous” drusen, these two categories being differentiated based on whether or not diffuse BlinD were present.<sup>78</sup> On light microscopy, these drusen are pale-staining and faintly periodic acid–Schiff-positive, with a finely granular or ground-glass appearance; they may even appear optically empty. However, on electron microscopy they contain tightly packed membrane coils (Figs. 68.11 and 68.27; see also Fig. 68.13). A small amount of amorphous material may be present within the coils, so their contents have also been described as vesicular and granular electron-dense, lipid-rich material.<sup>76,78</sup> This membranous debris is morphologically similar to that which forms basal mounds internal to the RPE basement membrane, and continuity between the mounds and drusen through the basement membrane can at times be observed (Fig. 68.27).

**FIG. 68.27** Electron micrograph corresponding to the area indicated in Fig. 68.11 shows formation of a soft druse made up of coiled lipid membranes lying external to the basement membrane of the retinal

pigment epithelium (RPE) (*arrows*). The membranes appear first at the base of the RPE, where they may form basal mounds (*MD*). At the site of the right-hand arrow, some membranes can be seen within the basement membrane of the RPE and appear to be entering the soft druse from the basal mound. Some of the coils appear empty, and others contain amorphous material (*double arrow*). These drusen are specific for age-related macular degeneration, since they are only found after membranous debris develops. *BlamD*, Basal laminar deposit (x2210). (Reproduced with permission from Sarks JP, Sarks SH, Killingsworth MC. Evolution of soft drusen in age-related macular degeneration. *Eye* 1994;8:269–283.)

The BlamD anterior to these drusen is usually the early type because membranous material declines as late BlamD appears. Although these soft drusen are believed to develop *de novo*, small, hard drusen are commonly also present and then become incorporated into the membranous drusen; the amorphous contents of the hard drusen break down ([Fig. 68.28](#)).

**FIG. 68.28** Electron micrograph of the same eye in [Figs. 68.11](#), [68.22](#) and [68.27](#) shows a cluster of subclinical, small, hard drusen (*open arrowhead*) apparently becoming eroded by membranous debris and breaking down into small membrane-bound particles (*central arrow*). At right (*shorter arrow*), druse consists of more characteristic membranous debris. This scenario suggests that small, hard drusen

become incorporated into soft drusen once membranous debris develops. Early-type basal laminar deposit (*BlamD*) lies over drusen. Note that the basal laminar deposit and retinal pigment epithelium remain anchored at the site of hard drusen but are separated from Bruch's membrane on either side by soft drusen. *Solid arrowhead* at left points to macrophage-type cell adjacent to outer surface of Bruch's membrane, where retina remains attached (x1260). (Courtesy of MC Killingsworth.)

Drusenoid PEDs, in some cases, represent large accumulations of membranous debris between the basement membrane of the RPE and the ICZ of Bruch's membrane.<sup>78</sup> It has been hypothesized that fluid may become trapped within drusenoid PEDs due to a failure of the RPE to pump water from this area due to lipoidal debris in Bruch's membrane creating a hydrophobic barrier.<sup>113</sup>

## Regressing Drusen

On histopathologic examination both the RPE and the photoreceptors anterior to regressing drusen disappear, leaving a thick layer of late-type amorphous BlamD over the apex of the druse (Fig. 68.10). Macrophage invasion of regressing drusen has led to the hypothesis that they are instrumental in removing membranous debris. Material that is not removed becomes invaded by glial cells or collagen fibers or undergoes dystrophic calcification.

## Imaging of Drusen

### Angiography: Fluorescein and Indocyanine Green

#### Small Drusen.

Small, hard drusen may be visible with FA, even when as small as 25  $\mu\text{m}$ , fluorescing brightly in the midvenous phase and fading soon after the background choroidal fluorescence does so<sup>81</sup> (Fig. 68.24). With coalescence of small, hard drusen, FA continues to show bright nonuniform fluorescence of these drusen through the midphase followed by late fading. The edges remain distinct initially but can become indistinct with softening of the margins of

the drusen. However, the presence of individual small drusen can usually still be discerned on FA (Fig. 68.19). In contrast to FA, with ICGA, small, hard drusen in aged individuals cannot be visualized in the early or the late phases of the ICG study.<sup>114</sup>

### Medium and Larger Drusen including Drusenoid PEDs.

As opposed to small and hard drusen, soft drusen are not generally hyperfluorescent in the early phases of FA (Fig. 68.29). They hyperfluorescence in later stages with less intensity than hard drusen and with some inherent variability in intensity<sup>103,114</sup> (Fig. 68.29). In late phases of the FA, some soft drusen fade while others stain.

**FIG. 68.29** Retina of 73-year-old subject with soft drusen and surrounding hard drusen. (A) Color photograph of retina. (B) Early phase fundus fluorescein angiogram showing early hyperfluorescence of hard drusen. (C) Late phase fundus fluorescein angiogram showing later staining of soft drusen. (D) Early phase indocyanine green angiogram (ICGA) showing hypofluorescence of the soft drusen centrally. Hard drusen are unable to be discerned. (E) Late phase ICGA showing persisting hypofluorescence of soft drusen. Note the surrounding relative hyperfluorescence of the margin of drusen. Hard drusen are isofluorescent. (Reproduced with permission from

The evolution of changes to drusen seen over a 6-year period in [Fig. 68.24](#) suggests that small drusen may become incorporated into larger drusen. In the more peripheral macula the brightly fluorescent small drusen remain discrete. In the more central macula they form clusters in which the individual druse become progressively more difficult to distinguish. These drusen fill more slowly with fluorescein than the peripheral drusen but often show a few brightly fluorescent highlights around the edge of the deposits. The drusen clusters closest to the fovea may become completely homogeneous in intensity and filling characteristics during FA.

Drusenoid PEDs appear shallowly elevated and manifest faint late fluorescence similar to the filling of the surrounding soft fluid drusen.<sup>104</sup> Hyperpigmentation overlying the drusen create hypofluorescent figures on the anterior surface of the drusenoid PEDs.

With ICGA, soft drusen in individuals age 55 and older tend to be hypofluorescent (darker) relative to the background choroidal fluorescence pattern throughout the study with a thin hyperfluorescent margin on the outside of the druse appearing in the late phase<sup>114</sup> ([Fig. 68.29](#)). ICG is also a water-soluble dye and may not accumulate within the substance of the central druse where hydrophobic neutral lipids may be present. The hypofluorescence with ICGA is even more prominent with drusenoid PEDs in early, mid, and late phases, with masking of the underlying choroidal vessels due to thick overlying drusen material.<sup>107</sup>

## **Fundus Autofluorescence**

Unless associated with overlying RPE changes, small drusen are not usually visible on FAF imaging. FAF imaging of soft drusen may show slight (mild intensity) hyperautofluorescence at the edges of the druse or throughout the druse ([Fig. 68.30](#)). Areas of hypoautofluorescence may indicate incipient atrophy over soft drusen.<sup>115</sup>

**FIG. 68.30** Color fundus photographs (A,B), fundus autofluorescence (FAF) image (C), and Heidelberg spectral domain optical coherence tomography (SD-OCT) (D) image of the right eye of a 72-year-old Caucasian woman with intermediate non-neovascular age-related macular degeneration with large drusen and retinal pigment epithelium (RPE) changes. (B–D) Magnification of region in blue box in (A). Areas of hyperautofluorescence on FAF imaging (C) correspond to some of the soft drusen and RPE changes on color photograph (A,B). Corresponding drusen are present in this area on SD-OCT image (D). Ellipsoid zone disruption is also noted over these drusen.

## Spectral Domain OCT

Small or hard drusen appear as slight elevations of the RPE using SD-OCT imaging, while soft drusen appear as 63–1000 µm wide deposits posterior to the RPE (Fig. 68.30D). Although soft drusen throughout the posterior pole of an individual eye may appear similar on clinical examination, they often manifest a variety of OCT appearances (Figs. 68.17C and 68.30D). The most common

appearance is convex-shaped deposits with homogenous medium internal reflectivity<sup>116</sup> (Fig. 68.30D). This pattern was seen in nearly all eyes (99%) with intermediate AMD in an ancillary study performed within the Age-Related Eye Disease Study 2 (AREDS2). The SD-OCT findings identified in this study among 314 eyes (314 participants) with intermediate AMD are shown in Fig. 68.31.<sup>117</sup> Drusen with high and low internal reflectivity were less common, present in 43% and 61% of eyes, respectively. Drusen with hypo- or hyperreflective cores (see Fig. 68.25C) were present in approximately 25% of eyes.<sup>117</sup> Anterior to the drusen more than 90% of eyes had thinning of the photoreceptor layer over some drusen with variable alterations in the ellipsoid zone (Figs. 68.17C and 68.30D). Foci of hyperreflectivity in the neurosensory retina anterior to the drusen was present in half<sup>117</sup> and may correlate with pigment or RPE cell migration into the retina<sup>86</sup> (Fig. 68.30D).

**FIG. 68.31** Prevalence of spectral domain optical coherence tomography (SD-OCT) retinal changes and drusen characteristics among 313 AREDS category 3 age-related macular degeneration study eyes in the AREDS2 ancillary SD-OCT study. (Reproduced with permission

Automated algorithms have been developed that are applied to SD-OCT images to quantitate the two-dimensional area and three-dimensional volume occupied by drusen<sup>96</sup> and drusenoid PEDs<sup>105</sup> in the macula. These software programs are likely to become commercially available. Measurements using these algorithms are highly reproducible with an intraclass correlation coefficient of >0.99 for drusen area and volume.<sup>96</sup> Serial imaging over time using these programs has confirmed the dynamic evolution of macular drusen. In a prospective study of 143 eyes of 100 patients, mean drusen volume and area increased over time. However, at 12 months drusen volume had increased in 48%, remained stable in 40%, and decreased in 12% of eyes. Drusen volume measurements were defined as stable if the value at follow-up was within the 95% test–retest tolerance limits for the baseline measurement and as increased or decreased if the measurements fell outside of this range. Decreases in drusen volume were more common in eyes with larger baseline drusen volume.<sup>118</sup> In a prospective natural history study of 130 patients (186 eyes with non-advanced AMD), 16 eyes of 11 patients with drusenoid PEDs were identified during the study. Eight of these eyes continued to have a drusenoid PED till the end of follow-up (mean 18.5 months). Among the remaining 8 eyes, 7 had an increase in drusenoid PED volume before regression of the drusenoid PED was associated with progression to GA (5 eyes) or development of CNV (2 eyes). One eye had at least a 50% reduction in drusenoid PED volume without progressing to GA or CNV.<sup>105</sup>

On near infrared reflectance (NIR) imaging obtained with scanning laser ophthalmoscopy, often while obtaining SD-OCT, soft drusen may show decreased brightness relative to the surrounding background.<sup>103</sup>

## Histochemistry of Drusen

Five substructural phenotypes of drusen have been described, but they do not correlate well with clinical drusen phenotypes as varying clinical phenotypes are comprised of similar molecules.<sup>102</sup> Drusen contain neutral fats and phospholipids,<sup>119</sup> as well as glycoconjugates containing specific carbohydrate residues.<sup>120,121</sup> The

latter were found in all classes of drusen, suggesting that both hard and soft drusen may have a similar origin.<sup>121</sup> Many hard and soft drusen contain specific cores with a carbohydrate-rich composition confined to distinct domains. These cores are positioned centrally within the drusen and are typically juxtapositioned to Bruch's membrane.<sup>120</sup> Some researchers have suggested that they may represent an early nucleation site around which other drusen-associated molecules including lipid are subsequently deposited.<sup>92,120</sup>

Other distinct components common to all phenotypes of hard and soft drusen include apolipoprotein E, immunoglobulins, factor X, amyloid P component, complement C5 and C5b-9 terminal complexes, fibrinogen, and thrombospondin.<sup>121</sup> Vitronectin is a major constituent of both hard and soft drusen, and vitronectin mRNA is expressed locally in the RPE, suggesting that vitronectin may participate in the pathogenesis of AMD.<sup>122</sup> A number of these drusen-associated constituents are participants in humoral and cellular immunity, including a number of acute-phase reactants, plasma proteins that rapidly elevate in response to inflammatory stimuli.

## Other Patterns of Drusen and RPE Abnormalities that May be Found in Eyes With NNVAMD

### Subretinal Drusenoid Deposits

#### Clinical Appearance.

Subretinal drusenoid deposits<sup>73,84,123</sup> (reticular pseudodrusen,<sup>124</sup> reticular drusen<sup>25,93</sup>) appear as a pale yellowish interlacing network of individual deposits, each about 250  $\mu\text{m}$  in diameter (range 25–1000  $\mu\text{m}$ ) that resemble soft confluent drusen.<sup>93,103</sup> They are more readily visible when the fundus is examined with blue light.<sup>84,103,125,126</sup> Initially they appear most prominent in the superior macula (Fig. 68.32) although the network may slowly extend into other quadrants while sparing the fovea.<sup>73,98</sup>

**FIG. 68.32** (A) The color photograph shows a lacy arrangement of subtle whitish accumulations in a 78-year-old patient. The spectral domain optical coherence tomography (SD-OCT) slice location is shown as a green line. (B) The accumulated material is evident in the blue channel of the color photograph. (C) Near infrared imaging shows a denser array of dark material. (D) Late-phase fluorescein angiogram shows subtle variation in the background fluorescence. (E) An OCT scan shows drusenoid deposits in the subretinal space (stage 1: diffuse material between retinal pigment epithelium (RPE) and ellipsoid zone, *black arrows*; stage 2: sufficient material to alter contour of ellipsoid layer, *arrowhead*; stage 3: material breaks through ellipsoid layer, *white arrows*). Note the lack of sub-RPE drusen in this section. (Reproduced with permission from Zweifel SA, Spaide RF, Curcio CA, et al. Reticular pseudodrusen are subretinal drusenoid deposits. *Ophthalmology*. 2010;117(2):303-12 e1.)

## Histology.

By light microscopy, the bases of reticular pseudodrusen appear to consist of flocculent material that lies in the subretinal space. This material has a dense cap that contains refractile material.<sup>84,127</sup> The photoreceptors anterior to these deposits show shortening or loss of outer segments and inner segment deflection or loss,<sup>73</sup> and the material can extend past the inner/outer-segment junction<sup>127</sup> (Fig. 68.33 and see Fig. 68.13). They can be present in isolation or in confluent drusenoid mounds and may be conical or flat in shape.<sup>73,103</sup> On TEM evaluation, subretinal drusenoid deposits have been shown to correspond to membranous debris in the subretinal space as had been described by Sarkis et al.<sup>73,75,84,103</sup> They are comprised of accumulations of membranous debris, as well as flocculent material (Fig. 68.13B), similar in appearance to that seen in BlinD and BlamD and soft drusen (Fig. 68.13C).<sup>73,75,103,127</sup> By immunohistochemistry, these deposits have been shown to contain unesterified cholesterol, apoE, complement factor H, and vitronectin components that are also present in soft drusen.<sup>127</sup>

**FIG. 68.33** Histologic analysis of subretinal drusenoid debris; 10- $\mu$ m-thick cryosections were stained with hematoxylin and viewed with bright field (A,C) and differential interference contrast (B,D) microscopy.

Scale bar: 50  $\mu$ m. (A) Note the accumulation of material above the retinal pigment epithelium (RPE) (*arrow*). This subretinal drusenoid deposit (*arrow*) had a loosely packed flocculent base with dense cap. Note the decrease in the number of overlying photoreceptor nuclei. (B) The cap had refractile material (*arrowhead*).

(C) In a separate section, a subretinal drusenoid deposit (*arrow*) extended from the RPE up to the outer nuclear layer. (D) There is refractile material on the upper surface of the deposit.

(E) The distribution of subretinal drusenoid deposits (all  $>20$   $\mu$ m wide) was evaluated by examining 100 cryosections, each approximately 11 mm in length, that were obtained starting 200  $\mu$ m inferior to the fovea, which is marked by an X. Typical drusen (all  $<45$   $\mu$ m) are shown as *black dots*. The subretinal drusenoid deposits formed an interconnected branching pattern. GCL, ganglion cell layer; INL, inner nuclear layer; ONL, outer nuclear

layer; *RPE*, retinal pigment epithelium. (Reproduced with permission from Zweifel SA, Spaide RF, Curcio CA, et al. Reticular pseudodrusen are subretinal drusenoid deposits. *Ophthalmology*. 2010;117(2):303-12 e1.)

## Imaging.

With en face viewing, subretinal drusenoid deposits are best visualized using the blue channel of color photographs (Figs. 68.32A–B) or best captured using red-free photographs or NIR images obtained with the scanning laser ophthalmoscope. With the latter, they appear darker than the uninvolved surrounding areas (Fig. 68.32C).<sup>103</sup> Likewise, on autofluorescence imaging they appear darker than the surrounding areas.<sup>103</sup> With FA, these deposits have either no visible appearance or display minimal hypofluorescence (Fig. 68.32D).<sup>103</sup> SD-OCT images show deposits of material anterior to the RPE, in the subretinal space (Fig. 68.32E).<sup>84,103</sup> The material can be configured as relatively flat aggregates to conical mounds that extend to the region between the inner and outer photoreceptor segments. The deposits appear to be smaller in size on NIR scanning laser ophthalmoscope images compared to color photographs or OCT images<sup>103</sup> and appear to be far more extensive when visualized with OCT as compared to color photographs.<sup>123</sup> Outer retinal atrophy in the absence of frank GA has been demonstrated by SD-OCT following regression of subretinal drusenoid deposits.<sup>128</sup>

## Vitelliform Lesions in Eyes With Non-neovascular AMD

The presence of yellowish, subretinal material in the central macula has been associated with cuticular drusen<sup>129</sup> (discussed below) or as part of a spectrum of changes that are now termed pattern dystrophy.<sup>130</sup> This material can also accumulate in the macula of eyes with typical AMD (defined either by histopathology or by presence of large drusen clinically) (Fig. 68.34).<sup>131,132</sup> Vitelliform lesions are not a common manifestation of AMD,<sup>131,132</sup> and its presence has not been correlated with any particular histologic stage of AMD.<sup>131</sup> As such, it is unclear if this material accumulates as part of the pathogenesis of AMD or whether it is a concomitant finding related to the simultaneous presence of a second disease

process.<sup>131,132</sup>

**FIG. 68.34** (A) Color fundus photograph of the left eye of an 83-year-old woman diagnosed with non-neovascular age-related macular degeneration showing a vitelliform lesion surrounded by several large drusen in the central macula. (B) Fundus autofluorescence revealing hyperautofluorescence in the macular area corresponding to the vitelliform lesion and areas of increased pigmentation seen on fundus photograph. (C) Spectral domain optical coherence tomography demonstrating hyperreflective material in the subretinal space corresponding to the vitelliform material (*wide arrow*). Large drusen are also present underneath the vitelliform material (*arrows*). (Reproduced with permission from Lima LH, Laud K, Freund KB, et al. Acquired vitelliform lesion associated with large drusen. *Retina*. 2012;32(4):647-51.)

On examination and color photographs ([Fig. 68.34A](#)), these lesions appear as yellow, semiopaque, slightly thickened deposits with indistinct borders through which areas of hyperpigmentation can sometimes be seen within or posterior to the yellow lesion. When present, they usually occur as a single lesion in the fovea, but can occur in multiple and noncentral macular locations.<sup>133</sup> In eyes with AMD, these lesions range from 350 to 1760  $\mu\text{m}$  in greatest linear diameter.<sup>132</sup> With time this material may enlarge or spontaneously resolve with development of outer retinal and RPE

atrophy in its place.

These lesions are invariably hyperautofluorescent in FAF imaging (Fig. 68.34B), with the pattern of hyperautofluorescence correlating well with the extent of the yellowish material.<sup>132,133</sup> During FA, these lesions are hypofluorescent in the early phase as the vitelliform material blocks background choroidal fluorescence. However, in the late phase of the study there is intense hyperfluorescence as the dye stains the vitelliform material.<sup>133</sup> The intense late hyperfluorescence of a vitelliform lesion can mimic that of choroidal neovascularization, making study of the early phase angiogram critical to differentiating the two processes. Less intense late staining on FA can also result in the face of RPE atrophy that may follow spontaneous resolution of the vitelliform lesion. On SD-OCT imaging, the vitelliform material is identified in the subretinal space as a fairly uniform hyperreflective deposit (Fig. 68.34C) that ranges from 32 to 580  $\mu\text{m}$  in thickness.<sup>132</sup> These lesions may also have within them or contiguous to them hyporefective subretinal spaces, which are thought to reflect a component of subretinal fluid that can occur in the absence of CNV.<sup>133</sup> Vitelliform lesions may lie anterior to drusen or retinal pigment epithelial detachments (PEDs). The ellipsoid layer anterior to the vitelliform lesion may range from completely intact to having complete disruption or absence.<sup>133</sup> In eyes in which the vitelliform lesion resolves with time, OCT has shown atrophy of the ellipsoid layer and RPE.

On histologic examination, this extracellular material appears as debris in the subretinal space that exhibits pale-staining rounded bodies with picro-Mallory, consistent with photoreceptor material.<sup>131</sup> The initiating mechanism is believed to be impaired phagocytosis of photoreceptor outer segments. Overlying photoreceptor loss and underlying central loss of RPE pigmentation with release of pigment granules into the material can be seen. Increased pigmentation and reduplication of the RPE can be seen at the edges of the lesion.<sup>131</sup> Ultrastructural analysis confirms the disorganization of photoreceptor outer segments and the presence of debris derived from photoreceptor outer segments and pigment from the RPE.<sup>131</sup>

## **Basal Laminar Drusen/Cuticular Drusen**

Gass first described the syndrome referred to as basal laminar or cuticular drusen in 1977.<sup>134</sup> This condition is distinct from AMD and most commonly is diagnosed in individuals who are in their 40s or 50s with a great degree of symmetry between their two eyes. On examination, innumerable, uniform, round, densely packed and transparent 50–75- $\mu\text{m}$  diameter sub-RPE deposits are present (Fig. 68.35A) that are best seen with retroillumination. Subretinal yellowish vitelliform material may also be present within the posterior pole.

Basal laminar drusen were initially attributed to internal nodularity of the RPE basement membrane<sup>129</sup> but with time have been more accurately recognized as nodularity due to diffuse drusen.<sup>135,136</sup> Histologic specimens are sparse but show that this material accumulates between the basement membrane of the RPE and the ICZ of Bruch's membrane, in the same location as typical drusen.<sup>136</sup> Green categorized this entity as “diffuse drusen with internal nodularity”<sup>78</sup> and considered the material to represent thickening of the internal portion of Bruch's membrane rather than lying anterior to the ICZ.<sup>78,135</sup> These deposits appear to protrude into the RPE, and the overlying RPE cells have been noted to be thinned at the apex of the deposit and show signs of degeneration.<sup>103,136</sup> At the ultrastructural level, two different compositions have been described that can be present side-by-side in the same eye, one type being comprised of a uniformly homogenous material, mostly of 20-nm “granules.”<sup>136</sup> The other type is heterogeneous and consists of electron-dense and electron-lucent inclusions, spherical profiles of various diameters, fibrin-like profiles, curvilinear profiles, and material that may represent cellular debris. This second type is further distinguished by calcium-containing inclusions.<sup>135,136</sup> Their composition also appears to be similar to that of “typical” drusen.<sup>136</sup>

During FA, basal laminar drusen show early and late pinpoint dots of hyperfluorescence and appear more numerous than can be appreciated on clinical exam. They produce a “starry-sky” appearance on FA, as the myriads of small, hard drusen fluoresce (Fig. 68.35B). Unlike the small, hard drusen seen in eyes with early AMD, basal laminar drusen appear slightly hyperfluorescent in early phase with increased hyperfluorescence on late phase with ICGA.<sup>137,138</sup> If vitelliform material is also present, this material

appears hypofluorescent throughout the time course of ICGA.<sup>138</sup> Using autofluorescence imaging these drusen are hypoautofluorescent, possibly due to thinning of the RPE at the apex of the deposit.<sup>103</sup> On SD-OCT, they appear to have a blunted triangular shape and their close proximity to one another and their marked numbers create a sawtooth pattern (Fig. 68.35C).<sup>103</sup>

**FIG. 68.35** Color photograph (A) and late phase fluorescein angiography (FA) image (B) of the right eye of a 62-year-old African American woman with basal laminar/cuticular drusen. Note that hyperfluorescent drusen on FA appear more numerous (“starry-sky appearance”) than can be appreciated on the color photograph. Vertical high-resolution spectral domain optical coherence tomography image (C) of the left eye of a 51-year-old Caucasian woman with basal laminar/cuticular drusen demonstrates a characteristic “saw-tooth” pattern of elevation of the retinal pigment epithelium (RPE). Increased transmission of signal through the RPE, posterior to the apex of the drusen

compared to the edges of the drusen, subtly visible in this image, has been described and has been attributed to relative thinning of the RPE at the apex and thickening of the RPE at the edges of this type of drusen.<sup>103</sup>

## **Retinal Pigment Epithelial Abnormalities: Nongeographic Atrophy, Focal Hyperpigmentation, and GA**

Along with drusen, the other hallmark features of AMD are noted to be RPE abnormalities. This is a collective term that includes a range of alterations from focal hyper- and hypopigmentation to geographic atrophy. This category of abnormalities increases the risk that an eye will have subsequent disease progression, independent of the drusen features that may be simultaneously present. The most extreme form of RPE abnormality, GA, is recognized clinically as sharply circumscribed areas of RPE loss through which the underlying choroidal vessels become visible.<sup>93</sup> Histopathologic examination of eyes with GA have identified well-demarcated regions of attenuated or absent RPE with associated loss of the overlying photoreceptors and underlying choriocapillaris. A continuum of pigment abnormalities that may culminate in GA have been described clinically, and this is complemented by histologic studies that suggest that progressive RPE abnormalities are markers for progression of NNVAMD.<sup>75,86</sup> Through clinicopathologic assessment, including use of SD-OCT, some correlation has been drawn between clinically apparent changes and those described with histology. As noted in the normal aging section, some loss and dysfunction/irregularity of RPE cells is considered a component of normal aging. However, more significant RPE changes occur as part of NNVAMD that may culminate in widespread RPE cell death and the formation of GA.

## **Clinical Findings in the Progression of RPE Abnormalities to GA**

## **Nongeographic Atrophy (Incipient Atrophy, RPE Degeneration, RPE Depigmentation, Hypopigmentation)**

Nongeographic atrophy (NGA)<sup>22</sup> may be thought of as incipient atrophy as it may immediately precede geographic atrophy in the same location. These alterations do not have distinct borders but are recognized as patches of RPE thinning or depigmentation or hypopigmentation, which may have associated clumps of pigment within them or along the border of the region. The affected region may appear more yellow or pink than the normal fundus background, due to attenuation of the RPE and partial visualization of choroidal blood flow.

## **Focal Hyperpigmentation**

Focal hyperpigmentation can develop in areas without drusen (Figs. 68.3C–D), but more commonly is noted surrounding the border of a druse or anterior to drusen or drusenoid PEDs (Figs. 68.23A and 68.30). On stereoscopic examination, focal hyperpigmentation may appear at the level of the RPE or it may be intraretinal. Focal hyperpigmentation is a more common finding than hypopigmentation or depigmentation. Of 3212 eyes within AREDS examined to construct the 9-step severity scale, 25% (800 eyes) were noted to have pigment changes by the AREDS centralized reading center. While 419 eyes were graded as containing macular depigmentation, 748 eyes had hyperpigmentation. It is possible that focal hyperpigmentation precedes depigmentation, or increases the likelihood of identifying depigmentation (which may be subtle) as only 52 eyes with depigmentation did not have focal hyperpigmentation.<sup>71</sup>

## **Development of GA**

Many eyes that progress to GA have large drusen that undergo regression<sup>75,82,139</sup> (Fig. 68.17). In fact, the total macular area occupied by drusen is an established risk factor for progression to GA.<sup>71,140</sup> RPE degeneration is usually more advanced immediately anterior to drusen, which may be appreciated clinically as RPE clumps or RPE depigmentation on the anterior surface of drusen (Figs. 68.20,

68.23 and 68.30). As this RPE alteration on the surface of the druse progresses, the drusen material may regress and the pattern of GA may initially reflect the distribution of past drusen (Fig. 68.17). In younger patients such foci of GA that form in this manner may remain as discrete lobules for many years (see Fig. 68.20), but when progressive AMD manifestations affect the RPE in between discrete areas, patches of GA may enlarge and coalesce in an irregular manner (Figs. 68.17 and 68.36). In eyes with more advanced GA, the only evidence that it evolved via a multifocal distribution in relation to drusen may be scattered calcified deposits within the GA as well as a few small outlying islands of GA.<sup>100,101</sup> Some eyes may show a continuum of all of these manifestations of NNVAMD simultaneously. Fig. 68.37 illustrates an eye with many large and confluent drusen remaining in the macular periphery surrounding a large central region of NGA. Within the NGA there is a focal area of hyperpigmentation and at least one area of extrafoveal GA is present in the superotemporal macula and another suspected superiorly. Areas of both NGA and GA may be more apparent on FA, in which the contrast of black, white, and grey changes is more striking than the varying shades of red, orange, pink, and yellow that are noted on clinical examination.

**FIG. 68.36** Regressing drusen, showing multifocal pattern of geographic atrophy (GA), in a patient 69 years of age. The separate patches of GA have spread into the surrounding retina, and many have coalesced to produce this pattern. The drusen within these areas have disappeared, and only calcified particles remain. Vision was 20/40, with partial preservation of an island of foveal retinal pigment epithelial, but the patient was unable to read along a line.

**FIG. 68.37** Color photograph (A) and midphase angiogram (B) of eye with nongeographic atrophy and geographic atrophy. Fluorescein angiogram revealed numerous, mostly small, hard drusen, although many aggregated into clusters. Drusen are fading centrally in an area of incipient atrophy of the retinal pigment epithelium, which appears as a pinker area of the fundus (A), showing diffuse hyperfluorescence (B). Geographic atrophy commences as rounded, more circumscribed, brighter window defects within the incipient atrophy (B). Vision was still 20/15.

In the AREDS, 95 eyes developed GA during the initial 4 years of

follow-up. A retrospective review of the annual fundus photographs that preceded the development of GA identified the following features present at the site that eventually developed GA: drusen >125  $\mu\text{m}$  in 96%, confluent drusen in 94%, hyperpigmentation in 96%, drusen >250  $\mu\text{m}$  in 83%, hypopigmentation in 82%, and refractile deposits presumed to be calcification in 23%.<sup>101</sup> The time between the documentation of each of these features and the incident GA varied by specific feature, ranging from 6 years for confluent drusen to 2.5 years for hypopigmentation or refractile deposits. In addition, an orderly sequence of these features was cataloged as drusen progressed to include sites of hyperpigmentation and then exhibit regression of the drusen material. These areas evolved into sites of RPE hypopigmentation and eventually GA.<sup>101</sup> Some of these observations were corroborated in the Complications of Age-Related Macular Degeneration Prevention Trial (CAPT), as among the 114 eyes in the observation arm that developed incident GA, 84% did so in areas previously occupied by drusen.<sup>100</sup>

This evolution of RPE alterations progressing to GA often begins in the perifoveal area, but the contiguous slow expansion of GA lobules becomes an increasing threat to foveal function with time. When GA is first noted to be present, it may exist as a single or as multifocal lobules that spare the foveal center. However, some eyes do present with GA affecting the foveal center. In the CAPT the location of GA among the incident cases was noted to be as follows: 20% involved the fovea, 18% were within 250  $\mu\text{m}$  of the fovea, 61% were 250–1500  $\mu\text{m}$  from the foveal center, and 1% were greater than 1500  $\mu\text{m}$  from the foveal center.

It should be noted that GA may also form independent of the location of drusen. This may occur in eyes in which large drusen are not captured in significant numbers at any point in time. Stippling of the RPE pigmentation and small or medium drusen may coexist, but GA does not begin in relation to individual drusen.<sup>75</sup> Rather the atrophy may begin around the perimeter of the fovea in a band of microreticular hyperpigmentation<sup>75</sup> (Fig. 68.38), although this is not always the case (Fig. 68.39 and see Fig. 68.3). Spread continues into retina affected by NGA and can be rapid when the ring of pigment clumps is pronounced. This pattern of

GA tends to expand in a horseshoe-like configuration around the central fovea, or it develops simultaneously in several areas around the foveal perimeter that eventually merge.<sup>75,141</sup> The nasal or temporal side of the horseshoe eventually becomes involved such that a complete bull's-eye pattern surrounds the fovea. The preserved foveal island eventually succumbs as the GA slowly expands concentrically.

**FIG. 68.38** An eye illustrating the spread of geographic atrophy (GA) unrelated to drusen. (A) At age 68, GA was developing in relation to a ring of nongeographic atrophy, which also contained reticular hyperpigmentation, located around the perimeter of the fovea. (B) As the GA expanded, 1 year later, in a horseshoe fashion, it replaced the nongeographic atrophy (incipient atrophy).

**FIG. 68.39** This is the same patient shown in [Fig. 68.3](#).

(A) Color and (B) red-free images at age 81. The patient is fixing between two small areas of geographic atrophy (GA) that occupy the site where previous focal pigmentation was seen. Pigment clumping and small drusen-like dots surround the GA. This surrounding nongeographic atrophy corresponds to the site at which GA developed subsequently in (C) and (D); vision is still 20/30. (C) At age 82, GA has expanded to involve the fovea and dots have faded. Vision has dropped to 20/200. (D) At age 84, the GA has almost doubled in size; vision is 20/400. Choroidal atrophy causes exposed vessels to appear white. Patient died at age 85. Pathology of this eye is shown in [Fig. 68.7](#).

(Reproduced from Sarks JP, Sarks SH, Killingsworth M. Evolution of geographic atrophy of the retinal pigment epithelium. *Eye* 1988;2:552–577.)

GA may also arise following collapse of an RPE detachment (see [Fig. 68.23](#)), particularly drusenoid RPE detachments that are formed by the confluence of large soft drusen.<sup>104,106</sup> The emergence of GA in this scenario is consistent with the mechanism of drusen-related GA described above; however, it should be differentiated from atrophy that is caused by resolution of a fibrovascular PED (FVPED). The latter is more appropriately considered atrophic scarring rather

than true GA given the presence of CNV. Also in the setting of CNV and FVPED, RPE rips may occur. The resulting retraction of the pigment epithelium leaves a sharply demarcated area of denuded RPE in which there is increased visualization of the choroidal vessels. Such an area may mimic an area of GA. Features that help distinguish an RPE rip from GA include the following: marked subretinal and intraretinal fluid overlying the area in the acute phase, visible scrolling or bunching of the RPE at the edge of the denuded RPE, and intense early fluorescence on a fluorescein angiogram with relative blockage in a linear configuration along the margin of the hyperfluorescent area from the scrolled RPE.

## **Histopathologic Alterations Associated With RPE Abnormalities With Progression to GA**

### **RPE Alterations**

Many of the histologic changes that occur to the RPE during the progression to GA are discussed in the “Histologic alterations of non-neovascular AMD which may not be apparent on ophthalmoscopy” section above. Zanzoterra et al. more recently described changes that occur in the RPE in late AMD, including eyes with GA, and proposed a morphologic grading system that introduced new nomenclature.<sup>86</sup> The earliest RPE changes they describe are a “nonuniform” morphology and pigmentation of RPE cells that is associated with patches of early BlamD (Fig. 68.9A). This may progress to “very nonuniform” appearance in shape and pigmentation of RPE cells that contain melanosomes in the apical processes (Fig. 68.9B). This is associated with increased BlamD as well as subretinal drusenoid deposits. Later changes include “shedding” of RPE cells (Fig. 68.9D), which is described as basal translocation of RPE cells or fragments into a continuous thick layer of BlamD, and the presence of “sloughed” RPE into the subretinal space (Fig. 68.9G). “Sloughed” RPE is felt to be a precursor to “intraretinal” RPE that has migrated past the external limiting membrane (ELM) (Fig. 68.9E). The presence of ELM indicates an area that is not considered to have GA. Further progression leads to “dissociated” RPE, cells that lack epithelial characteristics and are found in areas of GA (Fig. 68.9C). These cells were found associated

with BlamD in regions lacking ELM within degenerated ONL 34% of the time, within Henle fiber layer 60% of the time, and in the foveal inner nuclear layer 6% of the time. “Atrophy with BlamD” (Fig. 68.9H) and “atrophy without BlamD” (Fig. 68.9K) were used to described areas with no remaining RPE cells. Further categories of “bilaminar” RPE (Fig. 68.9I and see Fig. 68.7), with double layers of epithelial RPE, “vacuolated” RPE (Fig. 68.9J), and “entombed” RPE (within scar from CNV) (Fig. 68.9F) were described. All but the last category were present in eyes with GA, and “bilaminar” RPE was much more common in eyes with CNV compared to GA. The later changes (“dissociated” and “atrophy with and without BlamD”) were more prominent in central locations, with the earlier changes noted in sections taken from both the central and superior macula.<sup>86</sup> Clinical imaging correlates to many of these changes outlined above are discussed below in the imaging section.

## Photoreceptor Changes

As noted earlier, progressive derangement of the RPE is accompanied by dropout of photoreceptors, a reduction in the number of nuclei in the ONL, shorter and more bulbous inner segments, and termination of outer segments in collections of membranes over the apical surface of the RPE<sup>75</sup> (Figs. 68.7 and 68.9B). By histopathology, only a minority of cases of GA show sharply demarcated areas of photoreceptor loss at the perimeter of the GA.<sup>142</sup> It is more common to find a broad transition zone that shows loss of rods and altered cones. The cones lose their outer segments, and some lose their inner segments as well.<sup>142</sup> In the transition zone, the ONL progressively thins as it approaches the GA.<sup>142</sup>

## Changes to Choroid and Bruch's Membrane

In eyes that exhibit GA, within the portions of the macula that retain RPE, the choriocapillaris remains relatively normal. However, in areas with progressive RPE loss there is progressive loss of choriocapillaris.<sup>90</sup> In the macular regions that are not affected by GA, the choriocapillaris has a vascular area (defined as the percentage of the choriocapillaris layer occupied by blood vessels) of 72%, which is not significantly different from that of age-

matched eyes without AMD. In the regions that border GA this drops to 52%, and in the GA area itself it is reduced to 38%.<sup>90</sup> Likewise, mean capillary diameters were 13.9  $\mu\text{m}$  in areas unaffected by GA (not significantly different from age-matched eyes without AMD), 10.3  $\mu\text{m}$  in border regions, and 7.9  $\mu\text{m}$  in regions of GA.<sup>90</sup>

In the setting of GA, obliteration of the choriocapillaris is accompanied by erosion of the intercapillary pillars of Bruch's membrane, and in longstanding cases Bruch's membrane becomes thinner. Fibroblasts and macrophage processes are found in contact with the outer surface of Bruch's membrane, commonly splitting off fragments or even passing through small breaks in Bruch's membrane.<sup>92</sup> Pigmented cells, likely of RPE origin, described as "subducted" cells may also become associated with Bruch's membrane.<sup>143</sup>

In longstanding GA, there are fewer large choroidal vessels and the exposed choroidal arteries may display white sheathing of their walls or even appear bloodless (Fig. 68.39D). This appearance was formerly called senile choroidal sclerosis, but on histologic examination the white fibrotic appearance does not result from sclerosis; the majority of arteries show only fibrous replacement of the media without thickening of the walls and with retention of wide lumina. This appearance is instead an expression of choroidal atrophy,<sup>82</sup> as loss of the choriocapillaris and the middle layer of vessels throws the remaining larger vessels into greater prominence. The white sheathing is due to the disproportionate thickening of the vessel walls by becoming flattened in the thinned choroid, but in many cases it also reflects a reduced blood column.

## Imaging of Nongeographic Atrophy and Geographic Atrophy

### Fluorescein Angiography

With FA, areas of NGA demonstrate diffuse hyperfluorescence; however, the intensity of the fluorescence is not as bright as that associated with GA (Fig. 68.37). The reticular or punctate pattern of hyperpigmentation that is often associated with NGA (Fig. 68.37) is responsible for areas of blocked fluorescence that appear

hypofluorescent. GA is recognized as lobules of hyperfluorescence that appear during the transit phase of the angiogram, sometimes with visualization of the choroidal vessels passing through the region (Figs. 68.36 and 68.40A).<sup>144</sup> There may be a surrounding rim of blocked fluorescence from pigment at the border of GA. In late-phase images the areas may decrease in intensity, but some staining may persist (Fig. 68.40B). These sharply demarcated areas are bright but never as intensely fluorescent as an RPE rip. Small areas of GA, particularly in an environment of diffuse NGA, are more apparent and can be recognized as GA more readily using FA compared to traditional color fundus photography (Fig. 68.36).<sup>100</sup>

**FIG. 68.40** A 73-year-old man with geographic atrophy (GA) secondary to age-related macular degeneration

without any signs or history of choroidal neovascularization. (A) Early fluorescein angiogram (FA) demonstrates hyperfluorescence in the area of the transmission defect. (B) Late hyperfluorescence or staining of the choroid and sclera is visible in the area of the GA. (C) Early indocyanine green angiogram (ICGA) reveals a better visibility or accentuation of the choroidal vessels in the area of the transmission defect evident on FA. The gray veil-like fluorescence from the choriocapillaris is not evident. (D) Late ICGA reveals homogeneous hypofluorescence in the area of the transmission defect with no evidence of late hyperfluorescence. (Reproduced with permission from Schneider U, Sherif-Adel S, Gelissen F, et al. Indocyanine green angiography and transmission defects. *Acta Ophthalmol Scand.* 1997;75(6):653-6.)

## Indocyanine Green Angiography

Findings on ICGA of NGA are much more subtle than those seen on FA. Either no apparent change may be visible or a loss of the uniform background fluorescence, contributed by choriocapillaris, may be noted. However, changes on ICGA are more apparent when GA is present. In early phase ICGA images, GA appears as a well-defined area with increased visibility of the larger choroidal vessels (Fig. 68.40C). These regions correspond to the area of window defect that GA creates on FA. Loss of the uniform gray hyperfluorescence of the normal choriocapillaris and varying degrees of closure of the small and medium-size choroidal vessels are also noted on early phase images in the region of GA. In contrast to FA, late phase findings on ICGA are that of hypofluorescence in the area of GA, with an identical lesion size on these two types of fluorescent imaging (Fig. 68.40D).<sup>144</sup>

## Fundus Autofluorescence

The associated hyperpigmentation in NGA may be more easily delineated on autofluorescence images as areas lacking FAF due to absorption of the exciting light by melanin granules. Alternatively, the associated hyperpigmentation may appear as increased foci of FAF if melanolipofuscin has accumulated in the pigmented sites.<sup>145</sup> The areas of hypopigmentation generally are associated with

decreased FAF, suggesting the absence of RPE cells or degenerated RPE cells with reduced lipofuscin content.<sup>145</sup>

Actual lesions of GA appear as sharply defined and homogeneous areas of hypoautofluorescence on FAF imaging due to RPE loss with corresponding loss of lipofuscin accumulation (Figs. 68.41 and 68.42). The FAF pattern in the “junctional” area of the atrophic and nonatrophic tissue has a more varied appearance. In the junctional area, three patterns of high-intensity FAF have been noted including “banded,” “focal,” and “patchy.” Five additional patterns of hyperautofluorescence that appear more diffuse have also been described in AMD (Fig. 68.42). In these diffuse patterns, increased FAF is present at the margin of the GA and elsewhere in the posterior pole. The pattern of increased FAF may provide prognostic information for rates and location of GA enlargement. Eyes with GA and no hyperautofluorescence and eyes with a focal pattern have been noted to progress slowly, while eyes with the banded pattern or any of the diffuse patterns have been noted to progress more rapidly.<sup>145</sup> When diffuse patterns of FAF are identified, as existing GA enlarges, or as new areas of GA form, they do so at the sites that previously manifested increased FAF. In contrast to the high degree of variation in FAF patterns seen between individuals with GA, a high degree of symmetry has been noted for the pattern of increased FAF in patients with bilateral GA. As there is some evidence that specific patterns of increased FAF in the junctional zone are associated with GA growth rates, some clinical trials evaluating interventions to limit the growth of GA are presently requiring that these “high-risk” patterns, notably the banded or diffuse patterns, be present upon study entry.<sup>145</sup>

**FIG. 68.41** Fundus autofluorescence (FAF) (A) and spectral domain optical coherence tomography (SD-OCT) images (B,C) with horizontal scans at two different levels in a patient with geographic atrophy. (B) SD-OCT image showing irregular margins with structural alterations at the outer retina (*black and white dashed arrow*) corresponding to increased FAF (*black arrowhead*) at the nasal margin. (C) Horizontal scans through the area of no abnormal FAF (*white arrowhead*) showing smooth margins on the SD-OCT (*white arrow*). In B and C, enhanced signal from the choroid corresponds to the area of GA. In panel B, progressive thinning of the outer nuclear layer is present over the more central (older) portions of geographic atrophy. (Reproduced with permission from Brar M, Kozak I, Cheng L, et al. Correlation between spectral-domain optical coherence tomography and fundus autofluorescence at the margins of geographic atrophy. *Am J Ophthalmol.* 2009;148(3):439-44.)

**FIG. 68.42** Classification of fundus autofluorescence (FAF) patterns in the junctional zone in patients with geographic atrophy due to age-related macular degeneration. Eyes with no increased FAF intensity at all are graded as “None” (= slow progressor). The eyes with increased FAF are divided into two groups depending on the configuration of increased FAF surrounding atrophy. Eyes showing areas with increased FAF directly adjacent to the margin of the atrophic patch(es) and elsewhere are called “Diffuse” (= rapid progressors) and are subdivided in five groups. From left to right: (top row) fine granular, branching, (bottom row) trickling, reticular, and fine granular with punctuated spots. Eyes with increased FAF only at the margin of geographic atrophy (GA) are split into three subtypes (“Focal” [= slow progressor], “Banded” [= rapid progressor], and “Patchy” [= unclear progression rate, occurs rarely]) according to their typical FAF pattern around atrophy. (Reproduced with permission from Schmitz-Valckenberg S, Fleckenstein M, Scholl HP, et al. Fundus autofluorescence and progression of age-related macular degeneration. *Surv Ophthalmol.* 2009;54(1):96-117.)

One particular pattern of FAF in GA termed the “diffuse-trickling” phenotype (Fig. 68.42) has been associated with the fastest growth rate of GA. Eyes with this FAF pattern exhibit on clinical examination dense granular hyperpigmentary changes in the central macula, as well as hyperpigmentation at the borders of

the GA. Typically, large or soft drusen are not present in these eyes.<sup>146</sup> This rapidly progressive form of GA likely comprises at least some of the cases of GA that have been described to occur in locations independent of drusen.<sup>75,100</sup>

## **Spectral Domain Optical Coherence Tomography**

As noted previously, one of the earliest findings of RPE abnormalities that can be appreciated with SD-OCT<sup>87</sup> and ultrahigh resolution (UHR) OCT<sup>88,89</sup> is moderate to intense hyperreflective foci within various planes of the retina that correspond to foci of hyperpigmentation on clinical examination or on fundus photographs. It is common for eyes with drusen to have these intraretinal deposits recognized on histopathology or OCT directly anterior to the drusen, primarily in the subretinal space or ONL, but migration can occur into more anterior retinal layers.<sup>43,86,88</sup> Their histopathologic correlates are believed to be the “sloughed” and “intraretinal” grades of RPE that are commonly seen in nonatrophic area of eyes with GA (see Fig. 68.9E,G).<sup>86</sup> In the AREDS2, an ancillary study of SD-OCT findings in a sample of participants suggested that the number of these hyperreflective foci on SD-OCT progressively increased during a 2-year observation period and, with time, were increasingly common within more anterior layers of the retina.<sup>147</sup> In this ancillary study, hyperreflective foci in eyes with drusen increase the odds that an eye will progress to GA within 2 years by a factor of 4.7.<sup>147</sup> Furthermore, the magnitude of the increased risk of progression to GA is modulated by the number of baseline hyperreflective foci and the more anterior location of the hyperreflective foci.<sup>147</sup>

In the AREDS2 ancillary SD-OCT study referred to above, RPE atrophy or loss was noted in 23% of eyes identified to have intermediate AMD clinically while 2.5% were noted to have a patch of RPE atrophy exceeding a diameter of 360  $\mu\text{m}$  extending beneath the fovea. Had these regions of foveal GA been clinically apparent, the eyes would have been graded as advanced AMD rather than intermediate AMD, but neither the clinical examination nor the stereoscopic color photographs disclosed the presence of foveal GA.<sup>117</sup> SD-OCT may thus be a more sensitive means of detecting small areas of GA compared to fundus photography. Drusen with

high reflectivity, low reflectivity, and drusen with cores were less commonly seen than the ubiquitous drusen of medium reflectivity (see Fig. 68.30). However, eyes that contained drusen with these former characteristics, rather than eyes only with drusen with medium, homogenous reflectivity, were more likely to have areas of RPE atrophy or absence.<sup>117</sup>

In the setting of clinically apparent GA, SD-OCT images show the absence of several structures, including the ONL, ELM, and the ellipsoid layer, and either absence or marked attenuation of the RPE and Bruch's membrane complex (Figs. 68.17, 68.41 and 68.43).<sup>148,149</sup> As a result of these alterations, there is choroidal signal enhancement or relative choroidal hyperreflectivity (Figs. 68.17, 68.41 and 68.43). This group of OCT alterations corresponds to the same area with severe reduction of FAF signal on FAF images.<sup>149</sup> Junctional regions between GA and the surrounding macula show abrupt breaks in the ellipsoid layer and RPE/Bruch's membrane complex and curved endings of the ELM as it merges with the atrophic region. Areas of increased FAF on FAF images in eyes with GA have been shown to correspond to highly reflective material and thickening at the level of the RPE and increased outer retinal alterations compared to borders of GA that do not demonstrate increased FAF<sup>150</sup> (Figs. 68.41 and 68.43). Over areas of existing GA, progressive thinning of the ONL occurs with time, and the outer plexiform layer (OPL) becomes progressively closer to the level of the RPE (Fig. 68.41).<sup>148</sup>

**FIG. 68.43** Heidelberg Spectralis optical coherence tomography image in an eye with a large ring of geographic atrophy (GA) sparing the foveal center. (A) Near infrared image. (B) B-scan through the foveal center. The B-scan image shows two areas of GA on either side of a preserved island of tissue in the fovea. *Black arrows* denote enhanced signal from the choroid, which corresponds to the area of GA (*black arrows* mark where this begins and ends). Immediately anterior to the zone of enhanced choroidal signal there is attenuation or loss of the following layers: Bruch's membrane, retinal pigment epithelium, ellipsoid zone, and the external limiting membrane (ELM). Note the curved endings of the ELM at the lateral margins of the preserved foveal island as it merges with the atrophic region (*asterisks*).

Comparison of SD-OCT and FAF imaging in one prospective observational study of 81 eyes of 42 patients with GA demonstrated that delineation of GA borders using an OCT software algorithm that takes into account characteristics of the OPL, ELM, RPE, and choroidal signal enhancement, correlated with areas of lost FAF. Multivariate analysis showed that complete choroidal signal enhancement, OPL shifting, and loss of the ELM had a strong correlation to the hypoautofluorescent regions on FAF.<sup>151</sup> In this study, there was better intergrader agreement for identification of

foveal sparing GA with SD-OCT compared with FAF images and the findings on OCT had a higher correlation with visual acuity (VA) measurements compared to FAF.<sup>151</sup> NIR can also be used to more easily identify areas of GA compared to color photographs (Figs. 68.17A–B, see also Fig. 68.43). Within the Fundus Autofluorescence in Age-Related Macular Degeneration (FAM) study, a semi-automated software tool was used to combine NIR and FAF images to reliably monitor progression of GA in the subset of 47 eyes of 36 patients with foveal sparing of GA.<sup>152</sup> These results are discussed further in the following section.

An additional SD-OCT finding that has been described in eyes with late AMD, in the setting of either GA or CNV, is outer retinal tubulation (ORT).<sup>153,154</sup> ORT is a thick reflective line surrounding a sometimes extensive and branching tubular hyporeflective cavity within the ONL<sup>153</sup> (Figs. 68.44C–D). ORT can be differentiated from cystoid abnormalities, as only ORT has a hyperreflective border surrounding the hyporeflective space. (Figs. 68.44C–D).<sup>153</sup> ORT has recently been shown to correlate to a histopathologic finding that had been described earlier in eyes with AMD.<sup>153,155</sup> Histopathologically, ORT consists of degenerate red–green cones and Müller cells that surround these structures (Figs. 68.44A–B).<sup>155</sup> The hyperreflective border is thought to be due to mitochondria within the inner segments of the degenerate photoreceptors. When hyperreflective material is present within the cavity of ORT on SD-OCT images, this corresponds to RPE cells or macrophages on histopathologic sections within the cavities of ORTs.<sup>153</sup>

**FIG. 68.44** Histologic (A,B) and spectral domain optical coherence tomography (OCT) (C,D) appearance of outer retina tubulation (ORT). Images are from patients with neovascular age-related macular degeneration, but this finding is also present in eyes with geographic atrophy and no choroidal neovascularization. (A,B)

Toluidine blue-stained 0.8- $\mu$ m thick sections of maculas postfixed by osmium-tannic acid-paraphenylenediamine method. Scale bars: 25  $\mu$ m. (A)

Closed ORT: cone nuclei (C) surround a lumen delimited by the external limiting membrane (ELM) (*white arrowheads*). Cone inner segments, some with outer segments, protrude into the lumen, maintaining a radial organization with respect to the lumen center. Inner segments have mitochondria-containing ellipsoids, and less frequently, myoids (one cell containing both indicated by *black arrowheads*). One cell with green-staining lipofuscin granules is in the lumen (*red arrow*). Henle fiber layer (HFL) contains darkly stained cone fibers in cross-section. Sc, fibrocellular scar. *Green arrowheads*, Bruch's membrane, which is breached in this panel (79-year-old-man). (B) Nucleated retinal pigment epithelium (RPE) cell within an ORT lumen; *RPE\**, RPE-derived cells with spherical melanosomes; Sc, fibrovascular scar (87-year-old man). (C,D) Heidelberg Spectralis

Heidelberg Spectralis

OCT imaging (with signal averaging). (C) A flat and ovoid cross-section with a hyperreflective border (*orange arrow*) has internal hyperreflective material in the lumen. A circular cross-section has a hyperreflective border (*green arrow*). (D) A cross-section showing a forming tubulation (forme fruste ORT) with a free edge to scroll (*orange arrow*) next to an ovoid cross-section with internal hyporeflectivity lacking a hyperreflective border, located in the outer plexiform layer (cystoid space, *green arrow*). Also present is a circular cross-section of an ORT with a thick hyperreflective border (*pink arrow*) in the outer nuclear layer. (Adapted with permission from Schaal KB, Freund KB, Litts KM, et al. Outer retinal tubulation in advanced age-related macular degeneration: optical coherence tomographic findings correspond to histology. *Retina*. 2015;35(7):1339-50.)

SD-OCT has also been used to quantitate the degree of choroidal thinning that occurs in the presence of GA, and these findings parallel those seen with histopathologic examination.<sup>74,90,156,157</sup> Significant thinning of all of the choroidal layers has been demonstrated by SD-OCT.<sup>156,157</sup>

## Growth of Geographic Atrophy

In various clinical research studies the progression of GA has been monitored reliably using sequential color fundus photographs,<sup>158</sup> SD-OCT,<sup>148,159,160</sup> FAF images,<sup>152,161</sup> and NIR images.<sup>152</sup> The annual growth rate of GA has been associated with the total area of GA present at baseline, with larger lesions expanding at a faster annual rate.<sup>158,160-162</sup> However, this association is no longer present when areas are analyzed after applying a square root transformation, which adjusts growth rates to account for differences in baseline lesion size.<sup>160</sup> In AREDS the average change in GA area (across the spectrum of lesion sizes) was 1.78 mm<sup>2</sup> per year based on review of sequential color fundus photographs. Although the growth rate of GA is correlated between eyes of individuals with bilateral GA at the group level, there is a moderate degree of variation between right and left eyes at the individual level.<sup>158</sup> One prospective, longitudinal natural history study of 86 eyes from 64 participants

showed a mean annual enlargement rate of 1.2 mm<sup>2</sup> using sequential SD-OCT images; and a smaller baseline size of GA was hypothesized as the explanation for the slower rate of progression compared to other studies.<sup>160</sup> In a natural history cohort study of eyes with GA, the FAM study, the annual GA growth rate was 1.52 mm<sup>2</sup> using sequential FAF images with a range of progression rates from 0.38 to 3.02 mm<sup>2</sup> per year depending on the FAF phenotype.<sup>161</sup> The median baseline area of GA in this study was noted to be larger at 7.04 mm<sup>2</sup> as compared with 3.15 mm<sup>2</sup> in the SD-OCT study noted above.

In the subset of 47 eyes of 36 patients (mean age 73.8±7.5 years) with foveal sparing GA in the FAM study, FAF and NIR was used to monitor GA growth towards the periphery versus towards the fovea, with mean follow-up time of 25.2 ±16.9 months. The mean annual progression of GA was 2.27±0.22 mm<sup>2</sup> towards the periphery and 0.25 ± 0.03 mm<sup>2</sup> toward the fovea. This represented a 2.8-fold faster rate of atrophy progression toward the periphery than toward the fovea when square root-transformation analysis was performed.<sup>152</sup> This corresponds to the clinical observation that some foveal tissue often remains intact until very late in progression of GA. Sarks had previously noted that total GA area averaged 13.5 mm<sup>2</sup>, or more than 5 DD, when there was complete foveal involvement.<sup>75</sup>

There is also some evidence that the presence of outer retinal tubulation in the area of GA is associated with a slower GA growth rate.<sup>159</sup> This association warrants further study, as it may be a potential confounding variable that needs to be considered in intervention trials aiming to limit GA growth.

## Prognosis and Management of Non-Neovascular AMD

This section focuses on the clinical care of patients with NNVAMD and details data regarding the risk of future vision loss conferred by the presence of the changes noted in the prior sections. The impact that these alterations have on visual function, and the specific management of patients with NNVAMD, will be reviewed. The latter includes discussion of the role of micronutrient supplements on disease progression, use of patient self-monitoring devices, and standard care monitoring strategies, including discussion of recommended frequency of office visits, considerations regarding cataract surgery, the use of the implantable miniature telescope in eyes with endstage NNVAMD, and current phase 3 clinical trials for treatment of GA.

### Risk of AMD Anatomic Progression

The AREDS trial provides natural history data describing the natural course of AMD through at least 5 years for participants who were assigned to placebo. Eyes with early AMD, those with extensive (total area involved  $\geq 125\text{-}\mu\text{m}$  diameter circle) small drusen or nonextensive (total area  $\leq 360\text{-}\mu\text{m}$  diameter soft indistinct or  $\leq 660\text{-}\mu\text{m}$  diameter soft distinct) medium drusen, were shown to have an approximately 1% chance of progression to advanced AMD over 5 years. An individual who has intermediate AMD (extensive medium drusen, i.e., greater than the areas of medium drusen noted above; at least 1 large druse; or nonfoveal GA) in their most advanced eye had an 18% chance of progression to advanced AMD over 5 years. Of the patients with intermediate AMD in their most advanced eye, those who had large drusen in each eye or noncentral GA in at least one eye had a 27% chance of progression to advanced AMD in this time period compared with a 6% chance among those with intermediate AMD without these characteristics. The highest risk group was identified as the fellow eye of individuals with unilateral advanced AMD, or vision loss to below 20/32 from AMD in their first eye. The healthier fellow eyes among

these participants had a 43% probability to progress to advanced AMD by 5 years<sup>163</sup> (Fig. 68.45A).

**FIG. 68.45** Results of the Age-Related Eye Disease Study (AREDS) clinical trial. Risk of progressing to advanced age-related macular degeneration (AMD) within 5 years for patients with (A) early AMD, intermediate AMD, and unilateral advanced AMD assigned to placebo. (B) The effect of treatment with antioxidants and zinc for eyes with intermediate AMD or unilateral advanced AMD. (C) Effect of antioxidants and zinc on  $\geq 15$  letter vision loss in patients with intermediate or monocular advanced AMD.

The AREDS investigators also developed a detailed severity scale for AMD, largely for research purposes, as it is based on careful qualitative and quantitative review of stereoscopic color fundus photographs.<sup>71</sup> Photographs at study entry and annual photographs beginning at year 2 from AREDS participants were graded for drusen characteristics (size, type, and area), RPE abnormalities (increased pigment, depigmentation, and GA), and presence of

abnormalities consistent with neovascular AMD. Relationships between various combinations of baseline characteristics and development of advanced AMD (NVAMD or foveal GA) by the 5-year examination were explored to develop a 9-step severity scale that sorts the 5-year risk of progression to advanced AMD from less than 1% in step 1 to about 50% in step 9.<sup>71</sup> About half the eyes that had at least a 3-step progression between baseline, and the 5-year examination showed stepwise progression through intervening severity levels at intervening visits.<sup>71</sup>

Based on the fundus features that had the greatest prognostic value in the 9-step severity scale, the AREDS group developed a simple grading scale that lends itself to quantifying patient risk in clinical practice. Each eye of a person is scored individually, assigning one point for the presence of large drusen and one point for the presence of RPE abnormalities. A cumulative person score ranging from 0 to 4 is calculated. To apply this simplified scale to an individual with unilateral advanced AMD to calculate the risk for the fellow eye, the eye with foveal GA or NVAMD receives a score of 2, such that the person score would range from 2 to 4. Individuals who do not have large drusen in either eye but manifest bilateral medium drusen receive 1 total point and earn additional points if RPE abnormalities are present. Each person score has been associated with an escalating estimated 5-year risk that ranges from 0.5% to 50%<sup>72</sup> and 10-year risk that ranges from 1.5% to 71%<sup>164</sup> that at least 1 eye will progress to advanced AMD (Table 68.1).

**TABLE 68.1**  
**Risk of Development of Advanced AMD in at Least 1 Eye Per Year Based Upon Simple Scale Person Score at Baseline**

Simple Scale Score	Year									
	1	2	3	4	5	6	7	8	9	10
0	0.1	0.1	0.4	0.5	0.5	0.6	0.8	0.8	1.2	1.5

4	2.8	14.2	27.6	35.6	44.5	49.3	54.1	62.0	67.5	71.4

AMD, Age-related macular degeneration.

Data from Chew EY, Clemons TE, Agron E, et al. Ten-year follow-up of age-related

macular degeneration in the age-related eye disease study: AREDS report no. 36. JAMA Ophthalmol. 2014;132(3):272-7.

This simplified severity scale served as the basis of a more elaborate multivariate analysis to create a model that predicted risk of progression to advanced AMD (CNV or any GA) among AREDS participants. The final risk assessment model included additional factors (individual age, family history, smoking status, presence of very large ( $\geq 250 \mu\text{m}$ ) drusen, and complement factor H (CFH)) and ARMS2 gene polymorphisms that modify rates of AMD progression.<sup>94</sup> The variable with the strongest predictive value in this model remains the AREDS simple scale score, with hazard ratio (HR) of 50.65 for AMD progression comparing simple scale score of 4 to a score of 0. Although other person or ocular characteristics remained significant in this multivariate analysis, the magnitude of their effects was substantially less with hazard ratios ranging from 1.03 for each year of age greater than 55 to 2.00 for an ARMS2 genotype of TT compared to GG (Table 68.2). The final model did not incorporate polymorphisms in the C2, C3, complement factor I (CFI), and APOE genes as these did not modify risk of progression in this multivariate analysis. The validity of this model was confirmed by applying it to a subset of CAPT study participants in whom genetic testing was available.<sup>94</sup> This model can be accessed online via website and permits the user to enter patient data (optional inclusion of genotype) to calculate patient-specific probabilities of disease progression.

**TABLE 68.2**

**Hazard Ratios for Development of Advanced AMD Based on Multivariate Analysis in Risk Assessment Model developed by Klein et al.**

Variable	Total (%)	HR (95% CI)	<i>p</i> value
<b>Simple Scale Score</b>			
0	1006 (39)

<sup>b</sup>First-degree family member with any AMD.

Data from Klein ML, Francis PJ, Ferris FL, 3rd, et al. Risk assessment model for development of advanced age-related macular degeneration. Arch Ophthalmol. 2011;129(12):1543-50.)

Since the fundus AMD features identified on clinical examination – those that are reflected in the AREDS simple scale assessment – are the most powerful predictors of disease progression, genetic testing even in combination with other demographic information in the absence of fundus phenotype is not recommended. For example, using this model, for a 70-year-old patient with simple scale score of 0, the risk assessment for advanced AMD within 5 years falls between 0% if no other risk factors (those other than phenotype) are present and only 3% in the presence of the highest risk genotype and all other predictive factors being present. However, this 3% risk would soar to 53% if the simple scale value were 2 and drusen  $\geq 250$  µm were present. While genetic testing and the factors other than fundus phenotype should not be utilized in isolation, they can modify the risk and add significant predictive power for any given patient. Using the simple scale alone, a 70-year-old patient with a score of 4 would be assessed a 50% probability of progressing to advanced AMD within 5-years. However, using the full risk assessment model, the risk for this patient would be refined and may actually range from 19% to 93%. Additionally, this model provides predictions for development of

each of the two subtypes of advanced AMD, GA or CNV.

## Risk of AMD Progression Based on Specific AMD Manifestations

### Small Drusen

Population-based studies<sup>22,24–26,109</sup> have reported that one or more small drusen are commonly present in the macula. Small drusen were identified in 95.5% of a population-based survey among men aged 43–86 (mean 62.3)<sup>24</sup> and in 98.8% of individuals over age 49 participating in an Australian-based population survey.<sup>25</sup>

Pathologic studies support the conclusion that the presence of a few small, hard drusen is not a risk factor for AMD as they appear to be ubiquitous in histologic specimens from individuals age 50 and older.<sup>110</sup> However, several studies<sup>7,109,165</sup> have found that with increased numbers of (or area occupied by) small drusen, an eye is more likely to develop larger drusen with time. In the Beaver Dam Eye Study, among participants with only small hard drusen at baseline the 5-year incidence of intermediate-size drusen varied according to the area occupied by small drusen at baseline. Eyes with baseline small drusen area  $>9086 \mu\text{m}^2$  had 17% progress to intermediate drusen, whereas those with area  $<2596 \mu\text{m}^2$  had 8% progression.<sup>165</sup> The AREDS study confirmed eyes with small drusen may progress to large drusen. The 10-year probability that AREDS participants with only small drusen at baseline would progress to large drusen was 12.8%.<sup>9</sup>

Longitudinal clinical studies of at least 5 years' duration suggest advanced AMD rarely develops in eyes with only small drusen at presentation, regardless of the total area involved.<sup>7,94,163</sup> Within AREDS the 10-year rate of advanced AMD was 1.5% for eyes with only small drusen at baseline; even lower rates were observed among participants without advanced AMD in the fellow eye.<sup>164</sup>

### Intermediate or Large Drusen and RPE Changes

Eyes that present with intermediate-size drusen are at risk of progressing to large drusen and advanced AMD. In AREDS, 37% and 4.6% of participants who had medium-sized drusen (as their

largest size) in their most advanced eye developed large drusen and advanced AMD, respectively, within 10 years of follow-up. The prevalence of these events is greater, at 71% and 14%, respectively, when the participant has medium-size drusen in each eye at baseline.<sup>164</sup>

Eyes with large drusen remain at even higher risk of developing advanced AMD compared with those with medium drusen. AREDS participants with bilateral large drusen in the absence of baseline RPE abnormalities had 36% progress to advanced AMD by 10 years, while rates climbed to 66% when RPE abnormalities accompanied bilateral large drusen at baseline.<sup>164</sup> This highlights the fact that RPE abnormalities, independent of drusen, impart risk for AMD progression.

As AREDS was a prospective study, eyes that initially developed large drusen and RPE abnormalities during follow-up were identified. There were 570 eyes, all in participants without advanced AMD in the fellow eye at entry, in which temporal relationships were explored between development of these fundus features and further AMD progression. Nine percent developed advanced AMD within 5 years of the detection of large drusen and RPE abnormalities, with about a 3 : 1 ratio of NVAMD : FGA.

The location that large drusen occupy also modulates the risk of disease progression. When large drusen were present solely within 1 DD of the foveal center (the central zone), in the absence of advanced AMD in either eye, 22% progressed to advanced AMD within 10 years as compared to 4% among eyes with large drusen located within 1 and 2 DD (the outer zone) from the foveal center. Rates were higher (38%) when drusen occupied both areas, and even more substantial if RPE abnormalities were present. By year 10 nearly 60% of eyes with large drusen in the central and outer zones, in association with RPE abnormalities, progressed to advanced AMD.<sup>164</sup>

Population-based studies have also demonstrated that risk of progression to late forms of AMD is related to the size and extent of drusen, as well as the presence or absence of RPE abnormalities. In the Beaver Dam Eye Study, the 15-year cumulative incidence rate for late AMD (any GA or CNV) was nearly 40% among eyes of participants with large drusen and total drusen area >700  $\mu\text{m}^2$

diameter circle at baseline. In contrast, the 15-year cumulative incidence of late AMD was only 8% when the largest druse was medium size and the cumulative drusen area was  $>320\ \mu\text{m}$  diameter circle and 2% when only small drusen were present.<sup>166</sup> For participants whose baseline drusen area was in the largest quartile, simultaneous presence of RPE abnormalities increased the 15-year risk for late AMD from about 30% (eyes without RPE abnormalities) to  $>50\%$ . Application of the AREDS AMD severity scale to fundus photographs of Beaver Dam Eye Study participants generated an OR of 2.7 (95% CI 2.3–3.1) for each step increase AMD level at baseline and the 15-year progression rates to late AMD.<sup>166</sup>

### **Risk of Geographic Atrophy**

The 15-year cumulative incidence of any GA in the Beaver Dam Eye Study was approximately 1% in eyes with medium drusen and 7% in eyes with large drusen at baseline. When baseline drusen area was greater than a  $700\ \mu\text{m}$  diameter circle in eyes with large drusen, 24% developed GA.

The greater the severity of presenting levels of RPE abnormalities coexisting with large drusen, the greater likelihood that incident advanced AMD will be either FGA or NVAMD as compared to primarily NVAMD. When baseline bilateral large drusen and at least unilateral RPE abnormalities coexist, progression to FGA is common, occurring in 44% of AREDS participants within 10 years.<sup>164</sup> In the absence of pigment changes at baseline, even with baseline bilateral large drusen  $<1\%$  of AREDS participants developed FGA at 5 years and only 10% did so at 10 years, compared with 32% who developed NVAMD at 10 years.<sup>164</sup>

### **Risk of NVAMD**

The 15-year cumulative incidence of NVAMD in the Beaver Dam Eye Study was approximately 2% in eyes with medium drusen and 10% among those with large drusen at baseline. When baseline drusen area was  $>700\text{-}\mu\text{m}$  diameter circle in eyes with large drusen, this risk rose to 20%.

When bilateral large drusen are present, progression to NVAMD is common, occurring in 32% of AREDS participants without RPE abnormalities and 45% with at least unilateral baseline RPE

abnormalities within 10 years.<sup>164</sup> The development of GA does not protect an eye from also developing NVAMD; in fact, the risk of neovascular AMD is quite high in the presence of GA. Among 981 eyes with incident GA during AREDS follow-up, 16% progressed to NVAMD when the fellow eye did not have NVAMD at baseline, while 36% did so when the fellow eye had neovascular AMD.

### **Drusenoid PEDs.**

Within AREDS, 282 eyes with drusenoid PEDs (diagnosed in the absence of advanced AMD) were followed prospectively for at least 5 years. Within 5 years 42% developed advanced AMD with approximately 1 : 1 ratio of FGA : NVAMD.<sup>106</sup> Earlier progression to advanced AMD was more likely to manifest as NVAMD; however, Kaplan–Meier analysis showed the cumulative percentage of eyes developing FGA surpassed the number of eyes with NVAMD at 7 years. Five-year progression rates to advanced AMD (42% vs. 25%,  $p<.001$ ) and specifically rates of FGA (18% vs. 7%,  $p<.001$ ) were higher in this group of participants than those with large drusen and pigmentary abnormalities. Those that did not develop advanced AMD still tended to show evidence of disease progression with development of calcification, pigmentary changes (typically hypopigmentation), and noncentral GA.<sup>106</sup> By 10 years, 55% of eyes with drusenoid PEDs are expected to develop FGA and 40% NVAMD.

In a retrospective study, with 61 eyes of 32 patients with drusenoid PEDs (defined as 0.5 DD of soft, confluent drusen under the center of the macula), followed for median 2 years (range 1–17 years), Kaplan–Meier survival analysis suggested these eyes had a 50% chance of developing GA within 7 years.<sup>107</sup> Eyes with larger-size drusenoid PEDs and metamorphopsia were more apt to develop GA sooner than other eyes and remained at highest risk for incident CNV.<sup>107</sup>

### **Advanced AMD in Fellow Eye.**

Annual incidence rates of 5–14% were estimated for the development of advanced AMD in the fellow eye of individuals with unilateral NVAMD in a retrospective review of 101 patients followed for up to 9 years.<sup>167</sup> Drusen number, size, and confluence

were important predictive factors for progression among these fellow eyes.<sup>167</sup> In a prospective study of 670 individuals with unilateral CNV participating in the Macular Photocoagulation Study, risk factors for fellow eye progression to NVAMD included five or more drusen (any size) or  $\geq 1$  druse  $>63 \mu\text{m}$ .<sup>168</sup>

Actual 5-year progression rates to advanced AMD using the AREDS simple scale scoring system are slightly higher for each respective person score, when an individual has unilateral advanced AMD.<sup>72</sup> The risk assessment model that is based on AREDS data showed a hazard ratio of 1.21 (95% CI 1.02–1.45) for incident advanced AMD among individuals with unilateral advanced AMD compared with those without advanced AMD in either eye (Table 68.2).<sup>94</sup> Individuals with unilateral advanced AMD who had no drusen or only small drusen in AREDS had 10-year progression rates to advanced AMD of 8.6% in their fellow eye compared with 0.7% among individuals without any advanced AMD.<sup>164</sup> Similarly, advanced AMD in the first eye modulated the risk for progression to advanced AMD in a fellow eye with medium drusen with 10-year progression rates of 26% compared with 4% in the absence of first-eye advanced AMD. Among eyes with large drusen and RPE abnormalities, 10-year rates of progression to advanced AMD increased from 50% in the absence of first-eye advanced AMD to 77% in the presence of unilateral advanced AMD.<sup>164</sup>

### **Subretinal Drusenoid Deposits.**

Although eyes with soft drusen may also contain subretinal drusenoid deposits, the subretinal drusenoid deposits are an independent predictive factor for progression to advanced AMD. However, the magnitude of risk associated with soft drusen is far in excess of that associated with reticular drusen. In a prospective case–control study, the OR for development of any GA or CNV in eyes with soft drusen was 16.6 (95% CI 7.5–14.9), whereas the OR for subretinal drusenoid deposits was 2.6 (95% CI 1.1–6.5).<sup>123</sup>

## **Impact of NNVAMD on Vision Function**

### **Early and Intermediate NNVAMD**

## Visual Acuity.

Minimal, if any, deficits in VA are commonly associated with early and intermediate AMD. Within the Macular Photocoagulation Study (MPS) of extrafoveal CNV, 128 participants had a fellow eye with NNVAMD at baseline. At the 5-year examination, 76 of these eyes remained free of neovascular AMD. Median VA among these eyes was 20/20 at baseline and at the 5-year examination.<sup>169</sup> AREDS study eyes were required to have VA of  $\geq 20/32$  at enrollment, and the actual median baseline acuity was 83 letters (Snellen equivalent 20/20<sup>-</sup>) among eyes that entered with large drusen. At the 10-year examination, median VA was 81 letters (Snellen equivalent 20/25<sup>+</sup>) among this subset of large drusen eyes that had not progressed to advanced AMD.<sup>164</sup>

Drusenoid PEDs may exist in the setting of 20/40 or better VA with or without metamorphopsia.<sup>107</sup> Within AREDS, there were 282 eyes that had drusenoid PEDs in the absence of advanced AMD at baseline. Initial mean VA was about 80 letters (Snellen equivalent 20/25), and this fell to 72 letters (Snellen equivalent 20/40) at 5 years among the 57% that did not progress to advanced AMD. The rate of moderate vision loss ( $\geq 3$  lines) was 21% in this subset, which was higher than that seen among eyes that had large drusen and focal hyperpigmentation at entry and did not progress to advanced AMD (21% vs. 13%,  $p=.01$ ). Vision decline appeared related to development of incipient RPE atrophy (nongeographic atrophy) with functional loss of photoreceptors that lie anterior to the drusenoid PED. Among the eyes with drusenoid PED that progressed to FGA, much larger decreases in VA occurred.<sup>106</sup>

## Other Measures of Vision Function.

While VA often remains normal or close to normal in eyes with early or intermediate AMD, other measures of visual function may reflect pathology. A recent study assessed VA, low luminance acuity, dark adaptation, macular light sensitivity via 24-2 HVF testing, and spatial contrast sensitivity in 1260 eyes of 640 participants. This study included participants with minimum age of 60 without fundus lesions of AMD (1007 eyes) and with “early” AMD (253 eyes) identified on color fundus photographs.<sup>170</sup> Eyes were classified as normal (no AMD) if total drusen area was  $<125$

$\mu\text{m}$  in the absence of RPE abnormalities, whereas “early” AMD reflected steps 2, 3, or 4 on the AREDS AMD 9-step severity scale, which corresponds to a maximum drusen area (DA) of  $\leq 0.2$  DA without RPE changes or  $< 0.028$  DA if definite RPE changes were also present.<sup>71,170</sup> Mean ( $\pm$  SD) VA was logMAR  $0.043 \pm 0.13$  (Snellen equivalent 20/22) in the normal eyes and logMAR  $0.069 \pm 0.13$  (Snellen equivalent 20/23) in the AMD eyes. Rod-mediated dark adaptation was significantly reduced in the AMD eyes compared to controls, but the other vision function tests showed no significant difference.<sup>170</sup>

Midena et al. evaluated macular function among individuals with minimum age of 50, VA  $> 20/25$ , and  $> 10$  medium or large drusen within  $1500 \mu\text{m}$  of the fovea.<sup>171</sup> Each of 47 participants contributed one study eye. Thirty-four participants had NNVAMD in each eye (eye with better acuity chosen or randomly selected eye if acuity was the same in each eye), and in 13, the fellow eye had CNV. Thirty-six age-matched controls each contributed one study eye. Of note, noncentral GA was present in 10% and focal hyperpigmentation in one-third of the NNVAMD eyes. Both static and dynamic contrast sensitivity functions (sinusoidal spatial frequency gratings were static or modulated with time), macular recovery function following bright light stimuli, and central visual field sensitivity as measured by 10–2 Humphrey visual field, were impaired, to clinically relevant degrees, in the eyes with NNVAMD compared to age-matched control eyes ( $p$  values ranged from  $< .001$  to  $.008$ ). The only type of testing performed in this study with no significant difference between AMD and control subjects was Farnsworth–Munsell 100 hue testing.

Microperimetry testing has also identified deficits in eyes with NNVAMD. When retinal sensitivity in the macula of AMD eyes classified as AREDS category 2 (164 eyes) or AREDS category 3 (155 eyes) was compared with 200 age-matched controls, mean sensitivity was decreased among the AMD eyes relative to controls in each of 5 rings of test points around the fovea.<sup>172</sup> This test covered the central  $10^\circ$ , and greater decreases were seen among the AREDS category 3 eyes compared to category 2 eyes.<sup>172</sup> Mean sensitivities (dB) were  $29.8 \pm 1.7$  in age-matched controls,  $24.9 \pm 3.9$  in category 2 eyes, and  $21.8 \pm 5.34$  in category 3 eyes ( $p < .001$  for each

individual pairwise comparison).<sup>172</sup> While some studies have shown a relative decrease in sensitivity when testing is performed directly over large drusen,<sup>173</sup> other studies have been unable to confirm this while making similar observations only when testing is located in areas without clinical signs of drusen.<sup>174</sup> This conflicting data likely reflects the variable degree to which RPE and photoreceptors may become anatomically and functionally affected overlying drusen. In support of this concept it has been demonstrated that areas of decreased sensitivity in eyes with confluent soft drusen correspond to regions with ellipsoid band loss or RPE irregularity on OCT.<sup>175</sup>

Eyes with subretinal drusenoid deposits have been reported to manifest abnormalities in contrast sensitivity thresholds and microperimetry.<sup>176,177</sup> Using Pelli–Robson contrast sensitivity testing in 51 eyes of 36 patients with NNVAMD, the presence of subretinal drusenoid deposits was noted to be inversely correlated with contrast sensitivity score ( $p=.012$ ).<sup>176</sup> In a prospective case series of 22 eyes from 18 patients with well-demarcated subretinal drusenoid deposits, scotopic or rod-mediated function was compromised with a relatively sharp demarcation of reduced scotopic threshold noted in the areas with visible subretinal drusenoid deposits compared to areas without the deposits.<sup>177</sup>

## **Geographic Atrophy**

When GA affects the foveal center, VA compromise may be moderate to severe; however, prior to definitive foveal involvement eyes with GA may have a more insidious loss of acuity. In the CAPT, 91 fellow eyes developed GA at or beyond 2 years following study entry in the absence of other retinal disease or CNV.<sup>100</sup> For assessment of the effect incident GA had on VA, 87 of these eyes were each matched to a control eye that did not develop GA or CNV. The mean best corrected acuity was 81 letters (20/25<sup>+2</sup>) at baseline for cases and control eyes. One year prior to the date at which GA was recognized on fundus photographs in the GA cases, VA letter score had fallen on average ( $\pm$ SD) by 5( $\pm$ 9) letters relative to baseline. Among control eyes letter score had decreased an average of 0.7( $\pm$ 6) at the same time point. Among the GA cases, when GA was initially detected (located anywhere in the macula),

mean change in VA was  $-7(\pm 12)$  letters from baseline; however, the magnitude of vision loss at first detection of GA was directly related to the incident GA location. There was a mean loss of 24 letters for incident FGA, 5 letters for GA extending to the FAZ, and 2 letters when the proximal edge of GA was  $\geq 250 \mu\text{m}$  from the foveal center.<sup>100</sup>

These observations were corroborated in AREDS, as the median VA was 77 letters (Snellen equivalent 20/32<sup>+</sup>) at the visit one year prior to identification of FGA among 685 eyes with incident FGA during follow-up.<sup>164</sup> The median acuity fell by 12 letters from one year prior to identification of FGA to a score of 65 (Snellen equivalent 20/50) at the visit in which FGA was documented.<sup>164</sup> By 10 years following development of FGA the median acuity had fallen further to 27 letters ( $\sim 20/320$ ).<sup>164</sup> Among the incident cases of GA in AREDS, 35% presented with FGA. Among the remaining 65% that progressed to FGA from noncentral GA, the median time from noncentral GA to FGA was 2.5 years.<sup>158</sup> Within AREDS, 895 eyes of 686 participants who did not have any GA or CNV in either eye at baseline developed GA within  $1500 \mu\text{m}$  of the fovea. In 209 participants, incident GA developed in both eyes with median time of 7 years for second eye incident GA.<sup>158</sup>

The time course of progressive VA impairment from GA is highly dependent upon the initial location of GA and its growth rate (see previous section on "Growth of GA"). Prognostication therefore requires each case to be assessed individually. Several case series have provided natural history data.<sup>75,141,162,178-180</sup> In a longitudinal cohort study of 74 eyes with at least one area ( $\geq 500 \mu\text{m}$  in diameter) of GA within 1 DD of the fovea and VA of  $\geq 20/50$  at entry, at 2 years 50% lost  $\geq 3$  lines of acuity and 25% lost  $\geq 6$  lines.<sup>180</sup>

VA alone may not accurately represent the depth of vision impairment for many individuals with GA. Large single or multiple areas of atrophy may spare the foveal center and greatly impact near vision activities such as reading. Reading rate is slowed by paracentral scotomas, and some eyes with geographic atrophy also demonstrate abnormal foveal dark-adapted sensitivity, reduced VA in dim illumination, and reduced contrast sensitivity.<sup>180</sup> Even when the central fovea becomes involved with GA, vision function may vary depending on the patient's ability to find a surviving island of

retina within the atrophic area, or the least affected portion of retina outside the area.<sup>179</sup> There seems to be a preference to fixate with the scotoma to the right of the object of interest,<sup>181</sup> favoring the ability to see the beginning of a line when reading rather than the end of text. Visual retraining may enable a patient to use the closest viable area of retina. However, magnifying aids often do not help these individuals to read as the magnified image is projected into the sites of GA. The combination of reduced VA with progressive enlargement of atrophy, occurring bilaterally in most patients, can lead to significant impairment of visual function.<sup>162,179</sup>

## **The Role for Micronutrient Supplements in Management of Non-Neovascular AMD: AREDS and AREDS2**

The AREDS demonstrated that micronutrient supplements consisting of specific antioxidants (500 mg vitamin C, 400 IU vitamin E, and 15 mg beta-carotene) and minerals (80 mg zinc oxide with 2 mg cupric oxide to reduce the risk of zinc-induced, copper-deficiency anemia) reduce progression to advanced AMD. However, these benefits are only apparent among individuals with intermediate AMD or unilateral advanced AMD<sup>163</sup> (Fig. 68.45A). The treatment benefit was confirmed through 10 years of follow-up (Fig. 68.46), even though all participants were counseled to use the combination supplements when the randomized component of the trial ended.<sup>164</sup> The clinical trial ended when 90% of participants had completed 5 years of follow-up. The results were driven by a risk reduction for NVAMD as there was no definitive evidence to suggest that GA development or progression to FGA was affected (Fig. 68.46A).<sup>163,164</sup>

**FIG. 68.46** Rates of progression to advanced age-related macular degeneration (AMD) at 10-years within the Age-Related Eye Disease Study (AREDS), related to baseline characteristics in active versus placebo groups. (A) Rates of progression to central geographic atrophy (GA) correlate to baseline severity but are unaffected by use of supplements. (B) Rates of progression to neovascular AMD (NVAMD) correlate to baseline severity and are reduced by use of supplements. *AAMD-1*, advanced AMD in fellow eye at baseline; *L1*, large drusen as most advanced feature in one eye; *L2*, large drusen as most advanced feature in both eyes; *M1*, medium drusen as most advanced feature in 1 eye; *M2*, medium drusen as most advanced feature in both eyes; *Small*, small drusen only at baseline. (Adapted with permission from Chew EY, Clemons TE, Agron E, et al. Ten-year follow-up of age-related macular degeneration in the age-

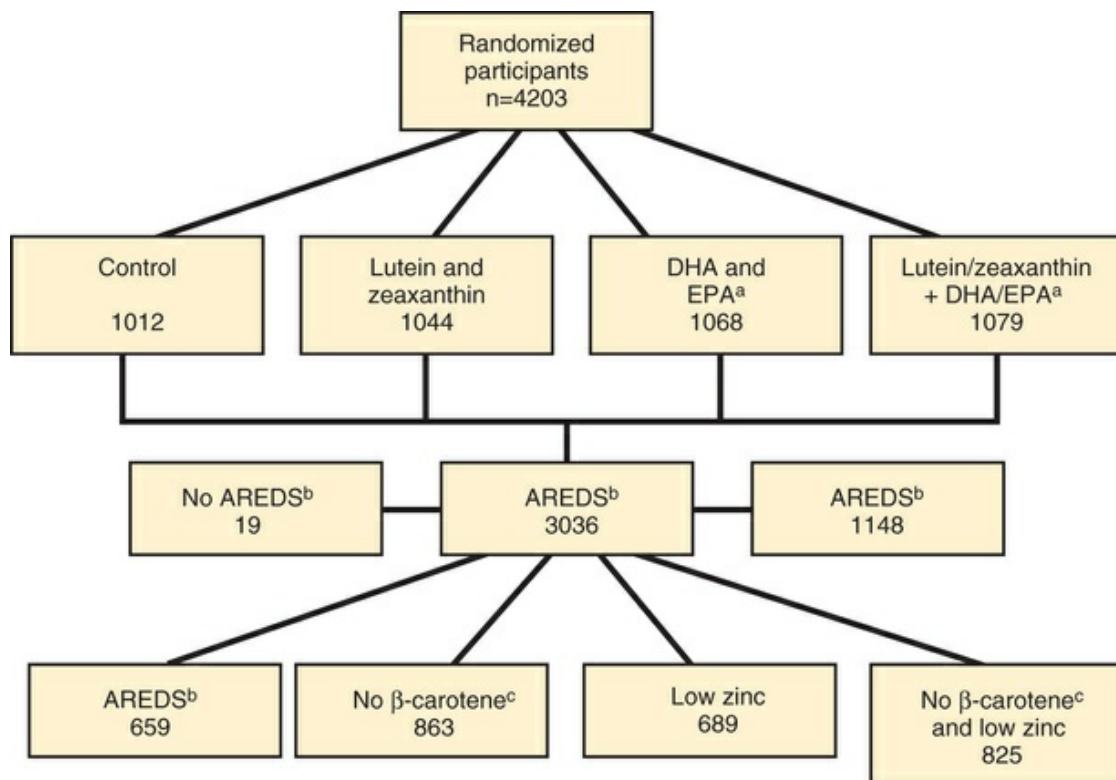

Klein et al. first reported a possible differential response to supplements within the AREDS study depending upon CFH genotype.<sup>182</sup> Using AREDS data, Awh reported analyses that indicated that participants with only some CFH and ARMS2 genotypes benefited from supplements and that AREDS participants with some genotypes at these loci showed an unfavorable response to supplements.<sup>183,184</sup> Chew and coworkers have also analyzed data from AREDS in this regard and did not find a differential effect of supplements based on genotype and have argued that Awh and colleagues analyses are biased as they were a post hoc analysis of the data.<sup>185</sup> The American Academy of Ophthalmology addressed these reports in its Preferred Practice Pattern for AMD that was updated in 2015 and did not recommend genetic testing when considering recommendations for use of supplements. A randomized, prospective trial would be needed to show the utility of genetic testing in this setting.

The objective of AREDS2 was to determine if a combination of lutein/zeaxanthin (L/Z 10 mg/2 mg ) and/or omega-3 long-chain polyunsaturated fatty acids in the form of eicosapentaenoic acid (EPA) (650 mg) and DHA (350 mg) could further reduce progression to advanced AMD when added to the AREDS supplements.<sup>186,187</sup> A secondary objective was to explore whether modifications to the original AREDS formulation could maintain the benefits and improve the safety of the micronutrient supplements when compared with the original formulation. These modifications included reducing the zinc dose to 25 mg and eliminating beta-carotene completely.<sup>187</sup> The obligatory primary and voluntary secondary randomization of this prospective clinical trial is shown in [Fig. 68.47](#). At entry participants were to be at least 50 years of age and have bilateral evidence of large drusen (contributing 2 study eyes) in the absence of advanced AMD or large drusen in one eye (contributing 1 study eye) and advanced AMD in the fellow eye. In the primary analysis, with median follow-up of 5 years, there was no significant reduction in progression to advanced AMD when comparing the lutein/zeaxanthin and/or DHA/EPA arms to control.<sup>186</sup> Progression

rates to advanced AMD were about 30% in each of the four treatment assignments at 5 years. Exploratory secondary analyses referred to as the “main effects” grouped all participants receiving L/Z and compared them to those assigned to supplements without L/Z, essentially doubling the number of eyes in the analysis and increasing the power of the analysis to find a statistically significant difference. This analysis suggested that L/Z may reduce progression to advanced AMD with a hazard ratio (HR) of 0.90 (95% CI 0.82–0.99,  $p=.04$ ).<sup>188</sup> Analysis of the secondary randomization showed that elimination of beta-carotene or reducing the zinc dosage had no significant effect on progression to advanced AMD.<sup>186</sup> Another exploratory secondary subgroup analysis utilized about one-third of the entire cohort to identify participants assigned to control in the primary randomization and the original AREDS formulation in the secondary randomization and compare them to those assigned to the L/Z only arm in the primary randomization and an AREDS supplement without any beta-carotene in the secondary randomization. This explores the efficacy associated with an AREDS supplement in which L/Z essentially would replace beta-carotene. This analysis provided HR 0.82 (95% CI 0.69–0.96) for advanced AMD, primarily due to a reduction in NVAMD (HR 0.78, 95% CI 0.64–0.94).<sup>188</sup> None of the analyses identified a difference between groups or subgroups for rates of at least moderate vision loss. The study did not incorporate a prespecified noninferiority analysis for any alterations to the original formulation in comparison to the original formulation for anatomic or functional outcomes. Therefore, questions remain as to whether an AREDS2 recommended formulation that substitutes L/Z for beta-carotene can achieve similar anatomic and functional outcomes relative to the original formula. No difference was seen in the rates of serious adverse events in any of the four primary treatment arms; however, more lung cancer cases were identified in the beta-carotene vs. no beta-carotene subgroups (2% vs. 0.9%,  $p=.04$ ), occurring mostly in former smokers.<sup>186</sup>

**FIG. 68.47** Age-Related Eye Disease Study 2 Study Design. Primary randomization was 1 : 1 : 1 : 1 into four groups: control (no lutein/zeaxanthin or DHA/EPA), lutein/zeaxanthin only, DHA/EPA only, or lutein/zeaxanthin and DHA/EPA. Participants were given the option of continuing the original AREDS formula ( $n=1148$ ) or undergoing secondary randomization into four groups: the original AREDS formula, the original formula with no beta-carotene, the original formula with reduced zinc, or the original formula with no beta-carotene and reduced zinc.

Nineteen individuals declined the secondary randomization and use of the AREDS supplement. <sup>a</sup>

DHA and EPA = docosahexaenoic acid and eicosapentaenoic acid; <sup>b</sup> AREDS supplements: vitamins C (500 mg) and E (400 international units), beta-carotene (15 mg), zinc (oxide 80 mg), and copper (cupric oxide 2 mg); <sup>c</sup> Smokers were randomly assigned to one of the two no beta-carotene arms; low zinc = 25 mg daily. ## Clinical Application of the AREDS and AREDS2 Results

The management of non-neovascular AMD begins with screening individuals at risk of the disease for its presence, essentially anyone that is age 50 and older. Applying disease prevalence rates from population-based studies to the US census report of 2000, it is estimated that 8 million Americans age  $\geq 55$  years have large drusen ( $\geq 125 \mu\text{m}$ ) in at least one eye.<sup>4,163</sup> By 2020 an estimated 6.4 million additional people in the United States are expected to have large drusen in at least one eye.<sup>4,163</sup> It is presumed that the majority of these individuals are asymptomatic and may present for care in the context of routine ophthalmologic examination or for an ophthalmic condition other than AMD. During such examinations, practitioners should consider screening for AMD. If on examination there is subretinal or intraretinal fluid, hemorrhage, lipid, or RPE elevation, then neovascular AMD may be present. A fluorescein angiogram and OCT would be indicated to confirm a diagnosis of NVAMD and to assist with management options, as outlined in [Chapter 69](#) (Neovascular (exudative or “wet”) age-related macular degeneration).

Assuming there are no overt signs of neovascular AMD, then the practitioner should be assessing RPE abnormalities and drusen. If there is no evidence of AMD, or if the clinical evaluation is consistent with early AMD (as the most advanced AMD feature in both eyes), then no supplements are indicated. This is based on the absence of any benefit when these individuals received active treatment within AREDS. Supplements did not reduce progression to intermediate or advanced AMD in these eyes. These individuals may be counseled that they are at very low risk of visually significant disease within the next 5 years. It is reasonable to suggest they undergo annual reassessments to look for intermediate AMD as generally one-third of AREDS participants with early AMD progressed to intermediate AMD during the first 5 years of follow-up.<sup>163</sup>

If intermediate AMD is noted in at least one eye, then consideration of a dietary supplement such as that used in AREDS or AREDS2 is reasonable providing the individual's physician knows of no contraindication to using these high-dose supplements

long term. Individuals with at least unilateral intermediate AMD or unilateral advanced AMD who were assigned to the original AREDS formulation of antioxidants plus zinc had lower rates of AMD progression (Fig. 68.45B) and of moderate vision loss (Fig. 68.45C) through at least 10 years of follow-up.

Although there is minimal risk associated with the use of these supplements (Tables 68.3 and 68.4), a discussion of the modest treatment benefit and the minimal risks is appropriate. The magnitude of the treatment benefit is affected by the AMD status at treatment initiation with those that have already lost function in one with AMD having the largest benefit. Individuals who are currently cigarette smokers should be advised that beta-carotene supplements have been associated with a small but definite increase in lung cancer and mortality in the context of randomized trials assessing beta-carotene in cohorts at risk of lung cancer.<sup>189,190</sup> For these patients, use of an AREDS-like supplement that omits beta-carotene and includes L/Z (a formulation recommended for consideration by the AREDS2 group) may achieve the desired reduction in AMD progression while avoiding a heightened risk of lung cancer. A similar discussion is reasonable for individuals who are former smokers, so they can make an informed decision as to which supplement they feel is most appropriate to maximize their protection from AMD progression and vision loss and minimize their risk of morbidity and mortality.

**Table 68.3**

**Safety – Antioxidants**

Condition	No Antioxidants (%)	Antioxidants (%)
Hospitalization for mild/moderate symptoms	10.1	7.4
Hospitalization for infections	0.8	1.6
Circulatory	0.8	0.3
Skin, subcutaneous tissue	1.0	2.2
Change in skin color	6.0	8.3
Chest pain	23.1	20.2

**TABLE 68.4**

**Safety – Zinc Oxide**

Condition	No Zinc (%)	Zinc (%)
-----------	-------------	----------

Hospitalization for mild/moderate symptoms	7.8	9.7
Hospitalization for genitourinary	4.9	7.5
Hospitalization for genitourinary problems in men	4.4	8.6
Circulatory	0.3	0.9
Anemia	10.2	13.2
Difficulty swallowing pills	15.3	17.8

If a person has unilateral advanced AMD (either central GA or neovascular AMD/disciform scar), the fellow eye is in the highest risk category, particularly if the fellow eye has large drusen and RPE abnormalities. These individuals (irrespective of specific non-neovascular AMD manifestations in this fellow eye) should be encouraged to use an AREDS supplement, with the smoking history caveats as discussed above.

If an individual has advanced AMD in both eyes, then the practitioner may consider recommending an AREDS-type supplement if visual acuity is relatively good (20/100 or better) in at least one eye in the presence of CNV. This consideration is based on AREDS data, which showed a decreased risk of further moderate vision loss in this NVAMD eye. However, this observation applied only to eyes with CNV and acuity of  $\geq 20/100$  at baseline (Table 68.5). The potential role of micronutrient supplements in patients with bilateral CNV undergoing management with anti-VEGF therapy is unknown, as this was not evaluated during AREDS or AREDS2.

**TABLE 68.5**

**Effect of Treatment on Risk of Moderate Vision Loss From Baseline in Eyes With Neovascular Age-Related Macular Degeneration at Baseline**

	Odds Ratio	99% CI	p value
<b>Baseline VA 20/100 or Better (n = 260)<sup>a</sup></b>			
Antioxidant vs. no antioxidant	0.54	0.30–0.95	0.005
Zinc vs. no zinc	0.99	0.56–1.74	0.96
Antioxidant vs placebo	0.35	0.15–0.81	0.001
Zinc vs placebo	0.65	0.28–1.50	0.18
Antioxidant + zinc vs. placebo	0.53	0.23–1.24	0.05
<b>Baseline VA 20/200 or Better (n = 352)<sup>b</sup></b>			
Antioxidant vs. no antioxidant	0.66	0.40–1.07	0.03
Zinc vs. no zinc	1.10	0.67–1.79	0.62
Antioxidant vs. placebo	0.56	0.27–1.13	0.03
Zinc vs. placebo	0.93	0.46–1.89	0.79
Antioxidant + zinc vs. placebo	0.72	0.36–1.46	0.24

<sup>a</sup>167 participants had moderate vision loss.

<sup>b</sup>206 participants had moderate vision loss.

CI, confidence interval; VA, visual acuity.

Modeling of data from AREDS and epidemiologic surveys of the US population reporting prevalence rates of AMD have suggested that approximately 300,000 individuals would avoid development of advanced AMD in at least one eye during a 5-year period if all 8 million people at risk of AMD progression were identified, educated in regards to supplement use, and were compliant in their use of an AREDS-type supplement. Nevertheless, an additional 1 million people will still develop advanced AMD over the same time period, of whom approximately two-thirds will develop NVAMD. With the availability of our current substantially effective anti-VEGF treatments for neovascular AMD, early diagnosis of neovascular AMD has become increasingly important. As anti-VEGF therapy is most effective at preventing further vision loss, as compared to vision improvement, initiation of treatment before vision is moderately compromised is critical to maximizing vision outcome for NVAMD patients. Therefore, individuals with intermediate AMD or unilateral advanced AMD are typically asked to return to their ophthalmologist on a regular basis for the following reasons: (1) to update staging of their AMD and update them on current AMD management practices; (2) to reassess functional needs related to any increased visual impairment related to progression of atrophic changes; (3) to identify any asymptomatic neovascular AMD for which prompt treatment may favorably affect final vision outcome; (4) to review the regular need and methods for periodic self-monitoring to increase the chance that the individual will identify progression to NVAMD should it occur in the setting of minimal vision loss; and (5) to be reminded to promptly contact their ophthalmologist if symptoms of progression are suspected. The frequency of regular visits for patients with unilateral or bilateral NNVAMD (or frequency of examination of eyes with NNVAMD in patients undergoing treatment for unilateral NVAMD) should be dictated by the projected risk for development of NVAMD based on the drusen and RPE abnormalities present in the eye(s).

## Home Monitoring for Progression to NVAMD

Amsler grid testing has been shown to have limited sensitivity for detection of incident NVAMD in eyes with previously documented NNVAMD,<sup>191-195</sup> for example, sensitivity 0.42 (95% CI, 0.15–0.72) for detection of incident CNV<sup>194</sup> and 0.526 for detection of any CNV when Amsler grid testing is administered in an office setting.<sup>195</sup> Despite these observations many eye care providers recommend its use to individuals at risk of AMD progression. More recently, a perimetry device, the Preferential Hyperacuity Perimeter (PreView PHP, Carl Zeiss Meditec, Dublin, CA) was shown, in an office setting, to have greater sensitivity for detection of NVAMD when compared to an Amsler grid test when evaluated in 19 individuals with neovascular AMD: sensitivity 100% with PHP vs. 53% with Amsler grid,  $p=.004$  (191). Additional in-office studies demonstrated that the device could differentiate eyes with recent-onset neovascular AMD from those with intermediate AMD with both a high sensitivity (85%) and high specificity (85%).<sup>196</sup> A similar device (ForeseePHP 2.05 Notal Vision, Ltd, Tel Aviv, Israel) was evaluated within a nested case–control study as part of the Carotenoids and coantioxidants in patients with Age-Related Maculopathy (CARMA) clinical trial. Eyes that progressed to CNV before the device was incorporated into the follow-up clinic visits had larger magnitude losses in visual acuity from baseline and larger choroidal neovascular lesion size at time of CNV detection than eyes that progressed to CNV after the device was adopted as part of the follow-up visit protocol. In this study, following the incorporation of the PHP device, 10 participants developed CNV, 9 of which were tested with the PHP device, and all 9 were detected with the device.<sup>197</sup>

The same technology has been developed into a home monitoring device (ForeseeHome, Notal Vision, Ltd, Tel Aviv, Israel) and was evaluated in a large-scale clinical trial performed at AREDS2 clinical trial sites, the HOME Study.<sup>198</sup> A total of 1520 participants (age 53 to 90 years) were randomly assigned to standard care home monitoring plus the home monitoring device versus standard care monitoring alone (with or without an Amsler grid). The primary outcome was the change in best corrected visual acuity letter score between baseline and CNV detection. Participants had bilateral

large drusen (2 potential study eyes) or large drusen in one eye (study eye) and advanced AMD in the fellow eye and at least 20/60 visual acuity in the study eye(s). Individuals assigned to the device were asked to test a minimum of twice/week but encouraged to test daily. Among the 51 eyes in the device group that progressed to CNV the median loss of acuity was 4 letters as compared with the 31 CNV events detected in the standard care arm, which suffered a median loss of 9 letters ( $p=.021$ ). Since the median acuity was 20/25 at study entry, this equated to 87% of the device group retaining vision of at least 20/40 at CNV detection compared with 62% in the standard care arm ( $p=.014$ ). A reasonably low false-positive rate was noted in the device arm, mean 0.24 false-positive device initiated alerts per patient per year, which equates to 1 false-positive visit per device user for every 4.2 monitoring years. Incorporating a home monitoring strategy as was evaluated in the HOME study ought to identify a larger proportion of patients with incident CNV who retain better levels of vision at diagnosis of CNV. This in turn should translate into superior vision outcomes when these eyes are managed with anti-VEGF therapy for their NVAMD. Even with the potential for devices such as this to improve our ability to detect disease progression, including progression in the setting of better vision preservation, it is unlikely that all incident CNV cases will be detected by this method. A sizeable minority of NVAMD patients will not be able to use the device, compliance may wane among users, and sensitivity for CNV events is not 100%. Periodic office examinations to identify progression among individuals who have failed to recognize or act upon new symptoms and to reinforce the need for regular self-vision checks is therefore still indicated.

## **Intermediate Stage of Age-Related Macular Degeneration and Cataract Surgery**

In an aged population, the question of cataract extraction commonly arises, requiring an estimation of the postoperative visual acuity and the duration of the anticipated vision benefits. Despite coexistence of AMD, most individuals can derive vision benefits following cataract surgery when lens opacity is assessed to be a component of the preexisting visual impairment. During the

AREDS, 1939 eyes underwent cataract surgery. Although eyes without AMD ( $n=626$ ) had the largest change in visual acuity at 8.4 letters between the two study visits that immediately straddled the time of cataract surgery, those with mild (early) AMD ( $n=406$ ) gained 6.1 letters, intermediate AMD ( $n=712$ ) eyes gained 3.9 letters, and even those with advanced AMD ( $n=195$ ) gained 1.9 letters.<sup>199</sup> In each AMD subgroup these improvements represented a statistically significant change from baseline and were associated with 10 or more letter improvements in each AMD subgroup as follows: no AMD 41%, mild AMD 32%, intermediate AMD 29%, and advanced AMD 24%. Analysis of the eyes with longer-term follow-up of at least 1 year following cataract surgery suggested the early improvements in visual acuity were sustained in all AMD subgroups.<sup>199</sup>

Favorable outcomes following cataract surgery were corroborated in 1232 eyes that covered the spectrum of AMD severity and underwent cataract surgery during participation in AREDS2. Eyes that underwent cataract surgery during AREDS2 were categorized using the AREDS AMD severity scale.<sup>71</sup> Eyes with mild AMD (severity scale 1–3,  $n=30$ ) gained 11.2 letters, moderate AMD (severity scale 4–6,  $n=346$ ) gained 11.1 letters, severe AMD (severity scale 7–8,  $n=462$ ) gained 8.7 letters, noncentral GA (severity scale 9,  $n=70$ ) gained 8.9 letters, and central GA and/or neovascular disease (severity scale 10–11,  $n=324$ ) gained 6.8 letters when comparing visual acuity changes between the two study visits that immediately straddled the cataract surgery.<sup>71</sup> This did represent a statistically significant mean gain in visual acuity from preoperative levels for each of the AMD subgroups. The proportion of patients that improved by 10 or more letters was highest at 37% among the mild AMD subgroup, and successively decreased along the AMD spectrum, but remained 24% among those with advanced AMD. Between 12 and 20% improved by 15 or more letters with cataract surgery, with minimal variations between the AMD subgroups.<sup>71</sup>

The findings of AREDS and AREDS2 provide evidence that argues against a harmful effect of cataract surgery on acceleration of AMD progression, a concern that has been raised by findings from epidemiologic studies. The biologic argument has been that

photic injury at or following cataract surgery and inflammation associated with the surgery may trigger AMD progression. A combined analysis of two population-based surveys (the Beaver Dam and Blue Mountains Eye Studies) suggested that cataract surgery increased the risk of incident neovascular AMD by a factor of 5 within 5 years of surgery.<sup>200</sup> These observations may have been due to easier visualization of the fundus after surgery and postoperative identification of neovascular AMD that was actually preexisting before cataract surgery. AREDS has the advantage of regular prospective data collection as compared to population-based surveys, which evaluate cross-sectional outcomes at different points in time. In the AREDS a variety of analytic methods were used to explore development of neovascular AMD or central GA following cataract surgery and no clear deleterious effect of any concerning magnitude was identified.<sup>201</sup>

The best evidence at this time suggests that patients with AMD can derive vision benefit from cataract surgery and that cataract surgery does not appear to increase the risk of AMD progression. These patients should not be discouraged from undergoing cataract surgery if there is concurrent cataract. Ophthalmologists should be aware of the possibility that eyes with advanced AMD (especially geographic atrophy in a blonde fundus or CNV with minimal subretinal fluid, hemorrhage, lipid, or scarring) might not be readily apparent through a cataract, despite preoperative imaging. Preexisting advanced AMD may explain the vision loss experienced by the patient, which may be mistakenly attributed to a cataract. When this is the case the vision outcomes following cataract surgery are more modest than what would be expected in the absence of advanced AMD. When and if vision continues to deteriorate following cataract surgery from progression of AMD that had not been identified prior to cataract surgery despite its preexistence, patients may inappropriately associate progression of their AMD and vision loss with the cataract surgery itself due to the temporal relationships of cataract surgery and making the more appropriate diagnosis of the AMD stage. As such, careful examination of the fundus for signs of advanced AMD, immediately before cataract surgery in any individual at risk for AMD, is important. Potential clues that advanced AMD may exist

posterior to a cataract include the presence of advanced AMD in the contralateral eye, pigmentary abnormalities in the macula (which may be associated with less visible atrophy or CNV), or glistening from calcification (which is usually associated with geographic atrophy). Performance of fluorescein angiography and OCT prior to cataract surgery can potentially identify areas of visually significant atrophy or raise suspicion of preexisting NVAMD. The presence of either of these may affect decisions to proceed with cataract surgery, as well as assist in formulating prognosis and AMD treatment plan. Even when atrophy is suspected on examination, angiography, or OCT, the indistinct landmarks and poor image quality can make it difficult to tell where the center of the fovea lies in relationship to preexisting RPE abnormalities and whether various layers of the neurosensory retina are intact.

## Management of Visual Impairment From NNVAMD

Among patients with unilateral or bilateral advanced non-neovascular AMD, as well as those with vision impairment attributed to nongeographic atrophy, noncentral GA, or confluent foveal drusen or drusenoid PED, rehabilitation with a low-vision service should be considered. Experienced eye care and social service professionals can determine what services or devices might help the individual optimize the vision function and simultaneously adapt and cope with their vision impairment. Issues specific to driving may need to be considered.

In phakic patients with bilateral advanced and endstage untreatable AMD (central GA or stable disciform scar from NVAMD), consideration can be given for implanting a visual prosthetic device, also referred to as an implantable miniature telescope (IMT; VisionCare Ophthalmic Technologies, Saratoga, CA) (Fig. 68.48).<sup>202</sup> This device provides 2.2 to 3 times magnification of the central visual field and affords approximately 2 times the field of view of that associated with a similar strength external telescope. A prospective, open-label, multicenter clinical trial of 217 participants (age 55–93) with bilateral central visual acuity loss (20/80–20/800) related to central GA or stable disciform scars

evaluated the device, limiting inclusion to individuals that prior to enrollment demonstrated at least a 5-letter improvement with an external telescope. Furthermore, study participants may have experimented with an external telescope for several days at home to evaluate the loss of binocularity and peripheral vision that comes with use of a telescope. The fellow eyes of these individuals were used as the control groups, they did not receive the implant, and the fellow eye was expected to provide peripheral vision for the participant. A total of 206 (95%) of 217 eyes were implanted with the device, as 11 procedures were aborted at the time of surgery. Two devices (1%) required removal one month after placement due to condensation within the telescopic cylinder due to device damage at the time of implantation.<sup>202</sup> Postoperatively, the patients were asked to participate in six visual rehabilitation sessions to learn how to adapt to use of the telescope in daily life. These visits included training in learning to use alternate viewing between eyes for peripheral and central tasks. Among the 192 implanted eyes for which 1-year follow-up information was reported, 67% of implanted eyes gained at least 3 lines of distance visual acuity as compared to 13% of the fellow eyes. An improvement of at least 3 lines at both distance and near occurred in 53% with the IMT vs. 10% of fellow eyes.<sup>202</sup> Safety concerns at 1 year included the observation that 5% experienced at least a 2-line visual acuity loss at distance or near. In addition, mean endothelial cell death following implantation of the device was 20% at 3 months and 25% at 12 months.<sup>202</sup> A potential limitation of this study was the lack of a control group that received intensive vision rehabilitation in the absence of the IMT, so the extent to which a placebo effect is associated with the device and the intensive rehabilitation are responsible for the study results is unknown.

**FIG. 68.48** (A) Side view of the implantable miniature telescope (top is anterior aspect of the device). The anterior quartz high-plus wide-angle microoptic is positioned behind the front window and a refractive air space. The posterior wide-angle microoptic is not visible because it is hidden inside the bushing that prevents light scatter in the posterior portion of the device cylinder. (B) Implanted study eye 6 weeks after surgery. The blue-light restrictor can be seen behind the iris. Photograph credit: James P. Gilman. (C) The anterior microoptical element can be seen illuminated behind the front window of the device. The front window protrudes marginally through the iris plane. Photograph credit: James P. Gilman. (Photograph credits panels B and C: James P. Gilman. Reproduced with permission from Hudson HL, Lane SS, Heier JS, et al. Implantable miniature telescope for the treatment of

This device has been FDA approved for patients 75 and older with bilateral central vision loss related to advanced AMD. Postoperative visual rehabilitation is critical in managing patients undergoing implantation of this device, as is thorough preoperative evaluation in conjunction with low vision specialists. In addition, the facility with which the retina can be examined and treated for new pathology following the surgery remains a potential concern, though successful imaging has been described in a patient with the IMT using scanning laser ultrawide-field autofluorescence and fluorescein angiography.<sup>203</sup> Therefore, consideration of candidates who are truly endstage and not AMD treatment candidates is important.

## Future Directions for Management of NNVAMD

Future research in AMD will likely focus on pathophysiology, new interventions, and enhanced means of preventing development and progression of the disease. On the horizon are the results of two phase III clinical trials evaluating treatments to limit vision impairment from progressive GA. The interventions under investigation will not reverse atrophy but may limit progressive enlargement of GA.

Emixustat hydrochloride (ACU-4429; Acucela, Inc., Tokyo, Japan) is an orally available small molecule that has been designed to inhibit the visual cycle isomerase (RPE-specific 65-kDa protein, RPE65) as a means of reducing the accumulation of vitamin A-based toxins, such as N-retinylidene-N-retinylethanolamine (A2E).<sup>204</sup> Reducing the concentration of such toxins within the RPE may slow GA progression. Based on its mechanism of action, it is expected to suppress rod photoreceptor activity, which may have adverse clinical side-effects. In a phase II, randomized, placebo-controlled study of 72 subjects with any GA, 54 patients were randomized to emixustat (2 mg, 5 mg, 7 mg, or 10 mg orally once daily) and 18 were randomized to placebo. The primary objective

was to explore the safety and tolerability over a 3-month period and evaluate the drug pharmacodynamics.<sup>204</sup> Chromatopsia (54% vs. 17%), described as a dark or colored tint to vision, as well as dark adaptation deficits (48% vs. 6%), were frequently reported by participants taking the drug when compared to placebo.<sup>204</sup> Rates were highest (83%) in the 10-mg treatment arm. Other adverse events were more prevalent in the combined emixustat groups compared with placebo and included the following subjective complaints: visual impairment (26% vs. 6%), blurred vision (15% vs. 6%), and visual field defect (15% vs. 0%). The objective measurement of reduced best corrected visual acuity was also more prevalent with the study drug (11% vs. 0%). Study drug was prematurely discontinued in the 7-mg and 10-mg arms (at a median of 25 days) due to the rate of adverse ocular events. Eighty-five percent of ocular adverse events resolved during the study or within 2 weeks of drug discontinuation and about half of the cases of chromatopsia resolved while still on study drug.<sup>204</sup> Suppression of rod photoreceptor activity as measured by ERG followed a dose response and recovered to baseline levels 7–14 days following drug discontinuation. No change in cone photoreceptor function was noted.<sup>204</sup> Emixustat is currently being evaluated in a 2-year, phase IIb/III (NCT01802866), randomized, placebo-controlled clinical trial of patients with GA. Active treatment arms are assigned to 2-mg, 5-mg, or the 10-mg dose. The study completion date was July of 2016.<sup>205</sup>

The other active intervention for GA that is in late phase development is lampalizumab (FCFD4514S; F. Hoffmann-La Roche, Ltd, Basel, Switzerland). This biologic product is an anticomplement factor D monoclonal antibody fragment.<sup>206</sup> As part of the alternative complement pathway, factor D acts upstream of complement factor H and is a rate-limiting step in the activation of the cascade and is present in lower levels than other complement factors.<sup>206,207</sup> The activation of complement pathways has been implicated in the pathogenesis of GA, both by demonstration of complement molecules in higher levels in pathologic specimens of eyes with AMD and GA and by genetic associations demonstrating that complement gene polymorphisms, and specifically complement factor H, are associated with increased risk of GA.<sup>208</sup>

The safety and tolerability of a single intravitreal injection of lampalizumab ranging from 0.1 to 10 mg was deemed acceptable in a phase Ia trial of 18 participants.<sup>206</sup>

The MAHALO study (NCT01229215), a phase II trial of intravitreal lampalizumab, 10 mg dosed monthly ( $n=43$ ) or every other month ( $n=44$ ) versus sham injection monthly ( $n=21$ ) or every other month ( $n=21$ ), reported 18-month, primary outcome findings in patients with GA at study entry at the 2013 American Society of Retina Specialist meeting in Toronto, Canada.<sup>205</sup> The study outcomes have not appeared in peer-reviewed literature at this time; however, further development of this drug is ongoing in the hopes that it will slow progression of GA, particularly in a subgroup of individuals who have the complement factor I (CFI) polymorphism. CFI also acts in the alternative complement cascade, and individuals with this polymorphism appeared to have larger areas of GA at baseline or faster GA expansion rates and possibly a larger treatment benefit was observed in this subgroup. Two identically designed parallel, double-masked, randomized, international phase III trials evaluating the safety and efficacy of lampalizumab (10 mg administered intravitreally every 4 or 6 weeks versus sham injection) are presently enrolling participants with GA: SPECTRI (NCT02247531) and CHROMA (NCT02247479). One eye of approximately 1879 patients with bilateral GA will be included in these studies, and the primary outcome will be the change in GA area at 48 weeks, while measures of visual function, including visual function questionnaire scores and high contrast and low-luminance visual acuity at 1 and 2 years, will provide important secondary outcomes.<sup>205</sup> Each treatment arm will include patients that are CFI biomarker positive or negative.

In parallel to these randomized clinical trials, there are two separate parallel, prospective observational studies of patients with GA that are presently enrolling participants. Between the two studies there is a combined goal of 560 participants to be followed for 48 months, with interim analysis at 24 months. These studies seek to better characterize the relationships between visual function and the progression of GA and to generate new information on the relationship between genotype and GA progression.<sup>205</sup> One of these studies, Proxima A (NCT02479386), will enroll participants with

bilateral GA, and the other study, Proxima B (NCT02399072), will enroll participants with unilateral GA in two cohorts, one with and one without CNV in the fellow eye.<sup>205</sup> The findings from these observational studies may aid in the design of future clinical trials for treatments of GA and could identify potential new targets for treatment.

\*The original observations by light microscopy distinguished only one deposit. This was referred to as the basal linear deposit, and it proved a useful histologic marker for the stage of the disease.<sup>43</sup> Subsequent electron microscopic studies showed that the deposit, originally via light microscopy, lies internal to the RPE basement membrane. Thus the name of this deposit was changed to basal laminar deposit. However, another layer could also be demonstrated, lying external to the basement membrane. Green and Enger<sup>76</sup> suggested retaining the term basal laminar deposit for the material internal to the basement membrane, but resurrecting the term basal

linear deposit for the diffuse layer of vesicular and granular material on the external aspect. The acronym BLD that has previously been used, however, could be used to represent either of these types of deposits. This chapter will use the acronyms BlamD for basal laminar deposit and BlinD for basal linear deposit and refer to both of them generically as basal deposits, as proposed by Curcio and Millican.<sup>77</sup>

# Neovascular (Exudative or “Wet”) Age-Related Macular Degeneration

## Epidemiology

Age-related macular degeneration (AMD), left untreated, is the major cause of severe visual loss in older adults.<sup>1,2</sup> Most AMD patients have macular drusen or retinal pigment epithelial abnormalities, or both.<sup>3</sup> Approximately 10% of AMD patients manifest the neovascular form of the disease.<sup>4</sup> Neovascular AMD includes choroidal neovascularization (CNV) and associated manifestations such as retinal pigment epithelial detachment (PED), retinal pigment epithelial tears, fibrovascular disciform scarring, and vitreous hemorrhage.<sup>3</sup> In the absence of anti-vascular endothelial growth factor (anti-VEGF) therapy, the vast majority of people with severe vision loss (20/200 or worse in either eye) from AMD have the neovascular form.<sup>4</sup>

## Risk Factors

The prevalence of AMD-associated vision loss in at least one eye increases with age. For example, AMD was the leading cause of blindness in white (prevalence 2.7 per 1000; 95% CI 1.2–5.4) but not black subjects randomly selected to participate in the Baltimore Eye Survey. In this study, AMD resulting in blindness affected 3% of all white subjects 80 years of age or older.<sup>5</sup>

AMD may be a multifactorial syndrome with different causative factors damaging the macula and resulting in common clinical manifestations that are recognized clinically as AMD. Risk factors implicated in clinical and laboratory studies include drusen, visible (but not ultraviolet) light injury, micronutrient deficiency as measured in blood serum levels or by dietary history, cigarette smoking, family history (genetic predisposition<sup>6,7</sup>), and cardiovascular risk factors (including systemic hypertension).<sup>8–10</sup> Recent epidemiologic studies have found an association with aspirin use and neovascular AMD,<sup>11</sup> but many authors have

suggested that a causative relationship needs to be proven before any widespread change in clinical practice relative to aspirin use is undertaken.<sup>12-15</sup> Likewise, a suggestion that cataract extraction may lead to neovascular AMD was not borne out in a prospective study.<sup>16</sup> More detailed information regarding the epidemiology of AMD is reviewed in [Chapter 66](#) (Epidemiology and risk factors for age-related macular degeneration).

## Clinical Presentation

### Overview

Blurred vision and distortion, especially distorted near vision, are the symptoms most patients with CNV notice first.<sup>3,17</sup> Patients also may complain of decreased vision, micropsia, metamorphopsia, or a scotoma; however, many times they volunteer no symptoms or report only vague visual complaints.<sup>18</sup> Symptoms generally arise from sub-RPE or subretinal fluid, intraretinal fluid, blood, or destruction of photoreceptors and the retinal pigment epithelium (RPE) by fibrocellular or fibrovascular tissue proliferating in the subretinal or sub-RPE space.<sup>19-22</sup> In some but not all cases, areas of distortion or scotoma can be mapped out on an Amsler grid. Visual acuity, although frequently decreased and often involving both eyes, may not always be affected or may affect only one eye. Functional vision generally declines in accordance with Snellen visual acuity, especially based on the better-seeing eye. Thus patients with poor Snellen acuity in the better-seeing eye generally report decreased ability to perform functional tasks (e.g., face recognition, telling time) with the affected eye.<sup>23</sup>

### Biomicroscopic Features

In some patients with AMD, CNV may appear as a gray-green elevation of tissue deep to the retina with overlying detachment of the neurosensory retina ([Fig. 69.1](#)). The gray-green color may arise from hyperplastic RPE in response to the CNV, as has typically been seen in patients, usually younger individuals, with the ocular histoplasmosis syndrome (OHS),<sup>24</sup> pathologic myopia, and other

conditions complicated by CNV. This gray-green appearance is not always present in older individuals with AMD. Often, the presence of blood or lipid or a sensory retinal detachment in an older patient with vision loss indicates the presence of CNV. The CNV capillary network may become more apparent when the overlying RPE has atrophied. Occasionally, a shallow neurosensory detachment may be the only presenting sign of underlying CNV. Elevated RPE, also termed a pigment epithelial detachment (PED), even without overlying subretinal fluid, may also suggest the presence of CNV to be identified subsequently by a fluorescein angiogram. RPE folds associated with a shallow RPE elevation usually indicate the presence of CNV.<sup>25</sup> These subtle clinical findings can be missed easily without careful stereoscopic slit-lamp biomicroscopic examination, facilitated with a contact lens.

**FIG. 69.1** Fundus photograph of choroidal neovascularization. Note area of hemorrhage (*large arrows*), as well as neurosensory retinal detachment (*small arrows*). (Reproduced with permission from Elman MJ. Age-related macular degeneration. *Int Ophthalmol Clin* 1986;26:117–44.)

## Retinal Pigment Epithelial Detachments

Retinal PEDs appear clinically as sharply demarcated, dome-shaped elevations of the RPE (Fig. 69.2). They usually transilluminate if they are filled predominantly with serous fluid. Often, there is accompanying RPE atrophy and “pigment figure” formation. Pigment figures, a reticulated pattern of increased pigmentation extending radially over the PED, likely due to migration of RPE cells into the outer retinal space, indicate chronicity of disease and probably have no prognostic significance. The presence of a PED may or may not be a feature of CNV, depending on whether neovascularization is present beneath or above the PED. The fluorescein angiographic pattern (see subsequent discussion) can differentiate a drusenoid PED,<sup>26</sup> which does not have CNV, from a fibrovascular PED, which is a form of occult CNV,<sup>27</sup> as well as from a serous PED, which may or may not overlie an area with CNV.<sup>27</sup> Several clinical signs suggest the presence of CNV underlying an area of PED identified biomicroscopically, including overlying sensory retinal detachment and lipid, blood, and chorioretinal folds radiating from the PED.<sup>3</sup> Although an overlying sensory retinal detachment on optical coherence tomography (OCT) may be a clue to the presence of CNV beneath a PED,<sup>28</sup> sometimes a shallow neurosensory detachment may occur as a result of breakdown of the physiologic RPE pump or from disruption of the tight junctions between adjacent RPE cells in the absence of CNV identified on fluorescein angiography (FA). Unlike a PED, the borders of a neurosensory detachment are not sharply demarcated. Blood within or surrounding a PED implies the presence of CNV (Fig. 69.3). When confined to the sub-RPE space, the blood may appear as a discretely elevated, green or dark-red mound. The hemorrhage can dissect through the RPE into the subsensory retinal space or into the retina. Rarely, blood may pass through the retina into the vitreous cavity, causing extensive vitreous hemorrhage. The Submacular Surgery Trials (SST) Research Group suggested that this event was more likely in predominantly hemorrhagic lesions that were large (>12 disc areas) or associated with very poor visual acuity (worse than 20/1280 Snellen equivalent) on presentation to a retina specialist.<sup>29</sup>

*Ophthalmol* 1988;32:375–413.)

## Massive Subretinal Hemorrhage

Massive subretinal hemorrhage is an unusual complication of neovascular AMD. If – extremely rarely – total hemorrhagic retinal detachment occurs, secondary angle closure glaucoma may develop. These patients may report sudden visual loss followed by pain.<sup>30</sup> Anticoagulation therapy may contribute to massive subretinal hemorrhage. In one report,<sup>31</sup> 19% of AMD patients with massive subretinal hemorrhage were taking sodium warfarin or aspirin, though in the Comparison of Age-Related Macular Degeneration Treatments Trial, an association with anticoagulant or antiplatelet therapy and subretinal hemorrhage was found only in patients with hypertension.<sup>32</sup> Although sodium warfarin therapy may contribute to massive subretinal hemorrhages in neovascular AMD, antiplatelet therapy (aspirin) likely is a chance association because several Macular Photocoagulation Study (MPS) reports did not observe any increased risk of hemorrhage associated with the use of aspirin.<sup>33–35</sup> Furthermore, comparing baseline characteristics in study participants with predominantly choroidal neovascular lesions in the SST Group N Trial<sup>36</sup> with participants with predominantly hemorrhagic lesions,<sup>29</sup> no difference in use of aspirin was detected. Epidemiology studies found an association of aspirin use with neovascular AMD as mentioned above,<sup>11</sup> but this finding does not necessarily confirm or refute a cause and effect relationship of aspirin with the development of predominantly hemorrhagic lesions or massive subretinal hemorrhages.<sup>37</sup>

The strongest evidence suggests that patients with AMD who need to follow a regimen of aspirin therapy should continue to do so without unnecessary fear they will increase their risk of subretinal hemorrhage.

## Breakthrough Vitreous Hemorrhage

In most cases of neovascular AMD, the peripheral visual field remains unaffected. If bleeding breaks through the retina into the vitreous cavity, however, patients may complain of severe and sudden visual loss involving the peripheral visual field, as well as the central field.

## Retinal Pigment Epithelial Tears

RPE dehiscence or tears of the RPE have been described as a complication associated with CNV, often in an eye with a serous or fibrovascular PED.<sup>38-41</sup> Tears occur at the junction of attached and detached RPE, perhaps when the PED no longer can resist the stretching forces from the fluid in the sub-RPE space emanating from the underlying occult CNV (Fig. 69.4) or from the contractile forces of the underlying fibrovascular tissue that may be associated intimately or entwined with the overlying RPE. When the RPE tears, the free edge of the RPE retracts and rolls toward the mound of fibrovascular tissue. Acutely, a serous detachment of the sensory retina may be caused by the leaking of fluid from the exposed choriocapillaris.<sup>26</sup> This is rarely seen after a few days following the tear. Though some ophthalmologists have suggested that RPE tears occur as a result of anti-VEGF therapy, data from 1298 patients in the three ranibizumab phase III trials showed no difference in the rate of RPE tear formation in the active ranibizumab arms compared with the control arms.<sup>42</sup>

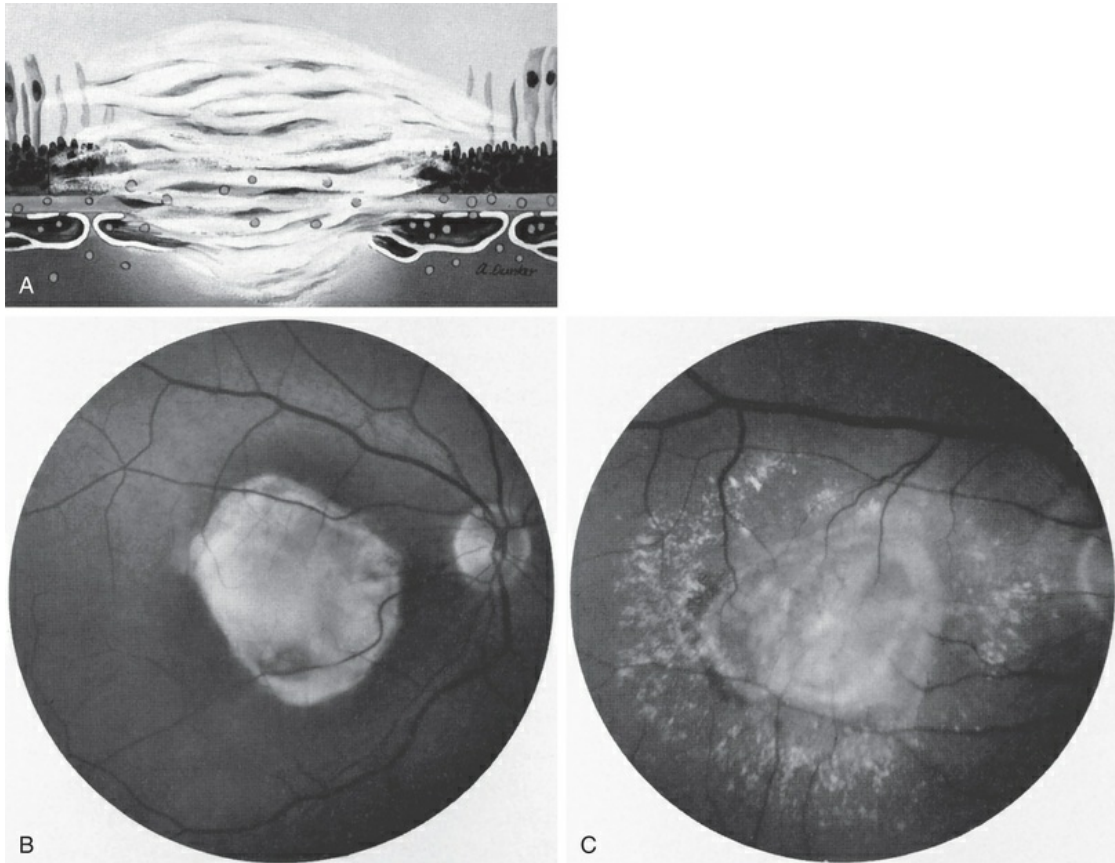

**FIG. 69.4** Sketch of tear or rip of the retinal pigment epithelium (RPE), showing contracted RPE tear. Cc + C, choriocapillaris and choroid. (Reproduced with permission from Bressler NM, Bressler SB, Fine SL. Age-related macular degeneration. *Surv Ophthalmol* 1988;32:375-413.)

## Disciform Scars

Histologically, CNV usually is accompanied by fibrous tissue, even when no fibrous tissue is readily apparent on initial presentation to an ophthalmologist.<sup>21,43,44</sup> This fibrous tissue may be accompanied by CNV (fibrovascular tissue) or not (fibroglial tissue).<sup>21</sup> The fibrous tissue complex may be beneath the RPE (usually proliferating within the inner aspect of an abnormally thickened Bruch's membrane) and has been termed type I, or between the RPE and the photoreceptors, termed type II.<sup>45</sup> While some authors speculate that these histopathologic types correspond to occult CNV and classic CNV respectively,<sup>46,47</sup> there is little evidence to support the universality of this histopathologic correlation.<sup>48</sup> Often, over time, the plane of the RPE is destroyed by the fibrovascular or fibroglial tissue, so the location of the CNV with respect to the RPE no longer can be identified readily. When the fibrous tissue becomes apparent clinically, the CNV and fibrous tissue complex may be termed a disciform scar.

Clinically, disciform lesions may vary in color, although typically they appear white to yellow. Hyperpigmented areas may be present depending on the degree of RPE hyperplasia within the scar tissue. Disciform fibrovascular scars may continue to grow, with new areas of neovascularization proliferating along the edge, invading previously unaffected areas of retina (Fig. 69.5). Varying degrees of subretinal hemorrhage and lipid may overlie or surround the scar. Occasionally, fibrovascular scars may precipitate massive transudation of fluid, mimicking a retinal detachment. The scars may be accompanied by massive lipid, as might be seen in retinal telangiectasis from Coats disease, and hence, historically sometimes were called a "senile Coats response" in AMD.<sup>19</sup> Disciform scars occasionally masquerade as choroidal tumors when substantial pigment is seen.<sup>49</sup> Not infrequently, anastomoses are observed between the retina and the fibrovascular tissue.<sup>20</sup> As a rule, most fibrovascular scars involve the fovea and cause severe visual loss. However, in some scars, surviving islands of intact photoreceptor cells noted histologically may explain the better visual performance than would be predicted from the morphologic appearance alone. Reading vision, rarely better than 20/200, becomes severely compromised in most cases with extensive scars.

**FIG. 69.5** Disciform scar. (A) Sketch demonstrating that most of the sensory retina, pigment epithelium, and inner choroid has been replaced by a fibrovascular scar. (B) Fundus photograph of a disciform scar after choroidal neovascularization. (C) Fundus photograph of a disciform scar in which continued subretinal fluid and lipid from persistent choroidal neovascularization at the periphery of the fibrous tissue can be seen.

## Ancillary Testing

### Optical Coherence Tomography

The development of anti-VEGF medicines developed alongside developments in retinal imaging, allowing clinicians to observe and record objective, relatively small changes in retinal thickness over time. While clinical examination, color fundus photography, and FA have been the standard means of retinal evaluation prior to the

development of optical coherence tomography (OCT), in recent studies, such as the Comparison of AMD Treatments Trial (CATT), in which investigators had discretion to use OCT or FA to make retreatment decisions, more than 95% of such decisions were based on OCT findings.<sup>50-52</sup> The technology underlying OCT and its clinical applications are discussed in detail in [Chapter 3](#) (Optical coherence tomography), with a detailed section discussing neovascular AMD.

In contrast to standard OCT for evaluating CNV in AMD, OCT angiography is a new technology, recently approved by the FDA for diagnostic use in the United States. By using differential measurements of blood cell flow, images of the retinal and choroidal vascular networks can be obtained without the administration of a contrast agent such as fluorescein. Utility in the management of patients with neovascular AMD has yet to be demonstrated but may provide helpful information without the additional discomfort and risk of parenteral injection of fluorescein.<sup>53</sup> Additionally, if the technology can reliably identify CNV, OCT angiography may prove particularly helpful in ascertaining the absence or presence of CNV in lesions that can be challenging to interpret on traditional FA, such as in the presence of vitelliform lesions or in the presence of underlying central serous chorioretinopathy.

## Fluorescein Angiography

### Overview

Whenever one suspects CNV for which treatment might be indicated, one should consider obtaining stereoscopic FA promptly, even in an era of ubiquitous spectral domain OCT. The treating ophthalmologist is about to embark on a recommendation for treatment involving medications that carry risks, potentially large expenses, and many years of follow-up. Although the clinical picture may be “obviously” CNV, other lesions masquerading as CNV can exist (see below). Having a fluorescein angiogram at the time of diagnosis reduces the possibility that an error in diagnosis will be made. In a systematic review of trials in which multiple

imaging modalities were used, OCT was found to be 85% sensitive for active neovascular AMD, but only 48% specific,<sup>54</sup> suggesting that a regimen using OCT alone to decide on treatment or retreatment might result in overtreatment. This is particularly relevant as regimens such as “as needed” and “treat and extend” are designed to minimize the burden of treatment but often based on OCT evaluations in the absence of FA. It is important to consider that no comparison of outcomes of treatment decisions based on results of using either or both tests has been published.

In addition, FA frequently allows one to determine the pattern of fluorescence (classic or occult), boundaries (well defined or poorly defined), composition (e.g., predominantly CNV, predominantly classic CNV, predominantly CNV with a minimally classic composition, predominantly CNV with an occult with no classic composition, predominantly hemorrhagic), and location of the neovascular lesions with respect to the geometric center of the foveal avascular zone (FAZ). Although many physicians no longer refer to CNV composition, entry criteria for most of the treatment trials cited later in this chapter relied in part on lesion composition. If one chooses to treat only patients who would have been eligible for, e.g., the MARINA trial, baseline angiography is necessary. Since eligibility for current clinical trials (e.g., <https://clinicaltrials.gov/show/NCT02462486>, <https://clinicaltrials.gov/show/NCT02418754>) continues to hinge upon lesion composition, clinician scientists who enroll subjects in clinical trials for neovascular AMD still should consider understanding the angiographic features of the disease. Finally, it is possible that some treatments may perform differently on different lesion subtypes, and knowledge of composition may allow for better outcomes in these subgroups.<sup>55</sup> Additional technical details about FA can be found in [Chapter 1](#) (Fluorescein angiography: Basic principles and interpretation).

High-quality stereoscopic fluorescein angiograms, together with meticulous slit-lamp biomicroscopic examination (ideally with a contact lens examination using topical anesthesia and hard contact lens wetting solution to avoid degradation of any subsequent image acquisition that might occur if an ophthalmic demulcent is used), facilitate detecting obvious and subtle features of CNV on

angiography.<sup>27,56,57</sup> It should be noted that the descriptive terms below refer to patterns of fluorescence on FA that have been shown to be reliable and reproducible in multicenter clinical trials,<sup>27,58,59</sup> and in practice, and are not related to terms based on other imaging such as OCT, indocyanine green angiography, histopathology, or immunohistochemistry. A comprehensive review of FA remains highly relevant to clinicians and researchers interested in neovascular AMD.

## Classic Choroidal Neovascularization

The fluorescein angiographic appearance of classic CNV consists of a discrete, well-demarcated focal area of hyperfluorescence that can be discerned in the early phases of the angiogram, sometimes before dye has completely filled the retinal vessels during choroidal filling.<sup>27,58,59</sup> Although fluorescein can occasionally be observed within the actual capillary network of CNV in the early phase of the angiogram (Fig. 69.6A), the ability to visualize the appearance of actual new vessels is not needed to diagnose classic CNV and is not a specific feature of classic versus occult CNV.<sup>27,58–60</sup> As the angiogram is evaluated within the area of classic CNV, hyperfluorescence increases in intensity and extends beyond the boundaries of the hyperfluorescent area identified in earlier phases of the angiogram through mid- and late-phase frames. Fluorescein may also pool in subsensory retinal fluid overlying the classic CNV (Fig. 69.6B), best seen when visualizing early- and late-phase frames of classic CNV on stereoscopic images. This presentation of classic CNV is in contrast to the appearance of an area of RPE atrophy on FA, which, like classic CNV, is hyperfluorescent during the early phase of the angiogram (Fig. 69.7A). The increased fluorescence through the atrophic patch results from increased transmission of fluorescein through an overlying RPE with a reduced amount of pigment that normally obscures the choroidal blush (sometimes termed a window, or transmission, defect). Unlike the increase in extent and intensity of hyperfluorescence due to leakage from the fluorescence of classic CNV, RPE atrophy does not show leakage of fluorescein at its boundaries through the mid- and late-phase frames. The fluorescence fades after several minutes (Fig. 69.7B),

without leakage of fluorescein beyond the boundaries of hyperfluorescence defined in the early stages. Two other lesions in AMD that may show an area of discrete hyperfluorescence in the early phase of the angiogram include a serous PED and a rip or tear of the RPE (angiographic features that differentiate these abnormalities from classic CNV are discussed later). Neither one of these latter abnormalities should show fluorescein leakage in later phases of the angiogram at the boundary of the hyperfluorescence noted in earlier phases.

**FIG. 69.6** (A) Early transit phase of fluorescein angiogram showing fine net of vessels corresponding to part of choroidal neovascular lesion (black arrows). (B) Late phase of the fluorescein angiogram, demonstrating an increase in the degree and size of fluorescence. In both panels (A) and (B) there is blocked fluorescence resulting from overlying hemorrhage (*white arrows*). (Reproduced with permission from

Elman MJ. Age-related macular degeneration. *Int Ophthalmol Clin* 1986;26:117–

44.)

**FIG. 69.7** (A) Transit phase of fluorescein angiogram, showing hyperfluorescence corresponding to atrophic zones of the retinal pigment epithelium (transmission, or window, defect) and easily visualized choroidal vessels (too large to be vessels of choroidal neovascularization). (B) Hypofluorescence does not increase in size and fades with the later phases of the angiogram. This is in contrast to the pattern seen in choroidal neovascularization (Fig. 69.5). (Reproduced with

permission from Elman M.J. Age-related macular degeneration. *Int Ophthalmol Clin* 1986;26:117–44.)

## Occult Choroidal Neovascularization

Occult CNV refers to two hyperfluorescent patterns on FA.<sup>27,58,59</sup> The first pattern, termed a fibrovascular pigment epithelial detachment (FVPED), is best appreciated with stereoscopic views, usually at approximately 1–2 min after dye injection. It appears as an irregular elevation of the RPE, often stippled with hyperfluorescent dots (Fig. 69.8). The boundaries may or may not show leakage in the late-phase frames as fluorescein collects within the fibrous tissue or pools in the subretinal space overlying the FVPED. The exact boundaries of a FVPED can usually be determined most accurately only when fluorescence sharply outlines the elevated RPE. The amount of elevation depends on the quality of the stereoscopic photographs and the thickness of the fibrovascular tissue. Stereoscopic pairs of fluorescein angiogram frames can sometimes facilitate identification of the boundaries of the elevated RPE, although not always, as the elevation can slope

gradually down to the normal level of the RPE. The second pattern, late leakage of an undetermined source (Fig. 69.9), refers to late choroidal-based leakage in which there is no clearly identifiable classic CNV or FVPED in the early or mid-phase of the angiogram to account for an area of leakage in the late phase. Often this pattern of occult CNV can appear as speckled hyperfluorescence with pooling of dye in the subretinal space overlying the speckles. Usually the boundaries of this type of CNV cannot be determined precisely.

**FIG. 69.8** Classic and occult choroidal neovascularization (CNV) with well-demarcated borders. (A) Color photograph shows scar from prior photocoagulation surrounded by several clues to suggest recurrent CNV, including subretinal hemorrhage, subretinal lipid, irregular elevation of retinal pigment epithelium (RPE) below the area of prior laser treatment, and overlying subretinal fluid. (B) Early phase of fluorescein angiogram shows area of classic CNV, scar from prior laser treatment, and irregular elevation of RPE with stippled hyperfluorescence representing fibrovascular pigment epithelial detachment (PED) inferior and temporal to the scar. (C) Photograph of the same eye 1 min after fluorescein injection. Note fluorescein leakage already apparent from classic CNV and increased intensity of stippled hyperfluorescence corresponding to fibrovascular PED. The boundaries of the fibrovascular PED remain well demarcated. (D) Angiogram taken 10 min after fluorescein injection shows persistence of fluorescein staining and leakage within a sensory retinal detachment overlying the lesion. It is difficult to determine the precise demarcation of fluorescence outlining the elevated RPE from these photographs alone. Although a fairly well-demarcated border can be seen in (C), the intensity of fluorescence at the boundary of elevated RPE is quite irregular in these late-phase photographs, with some areas fading relative to fluorescence of remaining areas of elevated RPE (D). (E,F) Composite drawings using multiple stereoscopic photographs from angiogram show

interpretation of the boundaries of the lesion. At each clock-hour, the boundary of the lesion is clearly demarcated; the lesion included classic CNV, which occupies the foveal center. (Reproduced with permission from Macular Photocoagulation Study Group. Subfoveal neovascular lesions in age-related macular degeneration: guidelines for evaluation and treatment in the Macular Photocoagulation Study. Arch Ophthalmol 1991;109:1242-57.)

**FIG. 69.9** Occult choroidal neovascularization (CNV) accompanied by classic CNV. (A) Subretinal fluid and hemorrhage in eye with drusen. (B) Early phase of fluorescein angiogram shows both feeder vessels to classic CNV and fibrovascular pigment epithelial detachment (PED). Blocked fluorescence due to thick blood obscures inferior boundary of occult CNV. (C) Mid-phase stereoscopic photographs of angiogram show leakage from classic CNV. (D) Late phase of angiogram shows other areas of late leakage of undetermined source with no discernible, discrete,

well-demarcated area of hyperfluorescence from classic CNV or fibrovascular PED detectable in early or mid-phase frames of angiogram that might be considered a source of late leakage. This lesion is considered poorly demarcated. (Reproduced with permission from Macular Photocoagulation Study Group. Subfoveal neovascular lesions in age-related macular degeneration: guidelines for evaluation and treatment in the Macular Photocoagulation Study. Arch Ophthalmol 1991;109:1242–57.)

## Other Terms Relevant to Interpreting Fluorescein Angiography of Choroidal Neovascularization

It is important to distinguish between what are termed the “lesion” and the various “lesion components” of which the lesion is composed when discussing fluorescein interpretation and treatment of CNV.<sup>27,58,59</sup> A lesion component may be described as classic or occult CNV or any of four angiographic features that could obscure the boundaries of classic or occult CNV. These four features include (1) blood that is visible on color fundus photographs and thick enough to obscure the normal choroidal fluorescence; (2) hypofluorescence due to hyperplastic pigment or fibrous tissue, or blood not visible on color fundus photographs; (3) a serous detachment of the RPE (Fig. 69.10); and (4) scar from CNV which either stains or blocks fluorescence (depending on the extent of RPE within the scar). The first two of these four features block the angiographic view of the choroid, making it impossible to determine whether CNV is located in the area of this component. The bright, reasonably uniform, early hyperfluorescence associated with a serous detachment of the RPE (described later) may obscure hyperfluorescence from classic or occult CNV and therefore interfere with the ability to judge whether CNV extends under the area of the serous detachment. The term “lesion,” again, refers to the entire complex of lesion components.

**FIG. 69.10** Fluorescein angiogram of serous retinal pigment epithelial detachment. (A) Early transit phase of a fluorescein angiogram demonstrates uniform fluorescence under the dome of the detachment. Note the deformation of the otherwise round detachment by a notch of the hyperfluorescence (*arrow*). (B) Later phase of the fluorescein angiogram demonstrates persistent hyperfluorescence that does not extend beyond the margins of the hyperfluorescence seen in the early transit phase. (Reproduced with permission from Bressler NM, Bressler SB, Fine SL. Age-related macular degeneration. *Surv Ophthalmol* 1988;32:375–413.)

The terms “well-defined” (synonymous with well-demarcated) and “poorly defined” (synonymous with poorly demarcated or ill-defined) refer to a description of the boundaries of the entire lesion (not of individual lesion components). In a well-defined lesion, the entire boundary for 360° is well demarcated (for example, [Figs. 69.6](#), [69.11](#) and [69.12](#)). If the entire boundary is not well demarcated for 360°, then the lesion is poorly defined (for example, [Fig. 69.9](#)). Thus the terms well-defined and classic should not be used interchangeably, nor should poorly defined and occult.

**FIG. 69.11** Classic and occult choroidal neovascularization (CNV) and elevated blocked fluorescence (EBF) with well-demarcated borders. (A) Recurrent subfoveal CNV. Note small area of hemorrhage temporal to recurrence. (B) Early phase of fluorescein angiogram shows sharp demarcation of hyperfluorescence of classic CNV. (C) Mid-phase photograph of angiogram with fluorescein leakage from classic CNV and sharply demarcated hyperfluorescence of elevated retinal pigment

epithelium due to fibrovascular pigment epithelial detachment and indicative of occult CNV. EBF still obscures choroidal fluorescence and possibly the inferior boundary of CNV. (D) Late phase of angiogram demonstrates fluorescein leakage from both classic and occult neovascularization. Note hardly discernible EBF. (E) Composite drawing using multiple stereoscopic photographs of angiogram shows interpretation of boundaries of lesion. Since each lesion component (classic CNV, occult CNV, blood, and EBF) has well-demarcated boundaries, boundaries of entire lesion are considered well demarcated. (Reproduced with permission from Macular Photocoagulation Study Group. Subfoveal neovascular lesions in age-related macular degeneration: guidelines for evaluation and treatment in the Macular Photocoagulation Study. Arch Ophthalmol 1991;109:1242-57.)

**FIG. 69.12** (A) Subfoveal choroidal neovascularization

(CNV) and contiguous blood. (B) Early phase of fluorescein angiogram shows classic CNV with blocked fluorescence corresponding to contiguous blood that obscures boundaries of CNV along temporal border.

Remaining blocked fluorescein surrounding CNV (elevated when viewed stereoscopically) was probably due to the fibrous component of CNV. (C) Late phase of fluorescein angiogram demonstrates that borders of CNV, blood, and elevated blocked fluorescence (green, red, and blue, respectively) in (D) were derived from viewing the entire stereoscopic fluorescein angiogram taken according to study protocol. (D) Drawing demonstrates that combined areas of blood and elevated blocked fluorescence that obscured borders of CNV did not exceed area of visible CNV.

Subfoveal neovascular lesions in age-related macular degeneration: guidelines for evaluation and treatment in the Macular Photocoagulation Study. Arch Ophthalmol 1991;109:1242–57.)

The term “predominantly CNV” indicates that at least 50% of the lesion is composed of either classic CNV or occult CNV, or both, while the term “predominantly hemorrhagic” indicates that at least 50% of the lesion is composed of hemorrhage.<sup>58,59</sup> These terms remain critical in the management of AMD, since treatments for CNV with anti-VEGF therapy, or less frequently, with laser photocoagulation, photodynamic therapy (PDT), or surgery, have been tested only in lesions that are predominantly CNV or predominantly hemorrhagic. After determining whether a lesion's composition is predominantly CNV, it should be determined whether the lesion is predominantly classic, rather than minimally classic or occult with no classic. If predominantly classic, then treatment could be considered with or without evidence of presumed recent disease progression (formally defined as evidence of blood associated with CNV, or definite visual acuity loss within 3 months, or definite growth of the lesion within 3 months). Treatment of minimally classic or occult with not classic lesions has only been demonstrated formally to be beneficial compared with no treatment with evidence of presumed recent disease progression. A therapeutic trial of anti-VEGF therapy might be considered in the setting of visual acuity loss and intraretinal or subretinal fluid

judged to be contributing to this visual acuity loss and judged likely to resolve following initiation of anti-VEGF therapy.

## Retinal Pigment Epithelium Detachments in Age-Related Macular Degeneration

Various changes in an eye with AMD may result in elevation or detachment of the RPE, as seen on stereoscopic biomicroscopic or angiographic evaluation. The term RPE detachment or retinal pigment epithelial detachment (retinal PED) secondary to AMD in the ophthalmic literature remains confusing because various RPE detachments may have quite different compositions, fluorescein angiographic appearances, prognoses, and management.

Fortunately, these various RPE detachments can usually be differentiated on the basis of fluorescein angiographic patterns of fluorescence. The patterns include the following: (1) fibrovascular PEDs,<sup>27</sup> a subset of occult CNV (see [Figs. 69.8](#) and [69.9](#)); (2) serous detachments of the RPE<sup>61</sup> (see [Fig. 69.10](#)); (3) hemorrhagic detachments of the RPE, in which blood from a choroidal neovascular lesion is noted beneath or exterior to the RPE (see [Fig. 69.3](#)); and (4) drusenoid RPE detachments,<sup>28</sup> in which large areas of confluent, soft drusen are noted. Fibrovascular PEDs show a stippled fluorescence along the surface of the RPE by the middle phase of the angiogram and may show pooling of dye in the overlying subsensory retinal space in the late phase (see [Fig. 69.8](#)). Serous PEDs in contrast, show uniform, bright hyperfluorescence in the early phase, with a smooth contour to the RPE by the middle phase, and little, if any, leakage at the borders of the PED by the late phase (see [Fig. 69.10](#)). The fluorescent pattern of a serous PED obscures the ability to determine whether classic or occult CNV exists within or beneath the area of the serous PED.

A hemorrhagic detachment of the RPE will block choroidal fluorescence because of the mound-like collection of blood beneath the RPE (see [Fig. 69.3](#)). Occasionally a hemorrhagic detachment of the RPE may be mistaken for a choroidal melanoma, but usually hemorrhagic detachments of the RPE do not demonstrate the low internal reflectivity on A-scan ultrasonography characteristically seen in choroidal melanomas. Finally, a drusenoid RPE

detachment<sup>26</sup> represents extensive areas of large, confluent drusen. Drusenoid RPE detachments can be distinguished from serous detachments of the RPE since the former fluoresce faintly during the transit and do not progress to bright hyperfluorescence in the late phase of the angiogram. In addition, drusenoid RPE detachments will usually have a less smooth, less distinct boundary compared with serous RPE detachments. Drusenoid RPE detachments can be distinguished from fibrovascular PEDs by their lack of stippled hyperfluorescence and lack of persistent staining or leakage in the late phase of the angiogram. RPE detachments due to large, soft, confluent drusen are usually smaller, shallower, and more irregular in outline than are fibrovascular PEDs. In addition, the drusenoid RPE detachments often have reticulated pigment clumping overlying the large, soft, confluent drusen, a scalloped border, and have less fluorescence in late-phase frames as compared with earlier-phase frames.

## Other Angiographic Features

### Speckled Hyperfluorescence

Speckled fluorescence (Fig. 69.13A) in the absence of fluorescein leakage consists of several punctuate spots of hyperfluorescence, usually within 500  $\mu\text{m}$  of each other that are apparent between 2 and 5 minutes after fluorescein injection and cannot be detected in early phase frames in contrast to drusen.<sup>56</sup> The fluorescence of these spots persists or increases in intensity by the late phase of the angiogram (Fig. 69.13B), in contrast to drusen or atrophy of the retinal pigment epithelium, which do not remain brightly hyperfluorescent by the late phase of the angiogram. Typically, clusters of speckles appear at the edge of the CNV lesion, rather than the typical distribution of drusen throughout the macular area. This angiographic feature was previously reported to be associated with recurrent CNV.<sup>56</sup> If speckled hyperfluorescence is noted in the presence of fluorescein leakage in the late phase frames in the absence of elevation of the RPE, this would be considered occult CNV.

**FIG. 69.13** (A,B) Example of speckled fluorescence noted in an eye with choroidal neovascularization. Multiple punctuate spots of hyperfluorescence within 500  $\mu\text{m}$  of each other are apparent in a late phase frame (B) but cannot be detected in early phase frame (A). Note the typical appearance of clusters of speckles at the edge of the CNV lesion. (© Neil M. Bressler, MD, Johns Hopkins University, 2011.)

### **Retinal Lesion Anastomosis (“Retinal Angiomatous Proliferans,” “RAP Lesion,” or “Chorioretinal Anastomosis”)**

Retinal vessels can anastomose with CNV from AMD.<sup>62</sup> The vessels can be seen dividing at right angles from the surface of the retina to the neovascular lesion (as may be seen with idiopathic parafoveal telangiectasis). These vessels may also be seen in the setting of disciform scarring. Some descriptions of these vessels have suggested that they can develop prior to the development of CNV (as is seen in the subretinal neovascularization that can develop in an individual with idiopathic parafoveal telangiectasis).

Theoretically, these descriptions seem plausible if sufficient VEGF production, which typically would be involved in the development of CNV, first led to the development of proliferation of retinal capillaries. However, there is no evidence that these vessels develop in the absence of CNV from AMD on histopathology. Furthermore, most cases show evidence of CNV in the presence of these

anastomoses of retinal vessels with the neovascular lesion, and those cases that do not show obvious CNV often have difficult angiograms to interpret to state with certainty that CNV is not present. The area of anastomosis, when noted before development of extensive visible scar tissue, often shows a bright area of fluorescence in the early phase, occasionally accompanied by a small area of intraretinal hemorrhage. While some reports have suggested that the natural history of lesions with these anastomoses is worse than the natural history without these anastomoses, there is no strong evidence to support this impression at this time.

### **Loculated Fluid**

This fluid consists of a well-demarcated area of hyperfluorescence that appears to represent pooling of fluorescein in a compartmentalized space anterior to the choroidal neovascular leakage, usually seen in the late phase of the angiogram.<sup>63</sup> Although the loculated fluid may conform to a pattern of typical cystoid macular edema, it can also pool within an area deep to the sensory retina in a shape that does not bear any resemblance to cystoid macular edema.

### **Retinal Pigment Epithelial Tears**

RPE tears have a characteristic fluorescein angiographic appearance.<sup>64</sup> The denuded RPE displays marked early hyperfluorescence. Later, staining of the choroid and sclera may be observed, but fluorescein generally does not leak from the denuded area. The folded pigment epithelial mound blocks fluorescence; however, this area may leak later during the angiogram, presumably from underlying CNV. Tears may occur following development of a serous PED in the absence of CNV. In addition, tears may occur following development of CNV, sometimes accompanied by large areas of hemorrhage. Tears in any of these situations may occur without any antecedent treatment or may occur soon after treatment, and need not preclude further therapy out of concern for worsening the tear.<sup>42</sup>

### **Disciform Scars**

Fibrovascular scars frequently hyperfluoresce from both fluorescein leakage and staining. Hypofluorescence due to blocking may also be observed if there is an RPE pigmentary reaction.

## Indocyanine Green Angiography

Indocyanine green (ICG) is a dye that is more highly protein-bound than sodium fluorescein and that fluoresces in the near-infrared wavelength. These properties have been suggested to be useful in the evaluation and management of CNV (see [Chapter 2](#), Indocyanine green angiography). Three basic patterns of fluorescence have been reported in ICG angiography (ICGA) of CNV judged to be occult on FA: a small, focal “hot spot” (a bright area of fluorescence more than one disc area that usually shows by the mid-phase of the angiogram), a plaque (a well-demarcated area of fluorescence more than one disc area in size that emerges relatively late in the angiogram), and ill-defined fluorescence.<sup>65,66</sup> Several types of lesions defined by the EVEREST study group as indicative of polypoidal choroidal vasculopathy (a pattern of CNV, just as classic and occult CNV are patterns of CNV on fluorescein angiography) including nodular polyps on stereo viewing, hypofluorescent halo around nodules, abnormal vascular channel supplying polyps, pulsatile filling of polyps, and orange subretinal nodules corresponding to hyperfluorescent polyps on angiogram.<sup>67</sup> PCV also typically is accompanied by multifocal areas of RPE abnormalities, similar to, or perhaps sometimes due to, underlying features of central serous choroidopathy.<sup>68</sup> PCV also shows multifocal areas of CNV, often outside of the posterior pole, accompanied by multifocal areas of PED, sometimes with breakthrough vitreous hemorrhage.<sup>69</sup> However, to date, it has not been demonstrated that detection or characterization of these lesions by ICG has a beneficial effect on patient outcomes in EVEREST, and additional studies such as PLANET (<https://clinicaltrials.gov/ct2/show/NCT02120950>) and EVEREST 2 (<https://clinicaltrials.gov/ct2/show/NCT01846273>) are awaited. Until carefully designed, randomized clinical trials are conducted that show that ICG-guided therapy of AMD-related CNV (that escaped detection by clinical examination, FA, and OCT), with or without

patterns of PCV, result in a better visual outcome than no treatment, one cannot know for sure if this particular diagnostic intervention or recognition of this pattern of CNV with or without ICGA is beneficial.<sup>70</sup> The role of ICGA in the setting of polypoidal choroidal vasculopathy patterns of CNV also is discussed further in [Chapter 74](#) (Polypoidal choroidal vasculopathy).

## Pathogenesis

### Choroidal Neovascularization

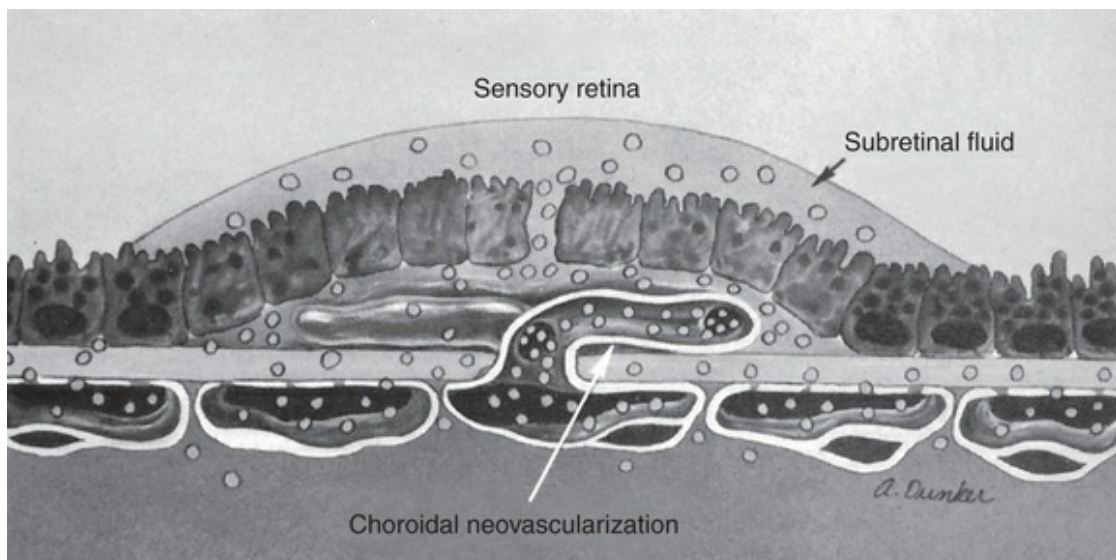

#### Histopathology

CNV appears as a neovascular sprout growing under or through the RPE via breaks in Bruch's membrane<sup>20</sup> (Figs. 69.14 and 69.15). Usually this occurs in association with evidence of fibroblasts, myofibroblasts, lymphocytes, and macrophages.<sup>71</sup> Various growth factors are suspected to be involved in the development of this CNV, such as vascular endothelial growth factor (VEGF).<sup>72</sup> It is clear, though, there are other factors involved, since diseases such as diabetic macular edema and macular edema due to retinal vein occlusion respond to VEGF blockade, but do not develop CNV. Following penetration of the inner aspect of Bruch's membrane, the new vessels proliferate laterally between the RPE and Bruch's membrane.<sup>20</sup> As these neovascular twigs mature, they develop a more organized vascular system stemming from a trunk of feeder vessels off the choroid, as well as proliferation of fibrous tissue. The endothelial cells in the arborizing neovascular tufts lack the barrier function of more mature endothelial cells. Hence these new vessels can leak fluid (and fluorescein) in the neurosensory, subsensory, and RPE layers of the retina. Proteins and lipids may accompany this process and precipitate in any layer of the retina. In addition, the fragile vessels are prone to hemorrhage. Occasionally, blood may extend through all the layers of the retina, breaking through into the vitreous cavity. Ultimately, in the absence of treatment, a fibrovascular scar results, usually causing disruption and death of the overlying sensory retinal tissue accompanied by severe visual loss.

## Associated Factors

The stimulus for vascular ingrowth of choroidal vessels remains unknown, but several theories have been advanced. Soft drusen have been associated histopathologically with CNV. The soft drusen represent focal accumulation of membranous debris (ultrastructurally termed basal linear deposits) accumulated as a diffuse, shallow layer between the RPE basement membrane and the inner aspect of Bruch's membrane.<sup>19,20,22,73-78</sup> This material should not be confused with basal laminar deposit, which is material that collects between the RPE plasma membrane and the basement membrane of the RPE and accumulates with age but may not lead to vision loss from CNV or geographic atrophy and therefore may not be part of AMD.<sup>73,74</sup> The term should also not be confused with basal laminar drusen, also called cuticular drusen, which usually present in midlife with a myriad of small, translucent drusen that appear like a starry sky on a fluorescein angiogram and may be associated with vitelliform macular detachments, as discussed below.<sup>3,79</sup> Some investigators believe that soft drusen represent extracellular matrix material produced by the RPE.<sup>73,80</sup> Deposition of this material may suggest a widespread RPE abnormality.<sup>73</sup> The diffusely thickened area is weakly attached, allowing the development of localized detachments seen clinically as soft drusen. These localized detachments can coalesce into larger drusenoid or serous RPE detachments.<sup>22</sup> Alternatively, drusen may act as an indirect angiogenic factor by attracting macrophages from the choroid.<sup>71</sup>

Breaks in Bruch's membrane permit ingrowth of new vessels from the choriocapillaris. However, these breaks can also be seen without ingrowth of choroidal new vessels. Some investigators have suggested that endothelial cells of growing CNV may actually produce the break in Bruch's membrane rather than grow through preexisting breaks in Bruch's membrane.<sup>81</sup> An inflammatory component seen in association with AMD may play a role in the development of CNV.<sup>82</sup> Eyes with AMD show an increased prevalence of lymphocytes, fibroblasts, and macrophages within Bruch's membrane as compared with control eyes without AMD. However, these findings are not specific to eyes with neovascular AMD.<sup>82,83</sup> The presence of macrophages and lymphocytes near

breaks in Bruch's membrane suggests that leukocytes may be involved in the induction of CNV growth and the release of collagenases from endothelial cells. It is postulated that leukocytes may initially stimulate neovascular proliferation, promote the release of factors leading to breakdown of Bruch's membrane, and even affect (with pericytes) the dilation of new vessels.<sup>84</sup> Whether these inflammatory cells act as mediators of the degenerative changes seen in Bruch's membrane or directly stimulate new vessel growth remains unknown. Finally, as mentioned above, other angiogenic factors, such as VEGF or a platelet-derived growth factor (PDGF),<sup>72,85,86</sup> may contribute to the ingrowth of new vessels from the choroid through Bruch's membrane into the sub-RPE space. Growth factors leading to neovascular formation may arise from an imbalance between stimulating and inhibiting chemical modulators. The RPE has been implicated as the source of these factors, but RPE cells may also act indirectly through the attraction of macrophages.<sup>87</sup>

## Differential Diagnosis by Clinical Presentation

### Choroidal Neovascularization

CNV may arise in association with a number of conditions other than AMD, such as presumed ocular histoplasmosis syndrome, pathologic myopia, angioid streaks (especially when associated with pseudoxanthoma elasticum), choroidal ruptures, and idiopathic causes. Whether AMD is present when CNV arises in patients older than 50 years without drusen is controversial.

CNV may masquerade as central serous chorioretinopathy (CSR). Although the classic case of CSR shows a “smokestack” configuration on FA, the more common presentation is a dot of hyperfluorescence that merely increases in size and intensity of fluorescence, much like a small area of CNV. One must strongly consider CNV in patients aged 50 and older who have even otherwise typical-appearing CSR, since the latter condition is most often seen prior to the fifth decade of life.

Basal laminar, or cuticular, drusen may be complicated by foveal

detachments of vitelliform material in one or both eyes that may mimic neovascular AMD. Contact lens examination with transillumination of the fundus in these cases reveals an appearance similar to that of pigskin, with a myriad of small drusen. Angiographically, literally hundreds of bright spots appear very early during the angiogram, an appearance that has been described as a “starry sky.” These patients are usually asymptomatic until they accumulate vitelliform lesions in the fovea. The ensuing foveal detachment by this material, which can be unilateral or bilateral, simulates the foveal detachment that occurs with subfoveal CNV. The hyperfluorescence usually progressively fills the area of vitelliform material, rather than showing one area of bright fluorescence early that leaks late in classic CNV. Unlike subfoveal CNV, which most often progresses to a disciform scar with visual acuity of 20/200 or worse, eyes with a foveal detachment secondary to cuticular drusen resolve without scarring. While the retina then may have an area of RPE atrophy about one to two disc areas in size, acuity is more often in the range of 20/80 to 20/125.

When one identifies any condition with a vitelliform detachment, it is critical to determine if the late-phase bright fluorescence is progressive fluorescein staining of the vitelliform material or leakage of fluorescein from CNV, which might benefit from initiating therapy. Pattern dystrophies of the RPE may also cause vitelliform detachments in which the angiographic pattern can mimic CNV. It is important to recognize that patients with cuticular drusen or pattern dystrophy can still develop typical drusen associated with AMD or actual CNV.

## Vitreous Hemorrhage

If a new patient has vitreous hemorrhage (VH) in one eye and signs of AMD in the other eye, other causes of vitreous hemorrhage must first be ruled out. Common causes of VH include retinal tear formation and retinal vascular diseases such as diabetic retinopathy or branch vein occlusion. Ultrasonography can often differentiate breakthrough VH secondary to neovascular AMD or retinal vascular causes from VH caused by a tumor (Fig. 69.16).

**FIG. 69.16** Ultrasound image of a vitreous hemorrhage associated with neovascular age-related macular degeneration in which a relatively flat and broad-based posterior pole lesion (*arrow*) with a fairly homogeneous pattern and with no choroidal excavation seen.

## Natural History

Most prospective natural history data of CNV comes from control (untreated) groups of individuals participating in randomized clinical trials conducted prior to the anti-VEGF era. As such, the natural-history information is specific to the eligibility criteria of those trials and not reflective of the natural history of the universe of choroidal neovascular lesions in the population. With this caveat in mind, the natural history from these trials is reviewed to provide some evidence regarding the outcome of these lesions without treatment. In the Macular Photocoagulation Study (MPS), approximately 50–60% of untreated eyes lost 6 or more lines of vision over 2–3 years.<sup>34,35,88–91</sup>

A broader group of subfoveal lesions in the Treatment of Age-related macular degeneration with Photodynamic therapy (TAP) investigation described a slightly better prognosis with approximately 50–60% losing 3 or more lines after 2 years and 20–30% losing 6 or more lines of visual acuity.<sup>83,92</sup> With increasing size

of predominantly classic lesions on presentation, the average visual acuity is more likely to be worse by 2 years.<sup>93</sup>

A variety of studies have shown that cases of predominantly CNV with a composition that is occult with no classic CNV, or minimally classic CNV, have a more heterogeneous outcome.<sup>93-99</sup> Most of this information is from series in clinical trials with presumed recent disease progression. Some cases may remain stable for years without visual loss, whereas other cases may develop severe visual loss at a rate similar to the deterioration noted for cases of classic CNV only. Furthermore, increasing size of minimally classic or occult with no classic lesions is not associated with a worse natural history outcome.<sup>93</sup>

Up to 50% of the cases with no classic CNV may develop classic CNV within a year of presentation.<sup>94-96,100</sup> Cases that develop some classic CNV may be more likely to have severe visual acuity loss.<sup>95,96,100</sup> Results from several clinical trials suggest that the natural history of lesions with classic CNV but no occult CNV is worse than the natural history of lesions with classic and occult CNV or occult with no classic CNV.<sup>96,98,101</sup> It is likely that the natural history of lesions with classic and occult CNV may lie somewhere between the natural course of lesions with classic CNV only and occult CNV only.<sup>96</sup>

## Natural Course of Large Subfoveal Subretinal Hemorrhage in AMD

Some eyes with subfoveal subretinal hemorrhage associated with AMD have poor outcomes. However, the visual acuity of other eyes does not deteriorate or may improve spontaneously.<sup>102-104</sup> Such findings underscore the importance of carefully evaluating the risks of therapeutic interventions for these cases, such as surgery<sup>105,106</sup> to remove subretinal hemorrhage and associated CNV, in randomized clinical trials.<sup>107</sup> The SST Group B Trial of relatively large, predominantly hemorrhagic subfoveal lesions demonstrated that although 36% of untreated eyes had severe visual loss, 41% of untreated eyes remained stable or improved over the course of 24 months of follow-up in the study.<sup>29</sup> Furthermore, this trial noted that 18% of large subfoveal subretinal hemorrhages progressed to a

vitreous hemorrhage as blood dissected from the subretinal space through the retina and into the vitreous cavity.<sup>36</sup>

## Retinal Pigment Epithelial Tears

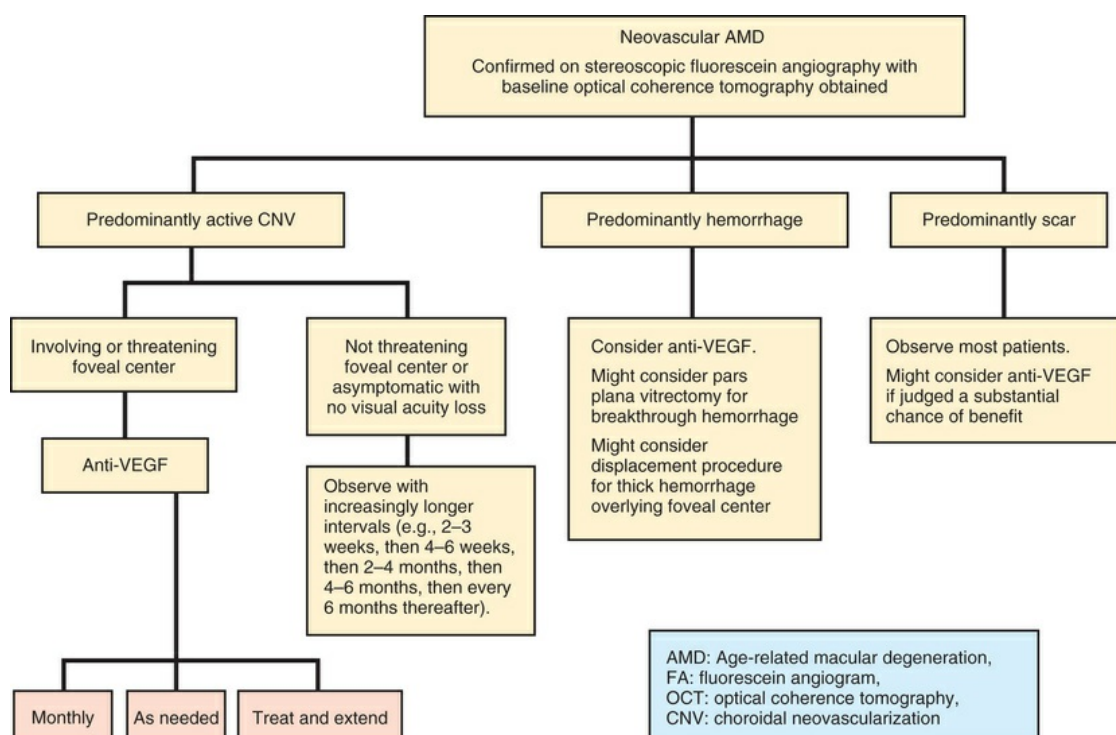

Patients with RPE tears involving the foveal center may initially maintain good vision but usually develop severe visual loss. However, cases with RPE tears through the fovea and preservation of good visual acuity have been reported.<sup>108</sup> Unfortunately, there is a substantial risk of AMD-related visual loss in the fellow eye. Schoeppner and associates<sup>109</sup> reported a cumulative risk of visual loss in the fellow eye of patients who had an RPE tear in the eye as 37% at 1 year, 59% at 2 years, and 80% at 3 years of follow-up. Visual loss usually arose from development of a PED, RPE tear, or CNV.

## Treatment

### Pharmacologic Therapy With Anti-VEGF Products and Overall Management Approach to CNV in AMD

A current approach to neovascular AMD is summarized in [Fig. 69.17](#).<sup>113</sup> Based on the results from several clinical trials evaluating anti-VEGF therapies for CNV in AMD,<sup>50,51,86,110,111</sup> and a Cochrane systematic review of the literature,<sup>112</sup> a current approach to management of subfoveal CNV in AMD in which the CNV is the predominant component (that is, the area of any classic CNV plus any occult CNV is at least 50% of the area of the lesion) is summarized in [Fig. 69.18](#). The retreatment criteria used in trials of discontinuous therapy are reviewed in [Table 69.1](#). The closer the lesion features resemble those of the cases enrolled in these trials, the more likely the results of those trials apply to those cases. The more the treatment regimen resembles the regimen followed in these trials, the more likely the results for patients will follow the results noted in the trials. For lesions that are predominantly scar or predominantly a serous PED, it is unknown if any treatment is beneficial. For lesions that are predominantly hemorrhagic (area of

blood at least 50% of the area of the lesion), anti-VEGF therapy might be considered to reduce the risk of additional severe visual acuity loss, although it is not known if such therapy might increase the chance of visual acuity improvement compared with no treatment.<sup>114,115</sup> The results of prospective case series<sup>114</sup> have suggested that the risk of substantial visual loss or breakthrough of hemorrhage into the vitreous is reduced with anti-VEGF therapy for these lesions, and the CATT investigation included some lesions in which the lesion was predominantly hemorrhagic.<sup>50</sup>

Pegaptanib sodium (Macugen®) was the first FDA-approved intravitreal anti-VEGF injection for neovascular AMD. While the initial trial results showed decreased loss of vision compared with PDT, this anti-VEGF therapy largely has been replaced based on the more favorable results utilizing 0.5-mg ranibizumab (Lucentis®),<sup>86,110</sup> repackaged or compounded 1.25-mg bevacizumab (Avastin®),<sup>50,51</sup> and aflibercept (EYLEA®).<sup>111</sup>

## Efficacy of Ranibizumab vs. PDT With Verteporfin for Predominantly Classic Subfoveal CNV Lesions

Trial participants in the ANCHOR study had CNV lesions that were predominantly classic CNV (at least 50% of the total area of the lesion was classic CNV).<sup>110</sup> Unlike eligibility requirements for the MARINA study (see following section), participants were not required to have presumed recent disease progression (usually defined as presence of blood, documented recent loss of visual

acuity, or documented recent growth of the CNV lesion). Participants in the experimental group received ranibizumab monthly for 24 months.

Mean visual acuity letter score at baseline was 47.1 (approximate Snellen equivalent of 20/125<sup>+2</sup>) in the 0.5-mg ranibizumab group. For the primary outcome (visual acuity decline of fewer than 15 letters from baseline at 12 months, an amount judged clinically relevant for a patient who might present with an average visual acuity of 20/80 to 20/100 from neovascular AMD), 96.4% of the 0.5-mg group ( $n=140$ ) and 64.3% of the verteporfin group ( $n=143$ ) avoided this loss ( $p<.001$ ).<sup>110</sup> These outcomes were maintained at 24 months for most subjects, with 89.9% of the 0.5-mg group and 65.7% of the verteporfin group avoiding a loss of 3 lines or greater. Investigators also reported that visual acuity improved by 15 letters or more in 40.3% of the 0.5-mg group, as compared with 5.6% of the verteporfin group ( $p<.001$ ) at 12 months,<sup>110</sup> and 41.0% of the 0.5-mg group gained 3 or more lines of visual acuity versus only 6.3% of the verteporfin group at 24 months. Differences in the mean visual acuity from baseline visual acuity were noted as early as 1 month, when 8.4 letters of improvement occurred in the 0.5-mg ranibizumab group compared with 0.5 letters in the PDT group ( $p<.001$ ).<sup>110</sup> At 12 months, mean visual acuity improved by 11.3 letters in the 0.5-mg ranibizumab group but decreased by a mean of 9.5 letters in the verteporfin group ( $p<.001$ ).<sup>110</sup> At 24 months, mean visual acuity improved by 10.7 letters in the 0.5-mg ranibizumab group but decreased by 9.8 letters in the verteporfin group.

Although PDT produced outcomes that likely were better than the natural course of the disease, the 24-month data reinforced the conclusions of the 12-month data previously published and indicated that the increased chance of avoiding 15 or more letter loss and of gaining 15 or more letters with monthly intravitreal ranibizumab persisted through at least 2 years compared with standard applications of PDT.

## **Efficacy of Ranibizumab vs. Sham Treatment for Minimally Classic or Occult With No Classic Subfoveal Choroidal Neovascular**

## Lesions and Presumed Recent Disease Progression

In a phase III, double-blind, sham-controlled, randomized clinical trial, eligibility criteria included subfoveal CNV with lesion composition on FA that was minimally classic or occult with no classic component accompanied by presumed recent disease progression.<sup>86</sup> Mean visual acuity letter score at baseline was 53.7 ( $20/80^{-1}$ ) in the 0.5-mg ranibizumab group.<sup>86</sup> Using the primary outcome of visual acuity decline of fewer than 15 letters from baseline as a measure of efficacy, 94.6% of those in the 0.5-mg ranibizumab group and 62.2% of those in the sham-injection group met the primary goal ( $p<.001$ ) after 12 months of treatment.<sup>86</sup> At 24 months, 90.0% of those in the 0.5-mg ranibizumab group and 52.9% of those in the sham-injection group met the primary goal ( $p<.001$ ).<sup>55</sup>

At 12 months, visual acuity improved by 15 or more letters in 33.8% of the 0.5-mg ranibizumab group, as compared with 5% of the sham-injection group ( $p<.001$ ).<sup>86</sup> Participants in the 0.5-mg ranibizumab group achieved mean increases in visual acuity of 7.2 letters, whereas the sham-injection group lost an average of 10.4 letters ( $p<.001$ ).<sup>86</sup> At 24 months, participants in the 0.5-mg ranibizumab group gained a mean of 6.6 letters of visual acuity, compared with a mean loss of 14.9 letters in the sham-injection group ( $p<.001$ ).<sup>86</sup>

In addition to experiencing improvements in objectively measurable visual outcomes, at 12 and 24 months, patients treated with ranibizumab were more likely to improve with respect to self-reported vision-related quality of life (QOL),<sup>23,116,117</sup> regardless of whether the better- or worse-seeing eye was treated. This information is complementary to the visual acuity outcomes described above because although most physicians and patients make decisions based on functional parameters such as a patient's ability to read, watch television, and avoid dependence on others because of vision, the primary outcome measure in most recent trials evaluating treatments for neovascular AMD has been visual acuity in the treated eye.<sup>86,110</sup> Although changes in visual acuity on an eye chart are important in understanding treatment effects, measures of visual acuity do not always completely capture the

degree of visual function. Clinicians may assume that visual function or patient's perception of visual function improves along with visual acuity; however, this is not always the case.<sup>118</sup> Among MARINA participants, scores on the National Eye Institute Visual Function Questionnaire-25 (NEI VFQ-25) relating to activities that require both near vision (such as sewing) and distance vision (such as watching television) were more likely to improve by 10 or more points, a clinically relevant amount, in the ranibizumab group than in the sham-injection group ( $p < 0.001$ ).<sup>116</sup> In addition, ranibizumab-treated patients were less likely to perceive themselves as being dependent on others because of their vision.<sup>116</sup> Similar results were confirmed in the ANCHOR trial.

## Impact of Noninferiority Results on the Role of Aflibercept or Bevacizumab and on Frequency of Treatment

The Comparison of Age-related Macular Degeneration Treatments Trial (CATT) protocol<sup>50,51</sup> was designed to answer two important questions relevant to treatment of CNV in AMD: (1) does bevacizumab injected every 4 weeks provide visual acuity results which are not worse (strictly speaking, which are noninferior) to ranibizumab injected every 4 weeks with an acceptable safety profile; and (2) does either bevacizumab or ranibizumab when provided “as needed” result in visual acuity outcomes equivalent to those following ranibizumab provided every 4 weeks? Here, “as needed” means that an initial injection is given with subsequent examinations of the eye every 4 weeks through 2 years; reinjection is given at the time of any examination at which any disease activity is noted. Activity includes subretinal or intraretinal fluid or thickening on OCT, new or persistent hemorrhage from CNV, persistent fluorescein leakage from CNV or growth of CNV on fluorescein angiography, or visual acuity loss since the most recent injection.

The major outcomes during the first year which are relevant to these important questions included the following: (1) visual acuity outcomes when using bevacizumab every 4 weeks were not worse (noninferior) to those when using ranibizumab every 4 weeks; (2)

visual acuity outcomes when using ranibizumab as needed, based on examinations every 4 weeks, were equivalent to those when ranibizumab was given every 4 weeks; (3) visual acuity outcomes when bevacizumab as needed was compared with ranibizumab every 4 weeks were inconclusive, i.e., possibly not worse but also possibly inferior; (4) CATT participants assigned to ranibizumab as needed received an average of approximately seven treatments in the first year and those assigned to bevacizumab as needed received an average of approximately eight treatments, a difference that likely was real but likely not clinically relevant given the total number of injections given over 2 years; (5) although no difference between ranibizumab and bevacizumab participants was identified with respect to proportions of participants who had myocardial infarction, cerebrovascular accidents, or endophthalmitis, the combined bevacizumab groups had a higher rate of systemic serious adverse events (AEs) than the combined ranibizumab groups (24% for bevacizumab, 19% for ranibizumab) – of note, the point estimates for these systemic serious AEs was higher in the bevacizumab as-needed group than the bevacizumab every-4-weeks group, and the bevacizumab group might have been at greater risk based on slight imbalances in baseline characteristics in the bevacizumab group that favored the development of these serious systemic AEs; and (6) the average cost of drug per patient for the first year was \$23,400 in the ranibizumab every-4-weeks group, \$13,800 in the ranibizumab as-needed group, and \$595 in the bevacizumab every-4-weeks group. Two-year data confirmed that every-4-week bevacizumab was equivalent to ranibizumab, the increased risk of serious systemic AEs with bevacizumab was sustained, and the average visual acuity in both the bevacizumab-as-needed and ranibizumab-as-needed groups continued to decline from year 1 to year 2.<sup>49</sup> In summary, there were some efficacy and safety differences favoring ranibizumab over bevacizumab if costs are not a consideration for the individual patient, although the large cost differences make bevacizumab the more cost-effective regimen from a societal perspective or from the business perspective of an insurance company.

The HARBOR trial confirmed the validity of using an “as needed” approach with monthly monitoring, but considered

mainly OCT in the decision process regarding retreatment (“≥ 5-letter decrease in vision from the previous visit or any evidence of disease activity on SD-OCT (e.g., intraretinal fluid, subretinal fluid, or subretinal pigment epithelial fluid)<sup>119</sup>). In this study, subjects received ranibizumab monthly or “as needed” following a 3-month loading period. After 24 months, the mean gain in visual acuity was 9.1 letters in the monthly group, compared with 7.9 in the “as needed” group. HARBOR also explored the use of 2.0 mg ranibizumab for neovascular AMD, but found slightly lower mean visual acuity gains at this higher dose, and therefore no justification for going above the standard approved 0.5-mg dose.

The 1-year results from the IVAN trial comparing bevacizumab and ranibizumab, and continuous and discontinuous treatment<sup>120</sup> confirmed that the bevacizumab group appeared to have a slightly smaller mean gain in visual acuity at 1 year compared with the ranibizumab group (when combining both continuous and discontinuous treatment groups), and the discontinuous group (which required three consecutive monthly injections whenever treatment was resumed) appeared to have only a slightly smaller gain in mean visual acuity when compared with the continuous group (combining the ranibizumab and bevacizumab groups). Analysis of the 2-year follow-up data was likewise inconclusive with respect to noninferiority or inferiority of bevacizumab versus ranibizumab groups, and was also inconclusive with respect to continuous versus discontinuous therapy (equivalent after year 1).<sup>121</sup> Two important differences between this trial were that a noninferiority limit of 3.5 letters was used (in contrast with 5 letters in CATT), and comparisons between bevacizumab and ranibizumab regimens were pooled, such that comparisons of the “as needed” regimens of each agent were not made. Likewise, bevacizumab as needed was not compared with monthly ranibizumab, so the failure to confidently demonstrate noninferiority of as needed bevacizumab with monthly ranibizumab, observed in CATT, could not be confirmed or disproven in IVAN.

With the publication of the VIEW 1 and VIEW 2 results, another anti-VEGF agent, aflibercept, became available for the treatment of neovascular AMD. These trials confirmed that aflibercept given

every 4 weeks for three doses followed by every 8 weeks through 48 weeks gave equivalent outcomes to ranibizumab every 4 weeks.<sup>111</sup> Unlike ANCHOR and MARINA trials, the second year of these trials tested discontinuous therapy of each agent. Either aflibercept or ranibizumab was given at least every 12 weeks, as well as when retreatment was judged to be indicated based on clinical parameters, including OCT, as evaluated every 4 weeks. In the second year, a small decline in the average visual acuity for each group was seen. Because no head-to-head comparison with bevacizumab was done, prospective trial data cannot be used to comment on relative efficacy of bevacizumab with aflibercept in neovascular AMD. This question is of relevance since aflibercept, on average, has been shown to be superior to bevacizumab in a randomized clinical trial comparing them for diabetic macular edema involving the center of the macula when visual acuity was relatively impaired (20/50 or worse).<sup>122</sup> The treatment of diabetic macular edema is discussed in detail in [Chapter 50](#) (Nonproliferative diabetic retinopathy and diabetic macular edema).

## Safety of Anti-VEGF Therapy

Safety issues with anti-VEGF intravitreal injections include local ocular AEs from the drug or the injection, as well as potential systemic AEs of the drug. Ocular AEs may be categorized as common but not serious, and rare but potentially serious. AEs that are common but not serious include subconjunctival hemorrhage, vitreous floaters from medication or vitreous hemorrhage, and discomfort from antiseptic used to prepare the ocular surface before the injection. Endophthalmitis is a rare but potentially serious ocular AE that may develop after any intravitreal injection, regardless of what is being injected. Just how much preparation is necessary to minimize the development of postinjection infections is controversial. Based on data from the Diabetic Retinopathy Clinical Research Network, there is little evidence to support the need for pretreatment or posttreatment topical antibiotics.<sup>123</sup> Some clinicians use sterile gloves and drapes. All clinicians seem to agree that retraction of the eyelids with either a lid speculum or manual

retraction, and povidone iodine treatment for at least 30 seconds overlying the area to receive the injection, are recommended to minimize endophthalmitis risks. Other rare but serious ocular AEs include sterile inflammation, vitreous hemorrhage, retinal tear or detachment, and increased intraocular pressure, which in the ANCHOR and MARINA trials was listed as a serious AE (SAE) but might not always be considered an SAE by a treating ophthalmologist.

Systemic AEs from intravitreal anti-VEGF agents can be a theoretic, if not real, concern; VEGF inhibitors that cross into the general circulation can compromise functions that rely on VEGF outside of the eye, such as wound healing and the formation of new blood vessels around the heart or brain in cases of ischemia. Patients with AMD already are at higher risk of cardiovascular disease than the general population by virtue of their age, and patients with such risk were not systematically excluded from participating in these clinical trials. Consequently, participants in clinical trials of VEGF inhibitors were carefully monitored for possible increases in blood pressure, occurrence of myocardial infarction/stroke, and nonocular hemorrhages.

There was no evidence that ranibizumab 0.5 mg was associated with increases in either diastolic or systolic blood pressure in ANCHOR. In fact, treatment-related hypertension emerged in a larger proportion of PDT patients (12 of 143, or 8.4%) than among 0.5-mg ranibizumab patients (9 of 140, or 6.4%).<sup>110</sup> Among participants in the MARINA trial, approximately 16% in both the 0.5-mg ranibizumab and sham-injection groups developed hypertension.<sup>86</sup>

Nonocular hemorrhages include events such as cerebral or gastrointestinal bleeding. In the ANCHOR trial, nonocular hemorrhage was more frequent in the 0.5-mg ranibizumab group (6.4%) than in the PDT group (2.1%). In the MARINA trial, the cumulative frequency of nonocular hemorrhage by month 24 was 5.5% (13 of 236) in the sham-injection group, compared with 8.8% (21 of 239) in the 0.5-mg ranibizumab group.

With respect to cardiovascular or cerebrovascular events, during the ANCHOR trial, 1 subject in the PDT group (0.7%) and 3 subjects in the ranibizumab 0.5 mg group (2.1%) developed nonfatal

myocardial infarctions, although the events occurred at times that were unrelated to treatment. The frequency of stroke (1 in each group) and cerebral infarction (0 in each group) in the ANCHOR trial were too low to draw meaningful conclusions.

At 24 months, the overall frequency of cardiovascular systemic events in the MARINA trial was similar in the 0.5-mg ranibizumab and sham-injection groups. There were only small differences in the frequency of thromboembolic events between the sham-injection group (3.8%) and the ranibizumab 0.5-mg group (4.6%). The frequency of death (2.5%) was the same in the ranibizumab 0.5-mg and sham-injection groups. Two individuals in each group died of stroke. A pooled analysis of five of the ranibizumab clinical trials showed a trend for increasing risk of cerebrovascular accident (CVA) over 2 years, although a definitive risk could not be identified. The odds ratio for 0.5 mg ranibizumab versus control was 2.2 (95% confidence interval: 0.8–7.1), though among patients at high risk for CVA, the odds ratio was higher (7.7; 95% confidence interval 1.2–177, although if controlling for multiple analyses, or using a 99% CI because of the multiple analyses performed in this study, the confidence interval would cross 1.0, precluding one from determining with certainty if there was an increased risk among patients at high risk for CVA).<sup>124</sup>

A Cochrane systematic review on the systematic safety of ranibizumab and bevacizumab analyzed data from nine non-industry-sponsored studies (which included CATT and IVAN), including 3665 subjects.<sup>125</sup> The authors were not able to determine a difference between the agents for deaths, all serious systemic adverse events, or specific subsets of adverse events in the first 24 months of therapy, with the exception of gastrointestinal disorders. The authors did note heterogeneity of subjects across the included trials but concluded there was inadequate evidence to suggest that systemic safety should be used as a justification of policies mandating one anti-VEGF agent over another.<sup>125</sup> Although event rates for these cerebrovascular or cardiovascular events appear to be low with anti-VEGF agents, ophthalmologists should discuss the theoretic potential for these risks, since only a moderate or large difference in event rates, not a small difference, has been ruled out from the current literature.

Since ranibizumab is a recombinant monoclonal antibody (mAb) that contains both mouse- and human-derived segments, the human segments are engineered into the monoclonal antibody to minimize the chance that the patient's immune system will react against the mAb. Nevertheless, some patients treated with ranibizumab may develop antibodies to it. Thus, ranibizumab trials included routine testing of participants for antirranibizumab antibodies using an electrochemiluminescent assay.

In the ANCHOR trial, 8% of 0.5-mg ranibizumab subjects and 1.5% of subjects with PDT had low levels of antibodies to ranibizumab at baseline. At trial conclusion, 3.9% of 0.5-mg ranibizumab subjects had developed antibodies to ranibizumab, compared with 0% in the PDT group. In the MARINA trial, none of the subjects in the 0.5-mg ranibizumab group and 0.5% of those in the sham-injection group had antibodies to ranibizumab at baseline. After 24 months, 6.3% of subjects treated with ranibizumab 0.5 mg and 1.1% of those in the sham-injection group developed antibodies to ranibizumab.

The clinical implications of baseline and postexposure immunoreactivity to ranibizumab remain unclear. Although the numbers were small, subjects in the ANCHOR trial who were immunoreactive were more likely to develop inflammation than those who were not. In the HORIZON open-label extension study of both ANCHOR and MARINA in which subjects were treated “as needed,” antirranibizumab antibodies were detected in <2.8% of subjects at months 36, 48, 60, or at an early termination visit in the subjects initially treated with ranibizumab and in none of the ranibizumab-untreated subjects, though this was a much smaller group ( $n=63$  samples). Of 15 subjects who experienced intraocular inflammation for whom antibody status was obtained, 1 subject was antibody-positive and another's antibody data were missing.<sup>126</sup>

## Evidence-Based Recommendations for Clinical Practice

Based on the information summarized above and published from other randomized clinical trials, the following implications should be considered.

If treatment with bevacizumab is to be initiated in an eye with CNV due to AMD, the patient should be informed that using bevacizumab, treatment every 4 weeks for at least the next year, without dependence on OCT or other imaging, has been shown by CATT to be equivalent to ranibizumab every 4 weeks. The ophthalmologist should keep in mind that comparison of visual acuity outcomes when bevacizumab or ranibizumab from treatment initiation, or aflibercept starting 1 year after treatment initiation, was given “as needed,” with examinations every 4 weeks, visual acuity outcomes appeared, on average, to be slightly worse. While a slightly worse outcome may not be clinically relevant one year after treatment initiation, it becomes relevant if the decline in the average visual acuity continues 2 years or more after initiating treatment, as it appears to do at least from 1–2 years after treatment initiation. Also, the ophthalmologist and patient must keep the following in mind: There are potentially slightly better visual acuity outcomes with ranibizumab as needed or aflibercept as needed or aflibercept every other month after several monthly injections when compared with outcomes using bevacizumab as needed but not necessarily bevacizumab monthly. However, from the societal perspective or perspective of the business of the insurance company, the knowledge that the use of bevacizumab leads to a very cost-effective management of this condition compared with use of ranibizumab or aflibercept should be considered.

Ranibizumab given as needed with examinations every 4 weeks, including OCT, to detect features that suggest the need for retreatment, provides equivalent visual acuity outcomes to ranibizumab every 4 weeks at 1 year and 2 years, but the regimen has not been evaluated beyond 2 years, when physicians must base their management on the individual patient's response for the previous two years. Aflibercept every-4 weeks for three doses followed by every-8-weeks to 1 year also provides equivalent results to every-4-weeks ranibizumab; when the group given this regimen received an as-needed regimen starting at 1 year, the average visual acuity declined by 2 years, although not by a clinically relevant amount. However, if this decline were to continue during treatment 3 or 5 years after initiating therapy, the

decline could be clinically relevant.

## Follow-Up After Deciding to Initiate Anti-VEGF Therapy for Neovascular AMD

Fig. 69.18 provides one approach<sup>113</sup> to consider if monthly anti-VEGF therapy with bevacizumab or ranibizumab, or three monthly doses of aflibercept followed by every-2-months aflibercept, is not employed. The approach considers repeating therapy as long as improvement is noted on subjective symptoms, visual acuity, biomicroscopic examination, OCT, or fluorescein angiography. The approach errs on the side of treatment since failure to treat when VEGF is present could result in irreversible visual acuity loss from fibrosis involving the retina or RPE.

Another approach, known as “treat and extend,” is widely used in the United States.<sup>127</sup> In this regimen, monthly therapy is administered until the macular OCT is free of fluid, and then the treatment interval is extended, typically by 1–2 weeks.<sup>128</sup> Several retrospective studies<sup>129–131</sup> and noncomparative prospective trials<sup>132,133</sup> have demonstrated improvement in visual acuity using treat and extend approaches. Limitations in the current retrospective studies include losses to follow-up which can bias the results, retrospective data collection, which also can bias the results, and an inability to know whether the cases might have done even better (or worse) if followed monthly with an “as needed” regimen for 2 years. The 1-year results of a prospective trial comparing monthly ranibizumab to a treat-and-extend regimen using ranibizumab showed change in vision in the treat-and-extend arm was no worse than (not inferior to) the monthly arm with a noninferiority margin (lower bounds of the 95% confidence interval in the difference in the outcomes between the arms) of 5 letters. However, the formal noninferiority results were not presented in the publication, nor were details of baseline characteristics for each treatment group. Differences in baseline characteristics in this relatively small study could have biased the results provided.<sup>134</sup> Additional prospective trials are underway or being planned,<sup>128</sup> which may help clarify any efficacy hierarchy among these three alternatives.

## Long-Term Results of Anti-VEGF Therapy

Most of the previously mentioned clinical trials of anti-VEGF agents followed subjects monthly for 24 months. There have been several reports of longer-term follow-up with large losses to follow-up that can bias the results to look better than the real results may be using treatment of anti-VEGF therapy for neovascular AMD,<sup>126,135,136</sup> all of which reveal a decline of visual acuity back to near baseline over 5–7 years. None of the studies continued monthly treatment or evaluation, and all were subject to high loss to follow-up rates. Several investigators have noted increased prevalence or growth of geographic atrophy with long-term anti-VEGF therapy<sup>137</sup> including an apparent “dose-response” in CATT with monthly ranibizumab causing more atrophy than bevacizumab and more in the continuous arms versus the “as needed” arms,<sup>138,139</sup> though it is not clear if such lesions are a result of the underlying disease (drusen going on to geographic atrophy because CNV and scar were avoided with anti-VEGF treatment), an alternative to fibrotic scar (a thin atrophic scar mimicking geographic atrophy), or an actual side-effect of VEGF blockade increasing the chance of drusen to progress to geographic atrophy compared with whether no anti-VEGF is given.<sup>140–142</sup> Since some of these studies<sup>141</sup> have shown progression of geographic atrophy in an eye receiving anti-VEGF therapy to be similar to the progression of geographic atrophy in the fellow eye in the absence of anti-VEGF therapy, at least some of the progressive geographic atrophy likely is due to the natural history of drusen progressing to geographic atrophy in the absence of CNV and scar avoided by the anti-VEGF treatment.

## Previously Employed Therapies

Prior to the advent of anti-VEGF therapy, several methods of treatment were employed in the treatment of neovascular AMD that are rarely in use today. These are fully discussed in the previous edition of this volume<sup>143</sup> and are summarized only briefly below.

## Laser Treatment of Well-Defined Choroidal

## Neovascular Lesions

Laser photocoagulation was shown to be beneficial<sup>33–35</sup> for well-defined lesions not involving the foveal center or very small lesions involving the foveal center with a component of classic CNV. Failure to cover the entire lesion increases the likelihood of recurrent CNV<sup>144–146</sup> and additional visual acuity loss.<sup>144,146,147</sup> Since treatment destroys retinal tissue (and corresponding function),<sup>146</sup> such treatment generally is reserved only for cases that are extrafoveal and in which it is judged that a scotoma from the laser is preferred over proceeding with anti-VEGF therapy.

## Photodynamic Therapy

Until 1999, no treatment other than laser photocoagulation had been shown to reduce the risk of vision loss in patients with CNV from AMD in large-scale, randomized clinical trials. The TAP Study Group<sup>92,148</sup> reported that PDT with verteporfin (Visudyne) can reduce the risk of moderate and severe visual acuity loss for at least 2 years in patients with predominantly classic subfoveal lesions.<sup>101</sup> For occult with no classic lesions, the Verteporfin In Photodynamic therapy (VIP) Trial in AMD showed that PDT could reduce the risk of moderate and severe visual acuity loss at 2 years, though the primary outcome was not met.<sup>99</sup>

PDT involves the use of an intravenously injected photosensitizing drug combined with a low-intensity laser light to cause damage of choroidal neovascular tissue through a photochemical reaction by the light-activated drug that appears to result in direct cellular injury, including damage to vascular endothelial cells and vessel thrombosis.<sup>149,150</sup> While most individuals lose some vision after PDT, this may not apply for patients with the polypoidal choroidal vasculopathy pattern of CNV, as suggested in small studies within an Asian population.<sup>151</sup> PCV is discussed further in [Chapter 74](#) (Polypoidal choroidal vasculopathy).

## Submacular Surgery

Studies, including a Cochrane systematic review,<sup>152</sup> have shown

that visual acuity outcomes with submacular surgery are no different compared with observation for subfoveal CNV in patients with AMD in which a majority of the lesion is CNV and there is evidence of classic CNV.<sup>36</sup> Alternative surgical approaches have also been explored for managing CNV and its neovascular complications, including macular translocation<sup>153</sup> and mechanical displacement of relatively large submacular hemorrhages using intraocular gas injection. A 2008 Cochrane systematic review identified only one randomized controlled trial comparing macular translocation to PDT and found the evidence was insufficient to recommend this intervention,<sup>154,155</sup> a conclusion that must recognize even greater differences likely would be seen if compared to anti-VEGF therapy. In a 5-year retrospective review of results from the 56 cases out of 255 cases whose complete records were available, there was a mean gain of 1.5 lines of vision from baseline. This led the authors to recommend consideration of macular translocation only to patients with bilateral disease unlikely to respond to anti-VEGF therapy,<sup>156</sup> and even then, the large bias of the results when almost 80% of the cases were missing from the 5-year follow-up suggests extreme caution with this conclusion.

When AMD-related CNV is associated with a large submacular hemorrhage, intraocular injection of gas with or without pars plana vitrectomy and face-forward or face-down positioning may allow for mechanical displacement of the blood and the potential for at least temporary recovery of visual acuity.<sup>157-160</sup> The improvement may not have long-term benefit if the underlying neovascular lesion and its accompanying destruction of the retina, not the blood, determines the ultimate visual outcome. For this reason, anti-VEGF therapy alone may be sufficient for some of these lesions.<sup>115</sup> Pars plana vitrectomy for clearing of hemorrhage that has broken through into the vitreous cavity also may be considered and may be lower risk than surgeries that involve mechanical manipulation of the retina itself.

## Radiation Therapy

The use of radiation therapy for CNV in AMD is based on the possibility that radiation can damage rapidly proliferating

neovascular tissue. Several early studies were inconsistent in documenting a benefit to this approach, either using external beam, plaques, or use of a probe with local irradiation.<sup>161–163</sup> A 2010 Cochrane systematic review of 13 trials of various design likewise concluded that the body of literature does not provide support for this approach and urged consideration of some form of masking in future trials.<sup>164</sup> A more recent randomized controlled trial comparing epiretinal macular brachytherapy in 494 treatment-naïve patients demonstrated that the radiation plus ranibizumab was inferior to quarterly plus “as needed” ranibizumab.<sup>165,166</sup> Studies that have evaluated the potential of these therapies to reduce the number of intravitreal injections have not provided concomitant evidence of similar or improved visual acuity outcomes in association with a decreased number of intravitreal injections.<sup>167</sup>

## Other Pharmacologic Therapies and Combination Therapies

A variety of other pharmacologic therapies are under investigation for the treatment of neovascular AMD, including inhibitors of platelet-derived growth factor,<sup>168</sup> complement,<sup>169</sup> and inflammatory modulators.<sup>170</sup> In addition, novel delivery devices for pharmacologic therapies,<sup>171</sup> and combinations of therapies, are under investigation,<sup>172,173</sup> as are viral vector-based gene therapy to deliver anti-VEGF<sup>174</sup> and other inhibitors of angiogenesis.<sup>175</sup> Given the public health importance and biologic variability of visual acuity outcomes with CNV in AMD, changes in the management of CNV in AMD should be influenced strongly by large-scale, appropriately designed randomized clinical trials with adequate follow-up that show benefit before new therapies are incorporated into standard practice.

## Early Identification of Choroidal Neovascularization

It has become critically important to identify, while potentially still at a treatable stage, those eyes at high risk for visual loss soon after

developing CNV. Unfortunately, the likelihood of finding a case that will benefit from treatment appears to be time-dependent. FA studies have suggested growth of CNV lesions at an average rate of 10–18  $\mu\text{m}$  per day.<sup>176,177</sup> Grey and colleagues<sup>178</sup> reported that patients with acute visual loss from AMD are more likely to still have extrafoveal CNV if they are examined within the first month after the onset of symptoms.

Clearly, identifying lesions before they extend under the foveal center, or more often, when visual acuity loss may be minimal even if the lesion extends under the foveal center, is worthwhile. Furthermore, identifying lesions while visual acuity is relatively good might result in better levels of final visual acuity since most cases treated with anti-VEGF therapy avoid substantial visual acuity loss but fewer than 50% have substantial visual acuity gain. A substudy of the Age-Related Eye Disease Study 2 that randomized patients at high risk for CNV to home testing with a hyperacuity visual field device versus conventional monitoring evaluated the decrease in visual acuity at the time of CNV detection. The study was terminated early by the Data and Safety Monitoring Committee at a prespecified interim analysis due to achievement of statistical significance with an average of fewer letters lost from baseline in the device arm (4 letters) compared with standard care monitoring (9 letters).<sup>179</sup> Similar technology also may prove helpful in monitoring patients already under treatment for neovascular AMD.<sup>180</sup> Whether other devices, such as those that can be used on smartphones, will be able to provide similar or better results remains to be proven in further studies.

## Prevention of Choroidal Neovascularization

The Age-Related Eye Disease Study (AREDS) suggested that dietary supplements of vitamins C, E, beta-carotene, and zinc can reduce the chance of CNV developing in eyes with large drusen, especially when retinal pigment epithelial abnormalities were present and when these features were in both eyes.<sup>181</sup> Likewise the AREDS 2 study demonstrated that while the substitution of lutein

and zeaxanthin for beta-carotene did not reduce progression to CNV compared with the beta-carotene formulation, this substitution may reduce the risk of lung cancer in current or recently former smokers.<sup>182</sup> The Complications of Age-related Macular Degeneration Prevention Trial (CAPT) was not able to demonstrate that light laser photocoagulation, which has been associated with a decreased visualization of drusen,<sup>183</sup> can prevent the development of complications of AMD associated with visual loss, including CNV and geographic atrophy.

## Risk of Fellow-Eye Involvement

When one eye has developed CNV, it is important to monitor the other eye for CNV.<sup>184</sup> Development of CNV in the second eye can be devastating, since patients may have functioned quite well with good vision in their remaining eye but would be abruptly confronted for the first time with severe lifestyle impairment with development of CNV in both eyes. It is therefore paramount to discover and treat CNV as soon as possible to maximize the possibility of detecting treatable lesions. Because patients may be aware of symptoms only when the fovea has become involved, it would be useful to stratify risk based on fundus appearance and perhaps employ more aggressive monitoring strategies in those deemed at high risk.

The investigators of the MPS Group studied the eyes of 670 patients enrolled in the trials of laser therapy for extrafoveal, juxtafoveal, and subfoveal CNV to identify fundus characteristics that might be predictive of CNV development in the uninvolved fellow eyes.<sup>185-187</sup> Follow-up ranged from 3 to 5 years and revealed an overall incidence of 35%, which is consistent with previously reported figures. Application of life table estimation methods to this data yielded cumulative incidence rates of 10%, 28%, and 42% at 1, 3, and 5 years respectively. Three characteristics of the central macula and one systemic factor were associated independently with increased risk of developing CNV: the presence of five or more drusen, one or more large drusen, focal hyperpigmentation, and systemic hypertension. A substantial difference in prognosis was seen depending on the number of risk factors present. Estimated 5-

year incidence rates ranged from 7% for the subgroup with no risk factors to 87% for the subgroup with all four risk factors. Similarly, in AREDS, subjects enrolled with advanced AMD (either neovascular AMD or central atrophy of the RPE) in one eye only at study entry had a 43% chance of developing advanced AMD in the fellow eye by 5 years.<sup>181</sup> The type of CNV present in the affected eye, classic versus occult, appeared to have no effect on the rate of CNV development in the fellow eye. It must be stressed that these figures do not apply to patients with non-neovascular abnormalities only in both eyes. They are, however, very important in counseling the AMD patient who has just experienced the initial development of CNV in one eye with respect to prognosis and frequency of follow-up to try to protect the vision in the other eye.

## Patient Education and Rehabilitation

Patient education is an extremely important part of the management of patients with AMD. All patients over the age of 50 who have drusen should be made aware of the importance of regular central visual acuity testing in each eye to facilitate early detection of CNV. Although the Amsler grid is often recommended, it is not particularly sensitive or specific; frequently, changes in near or distance vision herald underlying neovascularization not detected by the patient on an Amsler grid.<sup>17</sup> Therefore, patients experiencing any change in vision in eyes at risk for neovascularization should be encouraged to contact their ophthalmologist promptly. Although patients should be counseled about the risk of severe central visual loss, they should also be reassured that AMD almost never leads to total blindness. Patients at risk should be informed that, in its more severe neovascular form, central visual tasks can be severely and permanently impaired. In light of the therapeutic implications of prompt anti-VEGF therapy when indicated, the importance of quickly reporting new visual symptoms must be stressed to all patients. At the same time, they should be reassured that no harm will come by continuing to read or perform routine visual tasks. On the contrary, patients should be encouraged to continue reading and to pursue vigorously any visual activity that they enjoy.

Treatment does not end in the physician's office when the diagnosis is established or when anti-VEGF therapy is applied. Visual rehabilitation forms an integral part of patient care in AMD. Patients with central visual impairment should be evaluated and educated in the use of visual aids such as magnifiers. Magnification and improved contrast sensitivity through bright illumination are particularly helpful. To arrive at the best magnifying aid, one starts with a complete low vision evaluation. In addition, the patient should be counseled on available low-vision materials such as large-print newspapers, magazines, and books, as well as tablets and e-readers with high contrast screens and enlargeable fonts. Large-print materials or electronically magnified text permit many people who are unable to read normal print to continue reading for a considerable period of time. Many newspapers and periodicals are currently published in large-print editions or electronically as available through the internet. The local library can assist with the selection of magazines and books available in large print. The Library of Congress in Washington, DC, maintains a list of books and magazines available on loan without cost on virtually every subject. The combination of bright illumination, powerful magnification, high contrast, and large type allows all but the most severely impaired patients to continue reading, albeit on a more limited scale. Reading skills frequently need to be re-learned in a painstakingly slow process. Nevertheless, the ability to continue reading, even on a limited basis, may provide tremendous psychological benefit to these patients. Some patients with AMD may find the use of a closed-circuit television viewer helpful for reading. This machine uses a projection device to magnify one or several words on to a television screen. Unfortunately, this instrument is large and fairly expensive; thus it is generally purchased by people with sufficient economic means for use in primarily one location such as at work or at home. However, the nearly ubiquitous availability of electronic tablets, with their ability to magnify, has proven beneficial in place of more cumbersome closed-circuit television systems. For those patients who are unable to take advantage of large-print materials or who cannot use magnification devices, talking books or recordings are available. These may be borrowed through local libraries or from the Library

of Congress. Audio recordings of popular books are also sold at many bookstores and through web services such as [Audible.com](https://www.audible.com).

Patients with severe visual loss require early referral to an appropriate agency for low vision so that they can take advantage of community support services. Information can be obtained from the Directory of Agencies serving the visually handicapped in the United States through the American Foundation for the Blind. The American Foundation for the Blind also provides information regarding other aids such as talking books and clocks and watches that audibly tell time.

Because AMD can place severe restrictions on many activities such as driving and rapid reading of small print, visual rehabilitation efforts are directed toward preserving the patient's independence as much as possible. Toward this end, social service consultations are invaluable. In addition, in-house evaluations by agencies designed to assist the visually impaired are useful in helping with activities of daily living. Simple recommendations, such as using brightly colored utensils on a white or black background in the kitchen, as well as suggestions on improving existing lighting, can be of tremendous benefit. Similar ideas aimed at increasing contrast may improve the quality of life for these patients. Patients often become frustrated because of their inability to perform certain fine visual tasks, such as reading and sewing. Unable to recognize faces from across the room, patients with visual loss from AMD may feel isolated and withdraw from social contact. In the absence of any external tell-tale signs of blindness, friends and relatives may attribute the lack of recognition to a sudden "snobbishness" rather than to visual impairment. Patient and family alike should be educated about these problems. In particular, patients should be encouraged to become more outgoing, which in turn fosters recognition of others through speech rather than vision. Discussion of the patient's problems by the physician often helps to relieve patients of much of their burdens.

Ophthalmologists must recognize that older patients can have difficulty coping with the new onset of severe visual loss. Patients may resist efforts to use magnifying devices for a variety of reasons, including denial and secondary gain. Often tremulousness

interferes with the patient's ability to use certain aids. All these conditions may increase the tendency to depression or anxiety that many patients with visual loss have, including patients with AMD.<sup>188,189</sup> In addition to caring for the eye, the ophthalmologist should serve as the patient's advocate, marshaling his or her resources for the patient's benefit. This includes compassionate support, educating the patient and family, and making appropriate referrals to maintain the patient's quality of life. With complete care of the patient, many individuals at risk for, or suffering severe visual loss from, neovascular AMD can continue to enjoy fulfilling lives.

## Disclosure

The Johns Hopkins University School of Medicine receives research grants from Bayer, Genentech/Roche, Lumenis, Novartis, Optovue, Regeneron, for N.M.B.'s or S.B.B.'s effort in research activities with those industries.

**Summary**

## Introduction

Age-related macular degeneration (AMD) is a spectrum of related diseases that have in common the progressive decline of vision as a

consequence of dysfunction of the central retina and its underlying supporting elements, principally the retinal pigment epithelium (RPE) and choroid in older adults.<sup>1</sup> Although the disease is seen in all racial and ethnic groups, it is more commonly encountered in females and light-skinned individuals and typically presents after the 7th decade.<sup>2-5</sup> The disease has been traditionally classified into early, intermediate, and late stages.<sup>1</sup>

The early stages consist of alterations in the coloration of the macular pigment epithelium, both hypo- and hyperpigmentation, and the presence of drusen of greater than 125  $\mu\text{m}$  in diameter. The early phases have been variously referred to as nonexudative, preangiogenic, or dry AMD (Fig. 70.1). The intermediate stage of the disease consists of more extensive medium sized or large sized drusen. In contrast, exudative or neovascular AMD is a late onset phenomenon, occurring in eyes with high risk characteristics including the presence of extensive soft drusen, Bruch's membrane thickening, and focal hyperpigmentation. This phase of the disease is characteristically accompanied by rapid loss of vision over a period of 6–12 months and the development of a central disciform fibrotic scar. Without intervention, the visual acuity generally decreases to the range 20/200 or worse, over the 12 months following the onset of this phase.<sup>3,5</sup> In light of major improvements in therapy for this condition in the past 5–10 years, previously employed forms of treatment, including thermal laser photocoagulation and surgery, are now viewed to have limited benefit for this condition, particularly when it presents with involvement of the center of the fovea.<sup>6-10</sup> In recent years, AMD therapy has become increasingly targeted toward specific molecular pathways. The discovery of multiple genes and markers for AMD and neovascularization has identified a significant number of new targets for pharmacotherapy.

**FIG. 70.1** Color fundus photograph of right eye patient with early age-related macular degeneration. Note the extensive drusen throughout the posterior pole, some of which appear calcific and others large and soft. The patient has not yet progressed to the stage of either geographic atrophy, or choroidal neovascularization.

Relevant to the purpose of this chapter, it is important to understand that the mechanisms of vision loss in AMD differ according to the stage, and that different stages may be amenable to different points of attack.<sup>2,5</sup> Importantly, at least two separate and distinct mechanisms for vision loss occur in exudative AMD: (1) Proliferation of new vessels accompanied by secondary fibrosis and disorganization of the pigment epithelium and outer retina, which is a somewhat gradual process; (2) secondary alterations in the permeability of retinal and choroidal vessels accompanied by retinal pigment epithelial dysfunction leading to the accumulation of serous or serosanguinous fluid beneath the RPE, neurosensory retina, or within the retina itself, and are associated with more acute visual dysfunction. Preventing the vision loss associated with advanced forms of nonexudative disease has proved more challenging. In recent years an increased understanding of the mechanisms underlying drusen formation, pigment epithelial senescence, and loss of photoreceptors and choriocapillaris has made it more feasible to address therapeutically, visual dysfunction arising from the atrophic form of the disease (Fig. 70.2).

**FIG. 70.2** Color photograph of the left eye of another patient with the severe form of late exudative age-related macular degeneration. Note the extensive scarring beneath the sensory retina, hemorrhage, and lipid exudation.

## Etiologic Factors

A variety of factors are thought to play a role in the development of AMD, including genetic susceptibility, a localized inflammatory state, and a host of potentially modifiable environmental factors, including smoking, comorbidities, diet, medications, and light exposure.<sup>11</sup>

## The Genetics of Complement in AMD

Over the last decade high-resolution genome scans for susceptibility loci in populations enriched for either choroidal neovascularization (CNV), geographic atrophy (GA), or both suggest susceptibility loci on numerous chromosomes. A number of candidate genes and their functions are listed in [Table 70.1](#). An exhaustive discussion of the genetics and postulated mechanisms of AMD is beyond the scope of this chapter; however, several genes deserve mention.

**TABLE 70.1****Candidate Genes for Age-Related Macular Degeneration**

Location	Gene	Function	Strength of Association
1p22.1	<i>ABCA4</i>	ATP binding/ATPase	Possible
1q25– 1q32	<i>HMCN1</i>	Extracellular matrix	Possible
1q31.3	<i>CFH</i>	Complement component	Established
3p21.3	<i>CX3CR1</i>	Chemokine receptor regulator of immune response	Probable
4q35.1	<i>TLR3</i>	Toll-like receptor: activator of inflammatory cytokine response to viral dsRNA	Possible
6p12	<i>VEGFA</i>	Regulator of angiogenesis and vascular permeability	Possible
6p21.3	<i>C2</i>	Complement component (classical pathway)	Probable
6p21.3	<i>CFB</i>	Complement component (alternate pathway)	Probable
6q24– q14	<i>ELOVL4</i>	Photoreceptor-specific elongation enzyme of long-chain fatty acids	Possible
9p24	<i>VLDLR</i>	VLDL transporter	Possible
9q32– q33	<i>TLR4</i>	Activates inflammatory immunity in response to bacterial lipopolysaccharide	Possible
10q26.13	<i>HTRA1</i>	Serine protease	Locus established, individual gene contributions unknown
10q26.13	<i>PLEKHA1</i>	Phospholipid-binding protein	
10q26.13	<i>ARMS2</i>	Unknown	
12p11– p13	<i>LRP6</i>	Wnt signaling protein	Possible
14q32.12	<i>FBLN5</i>	ECM protein, promotes endothelial cell adhesion	Possible
19p13.3	<i>C3</i>	Complement component	Probable
19q13.2	<i>APOE</i>	Lipoprotein binding, internalization, metabolism	Established
22q12.3	<i>TIMP3</i>	Metalloproteinase inhibitor (extracellular matrix protein)	Possible

A significant breakthrough in the study of AMD genetics came in 2005, when it was discovered that single nucleotide polymorphisms (SNPs) in the regulation of the complement activation locus (RCA) of chromosome 1q31.3 increased the risk of AMD. The RCA locus contains the gene encoding complement factor H (*CFH*). The tyr402his protein polymorphism increased the risk of AMD between 2.7- and 7.4-fold and appeared to account for between 43% and 50% of the attributable risk of AMD. Additionally, it has been suggested that *CFH* genotypes may influence an individual's response to certain treatment modalities and medications, including bevacizumab, photodynamic therapy with verteporfin, and AREDS nutritional supplementation.<sup>12–16</sup> *CFH* is responsible for

downregulating activation of the complement system, including c5b-9, known as the membrane attack complex (MAC). MAC is thought to be important in the immune-mediated damage to the choriocapillaris and the RPE and an important pathogenic component of drusen.<sup>17,18</sup>

Two recent studies found protective associations against the development of advanced AMD in those with genetic polymorphisms of the complement components C2 (Odds ratio 0.35–0.46) and complement factor B (CFB) (OR 0.35–0.44). The complement component C3 is the central part of the complement cascade, and its gene, located on chromosome 19, is a candidate for involvement in AMD, in part because its cleavage component C3a has been identified in drusen.<sup>19,20a,20b</sup> Additionally, C3 has also been associated with the development of GA (OR 2.66–3.9). [Fig. 70.3](#) illustrates other complement components implicated in the pathogenesis of AMD.

**FIG. 70.3** AMD-associated mutations in the complement cascade. Four major activation pathways for the complement system are known, and three of these are illustrated. (The fibrinolytic-activated Intrinsic pathway is not shown.) Activation of the complement system plays an important role in immunity. Inappropriate complement activation can damage tissue. Multiple complement components have been linked to AMD (green circles), including drusen, geographic atrophy, and choroidal neovascularizations. Complement C3 (red circle) is the key point of convergence of all activation pathways. (Reproduced with permission from Zarbin M, Rosenfeld, PJ. Review of emerging treatments for age-related macular degeneration. In: Stratton RD, Hauswirth WW, Gardner TW, editors. Oxidative stress in applied basic research and clinical practice: Studies in retinal and choroidal disorders. New York: Humana Press; 2012.)

## Other Associated Genes

The genetic locus on chromosome 10q26 is the home to three genes, PLEKHA1, ARMS2, and HTRA1, which have been associated with AMD. Among these, ARMS2 has been the most consistent association, but its function is as yet unknown. HTRA1, in contrast, has been localized to drusen, but its association with AMD is inconsistent.<sup>20c</sup> The gene products of tissue inhibitor of metalloproteinase 3 (TIMP-3, chromosome 22) and endothelial growth factor (EGF) containing fibulin-like extracellular matrix protein 1 (EFEMP-1, chromosome 2), which act to inhibit the stimulatory effects of vascular endothelial growth factor (VEGF) on vascular cells, have been independently associated with advanced AMD in genome scans mentioned previously.<sup>21,22</sup> Multiple distinct alleles in exon5 of the gene encoding TIMP-3 have been causally linked to Sorsby fundus dystrophy, an autosomal dominant form of exudative macular degeneration with phenotypic similarities to exudative AMD,<sup>23-25</sup> although it is not thought to account for the majority of patients with exudative AMD.<sup>26</sup> TIMP-3 is also found in increasing quantities and associated with thickening of Bruch's membrane during aging, including within drusen and the RPE.<sup>27-29</sup> An Arg to Trp mutation in EFEMP-1 is thought to cause the abnormal accumulation of extensive drusen in malattia leventinese, an inherited macular degenerative disease with phenotypic characteristics closely correlated with advanced nonexudative AMD.<sup>27,30</sup>

Early onset macular retinal degenerations such as Stargardt disease, characterized by the accumulation of lipofuscin within the RPE, have shed light on both the pathophysiology of RPE apoptosis and potential therapeutic avenues.<sup>31,32</sup> While initial reports also suggested that the *ABCR* gene linked to Stargardt disease might also be a dominant susceptibility locus for AMD, subsequent investigators have been unable to confirm this apparent increased frequency.<sup>33,34</sup> Nonetheless, increased amounts of lipofuscin are present in both Stargardt disease and in the earlier stages of the nonexudative AMD, and both diseases are characterized by GA in their later stages, suggesting that an understanding of the common pathways expressed by these two different diseases may provide some pharmacologic insights. Biochemical studies on the lipofuscin

found in both Stargardt disease and AMD confirm that the principal component is A2E, which accumulates in cells of the RPE and results in RPE apoptosis, photoreceptor death, and vision loss.<sup>18,35,36</sup> This process is thought to be initiated by light activation of rhodopsin in the course of normal visual transduction as the first reactant in A2E biosynthesis. Isotretinoin, which slows the synthesis of 11-*cis* retinaldehyde and regeneration of rhodopsin, is able to slow the accumulation of lipofuscin in ABCR knock-out mice and also aged wild-type mice.<sup>35</sup> This suggests that compounds with mechanisms of action similar to isotretinoin, which is structurally related to vitamin A, may represent another therapeutic avenue for the slowing or prevention of AMD.<sup>18,32,34–36</sup>

## Environmental Factors

### Diet

The principal environmental factors thought to be associated with age-related macular degeneration include diet, history of smoking, light exposure, and use of supplemental medications. Earlier AREDS reports have established a relationship between dietary intake of omega-3 long-chain polyunsaturated fatty acids and reduced risk of neovascular AMD (Odds ratio 0.61), as well as progression from drusen to GA.<sup>37–39</sup> A large case control study has suggested that higher dietary intake of carotenoids, particularly lutein and zeaxanthin, was associated with a lower risk of AMD with the highest quintile having a 43% reduction compared with those in the lowest quintile. In that study no reduction could be found with the use of oral vitamin A, vitamin E, or vitamin C.<sup>40</sup> Subsequent studies suggest that the use of foods, particularly fruits rich in antioxidants and carotenoids, when consumed at the level of three servings or more per day result in a pooled multivariate reduced relative risk of 0.64 compared with persons who consumed less than 1.5 servings per day.<sup>2</sup> However, there have been a number of studies that have demonstrated little to no benefit with dietary regimens.<sup>21,41–43,44</sup> The AREDS2 has studied supplementation with lutein and zeaxanthin and omega-3 fatty acids (see below).

## Smoking<sup>a</sup>

Most studies have consistently implicated smoking as a statistically significant risk factor for the development of late-stage AMD.<sup>2,47</sup> In a meta-analysis of three pooled studies from the United States, The Netherlands, and Australia, smoking was one of only two significant associations identified with incident AMD along with total serum cholesterol. Current smoking is associated with a 4.55-fold increased risk of neovascular AMD (vs. “never” smokers) and a 2.54-fold increased risk of atrophic AMD (vs. “never” smokers).<sup>48</sup> Based on a pooled analysis of data, the risks of both neovascular and atrophic AMD seem to decrease once one stops smoking.<sup>48</sup>

## Light Exposure

Although there is a considerable body of compelling experimental data to suggest that increased retinal irradiance is positively correlated with an increased likelihood of advanced AMD, the epidemiologic evidence supporting this hypothesis is modest.<sup>3,49,50</sup> In the Beaver Dam Eye Study, participants exposed to summer sun for more than 5 hours a day during selected periods of time were at increased risk for increased retinal pigment (relative risk 3.17) and early AMD (relative risk 2.14) after 10 years of follow-up compared with those exposed to less than 2 hours per day.<sup>50</sup>

The underlying rationale for the hypothesis that increased light stress predisposes to AMD rests on the role of oxidative stress inherent with photo bleaching of the photoreceptors and to a lesser extent pigment epithelium. In particular, reactive oxygen intermediates (ROI) including hydrogen peroxide, singlet oxygen, and other short-lived species, which arise as the byproducts of cellular metabolism, are known to have a toxic effect on cellular membranes.<sup>41</sup> It is felt that the cumulative effects of chronic low levels of these species result in profound damage to the retina and pigment epithelium through lipid peroxidation, mitochondrial DNA damage, and induction of apoptosis.<sup>2,41</sup> Experimental studies have confirmed the deleterious effect of chronic light and in particular blue and ultraviolet light on the RPE in part through the creation of A2E oxiranes, a major component of lipofuscin. The presence of natural antioxidants derived from dietary sources

including lutein, zeaxanthin, lycopene, and ascorbate are thought to mitigate the effects of photo-oxidation by quenching free radicals and other intermediate species.<sup>41</sup> It has been hypothesized that this represents one, but not the only mechanism of action, of the antioxidants in the AREDS study.<sup>51</sup>

## Use of Medications

Meta-analyses of pooled prospective studies suggest that certain medications may be associated with an increased or decreased risk of age-related macular degeneration. Antihypertensive medications, particularly beta blockers, are associated with modest increased risk, whereas hormone replacement therapy in women, and tricyclic antidepressants, confer some relative protection.<sup>52a</sup> The potential effect of statins on AMD progression has been studied as a preplanned cohort of the Age-Related Eye Disease Study 2 (AREDS2), with no significant association with progression to late AMD (HR 1.08, 0.83–1.41). However, a more recent interventional pilot study in which 26 patients with many large, soft drusenoid deposits were administered 80 mg of atorvastatin demonstrated regression of drusen in 10 patients, with an average gain of 3 letters of vision in these patients.<sup>52b</sup> These observations may be able to be further exploited in the development of new classes of drugs in addition to avoiding potentially harmful drug interactions.

## The Pathophysiology of Exudative AMD: the Crucial Role of Cytokines

### Definition and Steps in Angiogenesis

Angiogenesis refers to the creation of new blood vessels from existing blood vessels, and therefore is contrasted from the process of vasculogenesis seen characteristically in utero in which vessels are created de novo. The process of angiogenesis has been characterized as occurring in a series of orderly events (adapted from The Angiogenesis Foundation, <https://www.angio.org/learn/angiogenesis/>). (1) To monitor and supply sufficient amounts of oxygen to surrounding tissues, blood

vessels have oxygen and hypoxia-induced sensors, or receptors, which allow vessel remodeling to adjust the blood flow accordingly. (2) Hypoxia or other endogenous signals activate cells and induce the release signaling factors (such as VEGF, Ang-2, fibroblast growth factor, and chemokines) to promote the growth of new blood capillaries from preexisting vessels. (3) Pericytes detach from the vessel, and endothelial cells are activated and lose their close contact as the vessel dilates. (4) In sprout formation, a tip cell is selected which releases matrix metalloproteases to degrade the basement membrane and remodel the extracellular matrix. (5) Tip cells are polarized and extend numerous filopodia to guide sprout migration toward angiogenic stimuli. (6) Stalk cells follow the tip cell and proliferate, extending the sprout. Proliferating stalk cells establish junctions with neighboring endothelial cells and release signals that bind to extracellular membrane components and regulate vascular lumen formation. (7) Fusion of neighboring branches occurs when two tip cells encounter each other, establish EC–EC junctions, and form a continuous lumen. Extracellular matrix is deposited to establish a new basement membrane, endothelial cell proliferation ceases, and pericytes are recruited to stabilize the new vessel. (8) Once blood flow is established, the perfusion of oxygen and nutrient reduces angiogenic stimuli and inactivates endothelial cell oxygen sensors, reestablishing the quiescent state of the blood vessel. Antiangiogenic therapies currently under investigation are thought to inhibit angiogenesis at various steps in this process.

## **VEGF and Other Modulators of Angiogenesis**

Regardless of the inciting stimulus involved in the development of pathologic neovascularization, it is now well established that VEGF plays a principal role including not only the neovascular forms of AMD, but also diabetic retinopathy, iris neovascularization, and retinopathy of prematurity. Additionally other cytokines may play an important role as well, including fibroblast growth factor (FGF), pigment epithelium-derived factor (PEDF), the integrins, angiopoietins, and matrix metalloproteinase (MMP) inhibitors.<sup>2,23,53–56</sup>

VEGF undoubtedly represents the putative factor X first postulated by Michaelson associated with pathologic neovascularization.<sup>2</sup> First described as a vasopermeability factor associated with tumors, the molecule has since been cloned and well characterized.<sup>57,58</sup> VEGF has two important characteristics relevant to its role in the pathogenesis of the neovascular forms of AMD: (1) induction of angiogenesis through endothelial proliferation, migration, and new capillary formation and (2) enhancement of vascular permeability.

## Vascular Permeability

VEGF produces important increases in hydraulic conductivity of isolated microvessels that are mediated by increased calcium influx and likely changes in levels of nitric oxide caused by induction of nitric oxide synthetase (NOS). While VEGF is both necessary and sufficient when administered exogenously to induce both these effects in vitro and in vivo, it is also well known that a number of other growth factors participate in this process. Some represent steps in a cascade initiated by VEGF while others act upstream.<sup>59,60</sup> The chemical structure of VEGF is that of a heparin-binding homodimeric glycoprotein of 45 kilodaltons.<sup>57</sup> VEGF has significant homology to PDGF. The human VEGF gene is organized into 8 exons separated by 7 introns and is localized in chromosome 6p21.3. Although there is only a single gene for VEGF-A, alternate posttranslational exon splicing results in the generation of between four and six different isoforms having 121, 145, 165, 183, 189, and 206 amino acids respectively after signal sequence cleavage<sup>56,57</sup> (Fig. 70.4). VEGF<sub>165</sub> exists in both soluble and bound forms<sup>57</sup> (Fig. 70.5) and is thought to be predominantly responsible for pathologic neovascularization.

**FIG. 70.4** Multiple isoforms of VEGF exist in nature and appear to participate to a differential degree in the normal events of vasculogenesis, as well as the pathologic events of angiogenesis occurring in response to local stimuli. Although there is only a single gene for VEGF, alternate splicing as well as posttranscriptional modification by plasminogen in the extracellular matrix accounts for a variety of isoforms that determine the relative balance between normal vascular homeostasis and pathologic neovascularization. The shorter amino acid length isoforms VEGF<sub>121</sub> and VEGF<sub>145</sub> are principally found in soluble form, whereas the longer spliced lengths 183, 189, and 206 are principally tissue fixed and bound by heparin. VEGF<sub>165</sub> is thought to stimulate pathologic neovascularization and exists both in soluble and tissue fixed configurations.

**FIG. 70.5** Pathways of VEGF expression and effects on vascular cells are demonstrated schematically. A variety of cells contribute to VEGF release, including monocytes, retinal pigment epithelial cells, and neurons responding to inflammation, oxidative stress, and hypoxia respectively. These and other cell types produce predominantly VEGF-A which is expressed in various isoforms through transcriptional and post-translational steps. VEGF165 and VEGF121 are the predominant forms, with VEGF 189 being cleaved in the extracellular matrix to VEGF110, a soluble form by activated plasmin. Each of these molecules, but principally VEGF165, bind to endothelial cells through specific receptors VEGFR-1 and VEGFR-2. A sequence of events is set in motion through subsequent intracellular messaging systems as well as extracellular events that result in the loss of tight junctions between individual endothelial cells, the formation of fenestrations within endothelial cells and calcium-mediated permeability channels resulting in loss of the normal inner and outer blood-retinal barriers. Additionally matrix metalloproteinase activation occurs through its interaction with integrin receptors alpha v beta 3 and alpha v beta 5, which are found on the surface of endothelial cells exclusively following induction of the cell through activation with

the VEGFR-1.

Although VEGF inhibitors share in common an attempt to mitigate the proliferative and permeability effects of VEGF on normal and neovascular tissue, there are likely to be differences in both efficacy and safety related to the choice of agents for several reasons. From a theoretical standpoint, since VEGF<sub>165</sub> is the principal isoform involved in pathologic neovascularization, it has been argued that leaving the other three principal isoforms intact (121, which is principally diffusible in soluble form, and 189 and 206, which are principally matrix-bound through high affinity heparin binding sites) avoids the possibility of interference with normal homeostatic mechanisms associated with constitutive VEGF expression. Indeed, previous animal studies suggested that blockade of VEGF<sub>164</sub> in the mouse (equivalent to VEGF<sub>165</sub> in humans) is as effective as nonselective antibody-mediated VEGF blockade in preventing pathologic neovascularization in a hypoxia-induced angiogenesis model, while not interfering with normal physiologic development of retinal vasculature.<sup>61,62</sup> However, it has become apparent with widespread use of bevacizumab and ranibizumab (monoclonal antibodies against multiple VEGF isoforms) that nonselective blockade has few untoward effects on normal retinal vascular physiology.

## VEGF Receptors

VEGF exerts its effects on cells through two highly related receptor tyrosine kinases (RTKs) VEGFR-1 and VEGFR-2.<sup>57</sup> VEGFR-1 also termed FLT-1 (FMS-like tyrosine kinase) was described first, but its role remains open to debate. Like VEGF, VEGFR-1 is upregulated by a hypoxia-inducing factor (HIF)-dependent mechanism. The receptor undergoes weak tyrosine autophosphorylation in response to VEGF. It is thought not to be primarily a mitogenic stimulus but rather a “decoy” receptor, which downregulates the activity of VEGF by sequestering and rendering the factor less available to VEGFR-2 (Figs. 70.5–70.6). This factor may be most important during embryogenesis rather than during pathologic neovascularization as well as in hematopoietic bone marrow-

derived cells and neural signaling.<sup>57,63</sup>

## **VEGFR-2 (KDR in Humans or FLK-1 in Mice)**

VEGFR-2 binds VEGF with lower affinity relative to VEGFR-1, but is felt to be the major mediator of the mitogenic, angiogenic, and permeability enhancing effects of VEGF. The binding site for VEGF on VEGFR-2 has been mapped to the second and third IgG-like domains, and it undergoes dimerization and strong ligand-dependent tyrosine phosphorylation resulting in a mitogenic chemotactic and pro-survival signal. It appears to have at least two separate tyrosine phosphorylation sites. VEGFR-2 is thought to be critical as a survival factor with apoptosis occurring in its absence.

A large body of evidence exists to support the critical and probably rate-limiting role of VEGF in neovascular forms of AMD. High messenger RNA levels and increased VEGF receptor levels are observed in areas of CNV in primates as well as in the extracted neovascular membranes of patients removed at surgery and following autopsy.<sup>2,64</sup> Additionally there are strong indications that elevated levels of VEGF are the proximal cause for the hyperpermeability seen not only in diabetic macular edema, but in patients with subsensory and intraretinal fluid associated with CNV as well. The permeability changes resulting from VEGFR-2 are thought to be mediated to a large extent by endothelial nitric oxide synthetase-based generation of increased nitric oxide levels and associated changes in calcium flux (Fig. 70.6). These alterations can be reversed either by direct blockade of VEGF, the receptor, or NOS using a knock-out model.<sup>2,58,59</sup> Inactivation of soluble VEGF by monoclonal antibodies directed against it or inhibition of ICAM also appear to be effective as well. Other methods of direct inhibition of VEGF include inhibition of its tyrosine kinase receptors (VEGFR-1 and -2), either by systemic administration or gene transfer.<sup>65</sup> Indirect inhibition of VEGF effects can be attained through modulation of intracellular adhesion molecule (ICAM), or indirect effects on nitric oxide phosphorylase, nitric oxide synthetase, or protein kinase C, another modulator of permeability.

**FIG. 70.6** Intracellular signaling including induction of nitric oxide synthetase (NOS), protein kinase C activation (PKC) and expression of ICAM-1 leading to leukocyte adherence and further changes in permeability mediated by calcium flux and protein kinase C.

A number of other cytokines and factors have been identified that influence VEGF or VEGF-associated effects in the process of angiogenesis.<sup>2,66-74</sup> Selected factors of interest are described in more detail below and represent possible targets for intervention.

## Platelet-Derived Growth Factor

PDGF is a homo- or heterodimeric glycoprotein that stimulates pericyte and vascular smooth muscle cell recruitment in angiogenesis, which are essential in the maintenance and survival of new vessels. The PDGF receptors (PDGFR-A and PDGFR-B) are tyrosine kinases and are expressed differentially on different cell types, with PDGFR-B being more extensively expressed in endothelial cells, vascular smooth muscle cells, and fibroblasts, among others.<sup>75,76</sup> In the absence of PDGFR-B signaling, vascular pericytes detach, and the integrity of vessels is lost. Immature vessels are highly sensitive to the withdrawal of VEGF prior to pericyte recruitment and coverage; conversely, when pericyte coverage is complete, new vessels are resistant to VEGF

withdrawal. This is the so-called plasticity window, during which time vessels can regress rapidly with changes in exposure to growth factors.<sup>77,78</sup> PDGF blockade in animal models of corneal neovascularization has resulted in prevention and regression of new vessels.<sup>79,80</sup> PDGF blockade alone or combined with VEGF inhibition (taking advantage of the plasticity window) may thus serve as a potent inhibitor of neovascular AMD.

## **Matrix Metalloproteinases and Tissue Inhibitors of Metalloproteinases**

Expression of matrix metalloproteinases (MMPs) and their associated RNA, particularly MMP-2 and MMP-9, have been associated with pathologic neovascularization. Both matrix metalloproteinases are activated by VEGF and other regulatory cytokines and act to digest the extracellular matrix and thereby facilitate the spreading and chemotaxis of actively proliferating endothelial cells as they aggregate to form new capillaries.<sup>2</sup> Matrix metalloproteinases appear to be modulated and principally downregulated by naturally occurring tissue inhibitors of metalloproteinases (TIMPs) of which TIMP-1, TIMP-2, and TIMP-4 are thought to be soluble, and TIMP-3 principally extracellular matrix-bound. TIMP-3 is thought to play an important and possibly critical role in the natural modulation of matrix metalloproteinase regulation in Bruch's membrane, and is found in increased amounts in drusen and thickened basement membranes associated with AMD.<sup>24,25,28,29,81</sup> An experimental model that either delivers increased amounts of TIMP-3 or induces over expression of TIMP-3 by gene therapy demonstrate potent antiangiogenic effects for this molecule.<sup>82,83</sup>

## **Tissue Factor**

Tissue factor (TF) is a transmembrane receptor for the coagulation factor VII/VIIa.<sup>84</sup> Upon vascular injury, TF forms a complex with factor VII, initiating the coagulation cascade. Constitutively expressed within vascular endothelium, the secondary activities of TF (and the TF/VIIa complex) include the promotion of inflammation and angiogenesis. In cancer biology, a link between

TF and VEGF expression has been established in a number of cancers, and TF is believed to induce angiogenesis in part through VEGF induction.<sup>85,86</sup> Relevant to AMD, in addition to the amyloid, apolipoprotein E, and complement factors that are found in drusen, factor X, and fibrinogen have also been identified, which are closely related to TF activity.<sup>87,88</sup> Tissue factor itself has been identified by immunostaining in RPE cells and macrophages in post-mortem eyes with CNV and in surgically excised CNV lesions, as well as in animal models of AMD.<sup>64,88</sup> Tissue factor inhibition through antibody targeting of factor VII has been demonstrated to obliterate lesions in laser-induced animal models of CNV.<sup>89,90</sup>

## **Angiopoietins**

Angiopoietins, which are also highly specific for endothelial cells, perform a variety of other regulatory activities related to supporting cells and the extracellular matrix. A laboratory study suggests that two different isoforms, Angiopoietin 1 and Angiopoietin 2, appear to have differential and counter-acting effects on the vasculature. Angiopoietin 2, which is upregulated by both hypoxia and VEGF, binds to an endothelial cell receptor TIE2 and enhances VEGF-mediated retinal neovascularization, but does not by itself stimulate endothelial cells or proliferation in vitro.<sup>2,91</sup> Angiopoietin 1 appears to play a maturation role and is associated with non-leaky behavior and may have potential therapeutic benefit through its inhibition of inflammatory pathways.<sup>2</sup> Another protein, angiopoietin-like protein 4 (ANGPTL4), has recently been found in elevated levels within the aqueous humor of eyes with proliferative diabetic retinopathy, and is upregulated by hypoxia and HIF and is both necessary and sufficient to promote retinal angiogenesis.<sup>92</sup> It is as yet unknown if this may also play a role in CNV.

## **Pigment Epithelium-Derived Factor**

A variety of naturally occurring cytokines are known to have a downregulatory effect on angiogenesis and VEGF-mediated effect on cells. Notably, pigment epithelium-derived factor (PEDF), which is secreted by the pigment epithelium in vivo as well as in cell culture, has been shown to be biochemically identical to the product

of the wild type of retinoblastoma tumor suppressor gene (*RB*) and is thought to induce differentiation of retinoblastoma cells, inhibit microglial growth, and other important regulatory functions in addition to its effects on angiogenesis.<sup>49</sup> Its relevance to AMD is likely related to its role in counterbalancing VEGF. In a study of donor human eyes with and without AMD, relative VEGF and PEDF levels were measured using immunoreactivity assays. Interestingly, VEGF levels were not significantly different between the two groups of eyes, even in the presence of advanced exudative change. In contrast, PEDF levels were much lower in the RPE and choroid of eyes with AMD, suggesting that it is lower levels of PEDF in the ocular milieu that may contribute to the formation of CNV.<sup>93</sup> Results from in vitro studies have suggested that the role of PEDF is regulation or inhibition of VEGF receptor signaling, rather than direct VEGF antagonism.<sup>94</sup>

## Pathogenic Factors in Atrophic AMD

The factors that result in the progression of mild or moderate AMD to advanced atrophic AMD (geographic atrophy) are poorly understood. It is clear that immune dysregulation, inflammation, and oxidative stress play key roles in the development and progression of AMD, with angiogenesis as one late-stage outcome of the chronic local inflammatory state. The genetics of the complement system and their associations with AMD have been discussed above, although it is still unclear how genotypic variations in complement lead to the AMD phenotype. Clinicopathologic specimens demonstrate the presence of inflammatory cells in Bruch's membrane, and bioactive fragments of C3 (C3a) and C5 (C5a) in drusen of AMD eyes and elevated vascular endothelial growth factor (VEGF) expression in RPE cells.<sup>95,96</sup> Inflammatory foci and white cells are also commonly seen in the choroid in autopsy specimens of patients with CNV.<sup>64,95-100</sup> Geographic atrophy has been associated with loss of a regulatory enzyme *DICER1*, and subsequent upregulation of an inflammatory complex called the NLRP3 inflammasome, leading to secretion of multiple inflammatory cytokines, including IL-6, TNF- $\alpha$ , IL-1 $\beta$ , and IL-18.<sup>101,102</sup> This process may be triggered by N-retinylidene-N-

retinylethanolamine (A2E), and associated free radicals and reactive oxygen intermediates related to the formation of this component of lipofuscin, ultimately stimulating both apoptotic and angiogenic signals<sup>18,41,103</sup> (Fig. 70.7). The inflammatory cascade is further characterized by retinal microglial activation and choroidal macrophage infiltration.<sup>104,105</sup> Given the compelling evidence that inflammation has a causative effect on the development and progression of AMD, therapy aimed at reducing inflammation through complement inhibition or regulation; immunomodulation; or stabilization of intracellular organelles, such as lysosomes and resultant proteolysis, may be successful pharmacologic strategies.<sup>104,105</sup>

**FIG. 70.7** Schematic diagram of pathogenic mechanisms associated with atrophic and exudative age-related macular degeneration. Normal constitutive release of VEGF, which is responsible for maintenance of fenestrations and other desirable permeability effects on the normal choriocapillaris through basal lateral secretion in an outward direction, appears to be effectively counterbalanced by the apical secretion of cytokines inhibitory for angiogenesis, including pigment epithelial derived (PEDF). This results in the relative avascularity of the outer retina as seen in the diagram on the right. In response to chronic light exposure and oxidation of phospholipids associated with the visual cycle, A2E and other oxidative byproducts accumulate in the retinal pigment epithelium, accounting for the characteristic autofluorescence seen on fundus photography. They also result in senescence of the

pigment epithelium and apoptotic death associated with secondary atrophic effects on the overlying photoreceptors and underlying choriocapillaris, seen on the left in the diagram. The accumulation of increased lipoproteins as well as other glycoproteins including TIMP-3 and EFEMP-1 contribute to the thickening of Bruch's membrane, characteristically seen in patients with more advanced forms of the disease (seen centrally). Low-grade inflammation, chemoattraction of monocytes, and proangiogenic signals both from the pigment epithelium and inflammatory cells lead to vascular ingrowth from the choroid through defects in calcific and fragmented Bruch's membrane.

Among the components of drusen is fibrillar amyloid, and specifically amyloid- $\beta$ , which has been associated with Alzheimer's disease, Huntington disease, Downs syndrome, and other neurodegenerative conditions.<sup>106</sup> Within the retina, amyloid is localized within vesicles in drusen, and chronic exposure of the retina to amyloid is postulated to lead to overexpression of proinflammatory cytokines such as IL-1 $\beta$  and IL-8, which play roles in generating reactive oxygen species and in chemotaxis. Amyloid- $\beta$  has also been demonstrated in degenerating brains to induce chronic inflammation via the complement system, and may play a similar role in the retina. Indeed, amyloid has been found to colocalize with the complement factor C3 in drusen.<sup>107,108</sup> As a component of drusen, amyloid deposition may contribute to RPE dysfunction and ultimately atrophy.

Choroidal ischemia may be another factor contributing to atrophic macular degeneration. Studies have demonstrated that eyes with age-related macular degeneration have decreased arterial blood flow on indocyanine green angiography.<sup>109</sup> Additionally, newer imaging technologies such as high-resolution ultrasound, as well as spectral domain optical coherence tomography (OCT) with enhanced depth imaging, have revealed characteristics consistent with choroidal ischemia in eyes with AMD.<sup>110,111a</sup> Additionally, histopathologic study of postmortem eyes demonstrated remodeling and loss of the choriocapillaris even in intermediate AMD.<sup>111b</sup>

# Agents Currently in Use or Under Investigation: Neovascular AMD

## VEGF Inhibition: Monotherapy

A variety of methods are now available to directly inhibit the VEGF<sub>165</sub> molecule and its various other isoforms. These include the use of monoclonal antibodies directed at one or more isoforms, antibody fragments, and molecules directed at one or more of the VEGF receptors including native decoys, tyrosine kinase inhibitors, fusion proteins, and modified naturally occurring proteins. Additionally, because VEGF is thought to initiate a cascade of intracellular signals initially, and subsequently extracellular events, it is possible to inhibit VEGF effects either through prevention of secretion of the molecule, direct inhibition of the molecule in the extracellular space, blockade of the receptors, or through interruption in the downstream intracellular signaling pathways leading to both intra- and extracellular events.<sup>112</sup> Finally, new technologies for sustained drug delivery are being explored.

### Monoclonal Antibody: Bevacizumab

Bevacizumab (Avastin; Genentech/Roche, South San Francisco, CA, USA) is a humanized monoclonal antibody (IgG1) against human VEGF-A that selectively inhibits all isoforms and bioactive proteolytic breakdown products of VEGF-A. Bevacizumab is an immunoglobulin G molecule comprised of amino acid sequences which are about 93% human and 7% murine. Preclinical studies in animal models of various tumor cell lines, as well as different forms of ocular neovascularization, indicated that the fully sized antibody had excellent efficacy against the primary permeability and proliferative effects of VEGF isoforms. Following extensive clinical testing, it was found to be effective in slowing tumor growth through its effects on angiogenesis.<sup>57</sup> Bevacizumab was FDA-approved in 2004 as a treatment for metastatic colorectal cancer when given intravenously at a dose of 5 mg/kg and infused every 2 weeks in combination with 5-fluorouracil. Bevacizumab was shown

to increase survival, response rate, and duration of response compared with conventional therapy consisting of irinotecan, fluorouracil, and leucovorin for metastatic colorectal cancer.<sup>113</sup> Additional phase III clinical trials with bevacizumab have since resulted in FDA-approval for the treatment of lung, kidney, and brain cancers.

In 2004, a study investigating the use of systemic bevacizumab in patients with exudative AMD (Systemic Avastin for Neovascular AMD – SANA) was initiated at the Bascom Palmer Eye Institute. This study was the first demonstration that bevacizumab was effective for this disease. In this open-label, uncontrolled study, 18 patients underwent two to three intravenous infusions of bevacizumab (5 mg/kg) to evaluate the potential safety and efficacy of systemic bevacizumab over 6 months.<sup>114,115</sup> Although clinical trials using intravitreal pegaptanib and ranibizumab for CNV were underway, the prior use of bevacizumab for ocular disease in humans using any route had previously been untested. While no serious adverse events were observed, and only a mild transient increase in blood pressure was identified, the SANA study was too small to establish the safety of bevacizumab. However, significant improvements in visual acuity and OCT central retinal thickness (CRT) measurements were observed comparable to the changes observed in the early phase ranibizumab trials.

While systemic bevacizumab (5 mg/kg) was shown to reduce leakage from CNV, decrease OCT central retinal thickness measurements, and significantly improve vision in exudative AMD, the intravenous use of bevacizumab for exudative AMD was never widely adopted, because the intravitreal approach uses up to 500-fold less drug, is much less expensive, and is perceived to be safer due to the smaller dose of drug. In the first-reported case of intravitreal bevacizumab,<sup>116</sup> a patient with recurrent CNV secondary to AMD, who had previously been treated with verteporfin photodynamic therapy (PDT) in combination with triamcinolone acetonide followed by treatment with pegaptanib injections, was shown to improve with a decrease in OCT central retinal thickness and subretinal fluid, as well as improvement of subjective visual distortion, within 1 week of a single injection of 1.0 mg bevacizumab.

The bevacizumab used for this injection was the commercially available form available as 100 mg and 400 mg preservative-free, single-use vials in volumes of 4 mL or 16 mL (25 mg/mL). The 100 mg product is formulated in 240 mg  $\alpha$ (alpha), $\alpha$ (alpha)-trehalose dihydrate, 23.2 mg sodium phosphate (monobasic, monohydrate), 4.8 mg sodium phosphate (dibasic, anhydrous), 1.6 mg polysorbate 20, and was diluted in water prior to intravenous infusion. For off-label intravitreal use, bevacizumab was not diluted, but rather dispensed into individual syringes for intravitreal injection and the volume (dose) of injection ranged from 0.05 mL (1.25 mg) to 0.1 mL (2.5 mg).

Initially, there was concern that a molecule as large as the 149-kilodalton bevacizumab could penetrate the retina and effectively treat CNV compared with ranibizumab, which is one-third the size. However, it became apparent that bevacizumab could penetrate the retina based upon the empiric observations of decreased subretinal fluid on OCT examination and improved visual acuities in treated patients. Subsequently, Han et al. were the first to show that a full-length immunoglobulin the size of bevacizumab was capable of penetrating the rabbit retina after an intravitreal injection.<sup>117</sup> Sharar et al. used qualitative immunofluorescence to confirm that intravitreal bevacizumab was able to completely penetrate the retina by 24 hours and was essentially absent at 4 weeks after an injection.<sup>118</sup> Moreover, Dib et al. demonstrated bevacizumab molecules in the subretinal space of all six eyes studied 2 hours after an intravitreal bevacizumab injection of 0.05 mL (1.25 mg), confirming the initial observations that the molecule could rapidly diffuse through the retina.<sup>119</sup>

The ocular pharmacokinetics of various other monoclonal antibodies injected into the vitreous cavity of monkeys and rabbits demonstrated a half-life of about 5.6 days.<sup>120,121</sup> Studies of bevacizumab in rabbits and monkeys suggest a half-life in the range of 4–6 days.<sup>122–124</sup> A human study reported that a single dose of intravitreal bevacizumab had a half-life of 3 days and was likely to provide complete intravitreal VEGF blockade for a minimum of 4 weeks.<sup>125</sup> One human study suggested a half-life of 6.7 days, and yet another study has reported a half-life of as long as 9.8 days.<sup>126,127</sup> It is likely that human ocular pharmacokinetics of bevacizumab varies

from patient to patient, depending on factors such as the extent of vitreous liquefaction and the phakic status of the eye.

Since the first case of intravitreal bevacizumab for the treatment of exudative AMD was reported, numerous retrospective studies and a few small prospective studies using a dose range between 1.0 and 2.5 mg have been published, all demonstrating clinically significant improvement in mean visual acuity, reduction in fluorescein angiographic leakage, and resolution of OCT-visualized edema in up to 90% of bevacizumab-treated patients. These reports also supported the apparent clinical safety of bevacizumab. As of the time of writing (2015), despite the subsequent approval of ranibizumab in 2006, the off-label use of intravitreal bevacizumab has become the most common treatment for exudative AMD in the United States.<sup>128,129</sup> In addition, it has also become frequently used for a wide range of other forms of macular new vessels including pathologic high myopia, multifocal choroiditis, and ocular histoplasmosis; it has also been used successfully for treatment of clinically significant macular edema from diabetic retinopathy, retinal venous occlusions, and retinopathy of prematurity.<sup>130-138</sup> Its efficacy relative to the FDA-approved ranibizumab was demonstrated in the CATT study (described later).

### **Antigen Binding Fragment: Ranibizumab**

Ranibizumab (Lucentis; Genentech/Roche, South San Francisco, CA, USA) is a humanized anti-VEGF-A recombinant Fab fragment that has been affinity-matured to increase its binding affinity for VEGF-A. Ranibizumab binds within the VEGFR binding domain of all biologically active isoforms of VEGF-A. Two randomized, double-masked, pivotal phase 3 clinical trials have demonstrated that monthly intravitreal injections of ranibizumab are an effective and safe treatment for subfoveal CNV in AMD patients.<sup>139,140</sup>

The MARINA study assessed the response of minimally classic or occult CNV to ranibizumab.<sup>139</sup> Patients (n=716) were assigned randomly to receive sham injection (n=238), 0.3 mg (n=238), or 0.5 mg (n=240) ranibizumab. After 4 months of follow-up, approximately 90% of ranibizumab-treated patients had lost fewer than 15 letters on the Bailey-Lovie (ETDRS) chart as compared to 53% of the sham-injected patients. This treatment response was

independent of lesion size, initial visual acuity, or whether the lesion was classified as minimally classic or occult with no classic CNV on fluorescein angiography. Vision improved by at least 15 letters in approximately 33% of patients receiving 0.5 mg ranibizumab at 24 months of follow-up vs. 4% in the sham-injected patients (Fig. 70.8). Approximately 1% of patients receiving intravitreal ranibizumab developed endophthalmitis. The risk of cataract was approximately 0.2%. There were no cases of retinal detachment among patients receiving intravitreal therapy. Despite the theoretical risk of systemic vascular complications, there was no imbalance among treated and control groups regarding hypertension, and the risk of myocardial infarction among sham-injected, 0.3-mg, and 0.5-mg cohorts was 1.7%, 2.5%, and 1.3%, respectively. The risk of stroke among the three groups was 0.8%, 1.3%, and 2.5%, respectively. The risk of nonocular hemorrhage was 5.5%, 9.2%, and 8.8% in each of the three cohorts, respectively. None of these differences was statistically significant, although the authors recognized that the study was not powered to detect small differences.

**FIG. 70.8** Mean change from baseline in best corrected visual acuity by month for (A) MARINA, (B) ANCHOR, (C) PIER, (D) EXCITE, (E) PrONTO, (F) SUSTAIN. An optical coherence tomography-guided, variable dosing regimen with intravitreal ranibizumab (Lucentis) for neovascular age-related macular degeneration. *Am J Ophthalmol* 2007;143:566–83, Copyright 2007, with permission from Elsevier. Compilation reproduced with permission from Mitchell P, Korobelnik JF, Lanzetta P, et al. Ranibizumab (Lucentis) in neovascular age-related macular degeneration: evidence from clinical trials. *Br J Ophthalmol* 2010;94(1):2–13.)

The ANCHOR study assessed the response of patients with predominantly classic CNV as determined by fluorescein angiography.<sup>140</sup> Patients (n=423) were randomly assigned to receive verteporfin-PDT plus sham injection (n=143) or sham PDT plus injection of either 0.3 mg (n=140) or 0.5 mg (n=140) ranibizumab. At 12 months follow-up, approximately 95% of ranibizumab-treated patients lost less than 15 letters of vision vs. 64% in the verteporfin active treatment control group. Forty percent of patients treated with 0.5 mg ranibizumab gained at least 15 letters vision vs. 6% in the verteporfin treatment cohort. At month 24, the visual benefit from ranibizumab remained statistically ( $p < .0001$  vs. PDT) and clinically significant: 89.9% to 90.0% of ranibizumab-treated patients had lost <15 letters from baseline (vs. 65.7% of PDT patients); 34% to 41.0% had gained  $\geq 15$  letters (vs. 6.3% of PDT group); and, on average, visual acuity was improved from baseline by 8.1 to 10.7 letters (vs. a mean decline of 9.8 letters in the PDT groups).<sup>141</sup> Changes in lesion anatomic characteristics on fluorescein angiography also favored ranibizumab (all comparisons  $p < .0001$  vs. PDT). Overall, there was no imbalance among groups in rates of serious ocular and nonocular adverse events. In the pooled ranibizumab groups, 3 (1.1%) of 277 patients developed presumed endophthalmitis in the study eye (rate per injection = 3/5921, or 0.05%). Retinal detachment was observed in one patient in both the verteporfin (0.7%) and 0.3-mg ranibizumab (0.7%) cohorts. There were no cases of lens injury. The risk of hypertension was the same in all cohorts. The risk of myocardial infarction among verteporfin, 0.3-mg ranibizumab, and 0.5-mg ranibizumab cohorts was 0.7%, 0.7%, and 2.1%, respectively. The risk of stroke or cerebral infarction was 0.7% in each of the three cohorts. The risk of

nonocular hemorrhage was 2.1%, 5.1%, and 6.4% in each of the three cohorts. Immunoreactivity to ranibizumab before treatment was 1.5%, 3.2%, and 0.8% among the verteporfin, 0.3-mg ranibizumab, and 0.5-mg ranibizumab cohorts, respectively. Immunoreactivity was present in 1.6%, 1.6%, and 3.9% of patients in each of these cohorts, respectively, after 12 months of treatment. The concern regarding immunoreactivity is that patients who develop an immune response might exhibit increased intraocular inflammation following intravitreal injection and consequently might not respond to the medication as well as patients who do not exhibit such a response. In practice, most retina surgeons have not observed this phenomenon and the drug has been minimally immunogenic in the doses tested.<sup>142</sup>

In both the MARINA and ANCHOR trials, visual acuity improvement seemed to reach a plateau by the 4-month time point (Fig. 70.8). Because monthly injections were considered inconvenient and daunting for some patients and their family members, and entailed risk as well as considerable expense, studies were undertaken to evaluate alternative treatment regimens. The PIER and EXCITE studies provided useful information in this regard.<sup>143,144</sup> In PIER, a phase IIIb multicenter, randomized, double-masked trial, patients with subfoveal CNV were randomly assigned to sham injection (n=63), 0.3 mg ranibizumab (n=60), or 0.5 mg ranibizumab (n=61). Patients received sham or ranibizumab injections every 4 weeks for three doses followed by additional treatment every 3 months. By month 12, mean changes from baseline visual acuity were -16.3, -1.6, and -0.2 letters for the sham, 0.3-mg, and 0.5-mg groups, respectively ( $p \leq .0001$ , each ranibizumab dose vs. sham). Ranibizumab arrested CNV growth and reduced leakage from CNV. The treatment effect declined, however, in the ranibizumab groups during quarterly dosing. At month 3, for example, the mean changes from baseline vision had been gains of +2.9 and +4.3 letters for the 0.3-mg and 0.5-mg doses, respectively. During study year 2, eligible sham-group patients crossed over to 0.5 mg ranibizumab quarterly. Later in year 2, all eligible randomized patients rolled over to 0.5 mg ranibizumab monthly dosing. The ranibizumab-treated patients showed an improvement in mean visual acuity during the first 3 months of the study, but

this improvement was not sustained. Nonetheless, the 0.5-mg ranibizumab cohort had a mean visual acuity change that was 16 letters better than that of the sham cohort by month 12 ( $p<.0001$ ). By month 24, visual acuity had decreased an average of 21.4, 2.2, and 2.3 letters from baseline in the sham, 0.3-mg, and 0.5-mg groups ( $p<.0001$  for each ranibizumab group vs. sham). The visual acuity of sham patients who crossed over to ranibizumab decreased over time, with an average loss of 3.5 letters 10 months after crossover. The visual acuity of patients in the 0.3-mg and 0.5-mg cohorts who rolled over to monthly ranibizumab injections increased for an average gain of 2.2 and 4.1 letters, respectively, 4 months after transition. These data indicate that injecting patients with ranibizumab every 3 months (after an induction phase of three monthly injections) does not produce the same chance for visual benefit as monthly injection, at least during the first 12 months of therapy. Ranibizumab appeared to provide additional visual benefit to treated patients who rolled over to monthly dosing, but not to patients who began receiving ranibizumab after >14 months of sham injections.

The EXCITE study was a 12-month, multicenter, randomized, double-masked, active-controlled, phase IIIb study designed to demonstrate the noninferiority of a quarterly treatment vs. monthly intravitreal ranibizumab treatment regimen in patients with AMD-associated CNV.<sup>145</sup> Patients with primary or recurrent subfoveal CNV secondary to AMD (353 patients), including those with predominantly classic, minimally classic, or occult (no classic component) lesions, were enrolled. Patients were randomized (1:1:1) to 0.3 mg quarterly, 0.5 mg quarterly, or 0.3 mg monthly doses of ranibizumab. Treatment comprised three consecutive monthly injections followed by a 9-month maintenance phase (either monthly or quarterly injection). In the per-protocol population (293 patients), visual acuity increased from baseline to month 12 by 4.9, 3.8, and 8.3 letters in the 0.3-mg-quarterly (104 patients), 0.5-mg-quarterly (88 patients), and 0.3-mg-monthly (101 patients) dosing groups, respectively. Similar results were observed in the intent-to-treat (ITT) population (353 patients). The mean decrease in CRT from baseline to month 12 in the ITT population was  $-96.0\ \mu\text{m}$  in 0.3-mg-quarterly,  $-105.6\ \mu\text{m}$  in 0.5-mg-quarterly,

and  $-105.3 \mu\text{m}$  in 0.3-mg-monthly group. At month 12, the visual acuity gain in the monthly treatment cohort was higher than that of the quarterly regimens. The noninferiority of a quarterly regimen was not achieved with reference to 5.0 letters.

The SUSTAIN study is a 12-month, phase III, multicenter, open-label, single-arm study involving 513 ranibizumab-naive patients with AMD-associated CNV.<sup>146</sup> In this study, patients received three initial monthly injections of ranibizumab (0.3 mg) and thereafter as-needed (pro re nata, PRN) retreatment for 9 months based on prespecified retreatment criteria. Patients switched to 0.5 mg ranibizumab after approval in Europe. The average number of retreatments from months 3 to 11 was 2.7. Mean best corrected visual acuity (BCVA) increased steadily from baseline to month 3 to reach +5.8 letters, decreased slightly from month 3 to 6, and remained stable from month 6 to 12, reaching +3.6 at month 12. The mean change in CRT was  $-101.1 \mu\text{m}$  from baseline to month 3 and  $-91.5 \mu\text{m}$  from baseline to month 12.

In summary, data from the ANCHOR, MARINA, PIER, EXCITE, and SUSTAIN studies indicated that after a loading dose period of three monthly injections, subsequently monthly ranibizumab injections give superior visual acuity outcomes compared to quarterly or PRN injections (Fig. 70.9).

**FIG. 70.9** Mean change in visual acuity from baseline at the end of the loading phase (●) and at 12 months (arrowhead) against the number of injections during 9 months of the maintenance phase (ranibizumab 0.5 mg data unless indicated). (Reproduced with permission from

Mitchell P, Korobelnik JF, Lanzetta P, et al. Ranibizumab (Lucentis) in neovascular age-related macular degeneration: evidence from clinical trials. *Br J Ophthalmol* 2010;94:2–13.)

In the PrONTO (Prospective OCT Imaging of Patients with Neovascular AMD Treated with Intraocular Lucentis) study, patients (n=40) received 0.5 mg ranibizumab at entry, month 1, and month 2.<sup>147</sup> OCT measurements were obtained at baseline and at least monthly after injection (more frequently during the first two months after entry). Fluorescein angiograms were obtained at baseline and every 3 months thereafter. Retreatment with

ranibizumab was done only if one or more of the following conditions was observed: (1) OCT central retinal thickness increased 100  $\mu\text{m}$ ; (2)  $\geq 5$  letter visual loss associated with subretinal fluid (as judged with OCT); (3) new onset classic CNV; (4) new macular hemorrhage; (5) persistent subretinal or intraretinal fluid was present one month after the previous injection. One day after the first injection, there was a decrease in the mean OCT thickness of 47  $\mu\text{m}$ . By month 12, the mean visual acuity improved by 9.3 letters ( $p < .001$ ), and the mean central thickness decreased by 178  $\mu\text{m}$  compared with baseline ( $p < .001$ ). Mean visual acuity improvement was 9.3 letters, and the mean RCT had decreased by 178  $\mu\text{m}$ . The average number of injections over the first year was 5.6. Visual acuity improved  $\geq 15$  letters in 35% of patients, and once macular fluid resorbed completely, the mean interval before another injection was 4.5 months. During the second year, the retreatment criteria were amended to include retreatment if any qualitative increase in the amount of fluid was detected using OCT.<sup>148</sup> Forty patients were enrolled and 37 completed the 2-year study. At month 24, the mean visual acuity improved by 11.1 letters ( $p < .001$ ), and CRT decreased by 212  $\mu\text{m}$  ( $p < .001$ ). Visual acuity improved by 15 letters or more in 43% of patients. These visual acuity and OCT outcomes were achieved with an average of 9.9 injections over 24 months. The PrONTO Study data suggested that OCT-guided variable-dosing regimens with intravitreal ranibizumab were capable of achieving visual acuity outcomes comparable to those from the phase III clinical studies, but with fewer intravitreal injections.

Although the risk of arterial thromboembolic events was not increased to a statistically significant degree among ranibizumab-treated patients in these phase III studies (overall risk  $\sim 2.1\%$  in ranibizumab-treated patients during year 1 vs.  $\sim 1.1\%$  among controls), some concerns were expressed about relative safety compared with alternative therapies, efficacy aside, as the studies were not powered for statistical significance between the two different ranibizumab doses. Year-2 data from the MARINA study indicate the overall rate of antiplatelet trialists' collaboration (APTC)-defined arterial thromboembolic events, which includes nonfatal myocardial infarction, nonfatal stroke, and death from a

vascular or unknown cause,<sup>149</sup> was 4.6%, 4.6%, and 3.8% among the 0.5-mg ranibizumab, 0.3-mg ranibizumab, and control cohorts, respectively. Year-2 data from the ANCHOR study indicate the overall rate of APTC arterial thromboembolic events was 5%, 4.4%, and 4.2% in the 0.5-mg, 0.3-mg, and verteporfin-PDT cohorts, respectively. The PIER<sup>143,144</sup> and EXCITE<sup>145</sup> studies had similar results in this regard.

The SAILOR study was a phase IIIb study whose objectives were to evaluate the safety of 0.3 mg and 0.5 mg Lucentis in patients with AMD-associated subfoveal CNV. In cohort 1 of this study, the dose was randomly assigned and administered once a month for 3 months and thereafter as needed based on retreatment criteria. In SAILOR, there was a numerically higher rate of cerebrovascular stroke with 0.5 mg ranibizumab compared with 0.3 mg ranibizumab (1.2 vs. 0.7%), which was not statistically significant in patients with a history of stroke.<sup>150</sup> In the SUSTAIN study, a total of 249 patients (48.5%) reported ocular adverse events, 5 patients (1.2%) with ocular serious adverse events involving the study eye (retinal hemorrhage, cataract, retinal pigment epithelial tear, reduced visual acuity, vitreous hemorrhage), 19 patients (3.7%) with arteriothromboembolic events were observed, with 8 deaths (1.5%).<sup>146</sup> The most frequent adverse events in the study eye were reduced visual acuity (18.5%), retinal hemorrhage (7.2%), increased intraocular pressure (7.0%), and conjunctival hemorrhage (5.5%). Overall, the ocular and systemic risks associated with ranibizumab use appear to be low and within a reasonable range when taking into account the associated likelihood of visual improvement in properly selected patients (Table 70.2).

## HARBOR

HARBOR is a 24-month duration phase III randomized clinical trial in which patients with active subfoveal CNV were randomized 1:1:1:1 to receive intravitreal ranibizumab 0.5 mg monthly, 0.5 mg × 3 loading doses with monthly follow-up and additional injections as needed, 2.0 mg monthly, or 2.0 mg × 3 loading doses with monthly follow-up and additional injections as needed (Fig. 70.10).<sup>151,152</sup> Patients in the PRN cohorts received additional injections if there was ≥5 ETDRS letter decrease from the previous visit or any evidence of disease activity on SD-OCT. The primary endpoint was the mean change from baseline in BCVA at month 12. Secondary endpoints included the mean change from baseline in BCVA at month 24, the mean number of ranibizumab injections, the mean change from baseline in central foveal thickness by SD-OCT over time, and the proportion of patients who gained ≥15 ETDRS letters in BCVA. There was no significant difference in visual outcome between the 0.5-mg-monthly and 2.0-mg-monthly cohorts (approximately 9 ETDRS letter gain), and there was no significant difference in outcome between the 0.5-mg-PRN and 2.0-mg-PRN cohorts (8 ETDRS letter gain) (Fig. 70.11). There was no clinically important difference in BCVA outcome between the monthly and PRN cohorts for each ranibizumab dose. Of note, the 0.5-mg-PRN cohort received a mean of 13.3 injections during the 24-month follow-up (vs. 21.4 in the monthly cohort), and the 2.0-mg-PRN cohort received a mean of 11.2 injections during the 24-month follow-up (vs. 21.6 in the monthly cohort). Thus, PRN injection posology (which includes 3 monthly loading doses) results in a 40–50% reduction in the number of injections without compromising BCVA outcome during the 24-month follow-up period. In fact, only 7% of the patients in the 0.5-mg-PRN cohort and only 2% in the 2-mg-PRN cohort required monthly injections during the 24-month

follow-up. Mean change in central foveal thickness at 24-month follow-up was comparable for all cohorts (~175  $\mu\text{m}$  reduction from baseline), with the majority of the reduction having occurred by month 3. The proportion of patients gaining  $\geq 15$  ETDRS letters was comparable in all cohorts (~30–35%). Higher dosing of ranibizumab was not associated with an increase risk of systemic complications such as antiplatelet trialists collaboration arterial thromboembolic events, death, nonfatal myocardial infarction, or nonfatal cerebrovascular accident.

AMD = age related macular degeneration; CNV = choroidal neovascularization; LD = Loading dose; PRN = as needed.

2013;120(5):1046-1056; Ho et al. *Ophthalmology*. 2014;121(11):2181-92.)

The development of GA was assessed in the HARBOR trial using fluorescein angiography and color fundus photographs. Atrophy was defined as well-defined areas of depigmentation with increased visibility of choroidal vessels at least 250  $\mu\text{m}$  in diameter that correspond to flat areas of well-demarcated staining on fluorescein angiography. Atrophy associated without RPE-tears was not included. Rates of atrophy in ranibizumab-treated eyes were 9% at month 3, 21% at month 12, and 29% at month 24. These rates are similar to those reported in the CATT (20%, month 24) and IVAN (28%, month 24) trials. Visual outcome was similar among patients with vs. without GA at baseline, indicating that even if GA is present at baseline and even if treatment increases the risk of developing GA (still an unproved hypothesis), BCVA outcome at month 24 in the setting of active subfoveal CNV is still far better with 0.5 mg ranibizumab therapy than without it. In the HARBOR trial, risk factors for developing GA included the presence of intraretinal cysts (by OCT) at baseline and presence of GA in the fellow eye. The presence of subretinal fluid at baseline seemed to be associated with a reduced risk of developing GA. It is important to note that patients with subretinal fluid were treated according to their preassigned protocol throughout the HARBOR trial to achieve the observed visual outcomes. There was a trend for the 2.0-mg-monthly cohort to have an increased risk of GA compared to the

0.5-mg-PRN cohort, but the difference in risk was not statistically significant. Patients receiving 0.5 mg ranibizumab monthly had a statistically significant increased risk of developing GA compared to patients receiving 0.5 mg as needed. Thus, monthly treatment may be associated with a higher risk of developing GA. Data with regard to GA from the HARBOR study should be interpreted with caution because (1) this analysis was done post-hoc; (2) there was no natural history control group; (3) detection methods for GA were not optimal (e.g., fundus autofluorescence was not obtained); and (4) quantitative data on progression were not obtained.

### **Comparison of Age-Related Macular Degeneration Treatments Trial (CATT)**

Despite a relative lack of level 1 evidence prior to 2011, bevacizumab had become the most widely used agent for AMD in the world due to a number of factors, including its low cost compared to ranibizumab, similarity in therapeutic mechanism, and its availability to physicians prior to the FDA approval of ranibizumab. A large amount of data from retrospective reviews, interventional case series, and anecdotal reports has provided physicians with evidence to support the continued off-label use of bevacizumab. However, in the absence of a large, randomized clinical controlled trial comparing bevacizumab to ranibizumab, the gold standard treatment, several questions have arisen: (1) Does one treatment offer superior visual outcomes to another? (2) What is the optimal treatment regimen and interval? (3) Is the safety profile of bevacizumab comparable to that of ranibizumab, which has been subjected to rigorous phase 1–phase 4 evaluation? The CATT was designed to address these questions.<sup>129</sup>

The CATT is a multicenter, randomized clinical trial, that enrolled 1,208 patients with previously untreated subfoveal CNV due to AMD, as determined by leakage on fluorescein angiogram and fluid on time-domain OCT. The primary outcome measure in the study was visual acuity change. The study designers also elected to examine the proportion of patients with a 15-letter difference in vision, number of injections, fluid and thickness on OCT, lesion size on fluorescein angiography, incidence of ocular and systemic adverse events, and annual treatment cost as

secondary treatment endpoints. Patients were randomized to one of four groups: (1) ranibizumab 0.5 mg monthly (every 28 days); (2) bevacizumab 1.25 mg monthly; (3) ranibizumab as needed (when signs of active neovascularization were present); (4) bevacizumab as needed (with the same indications for retreatment as in group 3). The study was designed to determine noninferiority of one treatment group with respect to each of the remaining three groups, using a statistically robust 99.2% confidence interval and a noninferiority limit of 5 ETDRS letters.

Visual acuity data were available for 1,105 patients at one year. The six pairwise comparisons showed the following: (1) bevacizumab monthly injections (8.0 letters gained) and ranibizumab monthly injections (+8.5 letters) yielded equivalent visual outcomes; (2) bevacizumab given as needed (+5.9 letters) was also equivalent to ranibizumab similarly given as needed (+6.8 letters); (3) ranibizumab given as needed was equivalent to ranibizumab given monthly; (4) ranibizumab given was also equivalent to bevacizumab given monthly; (5) bevacizumab given as needed when compared to bevacizumab given monthly or (6) ranibizumab given monthly, was not noninferior (inconclusive). Detailed visual and anatomic outcome data are shown in [Fig. 70.12](#) and [Table 70.3](#).

Mean ( $\pm$ SE) change in visual acuity score from baseline (no. of letters)

Ranibizumab monthly	+3.6 $\pm$ 0.5	+6.1 $\pm$ 0.7	+6.6 $\pm$ 0.8	+7.5 $\pm$ 0.9	+8.5 $\pm$ 0.8
Bevacizumab monthly	+4.3 $\pm$ 0.6	+6.1 $\pm$ 0.7	+7.3 $\pm$ 0.9	+7.7 $\pm$ 1.0	+8.0 $\pm$ 1.0
Ranibizumab as needed	+3.3 $\pm$ 0.6	+5.6 $\pm$ 0.7	+5.8 $\pm$ 0.7	+7.2 $\pm$ 0.7	+6.8 $\pm$ 0.8
Bevacizumab as needed	+3.2 $\pm$ 0.5	+5.6 $\pm$ 0.7	+5.8 $\pm$ 0.8	+7.1 $\pm$ 0.9	+5.9 $\pm$ 1.0

Average annual cost/patient	\$23 400	\$13 800	\$595	\$385	

<sup>a</sup>The total foveal thickness includes the retina, subretinal fluid, choroidal neovascularization, and retinal pigment epithelial elevation.

<sup>b</sup>Data were missing for 4 patients in the ranibizumab-monthly group, 4 patients in the

ranibizumab-as-needed group, 4 patients in the bevacizumab-monthly group, and 5 patients in the bevacizumab-as-needed group.

<sup>c</sup>Data were missing for 4 patients in the ranibizumab-monthly group, 7 patients in the ranibizumab-as-needed group, 5 patients in the bevacizumab-monthly group, and 6 patients in the bevacizumab-as-needed group.

Reproduced with permission from Martin DF, Maguire MG, Ying GS, et al. Ranibizumab and bevacizumab for neovascular age-related macular degeneration. *N Engl J Med* 2011;364:1897–908.

Secondary visual outcomes were similarly equivalent, with 91.5% (bevacizumab PRN) to 95.4% (ranibizumab PRN) of patients not having a decrease in vision of 15 letters or more from baseline, and 24.9% (ranibizumab PRN) to 34.2% (ranibizumab monthly) experiencing a gain of at least 15 letters. Anatomic outcomes showed that all groups had substantial decreases in retinal thickness as measured by OCT at 1 year, although the monthly ranibizumab group experienced a greater decrease in thickness ( $196\pm 176\ \mu\text{m}$ ) than those patients receiving bevacizumab as needed ( $152\pm 178\ \mu\text{m}$ ,  $p=.03$ ). The mean number of injections given in the PRN groups was  $7.7\pm 3.5$  (bevacizumab) and  $6.9\pm 3.0$  (ranibizumab) out of 13 possible, translating to an average yearly cost of \$385 vs. \$13,800, respectively. The average cost to patients given monthly injections was \$595 for bevacizumab and \$23,400 for ranibizumab (Table 70.3).

Deaths occurred in 2.0% of the entire study group over the one-year period, with no significant difference among any of the groups. The occurrence of arteriothrombotic events was 2–3% for each group, also without significant differences. Venous thrombotic events occurred in 4 out of 286 patients receiving bevacizumab monthly ( $p=.08$  difference between all groups) but occurred infrequently in all groups. When serious systemic adverse events were pooled among drug-specific groups, they occurred in 24.1% of patients receiving bevacizumab vs. 19.0% of those receiving ranibizumab ( $p=.04$ ). Endophthalmitis occurred in 0.05% of the total number of injections, without a significant difference between medication groups. All other serious ocular adverse events occurred with rare frequency (Table 70.4).

The impact of the one-year CATT study results was significant, establishing the equivalent visual outcomes of ranibizumab and bevacizumab when given monthly. Although bevacizumab as needed, when compared to ranibizumab or bevacizumab monthly, yielded inconclusive results, all other groups showed similar efficacy. Rosenfeld proposed in explanation that the treatment effect for bevacizumab may be less durable in some patients; thus, giving more frequent injections might improve visual outcomes in that subgroup.<sup>153a</sup> Importantly, the first-year study results also appeared to establish that as-needed ranibizumab (as well as monthly bevacizumab) was as effective as monthly ranibizumab, which not only has significant implications for treatment cost, but also for the cumulative risk of injection-associated adverse events, as well as patient anxiety surrounding treatment administration. Interestingly, although the effect of the medication on retinal thickness was more prominent for ranibizumab, this did not

translate to better vision as compared to bevacizumab. Finally, the study authors recognized that the CATT was insufficiently powered to determine a difference in infrequently occurring systemic and ocular adverse events, and although bevacizumab was associated with a higher overall rate of systemic adverse events, these events involved organ systems not typically associated with systemic anti-VEGF therapy. In particular, the rate of arteriothrombotic and venous thrombotic events was no different between the two medications, and was low in all groups. Additionally, the risk of adverse events was not noted to correlate with increased exposure to medication, with a higher rate of occurrence in patients receiving injections on an as-needed basis.

The second year results of CATT, published in mid-2012, described the visual impact of switching from monthly to PRN treatment after the first year, as well as any differences in disease activity or progression, as demonstrated by fluid on OCT, leakage on fluorescein angiography, and lesion size. In addition, the use of high-resolution spectral-domain OCT in year 2 allowed for comparison between standard and high-resolution imaging in the detection of disease activity.

At week 52 of the study, the study groups were modified such that monthly treatment groups were reassigned at random to either maintain monthly dosing or switch to as-needed dosing of the same medication. The existing PRN groups maintained the same dosing regimen. Comparisons in the second year were not made between each drug regimen group, as the reassignment resulted in a larger number of groups, and consequently reduced group size and statistical power. Rather, the analysis compared bevacizumab with ranibizumab, and monthly with as-needed dosing groups.

In patients maintaining the same dosing regimen (either monthly or as needed) through the 2-year study period, vision change remained similar, with monthly ranibizumab showing the greatest visual improvement (+8.8 letters), followed by monthly bevacizumab (+7.8), as-needed ranibizumab (+6.7), and as-needed bevacizumab (+5.0). There was no significant difference when comparing all ranibizumab groups with all bevacizumab groups (which showed 1.4 letters less gain relative to ranibizumab), but PRN therapy showed less vision improvement by 2.4 letters relative

to monthly therapy ( $p=.046$ ). Secondary visual outcomes were also similar, including the final mean acuity (Snellen equivalent about 20/40 in all groups), the proportion gaining or losing 15 letters, and the proportion with 20/20 or better or 20/200 or worse final vision. Of note, those receiving bevacizumab as needed required more injections over the course of the study (14.1 total injections) than those receiving ranibizumab as needed (12.6), a significant difference consistent with the higher proportion of visits with detectable fluid.

Anatomic outcomes showed improved retinal thickness in patients treated monthly as compared to those treated as needed (29  $\mu\text{m}$  difference,  $p=.005$ ). Additionally, the proportion of patients without fluid as detected by OCT was lower in both the ranibizumab group and the monthly group (up to 45.5% in the monthly ranibizumab group); similarly, the proportion of patients with no fluorescein leakage was higher in patients treated monthly, and lesion area remained stable in these patients while growing in the as-needed group. However, the study also found that the proportion of monthly patients developing GA was significantly higher in patients receiving monthly treatment as compared to the as-needed group, with the highest rate in those receiving ranibizumab monthly. (Vision and anatomic outcomes are detailed in [Fig. 70.13](#) and [Table 70.5](#)).

**FIG. 70.13** (A) The mean change in visual acuity from enrollment over time by dosing regimen within drug group ranibizumab (left) and bevacizumab (right). (B) Differences in mean change in visual acuity at 2 years and 95% confidence intervals in patients treated with the same dosing regimen for 2 years. <sup>b</sup>Number of unknown in each group unknown or missing: 3, 3, 3, 1.

<sup>c</sup>Number in each group unknown or missing: 3, 3, 6, 2.

<sup>d</sup>Includes choroidal neovascularization, hemorrhage, blocked fluorescence, serous pigment epithelium detachment, scar, geographic atrophy, nongeographic atrophy or tear of the retinal pigment epithelium, adjacent to the location of choroidal neovascularization at baseline. Number in each group unknown or missing: 12, 8, 16, 18.

<sup>e</sup>Number in each group unknown or missing: 16, 12, 22, 27.

<sup>f</sup>Areas of hypopigmentation or hyperfluorescence of  $\geq 250$   $\mu\text{m}$  diameter having  $\geq 2$  of the following characteristics: circular shape, sharp borders, visible choroidal vessels. Areas meeting this definition surrounding a scar were not considered geographic atrophy. Excluded those with geographic atrophy at enrollment: 6 (4.4%), 6 (4.7%), 20 (7.8%), 18 (7.2%).

OCT, optical coherence tomography; SD, standard deviation. The dashes indicate that calculation of a  $p$  value is not appropriate. The treatment groups are defined by dosing regimen; therefore, the role of random variation in producing a difference by regimen is not relevant because by definition they are different.

Reproduced with permission from Martin DF, Maguire MG, Fine SL, et al. Ranibizumab and bevacizumab for treatment of neovascular age-related macular degeneration: two-year results. *Ophthalmology* 2012;119(7):1388-98.

In contrast to patients maintaining monthly therapy through 2 years, those switching to as-needed therapy at week 52 lost from 1.8 (ranibizumab) to 3.6 (bevacizumab) letters after year 1 ( $p=.03$  when comparing monthly to PRN), resulting in very similar visual outcomes to patients maintained on as-needed therapy since study enrollment for both medications. Final visual acuity was similar for all groups, without significant differences between bevacizumab and ranibizumab, or between monthly and as-needed therapy. Anatomically, retinal thickness increased significantly, from 19  $\mu\text{m}$  (ranibizumab) to 31  $\mu\text{m}$  (bevacizumab) in patients who were reassigned to as-needed therapy. The proportion of patients without fluid on OCT was significantly lower in patients who switched regimens, as well as in patients receiving bevacizumab. As in patients receiving the same regimen through year 2, the proportion demonstrating dye leakage was higher in switched patients. Although the lesion area was not significantly different in either group, the rate of development of GA was higher in

ranibizumab patients as well as those receiving monthly dosing (Table 70.6).

Reproduced with permission from Martin DF, Maguire MG, Fine SL, et al. Ranibizumab and bevacizumab for treatment of neovascular age-related macular degeneration: two-year results. *Ophthalmology* 2012;119(7):1388-98.

In contrast to the first year of the study, when all study patients underwent testing with time domain OCT only, in year 2 22.6% of scans were performed on high-resolution spectral domain OCT. Treatment decisions in the second year were consistent with reading center interpretation of OCT fluid in 68.5% of the ranibizumab group and 69.6% of the bevacizumab group; 95% of these cases resulted in undertreatment (the reading center interpreted fluid, yet the patient did not receive injection). The use of spectral domain OCT did not appear to increase the consistency between treating physicians and the reading center, with 70.1% agreement in the spectral domain group versus 68.7% in the time domain group.

As reported in the first year of results, the rate of systemic adverse events was significantly higher in the bevacizumab group than in the ranibizumab group, at 39.9% as compared to 31.7% overall, and 24.4% vs. 18.0% in the second year alone. Interestingly, this difference persisted even after excluding vascular events previously associated with systemic anti-VEGF drugs. In addition, as noted in the first year, over the course of 2 years patients treated as needed had a higher rate of systemic serious adverse events than those treated monthly (risk ratio of 1.30, *p*=.009), although this

difference in the second year alone was not significant. There was no difference between drugs in the proportion of patients who died (6.1% vs. 5.3%) or in the number of arteriothrombotic (5.0% vs. 4.7%) or venous thrombotic events (1.7% vs. 0.5%). Endophthalmitis occurred in 7 patients receiving bevacizumab and 4 patients receiving ranibizumab ( $p=.38$ ), with 10 of these 11 cases occurring in patients receiving monthly therapy (Table 70.7).

Ranibizumab and bevacizumab for treatment of neovascular age-related macular degeneration: two-year results. *Ophthalmology*. 2012;119(7):1388-98.

The second year of the CATT was not designed to determine the relative efficacy of each dosing regimen for each medication. However, the following conclusions may be drawn:

1. In contrast to the first-year results, longer-term follow-up suggests that as-needed therapy is less effective than monthly therapy overall in terms of visual gain.
2. Visual acuity and visual gain are associated with, but do not closely mirror, retinal thickness or presence of fluid.
3. One year of monthly therapy does not appear to confer lesion stability when subsequently changing to as-needed therapy.
4. When given as needed, bevacizumab is required more frequently than ranibizumab, on average 1.5 more injections over the 2-year period.
5. Geographic atrophy appears to occur with greater frequency in patients receiving monthly therapy.
6. Spectral domain OCT does not appear to increase the accuracy of identifying retinal fluid by the treating physician.
7. Endophthalmitis occurs at similar rates in ranibizumab- and bevacizumab-treated patients, although (as one may expect) it appears to be associated with an increased rate of injections, occurring most often in patients treated monthly.
8. The increased rate of systemic serious adverse events in bevacizumab persisted in the second year. The authors remained unsure of the reason for the increased risk ratio of systemic adverse events. As in the first year, the rate of vascular events previously associated with anti-VEGF therapy was similar in both groups.

The two-year CATT results certainly supported the continued off-label use of bevacizumab for exudative AMD. In addition, it appears that monthly dosing for any anti-VEGF therapy results in

better and more sustained visual outcomes than as-needed dosing. However, the decision of which treatment regimen should be made with careful consideration, given the cost of monthly therapy (roughly twice that of as-needed therapy for each drug respectively), as well as the possible (although unproven) increased risk of GA, which over a treatment course of years may lead to significant visual loss. Five-year outcomes of the CATT were published in 2016. Follow up visual acuity was available from 647 of the 914 living patients, with results demonstrating that visual gains attained in the first two years were lost in the subsequent 3 years after the conclusion of the study (−3 letters from baseline, −11 letters from the second year). Fifty percent of patients had at least 20/40 vision, with 10% maintaining 20/20 vision and 20% with 20/200 or worse. The primary cited reasons for decreased vision over the 3 years following study completion were increase in patients with retinal thinning (<120 microns); increase in prevalence of geographic atrophy; and increase in lesion size. Although conclusions cannot be drawn regarding particular treatment regimens or medications, the five-year outcomes confirmed the role of anti-VEGF therapy for AMD.<sup>153b</sup>

## **IVAN and Other Trials**

Similar to the CATT, the IVAN (alternative treatments to Inhibit VEGF in Age-related choroidal Neovascularization) trial also compared administration of ranibizumab and bevacizumab in a continuous or regimen. The trial randomized 628 patients (with 610 receiving treatment) to one of the four groups (ranibizumab monthly or PRN, bevacizumab monthly or PRN), with the primary outcome measure of best corrected distance visual acuity (as measured by ETDRS letters). Secondary outcome measures included safety/adverse events, quality of life assessment, cost and resource use, and notably, serum VEGF levels. The trial specified a noninferiority limit of 3.5 letters. In contrast to CATT, eyes that met retreatment criteria (any subretinal or increasing intraretinal fluid or fresh blood, drop in vision, or specified criteria on fluorescein angiography in the absence of vision or OCT changes) required an additional cycle of 3 monthly injections.

Five hundred twenty-five patients completed 2-year follow-up in

the IVAN study. Visual acuity results were similar for each group (ranibizumab group: 67.8 letters; bevacizumab group: 66.1; continuous regimen: 66.6; discontinuous regimen: 67.3, see [Fig. 70.14](#)). Bevacizumab was neither noninferior nor inferior to ranibizumab, and the discontinuous regimen was neither noninferior nor inferior to the continuous regimen (inconclusive). As in the 1-year results, neurosensory retinal thickness and lesion thickness were lower in those receiving continuous therapy (314.7  $\mu\text{m}$  vs. 338.5  $\mu\text{m}$ ). Discontinuous therapy was also associated with significantly higher rates of fluid on OCT and active neovascularization, compared with continuous administration. No drug differences existed for these indices. Similar to the CATT, there was a significantly higher rate of new GA occurring in the continuous regimen group, although there were no drug differences with respect to this condition.

**FIG. 70.14** IVAN results. Upper panel: Mean differences in best corrected distance visual acuity at 2 years. By drug (top) and by regimen (bottom). Black dashed line shows non-inferiority limit of  $-3.5$  letters. Mean differences estimated with data from visits 0, 3, 6, 9, 12, 15, 18, 21, and 24, adjusted for center size. 95% CIs given in parentheses and shown by bars.

Lower panel: Secondary outcomes at 2 years: (A) by drug; (B) by regimen. 95% CIs given in parentheses and shown by bars. GMR, geometric mean ratio; IVAN, Inhibition of VEGF in Age-related choroidal Neovascularization trial; MD, mean difference; OR, odds ratio. (Reproduced with permission from Chakravarthy U, Harding SP, Rogers CA, et al. Alternative treatments to inhibit VEGF in age-related choroidal neovascularisation: 2-year findings of the IVAN randomised controlled trial. *Lancet*. 2013;382(9900):1258-67, Figs. 1,2.)

The rate of death was similar for each drug group, although more patients died in the discontinuous group than the continuous group. The rates of arteriothrombotic events or heart failure were similar in all groups, as were the rates of developing at least one systemic serious adverse event.

The authors of the IVAN pooled data from both the IVAN and CATT studies, confirming that bevacizumab was noninferior to ranibizumab, but also showing that discontinuous treatment was inferior to continuous treatment in terms of best corrected distance visual acuity (Fig. 70.15). Importantly, the finding from the CATT that continuous therapy led to higher rates of GA than discontinuous therapy was confirmed in the IVAN trial as well. The meta-analysis also showed that both mortality and the risk of serious adverse events were higher with discontinuous treatment, leading the authors to speculate that immunologic sensitization with intermittent dosing may play a role; there was no difference in mortality, serious adverse events, or vascular/arteriothrombotic events when comparing the two drugs (Fig. 70.16). As with the CATT, the IVAN trial suggests that bevacizumab and ranibizumab, and continuous and discontinuous, have similar efficacy (or at least very little clinically significant difference). However, the authors concluded that choosing a single optimal treatment strategy remains challenging, particularly in light of the mortality difference favoring continuous therapy, in contrast to the increased rate of GA (as well as the difference in cost) favoring discontinuous therapy.

Since the CATT, several other studies have also compared ranibizumab and bevacizumab with various treatment strategies.

The Groupe d'Evaluation Français Avastin vs. Lucentis (GEFAL) study was a noninferiority trial performed in France, enrolling and randomizing 501 patients to bevacizumab and ranibizumab, given PRN with monthly follow-up, after an initial loading-dose period of three monthly injections. Bevacizumab and ranibizumab showed equivalent changes in BCVA (5.4 vs. 3.6 letters, respectively), and in the percentages of patients gaining or losing either 5 or 15 letters, with a similar number of injections required (6.8 vs. 6.5). There were no differences in the rate of adverse events. These results were felt to be consistent with the CATT results, although the visual gains were less than in the CATT due to a larger percentage of patients with poor vision (<20/200) at baseline in GEFAL, and hence fewer letters gained in this subgroup.<sup>154</sup> Similarly, the Multicenter Anti-VEGF Trial in Austria (MANTA) randomized 321 patients 1 : 1 to either bevacizumab or ranibizumab, given PRN (with monthly follow-up) after three monthly loading injections. The primary outcome (gain in BCVA at one year) was similar in each group, with a gain of 4.9 vs. 4.1 letters for bevacizumab and ranibizumab, respectively, requiring a mean of 6.1 vs. 5.8 injections. As in previous studies, the proportions of patients gaining or losing 5 or 15 letters were similar in both groups, as were the rates of significant adverse events.<sup>155</sup> In contrast to GEFAL and MANTA, the Comparison of Bevacizumab (Avastin) and Ranibizumab (Lucentis) in exudative Age-related Macular Degeneration (BRAMD) study randomized 327 patients to bevacizumab or ranibizumab, given monthly. Although the gain in BCVA was similar between the two groups (5.1 vs. 6.4 letters for bevacizumab and ranibizumab, respectively), a higher percentage of patients receiving bevacizumab experienced a gain (24% vs. 19%) or a loss (11% vs. 5%) of at least 15 letters when compared to ranibizumab. As in previous studies, anatomic outcomes revealed a higher percentage of patients receiving bevacizumab had fluid on OCT. Safety outcomes were similar in both groups.<sup>156</sup>

Many physicians have adopted the so-called “treat-and-extend” therapy as a strategy to reduce injection burden while maintaining regular surveillance for active exudative disease. The Lucentis Compared to Avastin Study (LUCAS) in Norway was first to address this regimen in a randomized controlled trial. Enrolling 441

patients, the trial randomized patients to receive either ranibizumab or bevacizumab to be given every 4 weeks until no active exudative disease was present as determined by OCT and fundus biomicroscopy.<sup>157</sup> The next follow-up and injection was then extended by 2 weeks at a time (6-week interval, followed by 8-week interval, and so on) until active neovascular disease was detected, to a maximum of 12 weeks. If a study examiner determined that there was disease recurrence or persistent activity, the interval was then shortened by 2 weeks at a time until the disease became inactive again, with subsequent extension to a maximum of 2 weeks shorter than the interval at the previous recurrence. Nonresponders (patients with no change or increase in central retinal thickness after the first three injections) were allowed to withdraw from the study (20 patients). The study was designed as a noninferiority trial with a limit of 5 letters. In the 86% of study patients who completed one year of follow-up, the change in BCVA was equivalent in both the bevacizumab (+7.9 letters) and ranibizumab (+8.2 letters) groups, and the proportions of patients gaining or losing 5 or 15 letters were also similar. Anatomic outcomes revealed a similar decrease in CRT in both groups (-112  $\mu\text{m}$  vs. -120  $\mu\text{m}$  for bevacizumab and ranibizumab, respectively). The mean number of treatments required, however, was significantly higher in the bevacizumab group (8.9 injections vs. 8.0 injections,  $p=.001$ ). The incidence of arteriothrombotic events, and specifically nonfatal myocardial infarction (MI), was higher in the ranibizumab group (although at baseline, more patients in this group had history of MI). The study authors concluded that bevacizumab and ranibizumab were equivalent when administered in a treat-and-extend protocol.<sup>157</sup>

The results of the above studies comparing bevacizumab and ranibizumab seem to support the same conclusions: although ranibizumab may result in slightly better anatomic outcomes, this does not necessarily translate to better vision. Additionally, the higher rate of systemic adverse events experienced by the patients treated with bevacizumab in the CATT has not been confirmed in other studies.

### **Soluble Receptor: Aflibercept**

Aflibercept (VEGF-TRAP EYE, Eylea™; Regeneron

Pharmaceuticals, Tarrytown, NY, USA) is a soluble fusion protein that combines ligand-binding elements taken from the extracellular components of VEGF receptors 1 and 2 fused to the Fc portion of IgG1.<sup>158</sup> As with ranibizumab, it has a high affinity for VEGF,<sup>159</sup> and aflibercept is thought penetrate all layers of the retina.<sup>160</sup> Unlike bevacizumab and ranibizumab that inhibit just VEGF-A, aflibercept also binds VEGF-B and PlGF.<sup>159,161</sup> The phase 1 study of aflibercept, known as CLEAR-IT 1 (CLinical Evaluation of Anti-angiogenesis in the Retina Intravitreal Trial), showed safety and a functional and anatomical improvement with a dose of 0.5 and 2 mg.<sup>162</sup> The phase II trial, known as CLEAR-IT 2, evaluated the biologic effects and safety of aflibercept during a 12-week fixed-dosing period in patients with exudative AMD followed by PRN dosing out to 1 year.<sup>163,164</sup> Patients were randomized 1:1:1:1 to aflibercept during the fixed-dosing phase (day 1 to week 12): 0.5 or 2 mg every 4 weeks on day 1 and at weeks 4, 8, and 12; or 0.5, 2, or 4 mg every 12 weeks on day 1 and at week 12. At week 12, treatment with aflibercept resulted in a significant mean decrease in CRT from baseline in all groups combined ( $p < .0001$ ). The reduction with the 2 mg every 4 week and 0.5 mg every 4 week regimens was significantly greater than each of the quarterly dosing regimens. Visual acuity increased significantly by a mean of 5.7 letters at 12 weeks in the combined group ( $p < .0001$ ), with the greatest mean gain of >8 letters in the monthly dosing groups.

In the PRN dosing phase of the study out to week 52, the decrease in CRT observed at week 12 versus baseline remained significant at weeks 12 to 52 ( $-130 \mu\text{m}$  from baseline at week 52), and CNV size regressed from baseline. After achieving a significant improvement in visual acuity during the 12 weeks, PRN dosing for 40 weeks maintained improvements in visual acuity out to 52 weeks (5.3-letter gain;  $p < .0001$ ). The most robust improvements and consistent maintenance of visual acuity generally occurred in patients initially dosed with 2 mg every 4 weeks for 12 weeks. These patients demonstrated a gain of 9 letters at 52 weeks. Overall, a mean of 2 injections was administered after the 12-week fixed-dosing phase, and the mean time to first reinjection was 129 days. Nineteen percent of patients received no injections and 45% received 1 or 2 injections. During the year long study, PRN dosing

at weeks 16–52 maintained the significant anatomic and vision improvements established during the 12-week fixed-dosing phase with a low frequency of reinjection, and the drug was generally safe and well tolerated.

Based on the phase 2 results, aflibercept appeared to be a new anti-VEGF treatment requiring fewer intravitreal injections compared with ranibizumab and bevacizumab. This hypothesis was tested in the phase III VIEW 1 and VIEW 2 studies (VEGF Trap-Eye: Investigation of Efficacy and Safety in Wet AMD) in which aflibercept was compared with the standard monthly dosing regimen of 0.5 mg ranibizumab (NCT00509795). In these two parallel phase III studies (VIEW 1 in the United States and Canada, VIEW 2 in Europe, the Middle East, Asia-Pacific, and Latin America), patients with exudative AMD were randomized 1:1:1:1 to aflibercept 0.5 mg monthly (0.5q4), aflibercept 2 mg monthly (2q4), aflibercept 2 mg every 2 months (following three monthly loading doses – 2q8), or ranibizumab administered 0.5 mg every month during the first year of the studies (Rq4). Over 1,200 patients were randomized in each study. The studies were designed as noninferiority trials with the primary endpoint as the proportion of patients who maintained vision over 52 weeks compared to ranibizumab.

After 1 year, at least 94% of all groups achieved the primary endpoint of <15 ETDRS letters lost. There was no difference in the outcomes when the three aflibercept groups were compared with the ranibizumab group.<sup>165–167</sup> When comparing secondary outcomes, the VIEW 1 study demonstrated that the mean change in BCVA was significantly higher in the 2q4 group than the ranibizumab group (10.9 vs. 8.1 letters), although VIEW 2 seemed to demonstrate an opposite effect, with mean improvement 2.1 letters greater in the ranibizumab group (not statistically significant). All other groups in VIEW 1 and 2, and when the data were integrated, showed no significant differences. Most notably, there was no difference between intravitreal aflibercept dosed every 2 months, and ranibizumab dosed monthly. This was true with respect to visual acuity improvement, OCT central retinal thickness, and safety outcomes. Similar to the paradoxical dose-response seen in the IVAN trial, the group with the highest exposure to aflibercept (2q4)

experienced the lowest rate of systemic adverse events. Specifically, there were no differences in the rates of arterial thromboembolic events or death between ranibizumab and aflibercept. When the 1-year data were presented to the FDA in 2011, the panel unanimously recommended approval.

After the 52-week endpoint, all regimen groups switched from a fixed monthly or bimonthly injection schedule to a variable dosing schedule, with injections given at least quarterly.<sup>168</sup> Follow-up was monthly with reinjection allowed according to visual and anatomic criteria. At 96 weeks, 91.5–92.4% of patients maintained vision, with average gains of 7.9, 7.6, 6.6, and 7.6 letters in the Rq4, 2q4, 0.5q4, and 2q8 groups, with similar numbers of patients attaining 15 letters of improvement or more in the second phase of the study as in the first (Fig. 70.17). During this phase, there was also an average increase in OCT central retinal thickness and a modest decline in the percentage of patients with no fluid on OCT in all treatment groups. The mean number of injections administered was similar (about 16 over the 96 week study period) in each group with the exception of the 2q8 group, which received about 11 injections on average. As in the 52-week data, safety was comparable and revealed no significant differences between the groups in all serious adverse events or in arterial thrombotic events. The authors concluded that over the 96-week study period, aflibercept offered similar visual and anatomic outcomes as ranibizumab, and could be given less frequently, with an average of five fewer injections.<sup>169</sup>

**FIG. 70.17** VIEW 1/2 study cohort visual acuity and anatomic outcomes. (A) Mean change from baseline best corrected visual acuity (BCVA). The inset shows the difference in least square (LS) mean (with 95% confidence interval) between intravitreal aflibercept arms and ranibizumab (aflibercept minus ranibizumab) for BCVA change from baseline to week 96, full analysis set. (B) Mean change from baseline central

retinal thickness, full analysis set. Missing values were imputed using the last-observation-carried-forward method. The outcomes for the aflibercept and ranibizumab groups were similar at both weeks 52 and 96. (Reproduced with permission from Schmidt-Erfurth et al., *Ophthalmology* 2014;121(1):193-201, Figs. 1B and 2A.)

## **Conbercept (Previously KH902)**

Conbercept (Chengdu Kanghong Biotechnology Ltd, Sichuan, People's Republic of China) is a fusion protein that combines ligand-binding elements taken from the second extracellular domain of VEGF receptor 1 (Flt-1) and the third and fourth binding domain of VEGF receptor 2 (KDR) to the Fc portion of IgG1.<sup>170</sup> Compared with aflibercept, the inclusion of the additional extracellular domain 4 of VEGF receptor 2 (KDRd4) may stabilize the three-dimensional structure and increase the efficiency of dimerization.<sup>171</sup> Conbercept has a much higher affinity for VEGF due to this extra extracellular domain and may have a longer half-life in the vitreous.<sup>170,172</sup> Additionally, conbercept has affinity for placental growth factor (PlGF), another member of the VEGF family implicated in the development of CNV.<sup>173,174</sup> Preclinical in vivo experiments have shown that intravitreal conbercept is able to inhibit leakage and growth of CNV in rhesus monkeys without signs of toxicity at doses of 300 and 500 µg.<sup>170</sup> In a phase 1, dose escalation study, intravitreal injections of conbercept up to a dose of 3.0 mg were well tolerated in 28 patients. On day 42 after a single injection, the mean change in visual acuity from baseline was +19.6 letters with no subjects losing 1 letter or more and 57% of patients gaining 15 letters or more from baseline. The mean change in center point retinal thickness from baseline was -77.2 µm and the mean decrease in CNV area was 12.6%. No safety concerns were detected after a single intravitreal injection.

A phase 2 study performed in China (AURORA) randomized 122 patients to 0.5 mg or 2 mg doses, administered for three monthly loading doses, followed by a secondary randomization to either monthly (Q1M) or PRN administration at the same dose for the remaining 9 months of the 12-month study. At 3 months, the 0.5-mg group experienced almost 9 letters of visual improvement,

compared with 10.4 letters of improvement in the 2-mg group. At 12 months, the visual gains were similar in each of the four groups: 9.3 (0.5 mg Q1M); 14.3 (0.5 mg PRN); 15.4 (2 mg Q1M); 12.4 (2 mg PRN). The proportion of patients with a 15-letter gain was similar, with 31%, 50%, 46.7%, and 42.3% of eyes reaching this threshold in the 0.5-mg Q1M, 0.5-mg PRN, 2-mg Q1M, and 2-mg PRN groups, respectively. At least 96% of all eyes lost fewer than 15 letters in all groups (Fig. 70.18). Central retinal thickness on OCT showed significant decrease, as did CNV size and leakage area on fluorescein angiography at 12 months without significant differences among the groups. Less than five injections over the 12-month period were administered in each PRN group, while, as expected, each monthly group received more than eight injections in the maintenance phase.

**FIG. 70.18** AURORA study visual and anatomic outcomes. Upper panel: The mean change in best corrected visual acuity (BCVA) from baseline over time in patients in the four dosing regimen treatment groups through 12 months. Lower panel: The mean change in central retinal thickness (CRT) from baseline over time using the four dosing regimens through 12 months. The CRT reduced rapidly during the first 3-month loading phase and then continued to decrease through month 12. (Reproduced with permission from Li X, Xu G, Wang Y, et al.

Safety and efficacy of conbercept in neovascular age-related macular degeneration: results from a 12-month randomized phase 2 study: AURORA study. *Ophthalmology*. 2014;121(9):1740-7.)

Adverse events were reported in the majority of patients in the study, although most were mild or moderate and self-limited. Serious adverse events related to the study intervention included

cataract progression in one eye, which necessitated cataract extraction, and a patient with post-injection culture-negative endophthalmitis, treated with antibiotics. There were no systemic adverse events, including arteriothrombotic, cardiovascular, or cerebrovascular complications, during the study.

Based on the promising phase II results, the phase 3 PHOENIX trial was initiated, assigning 125 patients in a 2 : 1 randomization to the treatment group with three monthly injections of conbercept 0.5 mg, followed by two monthly sham injections and a trimonthly injection with conbercept until month 12 (treatment at months 0, 1, 2, 5, 8, and 11); or the sham group, which received three sham injections at months 0, 1, and 2, followed by crossover into the treatment group. Twelve-month results showed a 10-letter improvement in the treatment group. There was a decrease in OCT central macular thickness of 79  $\mu\text{m}$  at 3 months. No additional safety data were available at the time of publication.<sup>175</sup> Based on phase III results, the potential for quarterly dosing of conbercept compares favorably with ranibizumab (dosed monthly) and aflibercept (dosed bimonthly) in terms of treatment burden and cost, particularly in China, where at the time of publication, the off-label use of bevacizumab is still prohibited. Conbercept was approved by the China State Food and Drug Administration for use in exudative macular degeneration in 2013.

## **Anti-VEGF Agents Under Investigation**

### **RTH258 (Formerly ESBA1008).**

RTH258 (Alcon/Novartis, Fort Worth, TX, USA) is single-chain antibody fragment that targets all isoforms of VEGF-A. With a molecular weight 26 kDa, it is considerably smaller than other VEGF inhibitors, which may theoretically increase retinal penetration, allow for higher concentration of drug at the target tissue, and reduce systemic exposure, all of which have been supported in animal studies. After encouraging phase I results, showing favorable visual acuity improvement when compared to ranibizumab, a recent dose escalation, randomized phase II trial compared a single injection of the medication, with ranibizumab 0.5 mg in 194 patients. The primary endpoint was change in OCT

central retinal thickness at 1 month, with the noninferiority endpoint met at the two highest dosing groups (4.5 and 6 mg).<sup>176</sup> Additionally, after the single injection, the OCT thickness remained relatively stable over months 1 and 2 compared to a relative increase in the ranibizumab group, implying a longer duration of action of the study medication. Visual acuity results were similar, with the highest-dose group attaining 10.4 letters, versus 6.5 letters gained for ranibizumab. The study was not powered to detect differences in adverse events, but there were no significant concerns. In a second phase II study, the OSPREY trial compared RTH258 6 mg to aflibercept 2 mg at weeks 12 and 16 of a 56-week study. Treatment was dosed every 8 weeks through week 32, then every 12 weeks until the end of the study, with rescue treatments given as frequently as every month in between scheduled injections. The 89 patient study demonstrated noninferiority, with no significant adverse events. Importantly, fewer rescue treatments were required in the RTH258 group through both phases of the study, with about half of patients maintained on q12week injections.<sup>177</sup> These results support the further investigation of this medication for the treatment of neovascular AMD in phase III trials, and in particular, the potential use in sustained drug delivery devices, where a high localized concentration and long duration of action are of particular value.

### **DARPinS and Abicipar Pegol.**

The designed ankyrin repeat proteins (DARPin) are a family of small (14–21 kDa) single-domain proteins that are genetically engineered to bind to a target with high affinity and specificity. Derived from natural ankyrin repeat proteins, the DARPin consists of a repeat protein domain, whose purpose in nature is to bind a target with any number of consequent actions. As a therapeutic agent, DARPinS address many of the shortcomings of antibodies: at one-tenth the size of an IgG antibody, they demonstrate excellent tissue penetration; they demonstrate exceptional thermal stability, with half-lives of more than 60 days in some cases; they have very low risk of immunogenicity due to the absence of an Fc antibody portion; they can be purified and concentrated to high levels; and importantly, they are easily produced.<sup>178</sup>

The DARPin abicipar pegol (formerly MP0112; Molecular Partners, Zurich-Schlieren, Switzerland) is a potent antagonist to all VEGF-A isoforms and binds with high affinity (K<sub>d</sub> 1-4 pM). Additionally, the intravitreal half-life is at least 2 weeks. Ranibizumab, in contrast, has a K<sub>d</sub> of ≤192 pM for the active isoforms of VEGF-A, and has a half-life of about 7 days.<sup>179</sup> Similar to the currently used VEGF antagonists, abicipar inhibits VEGF-A activity through direct binding.

A phase I/II trial (NCT01086761) examining the safety and dosing of abicipar was performed in France, Switzerland, and the Czech Republic.<sup>180</sup> The nonrandomized study enrolled 32 patients, injecting one eye with a single dose of abicipar. The primary aim of the study was to assess safety and tolerability, with efficacy as a secondary outcome measure. The medication was administered in a dose-escalation design, with six dosing cohorts (0.04 mg, 0.15 mg, 0.4 mg, 1 mg, 2 mg, and 3.6 mg). There was no control group, although rescue therapy was allowed, with the specific criteria varying by region. One patient in the 2-mg cohort developed endophthalmitis, which was believed to be sterile; thus, 1 mg was determined to be the maximum tolerated dose, and no patients were enrolled in the highest-dosing cohort. Milder inflammatory responses, both anterior and posterior, were also seen and resolved either with steroid therapy or without any intervention. Other adverse events included conjunctival hemorrhage, vitreous hemorrhage, and hypertension, each occurring in one patient. Notably, serum antidrug antibodies were detected in eight patients. In all dosing cohorts, there was decrease in CRT after the first week, with further reduction at week 4 in the higher-dosing cohorts. Fluorescein angiography also showed a decrease in lesion size and leakage area at week 4. Vision remained stable in all cohorts over the duration of the study, with no significant gain or loss at 16 weeks. Over the course of the 16-week study, rescue therapy was required in 20 of 22 patients in the 0.04–0.4 mg cohorts, and 4 of the 10 patients receiving 1 or 2 mg, with a longer time to rescue therapy in the higher-dose cohorts (up to 10 weeks, vs. 5–7 weeks in the lower dose cohorts). The drug was detectable in the serum up to 2 weeks only in the highest-dosing cohort.

The study authors concluded that abicipar/MP0112 had no

systemic safety concerns, and that the dose-limiting intraocular inflammation was likely related to impurities in drug processing; a new purification process was initiated as a result. Although they acknowledged that the study was small and uncontrolled, the preliminary efficacy results suggested that DARPins indeed offer improved duration of action over antibody therapy, and that further study would be warranted.

## **Sustained Drug Delivery**

Although VEGF inhibitors are the mainstay of AMD therapy, their effectiveness is limited by the half-life of the molecules within the eye. After intravitreal injection with bevacizumab, the elimination half-life can range from 8 to 11 days, with detectable antibody for up to 2 months.<sup>181</sup> The half-life of ranibizumab is slightly shorter, at just over 7 days,<sup>179</sup> with monthly dosing recommended by the manufacturer. Many studies have demonstrated comparable visual outcomes using PRN or treat-and-extend strategies; however, PRN dosing requires monthly follow-up, and many clinicians still favor dosing at least quarterly for maintenance. Additionally, as the intravitreal concentration of the drug declines over time, the risk of reactivation and breakthrough bleeding increases toward the end of the treatment interval. These limitations of the current treatments may lead to considerable treatment burden for patients; pharmaceutical and device manufacturers have consequently investigated various ways to increase the duration of effect of anti-VEGF therapy.

## **Encapsulated Cell Technology**

Encapsulated cell technology (ECT) involves the insertion of living cells into a tissue to produce and secrete a recombinant gene product. These cells are encapsulated within a semipermeable polymer,<sup>182</sup> which prevents immune response from the host antibodies and immune cells while allowing for diffusion of oxygen and nutrients to nourish the cells contained within. The technology is flexible, allowing for any number of gene products to be secreted, and allowing for dose modification or removal if treatment is no longer desired, unlike gene therapy. The constitutive secretion from

the implant may also allow for lower concentrations necessary for therapeutic effect, compared with bolus intravitreal injection therapy.

Neurotech (Lincoln, RI, USA) has developed an ECT implant specifically for use in the eye. It is 6–8 mm long and designed to be placed through a pars plana incision 2–3 mm in length. The NT-503 implant consists of an encapsulated human RPE cell line transfected to secrete a soluble VEGF-receptor-Fc fusion protein (VEGF-R). Preclinical data suggested that the intravitreal concentration of VEGF antagonist could be maintained at a level comparable to or exceeding that of bevacizumab injections.<sup>183</sup> Human studies showed that implant was well tolerated,<sup>184</sup> and the VEGF-R produced by the cell lines binds with high affinity to its target. The second generation of device showed safety and efficacy when two devices were implanted in the same eye, with improvements in vision (5 of 7 patients) and decreases in OCT fluid (5 of 6 patients) in preliminary results.<sup>185</sup> The latest generation of implant, the NT-503-3, contains multiple chambers, allowing for the release of higher doses of the therapeutic agent at rates of up to 12 µg/day, as well as the possibility of combination therapies, with the use of multiple cell lines within the same device (Fig. 70.19). A phase I/II study was terminated in 2016 after failing to meet its primary endpoint. An implant that releases both anti-PDGF and anti-VEGF (NT-506) is currently in preclinical development (see below for discussion on PDGF). The NT-501 implant that secretes ciliary neurotrophic factor (CNTF) was evaluated in a phase II study for GA,<sup>186</sup> although the company has not pursued this avenue further.

**FIG. 70.19** Schematic illustration of implant using encapsulated cell technology. The implant (panel A) is composed of a section of semipermeable membrane capsule which contains cells and scaffold. The membrane capsule is sealed at both ends with a suture clip at one end for anchoring on the sclera. The membrane allows oxygen and nutrients to diffuse in and therapeutic agent (CNTF in this case) to diffuse out. It also keeps components of the immune system out (panel B). The implant is 6 mm in length and 1 mm in diameter. It is outside the visual axis of the eye when anchored to the sclera (panel C). (Reproduced with permission from Wen R, Tao W, Li Y, et al. CNTF and retina. *Prog Retin Eye Res.* 2012;31(2):136-51.)

## Port Delivery System

ForSight VISION4 (Menlo Park, CA, USA) has developed a refillable port drug delivery system (PDS), and in 2010 entered into a collaboration agreement with Genentech/Roche to develop anti-VEGF therapies using this modality. The PDS is an implantable device, placed surgically through the pars plana with a 3.2-mm sutureless incision. Ranibizumab solution is preloaded into the device, which controls the continuous release of the medication between refill procedures, which can be performed in the office. A phase I study implanted the PDS in 20 patients, following them

monthly, using OCT and visual acuity to determine when to refill the device. The PDS was refilled with 500 µg, of which 250 µg was given in a bolus and 250 µg released over time.

There was significant visual and anatomic improvement at 12 months, with an average of 12 letters gained. Fifty percent of patients gained 3 lines or more. Patients required a mean of 4.2 refills over the 12 months. Four of the 20 patients suffered adverse events associated with the implant: one developed endophthalmitis, two suffered vitreous hemorrhage, and one developed traumatic cataract associated with the implantation procedure.

As the study was designed to test the proof of concept and evaluate safety, efficacy was not the primary goal. As such, six implants were removed after 12 months to examine for integrity over the course of the study and were found to have similar performance to new implants. The phase II LADDER study is underway, testing three doses of ranibizumab, compared to monthly therapy over 9 months.<sup>187</sup>

## **Replenish MicroPump**

The MicroPump (Replenish, Inc., Pasadena, CA, USA) is an microelectromechanical systems (MEMS) device designed to release medication from a refillable reservoir into the eye at a controlled rate. Implanted in a similar manner as a glaucoma drainage device, the pump system is sutured to the sclera under the conjunctiva and the Tenon capsule, with a cannula inserted transclerally through the pars plana. Medication is contained in a drug reservoir and is pumped through the cannula and into the eye via a one-way check valve. Although the first generation device was actuated manually, there was significant variation in drug delivery according to the duration and pressure applied to the device.<sup>188</sup> In the second generation of device, the drug reservoir contains a current-regulated electrolysis pump, which induces a phase change of water to hydrogen and oxygen gas, generating positive pressure in the reservoir that pumps the medication into the eye (Fig. 70.20).<sup>189</sup> Precise control of drug delivery and communication with the device is performed wirelessly through a proprietary telemetry system. The reservoir can be refilled via a 31-gauge needle.

**FIG. 70.20** (A) Schematic representation of the Posterior MicroPump Drug Delivery System (PMP; Replenish, Inc) implanted into the subconjunctival space between the superior and lateral rectus muscles. *Blue arrow* indicates the intraocular cannula at the pars plana location. *Red arrow* indicates the refill port. *Black arrow* indicates the body of the PMP that contains the hermetic sealing package with all electronics, the drug reservoir, and the check valve. (B) Gas bubble evolution resulting from electrolysis in drug reservoir of packaged electrically controlled device. (Panel A reproduced with permission from Humayun et al., *Transl Vis Sci Technol.* 2014;3(6):5; panel B reproduced with permission from Saati et al., *Trans Am Ophthalmol Soc.* 2009;107:60-70.)

Preclinical studies demonstrated good biocompatibility, with only minimal chronic external inflammation and capsular formation around the implant in animal studies, and no extrusion of the device or evidence of fibrous ingrowth through the cannula tract on histopathology.<sup>190</sup> The implant device is expected to remain functional within the eye for more than 5 years. A feasibility study in patients with diabetic macular edema demonstrated proper functioning of the pump in delivering the preprogrammed dosage of 0.085 mg ranibizumab within 90 minutes of filling the reservoir in 7 of the 11 study patients. The surgical implantation procedure was tolerated well without complications, and there were no serious ocular adverse events during the 90-day study period.<sup>191</sup>

This study represented the first implantation of an electronic drug delivery pump within the eye for retinal disease, and demonstrated its feasibility as a potential future avenue for treatment of macular degeneration.

## **Adeno-Associated Viral Vector (AAV) Gene Transduction**

Another important strategy for sustained drug delivery is gene therapy via viral vector genetic transduction. Several targets have been explored, including VEGFR-1 and PEDF.

As previously discussed, the angiogenic effects of VEGF are mediated through the endothelial receptor tyrosine kinases, VEGFR-1 (also called Flt-1) and VEGFR-2 (Flk-1/KDR), with Flt-1 having a tenfold-higher affinity for VEGF.<sup>192</sup> A naturally existing soluble form of Flt-1 (sFlt-1) has no transmembrane domains, and thus has no signal transduction properties, instead forming a heterodimer with Flt-1 and Flk-1 extracellular domains.<sup>193</sup> This molecule has provided a unique target for gene therapy using an adeno-associated viral (AAV) vector.

AAV vectors are particularly suited for gene therapy in part because of their low immunogenicity and pathogenicity, and ability to induce long-term gene expression in the eye. They have been used with success for gene transduction of PEDF for animal models of CNV,<sup>194</sup> and have been tested in human trials for RPE65-associated Leber congenital amaurosis.<sup>195-197</sup> Moreover, for a soluble gene product such as sFlt-1, gene therapy may be especially effective, as transduction need not be cell-specific.<sup>192</sup>

AAV-mediated sFlt-1 (and related fusion protein) gene therapy has been successful in a number of animal models, including rodent and primate.<sup>192,198-201</sup> Lai et al. tested gene transfer using an injected AAV vector with full-length sFlt-1 on both mice and monkeys.<sup>192</sup> In the mouse, they found a marked decrease in hyperfluorescence on fluorescein angiography in sFlt-1 transduced eyes when compared to noninjected and control AAV-Green Fluorescent Protein (GFP)-injected eyes. Morphologically, they found that more extensive CNV-induced photoreceptor loss occurred in the noninjected and control eyes when compared to sFlt-1 eyes. Electroretinographic studies showed no significant loss of function as a result of sFlt-1

transduction. Primate studies showed similarly encouraging results, including prevention of CNV induced by laser, without evidence of toxicity on histology. Importantly, long-term expression of transduced gene products, with detection of sFlt-1 mRNA at up to 17 months after injection. A similar recent primate study tested an AAV vector tied to a gene for a novel fusion protein of a single domain of sFlt-1 and a human IgG1 heavy chain Fc fragment (termed sFLT01), finding both long-term expression over 5 months, as well as inhibition of CNV in a dose-dependent fashion.<sup>200</sup>

Results from a recent phase I trial of recombinant AAV vector (rAAV) encoding sFLT-1 were published in 2015.<sup>202</sup> The study randomized eight patients in a 3 : 1 fashion to either low-dose ( $1 \times 10^{10}$  vector genomes) or high-dose ( $1 \times 10^{11}$  vector genomes) gene therapy via subretinal injection, or to no gene therapy. After an initial 8-week safety evaluation period of the patients randomized to the low-dose group, a second group was randomized to the high-dose group. Notably, patients previously treated with anti-VEGF therapy were not excluded, with no washout period prior to baseline visit. All patients received an injection of ranibizumab at baseline and at week 4. Additional ranibizumab was given according to rescue criteria suggesting active progression of CNV. Among the six patients receiving treatment, BCVA improved in five compared with baseline, with three gaining at least 10 letters, and one patient improving by 15 letters. A single rescue injection with ranibizumab was required in two patients over the course of 52 weeks. One patient had an increase in anti-AAV2 antibodies over the course of the study, but was not deemed to be associated with safety or efficacy. The authors concluded that the rAAV2.sFLT-1 was safe and well tolerated, with potential as a long-term treatment option for AMD. Readers are referred to [Chapter 36](#), Gene therapy for retinal disease, for more information on this developing technology.

## Other Targets

### hI-con1.

hI-con1 (ICON-1; Iconic Therapeutics, Inc., South San Francisco, CA, USA) is a recombinant protein targeting TF, consisting of two

identical chains of mutant human factor VII (fVII), fused to human IgG1 Fc. In order to minimize the risk of inducing disseminated intravascular coagulation through fVII binding to TF, an amino acid substitution is introduced into the hI-con1 fVII domain, inhibiting the initiation of the coagulation pathway. A 24-week phase 1 trial (NCT01485588) established safety and tolerability of a single intravitreal injection of hI-con1 in patients with exudative AMD in a dose-escalating fashion. In results presented at the American Academy of Ophthalmology Retina Subspecialty Day in November 2012, the compound was found to be well tolerated without ocular or systemic safety concerns, with gains in visual acuity, improvement in OCT thickness, and reduction in angiographic lesion size. The phase II randomized, double-masked controlled EMERGE trial (NCT02358889) was initiated in February 2015, and will compare hI-con1 as monotherapy to combination therapy using both hI-con1 and ranibizumab, versus monthly ranibizumab as control.

### **Regorafenib.**

Regorafenib (Bayer, Wuppertal, Germany) is a multikinase inhibitor developed for oncology, targeting a number of intracellular and membrane-bound receptor tyrosine kinases involved in tumor angiogenesis, oncogenesis, and maintenance. Among its targets are VEGF receptors 1–3 and platelet-derived growth factor receptor  $\beta$  (PDGFR- $\beta$ ). Originally an orally administered agent, Bayer has developed a formulation for topical ophthalmic delivery (BAY-73-4506). A phase 1 study in healthy volunteers established that the topical drop was well tolerated, and animal studies have established efficacy in models of both corneal and CNV.<sup>203–205</sup> A nonhuman primate study found reduction in the development of CNV-type lesions similar to the rates found when using ranibizumab.<sup>204</sup> Based on these encouraging results, a phase II trial was initiated in humans testing regorafenib topical drops in patients with exudative AMD (NCT02222207).

### **Complement Inhibition.<sup>a</sup>**

Complement inhibitors are thought to be a promising class of agents for the treatment of both atrophic and exudative AMD. POT-

4 (AL-78898A, Alcon/Potentia Pharmaceuticals, Fort Worth, TX and Crestwood, KY, USA), a cyclic peptide derivative of Compstatin 13 amino acids in length, is a C3 inhibitor administered by intravitreal injection. Gel-like deposits form in the vitreous when POT-4 is injected at high concentrations (>0.45 mg dose), which may last as long as 6 months, thus providing a sustained-release delivery system. A phase I study of POT-4 in AMD eyes with CNV was completed successfully without any safety concerns at doses up to 1.05 mg (NCT00473928), although the systemic effects of intravitreal administration are unknown. A phase II study was completed in 2013 (NCT01157065), which did not demonstrate any positive results. Further investigation of the compound was terminated. However, in 2014, Apellis Pharmaceuticals acquired the intellectual property rights to POT-4, renamed APL-2. Phase I data are currently being analyzed C3 inhibition should block complement activation arising from many of the currently described complement pathway mutations, as the classical, lectin, fibrinolytic, and alternative pathways all generate the bioactive fragments C3a and C5a and the membrane attack complex (C5b,6,7,8,9) via C3 cleavage (see [Fig. 70.3](#)). This targets a relatively large population of AMD patients; however, the broad degree of complement inhibition may theoretically increase risk of intravitreal injection-associated endophthalmitis. In a murine model, it seems that C3 deficiency does not increase the risk of *Staphylococcus aureus* endophthalmitis.<sup>206</sup> In contrast, in a guinea-pig model, complement depletion with cobra venom factor does seem to increase the risk of *S. aureus*, *S. epidermidis*, and *Pseudomonas aeruginosa* endophthalmitis.<sup>207-209</sup> Other treatments related to complement factors are being examined in the context of nonexudative AMD (see below).

## Combination Therapies<sup>a</sup>

The principles of combination therapy have been well established in the treatment of infectious diseases such as HIV,<sup>210</sup> or in cancer therapy. The combination of VEGF blockade (e.g., with bevacizumab) with chemotherapy or radiation therapy, for example, results in a greater antitumor effect than with either treatment alone.<sup>211,212</sup> Combining AMD treatments with differing mechanisms of action may have synergistic effects that might result in (1) better visual outcome; (2) reduced frequency of treatment; (3) greater patient convenience (e.g., subconjunctival vs. intravitreal injection); (4) lower risk of adverse events such as endophthalmitis; and/or (5) less likelihood of “escape” (a phenomenon in which cells, e.g., infectious agents or tumor cells, develop alternative pathways that allow them to overcome the inhibition of a pathway essential for their survival or growth). A number of variations have been examined in the past, including retrospective and prospective trials of verteporfin photodynamic therapy with anti-VEGF therapy and/or intraocular or periocular triamcinolone or dexamethasone.<sup>213–227</sup> Newer targeted therapies are discussed below.

### **Pegpleranib (Fovista) (PDGF Inhibition)**

In the early stages of angiogenesis, pericytes contract and reduce their contact with vascular endothelial cells.<sup>228–232</sup> The endothelial cells proliferate and migrate, followed by pericyte migration into the forming vascular bed. During the time that endothelial cells lack pericytes, they are sensitive to VEGF inhibition. Once pericytes reestablish a close relationship with the endothelial cells, they may provide VEGF to the endothelial cells as well as use other signaling systems, such as ang-1/Tie-2,<sup>233</sup> to promote endothelial cell survival, thus rendering the mature capillary network resistant to VEGF-A inhibition with agents such as aflibercept, bevacizumab, and ranibizumab.

Platelet-derived growth factor (PDGF) is produced by platelets, RPE cells, fibroblasts, and macrophages and, among other things, promotes extracellular matrix deposition.<sup>234</sup> PDGF stimulates

pericyte recruitment and promotes maturation of a newly formed vascular bed. There are five members of the PDGF family (all dimers: AA, AB, BB, CC, DD), and endothelial cells primarily express PDGF-B.<sup>235</sup> There are two PDGF receptors, PDGFR $\alpha$  and PDGFR $\beta$ , both of which are tyrosine kinases. PDGFR $\beta$  binds PDGF-B (BB, AB) and PDGF-DD. VEGF impairs vessel maturation by stimulating the formation of VEGFR2-PDGFR $\beta$  complexes, which suppresses PDGF signaling pathways.<sup>236</sup> PDGF-B mediates pericyte recruitment to the growing endothelial cell tube.

In preclinical models, combination therapy using inhibitors of PDGF and VEGF signaling was superior to monotherapy with VEGF inhibitors in multiple models of angiogenesis.<sup>237</sup> Most importantly, these experiments demonstrated that neovessels become refractory to VEGF-A deprivation as they mature, but combination therapy can induce regression of such vessels. Several agents that target PDGF signaling have been developed, e.g., CR002 (anti-PDGF-D, CuraGen Corp., Branford, CT, USA),<sup>238</sup> mAb 3G3 (anti-PDGFR $\alpha$ , ImClone Systems, Branchburg, NJ, USA/Eli Lilly, Indianapolis, IN, USA),<sup>239</sup> and pegpleranib (Fovista, E10030) (anti-PDGF-B, Ophthotech Corp. New York, NY, USA).

Pegpleranib is a 50 kDa pegylated DNA aptamer that binds PDGF-B with ~300 pM affinity. A phase I trial (NCT01089517) enrolled 57 patients with advanced AMD-associated CNV.<sup>240</sup> Patients were treated with a single dose of 0.03 mg pegpleranib plus three monthly injections of ranibizumab or three monthly doses of pegpleranib (0.3 mg, 1 mg, or 3 mg) combined with three doses of 0.5 mg ranibizumab. Among patients completing follow-up at 4, 8, and 12 weeks, 32% (pegpleranib 0.3-mg cohort), 45% (pegpleranib 1-mg cohort), and 60% (pegpleranib 3-mg cohort) of patients gained at least 15 ETDRS letters. Mean improvement in BCVA was +11.1, +13.4, and +15.7 letters, respectively. Central foveal thickness, as measured by OCT, also decreased significantly, and fluorescein angiography demonstrated regression of the CNV in 85% of eyes. There were no drug-related adverse events. A 24-week phase IIb superiority trial involving 449 patients randomly assigned to receive monthly ranibizumab 0.5 mg or monthly ranibizumab 0.5 mg plus pegpleranib (0.3 mg or 1.5 mg) also was conducted (NCT01089517).<sup>241</sup> The pegpleranib 1.5 mg combination

therapy cohort demonstrated a mean +10.6 ETDRS letter improvement vs. +6.5 letters in the ranibizumab monotherapy cohort ( $p=.019$ ) (Figs. 70.21–70.22). Improvements in vision, central foveal thickness, and angiographic CNV regression were greater in the combination therapy cohort vs. the monotherapy cohort regardless of CNV subtype. Other than transient intraocular pressure increases in the combination therapy cohort, no safety signals were identified. Twelve month results of two parallel phase III studies (NCT 01944839 and NCT 01940900, 1248 patients enrolled) published in 2015, however, showed that combination therapy with pegpleranib and ranibizumab did not meet the primary endpoint of visual acuity superiority over ranibizumab monotherapy. The 24-month study was terminated early. Another trial (NCT01940887) combining pegpleranib and either bevacizumab or aflibercept is currently underway, and other combination therapies in development may provide synergistic biologic effects that could improve visual outcome, decrease treatment burden, and, ultimately, reduce the overall cost of treatment as well as the incidence of blindness associated with AMD-CNV.

## OHR-102/Squalamine

Squalamine (Ohr Pharmaceuticals, New York, NY, USA) is an antiangiogenic amino sterol derived from the cartilage of the dogfish shark, *Squalus acanthus*, targeting VEGF, PDGF, and basic fibroblast growth factor (bFGF) through calmodulin binding. It has been found to inhibit iris neovascularization when administered by intravenous injection, although it is ineffective when administered by intravitreal injection.<sup>242,243</sup> Squalamine also induces regression of experimental retinopathy of prematurity in a mouse model<sup>244</sup> and was tested in a phase I study of CNV in patients with no safety concerns expressed leading to several phase II trials. Initial visual results were promising, with improvement or stability in those patients receiving higher doses of the drug. Interestingly, the fellow non-study eyes with advanced macular degeneration also showed significant improvement after drug administration. A phase III study was initiated; however, the manufacturer abandoned further development.

Ohr pharmaceuticals later developed a topical formulation of squalamine (0.2%, OHR-102), modified to reduce aqueous

penetration and to maximize transscleral penetration into the choroidal tissue.<sup>245</sup> In the phase II IMPACT study, OHR-102 drops were given twice daily in combination with ranibizumab, compared with ranibizumab with placebo (vehicle drops). Injections were given on a PRN basis according to OCT criteria. The 9-month study enrolled 142 patients. Although results at the midpoint of the study were encouraging for the first 62 enrolled patients completing the study (10 vs. 6 letter improvement in the combination group versus the ranibizumab monotherapy group), by the study's end, there were no significant differences between the combination and monotherapy groups overall (+7.8 compared with +5.3 letters, respectively, with no difference in the number of injections required).<sup>246</sup> However, in subgroup analyses, there was a difference when considering lesions containing classic CNV, with 11 vs. 5 letters gained, 42% vs. 28% gaining 3 lines of vision. Similarly, a higher percentage of patients in this subgroup achieved 4 and 5 lines of vision gain when treated with combination therapy compared with monotherapy. Early post-hoc analyses found that lesion size may have an impact on treatment response as well, as smaller (<10 mm<sup>2</sup>) occult lesions had a significantly better response to combination therapy. These data supported a phase III trial in a more targeted patient population.

## **X-82**

The dual-kinase inhibitor X-82 (Tyrogenex, West Palm Beach, FL, USA) is a small molecule that targets the VEGF receptor and PDGF receptor. In the oncology literature, the compound has been advanced as a next generation tyrosine kinase inhibitor that is orally available with an improved safety profile.<sup>247</sup> A phase I dose-escalation study enrolled 35 patients who had previously been treated for exudative AMD, with results presented at ARVO in 2015. Of the 27 patients completing the 24-week treatment, a majority demonstrated either maintenance or improvement from baseline vision, and 89% did not require rescue therapy with ranibizumab.<sup>248</sup> The phase II APEX study has been initiated by Tyrogenex, with visual acuity change and reduction in injections as key endpoints.

## Zimura

As discussed previously, complement is believed to play an important role in AMD pathogenesis. Complement factors have been isolated in drusen, and complement factor polymorphisms have been associated with AMD risk. Inhibition of C5 blocks terminal complement activity, but proximal complement functions remain intact, e.g., C3a anaphylatoxin production, C3b opsonization, and immune complex and apoptotic body clearance. Zimura (previously ARC1905; Ophthotech Corp., Princeton, NJ, USA) is an anti-C5 aptamer delivered by intravitreal injection. It binds C5 with high affinity ( $K_D = \sim 700$  pM) and prevents cleavage to C5a and C5b. A phase I trial of Zimura was completed and the results reported in 2010. In this nonrandomized safety study, Zimura was administered with monthly injections with ranibizumab 0.5 mg. There were no safety concerns or dose-limiting toxicities. In 43 patients receiving 6-monthly injections, the mean change in visual acuity at 24 weeks was +13.6, +11.7, and +15.3 letters in the 0.3-mg, 1-mg, and 2-g dosing groups, respectively.<sup>249</sup> Ophthotech has initiated plans for a phase II/III trial. A phase I trial (NCT00950638) for Zimura for GA has also been completed.

## Non-Neovascular AMD

### Antioxidants, Vitamins, and Cofactors

The rationale for the use of antioxidants, multivitamins, and other cofactors is based upon several lines of evidence, including the essential role of vitamin A in the visual transduction cycle, the known and predicted effects of oxidative stress resulting in reactive oxygen intermediates, and the requirement of certain critical metal ions including zinc in the functioning of critical proteases and other naturally occurring defense mechanisms against oxidative injury. Prior to the release of the data from the AREDS study, there remained some controversy as to whether or not antioxidant multivitamin therapy was efficacious, with some studies suggesting a protective effect, and others not.<sup>42,43,250</sup>

### Age-Related Eye Disease Study (AREDS) and AREDS2

The AREDS trial was a large multicenter RCT, which evaluated the effect of high-dose vitamin C and E, beta-carotene, and zinc supplements on AMD progression and visual acuity. A total 4,757 persons were enrolled and stratified into one of four categories of increasing severity of disease. Due to the low rate of progression of Category 1 consisting of drusen area of less than 5 small drusen of 63  $\mu\text{m}$  or less, statistical analysis was only performed on the remaining 3,640 patients with Categories 2, 3, 4. Only the latter two (Categories 3 and 4) were ultimately found to be at more than a trivial risk for progression. Patients in Category 2 with at least one intermediate size druse, but not extensive drusen, had only a 1.3% probability of progression to advanced AMD by year 5 and no meaningful inference could be drawn regarding their risk with or without intervention. Patients in Category 3 had either extensive intermediate drusen, large drusen or non-central GA, and patients in Category 4 had visual acuity of less than 20/32 due to AMD in one eye related either to GA involving the center of the macula or CNV in the fellow eye, but not the study eye, which had visual acuity 20/32 or better. The average follow-up of the 3,640 enrolled study participants aged 55 to 80 was 6.3 years, and by comparison with placebo, patients treated with antioxidants plus zinc demonstrated a statistically significant odds reduction for the development of advanced AMD (odds ratio 0.72, 99% confidence interval, 0.52–0.98). The odds ratios for zinc alone and antioxidants alone were 0.75 and 0.8 respectively, and the odds reduction estimates increased when only patients with Category 3 or Category 4 drusen were included, reducing to 0.66, 0.71, and 0.76 for antioxidants plus zinc, zinc alone, and antioxidants alone, respectively. These data are further reflected in [Fig. 70.23](#).

**FIG. 70.23** Repeated-measures estimates of the probability of loss in the visual acuity score of at least 15 letters in at least one study eye of participants within categories 3 and 4. (Reproduced with permission from AREDS Research Group. Arch Ophthalmol. 2001;119(10):1417-1436.)

Based on these findings, and extrapolation of the US population at risk, it has been estimated that of the 8 million persons in the United States at least age 55 or greater with AMD, if those at highest risk, including Categories 3 and 4, were to receive therapy with the formulation employed in the AREDS trial, as many as 300,000 of the 1.3 million at highest risk for advancement might avoid progression to the severe forms of the disease.<sup>251</sup>

Additionally, based upon recent epidemiologic data, exclusion of beta-carotene was recommended for persons with a current history of smoking or a long smoking history based upon a theoretical increased risk of lung cancer.

The macular carotenoids thought to be the principal contributors to macular yellow include lutein and zeaxanthin. One study

suggested that a high dietary intake of these carotenoids protected against AMD, resulting in a 43% reduction in risk for AMD when the upper quartile of use was compared with the lowest quartile.<sup>40</sup> The AREDS reports have supported these findings, showing in cohort studies that those with a high level of dietary intake of lutein and zeaxanthin were less likely to have advanced AMD, as well as large or extensive intermediate drusen.<sup>252</sup> High dietary intake of omega-3 long-chain polyunsaturated fatty acids were also found by the AREDS investigators to be inversely related to progression to both GA as well as neovascular AMD.<sup>37-39</sup> Consequently, the AREDS2 randomized multicenter phase III clinical trial (NCT00345176) was designed to address (1) the role of lutein and zeaxanthin and the omega-3 long-chain polyunsaturated fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) in prevention of development of GA or CNV; (2) the effect of possible deletion of beta-carotene and lowering the daily zinc oxide dose from 80 mg to 25 mg.

The 4203 AREDS2 study participants (6916 eyes) were randomized to one of four interventions: (1) placebo (the original AREDS supplement, and thus not a true placebo group); (2) lutein (10 mg) and zeaxanthin (2 mg); (3) DHA (350 mg) and EPA (650 mg); (4) both lutein/zeaxanthin and DHA/EPA. A second-tier randomization assigned 3,036 patients (4,987 eyes) to receive (1) the original AREDS supplement; (2) the AREDS supplement without beta-carotene; (3) AREDS supplement with lower dose zinc; or (4) both without beta-carotene and with lower dose zinc. The primary outcome measure was the development of central GA or CNV.

Five-year progression to advanced AMD was similar for all groups in the primary randomization (31% for placebo, 29% for lutein + zeaxanthin, 31% for DHA + EPA, and 30% for lutein + zeaxanthin and DHA + EPA). No intervention resulted in significant reduction in progression to advanced AMD (Fig. 70.24). Similarly, analysis of the secondary randomization showed no difference in progression when lowering zinc or eliminating beta-carotene. There was no effect of any supplement on the risk of moderate visual acuity loss (15 or more letters). All groups in the primary randomization had similar safety outcomes, with no significant differences in serious adverse events; however, in the

secondary randomization, more participants in the beta-carotene group than the no beta-carotene group developed lung cancer (91% of whom were former smokers).

**FIG. 70.24** Primary analyses of lutein + zeaxanthin + omega-3 long-chain polyunsaturated fatty acids vs. placebo for treatment of progression to advanced age-related macular degeneration (AMD). (Participants assigned to the placebo group were also given Age-Related Eye Disease Study (AREDS) supplement either within or outside of the secondary randomization for the four variations of the AREDS supplements; thus, there is no true placebo group.) DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid. (Reproduced with permission from Age-Related Eye Disease Study 2 Research Group. Lutein + zeaxanthin and omega-3 fatty acids for age-related macular degeneration: the Age-Related Eye Disease Study 2 (AREDS2) randomized clinical trial. JAMA. 2013;309(19):2005-15.)

Although the primary analysis of AREDS2 did not show additional benefit when substituting lutein and zeaxanthin for beta-carotene, or when adding DHA and EPA, the potential increased risk of lung cancer in current and former smokers when taking beta-carotene suggested a more favorable safety profile with the naturally occurring macular pigments lutein and zeaxanthin. Additionally, in a prespecified secondary analysis, there was a protective effect associated with lutein and zeaxanthin supplementation for progression to advanced AMD in those patients with the lowest dietary intake of these nutrients. The study also found that the serum levels of lutein and zeaxanthin were lower in those patients who were assigned to the group receiving the supplement including beta-carotene; previous preclinical animal and human studies had suggested that beta-carotene and

lutein + zeaxanthin administered concurrently may result in lower serum and tissue levels of lutein + zeaxanthin due to competitive absorption, leading to the hypothesis that lutein and zeaxanthin may reduce the risk of progression when given without additional beta-carotene.

Additional secondary analysis of the AREDS2 data exploring this hypothesis found that lutein/zeaxanthin alone compared to beta-carotene alone showed a favorable effect of lutein/zeaxanthin in reducing the risk of progression to neovascular AMD, although not central GA (Fig. 70.25). There was no apparent additional synergistic effect when adding beta-carotene to lutein/zeaxanthin, as the hazard ratios for progression remained similar when compared to beta-carotene alone.<sup>253</sup> Lutein/zeaxanthin also compared favorably with beta-carotene for disease progression along the AREDS AMD Scale, as well as for progression to advanced AMD in those patients with bilateral large drusen (although not for those patients with baseline late AMD in one eye). In contrast to AREDS, there was no reduction of vision loss in AREDS2 except in the exploratory analysis of rates of severe vision loss (<20/100). In the secondary analysis of nonsmokers, lung cancer developed more frequently in patients receiving beta-carotene than in those not receiving beta-carotene (91% of whom were former smokers).

**FIG. 70.25** Subgroup analyses of main effects of lutein + zeaxanthin and the comparison of participants randomized to receive lutein + zeaxanthin and Age-

Related Eye Disease Study (AREDS) supplements with lutein + zeaxanthin and without beta carotene vs. those randomized to receive original AREDS supplements with beta-carotene for progression to advanced age-related macular degeneration (AMD) and the two forms of AMD, neovascular AMD and central geographic atrophy. (Reproduced with permission from Age-Related Eye Disease Study 2 Research Group. Lutein + zeaxanthin and omega-3 fatty acids for age-related macular degeneration: the Age-Related Eye Disease Study 2 (AREDS2) randomized clinical trial. JAMA. 2013;309(19):2005-15.)

The AREDS2 data supported the use of supplementation with lutein/zeaxanthin in the reduction of progression to late AMD, and supported the finding in AREDS that beta-carotene increases the risk of lung cancer in current and former smokers. These findings taken together suggested that lutein/zeaxanthin may be a more appropriate carotenoid supplement than beta-carotene, both in safety profile, as well as in protection against the development of neovascular AMD.

## Visual Cycle Inhibitors<sup>a</sup>

Visual cycle modulators are intended to reduce the accumulation of toxic fluorophores such as A2E in RPE cells. Fenretinide (ReVision Therapeutics, Inc., San Diego, CA, USA) is a synthetic vitamin A derivative that causes a dose-dependent, reversible reduction in circulating retinal binding protein (RBP) and retinol by competitive displacement of retinol from RBP, as well as interfering with RBP binding to transthyretin (TTR), thus facilitating their elimination via glomerular filtration. In ABCA4<sup>-/-</sup> mice, fenretinide reduces RPE lipofuscin and A2E accumulation, although it causes modest delays in dark adaptation.<sup>254</sup> Notably, however, despite low blood retinol levels, RPB<sup>-/-</sup> mice acquire normal vision by 5 months of age when given a vitamin A-sufficient diet.<sup>255,256</sup> Thus, it is not clear that blockade of vitamin A transport to RPE by inhibition of vitamin A binding to RBP will block vitamin A uptake by the RPE during long-term administration unless dietary vitamin A is restricted also. In a phase IIb clinical trial of oral fenretinide, 246 patients were randomized to receive placebo, 100 mg, or a 300 mg daily dose for 24 months (NCT00429936).<sup>257</sup> At the conclusion of the 2-year study,

analysis of GA lesion growth by color fundus photography showed a trend for slowing of lesion growth in the 300-mg fenretinide dose cohort, particularly among patients who had serum RBP levels of  $\leq 2$  mg/dL ( $1.70 \pm 0.77$  mm<sup>2</sup>/year vs.  $2.03 \pm 1.24$  mm<sup>2</sup>/year,  $p=.1848$ ). Moreover, an exploratory and ad hoc analysis of the data revealed that 15 (18.3%) of 82 patients in the placebo arm progressed to CNV, compared with 15 (9.2%) of 163 patients receiving fenretinide at either dose ( $p=.06$ ), despite the higher baseline risk of developing CNV (based on previous fellow-eye CNV) compared with the placebo group.<sup>257</sup> Although fenretinide can affect dark adaptation<sup>258–265</sup> and ERG readings,<sup>266–269</sup> and is associated with symptoms of dry eye,<sup>263,264</sup> it was generally well tolerated in this study, with four patients (2.5%) withdrawing from the study due to dark adaptation complications, and four other patients in the 300-mg group withdrawing citing visual disturbances.

Emixustat (formerly ACU-442; Acucela, Seattle, WA, USA) is an orally administered compound that inhibits conversion of all-*trans*-retinyl ester to 11-*cis*-retinol via blockade of RPE65 as a means of reducing toxic metabolites of the visual cycle. Emixustat has been shown to reduce lipofuscin and A2E accumulation in the RPE of ABCA4<sup>-/-</sup> mice. A phase I clinical trial (NCT00942240) in 46 healthy volunteers was completed successfully up to doses of 75 mg.<sup>270</sup> The most common adverse events were vision-related, occurring in 50% of patients receiving the medication, which included dyschromatopsia (32%), unspecified visual disturbance (29%), night blindness (18%), blurred vision (11%), and photophobia (8%). All adverse events were mild or moderate in intensity and were transient in nature, resolving within a few days after onset. There was dose-dependent suppression of the ERG b-wave as expected. Similarly, in a second, multiple-dose, placebo-controlled phase I study, an additional 40 healthy volunteers (30 study medication patients, 10 placebo) were given an oral course of emixustat for 14 days, with doses up to 40 mg. The mean elimination half-life was determined to be 4.6 to 7.9 hours, with peak plasma levels within 3–5 hours after each dose. There was no significant plasma accumulation or systemic adverse events. Visual side-effects were similar to those described above.

A double-masked, dose escalation phase IIa study was completed

with study results reported in 2015 (NCT01002950).<sup>271a</sup> Seventy-two patients with GA were randomized in a 3 : 1 fashion to receive either emixustat (n=54) or placebo (n=18) daily for 90 days, in five dosing cohorts (2, 5, 7, 10 mg given every morning, or 5 mg given every evening). Drug effect on the visual cycle was assessed by measurement of ERG rod sensitivity after photobleaching. After 14 days of study drug administration, there was dose-dependent rod suppression in the emixustat group, with the least suppression in the 2-mg group, and the most suppression in the 10-mg group. One to two weeks after drug cessation, post-bleach amplitudes returned to normal with exception one outlier patient in the 10-mg group that skewed the results in that group. There was no effect on the cone ERG. Fifty-three percent of patients receiving emixustat completed the study, with the higher dosing cohorts (7 and 10 mg) discontinued early because of adverse events, which occurred in 7 of 18 patients in those groups. Eight subjects overall (all receiving study drug) discontinued the study drug due to an adverse event, which were ocular in nature. Ocular adverse events were seen in 93% of emixustat subjects (most commonly visual disturbances such as chromatopsia and delayed dark adaptation), while systemic adverse events were seen in 57%. The majority of these events resolved within 7–14 days after discontinuing the study drug. The phase II study served a proof of concept that emixustat can indeed modulate the visual cycle, with temporary and reversible rod suppression and mild to moderate ocular adverse events. Additional studies are planned; however, it may also be worth noting that histopathologic studies have demonstrated that abnormal fundus autofluorescence in geographic atrophy may result primarily from vertically superimposed or layering of RPE cells rather than intracellular lipofuscin accumulation. As such, there remains some debate regarding the utility of targeting the visual cycle for this disease process.<sup>271b,271c</sup>

## Complement Inhibition

Factor D is the rate-limiting enzyme in the activation of the complement alternative pathway. It plays an important role in the positive feedback loop that results in the amplification of

proinflammatory effectors.<sup>272</sup> Lampalizumab (formerly FCFD4514S; Genentech/Roche, South San Francisco, CA, USA) is a monoclonal antibody fragment (Fab) directed against Factor D. An 18-patient, open-label escalating-dose phase Ia clinical trial (NCT00973011) of intravitreal therapy for GA showed that the medication was well tolerated, with no significant adverse events up to the maximum-tested 10 mg dose. The subsequent phase II MAHALO study (NCT01229215) enrolled 143 patients (including a 14-patient phase Ib run-in), testing lampalizumab at the 10-mg dose. The placebo-controlled study dosed lampalizumab monthly or bimonthly, compared with sham injections, also given monthly or bimonthly, randomized 1:2:1:2, with twice the number in the treatment groups. The primary study endpoint was the mean change in GA area from baseline to 18 months, as measured by fundus autofluorescence. Other endpoints included GA on color fundus photographs and BCVA. At the study endpoint, there was a 20.4% reduction in the rate of expansion of GA lesions in the monthly lampalizumab injection group relative to the pooled sham groups, which was statistically significant to the predetermined *p*-value of 0.2. There was no difference in rate of GA expansion in the bimonthly lampalizumab group versus sham. In a subgroup analysis of patients with exploratory biomarkers (mutations in CFH, C3, C2/CFB, and CFI, positive in 57% of the patients assayed), there was a 44% reduction relative to sham (*p*<.005, n=28). Final BCVA was worse in all groups relative to baseline, without differences, although the study was not powered to detect differences in visual acuity. There were no significant safety concerns, although there were 7 ocular adverse events in the treatment groups (4 in the monthly group, 3 in the bimonthly group). There was one nonocular adverse event in each of the study groups suspected to be caused by the study drug. The MAHALO study was the first to demonstrate any positive effect on GA progression, with the results prompting a phase III trial.

Inhibition of C5 blocks terminal complement activity, with proximal complement functions remaining intact, e.g., C3a anaphylatoxin production, C3b opsonization, and immune complex and apoptotic body clearance. Previous trials have attempted to slow the rate of GA progression by inhibiting the actions of C5 (or

its cleavage product C5a) without demonstrating efficacy.<sup>95,273</sup> Notably, a double-masked randomized clinical trial of eculizumab, a systemic inhibitor of C5, failed to demonstrate any difference in progression of GA in 30 patients over a 6-month period.<sup>273</sup> However, there is still interest in this area. The monoclonal antibody LFG316 binds C5 with high affinity and prevents its cleavage into C5a and C5b.<sup>274,275</sup> A phase 1 dose-escalation trial in 24 patients with advanced AMD demonstrated safety with a single intravitreal injection of up to 5 mg. There were no significant adverse events, and no change in serum C5 levels or evidence of activation of serum alternative complement pathway. A phase II trial is underway (NCT01527500).

The complement factor C3 is also a target of interest for dry AMD. The cyclic peptide POT-4 was originally developed at the University of Pennsylvania and represented the first complement inhibitor to be tested in patients with AMD. The compound blocks C3 and all downstream effector pathways. A phase I study (NCT00473928) tested a single intravitreal injection of POT-4 in patients with neovascular AMD and was found to be safe and well tolerated.<sup>276</sup> Alcon/Novartis (Fort Worth, Texas, USA) licensed POT-4 and initiated a phase 2 trial, but subsequently terminated its development. Apellis Pharmaceuticals (Crestwood, KY, USA) acquired the rights to POT-4 in 2014 and has continued to develop the technology as APL-2, with the same therapeutic target but with a longer half-life. A phase I trial is in process for neovascular AMD (NCT02461771), with a phase II trial planned for GA (NCT02503332). [Fig. 70.26](#) illustrates the complement pathways and compounds in various stages of investigation.

**FIG. 70.26** Numerous compounds that modulate the complement pathway are in development for or in clinical trials for AMD treatment. \* Currently being investigated for AMD. Red circles indicate the parts of the complement pathway that are being modified. The complement pathway illustrated is adapted from Donoso et al.<sup>277</sup> (Reproduced from Zarbin MA, Rosenfeld PJ. Pathway-based therapies for age-related macular degeneration: an integrated survey of emerging treatment alternatives. *Retina* 2010; 30: 1350-67, with permission of Springer Science+Business Media.)

## Other Agents

### Sirolimus

Sirolimus (or rapamycin; MacuSight/Santen, Union City, CA, USA); is a macrocyclic, naturally occurring lactone that was initially isolated from the species *Streptomyces hygroscopicus* and given its name from Rapa Nui (Easter Island) during the course of a search

for novel antifungal agents. Sirolimus interacts with the protein kinase, mechanistic target of rapamycin (mTOR), which regulates various aspects of cell function, including metabolism and apoptotic pathways. Additionally, through its intrinsic immunomodulatory effects, may reduce macrophage chemotaxis and activation, and suppresses T-cell and B-cell proliferation.

It has been shown to inhibit angiogenesis through direct inhibition of vascular endothelial growth factors as well as endothelial cell responses to VEGF.<sup>278</sup> Inhibition has been demonstrated in a murine model of retinopathy of prematurity and laser-induced neovascularization when the drug was administered by an intraperitoneal route.<sup>279</sup> Although sirolimus has been investigated as an agent for neovascular AMD,<sup>280</sup> there is currently more interest as an agent for nonexudative disease.

A single-center, open-label phase I/II study examined subconjunctival administration of sirolimus for the treatment of GA (NCT00766649). The study enrolled 11 patients, 8 of whom completed 24 months of follow-up. Sirolimus was administered quarterly in one eye, with the fellow eye serving as a control. Although sirolimus was well tolerated without significant safety concerns, there was no significant benefit demonstrated.<sup>281</sup> At 24 months, mean GA area increased by 54.5% in the study eye, compared with 39.7% in the fellow eye ( $p=.41$ ), with significantly more vision loss associated with the study drug (loss of 21 letters compared with 3 letters in the study eye versus the fellow eye). There were no differences in drusen area, retinal thickness, or macular sensitivity. It was postulated that subconjunctival administration may be insufficient to reach the posterior segment of the eye; thus a second study examined the effect of sirolimus delivered via intravitreal injection (NCT01675947). Among the six study participants, two developed accelerated retinal thinning in the treated eye, one of which was associated with paralesional fundus autofluorescence changes. The study was terminated due to safety concerns.<sup>282</sup>

## **Amyloid**

As discussed above, amyloid is thought to be an activator of the complement system in AMD.<sup>106-108</sup> GlaxoSmithKline has developed

a monoclonal antibody to amyloid- $\beta$ , called GSK933776, which is administered intravenously. Preclinical animal studies demonstrated that the antibody reduced the accumulation amyloid- $\beta$  and C3a deposition within Bruch's membrane. A phase I trial has been completed and a multicenter, double-masked, placebo-controlled phase II trial is underway.<sup>283</sup>

## **Increasing Choroidal Blood Flow**

Choroidal bloodflow decreases in the normally aging eye, and choroidal hypoperfusion has been implicated in the pathogenesis of AMD.<sup>284–286</sup> Increasing choroidal bloodflow, then, may represent one method of decreasing the risk of progressing to advanced neovascular or atrophic AMD. MacuCLEAR has developed a choroidal vasodilator called MC-1101 that can be given topically. Mechanistically, MC-1101 operates in part through the production nitric oxide, but theoretically without significant systemic side effects due to its route of administration. A phase Ib trial was completed, and demonstrated a significant increase in choroidal bloodflow (over 5-fold) one hour after administration. A phase II/III trial is currently underway (NCT01601483).

## **Neuroprotection**

In many degenerative retinal conditions, such as retinitis pigmentosa, a therapeutic modality of interest is in the area of neuroprotection, exposing the degenerating tissue to an agent that can retard cell population death. Although different diseases processes, apoptotic degeneration appears to play a role in both inherited retinal degenerations as well as macular degeneration, and investigators are exploring some of the same therapeutic principles.<sup>287</sup> Ciliary neurotrophic factor (CNTF) is in the IL-6 cytokine family that has been shown to slow the loss of photoreceptors in multiple animal models of inherited retinal degenerative conditions.<sup>288–290</sup> In a proof-of-concept, randomized phase II clinical trial, CNTF was administered by encapsulated cell technology (ECT-NT-501; see above section for more background on this technology and for its role in neovascular AMD).<sup>186</sup> The study enrolled 51 patients, with 27 patients receiving the high-dose implant, and 12 patients each receiving sham or low-dose implant,

followed for 12 months. Visual acuity remained stable in the high-dose implant group, with 96.3% of patients losing fewer than 15 letters of vision, compared with 75% of the sham group ( $p=.078$ ). This difference was statistically significant in those with better baseline vision ( $>20/63$ ): 10/10 patients maintained vision in the high-dose group, compared with 5/9 in the combined low-dose/sham group ( $p=.033$ ). Macular OCT measurements demonstrated significant increase in volume in patients receiving the study intervention, regardless of dose, and exclusive of any pathologic change (e.g., CNV, macular edema, epiretinal membrane). No change in GA was found in any group. No treatment-related severe adverse events were reported. The study demonstrated a biologic effect of CNTF (increase in OCT macular volume), as well as proof-of-concept for the CNTF ECT implant. However, no further trials for this indication are currently planned.

Brimonidine given for glaucoma has long been believed to offer additional benefit as a neuroprotective agent. Multiple animal models have shown this effect in a number of cell types, including retinal ganglion cells, bipolar cells, and photoreceptors.<sup>291-293</sup> The mechanism of neuroprotection has not been elucidated, but is likely due to induced expression or upregulation of trophic factors such as brain-derived neurotrophic factor (BDNF) and cytokines that inhibit apoptotic pathways and stimuli.<sup>294,295</sup> A brimonidine sustained-release intravitreal implant has been developed by Allergan<sup>296</sup> (Irvine, CA, USA) and has been tested in a 2-year phase II study of GA (NCT00658619). The randomized double-masked sham-controlled trial enrolled 119 patients with bilateral GA, with one eye serving as the study or sham eye, and the fellow eye acting as a sham control. Study eyes were given either a 200  $\mu\text{g}$  or 400  $\mu\text{g}$  implant or a sham treatment at day 1 of the study and again at 6 months, with the primary outcome of change in GA from baseline to 1 year. At the time of writing, a second phase II study has completed enrollment (NCT02087085).

### **Doxycycline/Matrix Metalloproteinase Inhibitor**

As indicated above, the matrix metalloproteinases, such as MMP-2 and -9, are believed to play a role in the process of angiogenesis in AMD, and are known to be expressed in choroidal neovascular

membranes removed from patients with subfoveal CNV.<sup>82</sup>

Doxycycline has long been known to be a potent matrix metalloproteinase (MMP) inhibitor, acting as a noncompetitive inhibitor through its interactions with zinc or calcium within the center of this class of proteins.<sup>297</sup> In an animal model of CNV, doxycycline administration decreased laser-induced CNV size significantly. Based on this activity and the possible association of matrix metalloproteinases with the pathogenesis of macular degeneration, a phase II/III trial has been initiated testing doxycycline for GA.

## Home Monitoring for AMD

The goal of current pharmacotherapies for treatment-warranted AMD is to preserve retinal structure and function. Treatment studies have demonstrated better visual outcomes in patients with improved vision at the time of initiating treatment.<sup>298-300</sup> As such, earlier detection of treatment-warranted disease is paramount to improved visual outcomes with treatment.

Because the interval between scheduled clinic visits for patients with AMD may span up to one year, an area of interest has been the development of out-of-office tools to aid in the diagnosis and surveillance of patients for treatment-warranted disease, specifically the development or reactivation of CNV.

Pathology<sup>301</sup> and psychophysical<sup>302</sup> studies have demonstrated that there is an early susceptibility of the parafoveal rod photoreceptors in both dry and wet AMD. Several targeted monitoring tools have been developed. Validation against age-matched controls and with serial measurements versus a given patient's baseline have indicated promise with regard to the detection of de novo and recurrent treatment-warranted disease, respectively.

The utility of at-home self-monitoring remains dependent on patient adherence to the testing procedures and may be improved through better patient education and tools. For example, the Vision and Memory Stimulating Journal (KeepSight; Hebron, CT), which includes an Amsler-type grid for home testing, demonstrated improved adherence to weekly testing (80% vs. 50%,  $p=.002$ ) and

patient confidence in self-monitoring ( $p=.002$ ).<sup>317</sup>

## Hyperacuity-Based Testing

Hyperacuity, or vernier acuity, relies on the integration of visual input over an area of retina, and as such, hyperacuity tasks may detect subtle defects in the photoreceptor mosaic.

### Amsler Grid

The traditional Amsler macular grid is a handheld, paper-based test in which patients fixate centrally on a grid wherein each block subtends about 1 degree of visual angle, noting areas of scotoma or metamorphopsia.<sup>303</sup> Amsler grid testing was found to correlate well with areas of RPE atrophy ( $r=0.73$ ,  $p<.001$ ),<sup>304</sup> and in a meta-analysis, to have a sensitivity and specificity to detect neovascular AMD of 64–87% and 91–99%, respectively.<sup>305</sup> As such, it has been a mainstay of out-of-office screening for treatment-warranted AMD since the 1960s.

### Preferential Hyperacuity Perimetry/ForeseeHome

ForeseeHome (Notal Vision, Ltd; Tel Aviv, Israel) is a fixed, device-based preferential hyperacuity perimetry (PHP) test that presents patients with dotted-line stimuli within a 14° diameter area of retina, and a subset of the dots are misaligned. Patients are tasked with indicating the location of misalignment.<sup>306</sup> A recent meta-analysis<sup>305</sup> of studies evaluating preferential hyperacuity perimetry testing found that it has a sensitivity and specificity to detect neovascular AMD of 80–89% and 82–91%, respectively. A recent prospective, randomized, unmasked clinical trial comparing the ForeseeHome device plus standard care versus standard care alone demonstrated detection of CNV at an earlier stage of functional loss (20/32 vs. 20/40, loss of 4 vs. 9 ETDRS letters from baseline,  $p=.021$ ).<sup>307</sup>

### Shape Discrimination Hyperacuity/myVisionTrack

myVisionTrack (Vital Art and Science, Inc; Richardson, TX) is a handheld, smartphone-based shape discrimination hyperacuity

(SDH) test in which patients are presented with an alternate forced-choice task to determine which of three circular shapes, subtending a 3° diameter area of retina, is radially distorted.<sup>308</sup> In a cross-sectional study of 32 patients with AMD and 10 age-matched controls, SDH scores in 31 (97%) of the patients with AMD were significantly worse than the mean control score, resulting in a test sensitivity and specificity of 97% and 100%, respectively.<sup>309</sup> In a cross-sectional study of 37 patients with AMD and 27 age-matched controls, worse SDH was correlated with increasing OCT central subfield thickness ( $r=0.56$ ,  $p<.0001$ ).<sup>308</sup> In both studies, SDH scores in patients with AMD were significantly worse than controls, to a degree that correlated with severity of disease. Additional studies are ongoing to assess the validity of this test to detect early treatment-warranted AMD.

### **Rarebit/MultiBitTest**

Rarebits are small stimuli presented for short durations that assess the receptive field matrix. MultiBitTest (MBT; Visumetrics AB; Gothenburg, Sweden) is a handheld, smartphone-based rarebit integration test in which patients are tasked with identifying numerical digits that have been segmented into receptive field-sized stimuli, which in aggregate subtend a 7° diameter area of retina. In a cross-sectional study of 28 patients with AMD and 20 aged controls, MBT demonstrated an area under the receiver-operating characteristic curve of 0.95, indicating promise to detect disease.<sup>310</sup>

## **Perimetry-Based Testing**

Perimetry-based tests, such as microperimetry, seek to localize areas of absolute and relative scotoma by applying direct stimuli.<sup>311</sup>

### **Macular Mapping Test**

The Macular Mapping Test (MMT; Aston University; Birmingham, UK) is a computer-based test in which Sloan letters are displayed at eccentricities up to 18° from fixation, which is maintained by a radially symmetric wagon-wheel pattern. The patient is queried on detection and recognition of the letter. In a cross-sectional study of

29 eyes with AMD and 31 eyes of age-matched controls, there was a significant difference in mean MMT scores between eyes with advanced AMD versus controls ( $p < .001$ ),<sup>312</sup> indicating promise to detect disease.

## Luminance-Based Testing

As there is preferential parafoveal rod > cone loss in early AMD,<sup>301</sup> low luminance tasks, such as dark adaptation<sup>313</sup> and photostress recovery,<sup>314</sup> have been found to be affected in patients with AMD.

## Low Luminance Visual Acuity/SKILL Card

The Smith–Kettlewell Institute Low Luminance (SKILL) card measures the difference between standard high-contrast versus a low-luminance, low-contrast near visual acuity.<sup>315</sup> In a cross-sectional study of 17 patients with AMD and 20 age-matched controls, there was a significant difference in mean SKILL scores between eyes with advanced AMD versus controls ( $p = .01$ ).<sup>316</sup>

## Summary

A variety of molecules, specifically targeted to different pathologic pathways in AMD, have been identified for their therapeutic potential. Additionally, our understanding of the genetic basis for AMD continues to increase rapidly, which has led to a systematic and rational basis for pharmacotherapy. A number of associated genes and alleles have been identified that confer risk or are protective against the disease, and as the related pathways are elaborated, we are able to not only target these pathways with great specificity, but also identify those individuals who are most likely to benefit from a particular therapy. Research is actively being pursued in preclinical models both in academic laboratories and in the pharmaceutical industry, including a large number of early-stage clinical trials in recent years. The success of VEGF inhibition has shown that targeted therapies are a key component of the treatment of macular degeneration. It is anticipated that agents that can modulate and inhibit various stages of the disease, and especially including those multiple stages relating to RPE function,

the visual transduction cycle, and inflammatory pathways, will find prominent roles either alone or in combination. It is also increasingly likely that not only treatments targeted at specific molecular pathways, but also gene transformation and replacement, should become increasingly important tools in addition to standard VEGF inhibitors and other classes of small molecules and specific monoclonals in the management of this disease.

**Conclusion**

Pathologic myopia is a major cause of legal blindness and low vision worldwide,<sup>1-5</sup> and its prevalence is increasing in modern society, presumably due to an increase of near activities. In patients with pathologic myopia, various kinds of macular lesions develop in the posterior fundus, and these are the cause of visual impairment.<sup>6,7,1-5</sup> There are new ideas concerning the pathogenesis of pathologic myopia and novel treatments for macular complications. Although macular lesions in eyes with pathologic myopia had been an incurable degenerative disorder, the recent application of anti-vascular endothelial growth factor (VEGF) therapy for myopic choroidal neovascularization (CNV)<sup>6-9</sup> and vitreoretinal surgery for myopic traction maculopathy have enabled the treatment of these complications due to pathologic myopia.<sup>10-18</sup> With these advances, pathologic myopia is now a curable disorder in some patients to some extent.

## Epidemiology

Myopia is more common among Asian populations, especially in East Asian countries, than among white, black, or Hispanic people. The prevalence of myopia (spherical equivalent [SE],  $<-0.5$  or  $-1.0$  diopters [D]) is reported to range from 17% to 43% among Asian populations.<sup>19-27</sup> Among white populations in Europe, the United States, and Australia, it is reported to be between 13% and 27%.<sup>28-31</sup> In Hispanic and black populations, it is reported to be 17% and 21%, respectively.<sup>29,32</sup> The prevalence of high myopia (SE,  $<-5.0$  or  $-6.0$  D) is also greater in Asian populations, ranging from 1.7% to 9.1%, than that in white, Hispanic, and black populations (2.0%, 2.4%, 1.0%, respectively).<sup>19-32</sup>

Pathologic myopia is one of the major causes of visual impairment and blindness worldwide. For example, myopic macular degeneration is the leading cause of blindness in Japan, the second most common cause in Denmark<sup>33</sup> and in China,<sup>23</sup> and the third cause of blindness in Latinos 40 years and older in the United States.<sup>3</sup> Myopic macular degeneration was the leading cause of impaired vision for persons aged between 55 and 75 years in The Netherlands.<sup>34-36</sup> In Italy and Taiwan, it is the second most common cause of low vision.<sup>37,38</sup> The impact of myopic retinopathy on visual

impairment is of great concern because it is often bilateral, irreversible, and it frequently affects individuals during their most productive ages.<sup>39,40</sup>

To date, three population-based studies have estimated the prevalence of myopic retinopathy. The Blue Mountains Eye Study in Australia, which focused on a white population, reported that the prevalence of myopic retinopathy was 1.2%.<sup>40</sup> In the Beijing Eye Study in China and the Hisayama Study in Japan, the prevalence was 3.1% and 1.7%, respectively.<sup>41</sup> Study participants' characteristics, methodology, and study design (for example, the definition of myopic retinopathy) were different between those studies; therefore the precise racial difference in myopic retinopathy prevalence is unknown. But it may be higher in East Asian populations than in white populations, and the prevalence of high myopia is probably higher as well.

The prevalence of myopic retinopathy is increased with advancing age in those population-based studies. Histologic studies have shown a decreased density of photoreceptors, ganglion cells, retinal pigment epithelium, and optic nerve fibers with age.<sup>42,43</sup> However, several studies using optical coherence tomography (OCT) have examined subjects with healthy eyes with neither high myopia nor hyperopia and reported a negative relationship between retinal thickness and age.<sup>44,45</sup> In addition to the axial elongation of the eyeball in highly myopic eyes, increasing age may contribute to pathogenesis of myopic retinopathy by causing retinal thinning.

Although it is reported that men have longer axial length than women,<sup>46,47</sup> many hospital-based studies showed higher prevalence of myopic retinopathy in women than in men.<sup>48-50</sup> For example, Hayashi et al. showed that of 429 consecutive patients with pathologic myopia, 147 were men and 282 were women, which is about twice as many cases in women than in men.<sup>39</sup> Comparable findings were also observed in population-based studies. In the Blue Mountains Eye Study, the prevalence of myopic retinopathy in men was 0.06% and that in women was 0.4%. In the Hisayama Study, the prevalence of myopic retinopathy in men and in women was 1.2% and 2.2%, respectively. The Beijing Eye Study did not report the prevalence of myopic retinopathy by sex, but the female :

male ratios of the subjects with and without myopic retinopathy were 75 : 57 and 570 : 489, respectively. It suggests that not only greater axial length but other risk factors such as genetic factors and lifestyle risk factors may contribute to the pathogenesis of myopic retinopathy.

## Pathogenesis

Hereditary or genetic factors play important roles in the development of pathologic myopia. There is a large international linkage study on familial high myopia, in which linkage analyses were performed on 1201 samples from Asian, African-American, and Caucasian families, finding that the MYP1, MYP3, MYP6, MYP11, MYP12, and MYP14 loci were replicated.<sup>51</sup> Recent genomewide studies identified susceptibility loci at 15q14 and 15q25 for myopia.<sup>52,53</sup> The risk of myopia versus hyperopia showed an odds ratio (OR) 1.88 for homozygous carriers of the risk allele at the top-SNPs in locus 15q14 and OR 1.33 for heterozygous carriers. The 15q14 region contains the *GJD2* gene, encoding Connexin 36, which is associated with neurotransmission in the retina.<sup>54,55</sup> However, the genetic influence on the development of myopic macular degeneration is not clear. The genetic risk factors of age-related macular degeneration related to rs11200638 of HTRA1, and rs1061170 (Y402H) of complement factor H (CFH) did not appear to contribute significantly to the development of CNV in a highly myopic elderly Japanese population.<sup>56</sup> It was reported that the responsiveness of myopic CNV to PDT had a correlation with common coagulation-balance gene polymorphisms.<sup>57</sup>

Various factors such as aging and biomechanical factors in addition to hereditary factors have been considered to contribute to the development of myopic macular degeneration in highly myopic eyes.<sup>58–60</sup> Excessive axial elongation and posterior staphyloma formation are critical features of pathologic myopia, and these are considered important for the development and progression of myopic macular degeneration.<sup>59</sup> Large-scale studies show that a peripapillary crescent, chorioretinal atrophy, and posterior staphyloma are related significantly to increased axial length.<sup>41,59</sup> Above all, the incidence, size, and type of peripapillary crescent

have the strongest correlation with the axial length,<sup>59,61</sup> more than 95% of eyes with an axial length of 26.5 mm or more have a peripapillary crescent, while 0% of eyes with an axial length of 21.4 mm or less have a peripapillary crescent.<sup>59</sup> Chorioretinal atrophy has also been related directly to increased axial length.

In addition to the influence of biomechanical factors, aging is an important factor for the development of posterior staphyloma and subsequent myopic macular degeneration. A posterior staphyloma is rarely found in highly myopic patients younger than 40 years of age.<sup>62</sup> The posterior staphyloma develops as patients age, and this accelerates the further mechanical extension of the posterior fundus, and causes the development of myopic macular degeneration. The incidence of myopic chorioretinal atrophy increases with age, and these changes are rarely seen in persons less than 20 years old.<sup>59,61</sup> Childhood high myopes do not develop myopic macular degeneration or posterior staphyloma.<sup>63</sup>

The development of myopic choroidal neovascularization (myopic CNV) and lacquer cracks are not directly correlated with axial length. The incidence of myopic CNV peaks in the fourth decade. There may be biologic mechanisms of neovascular membrane formation other than axial elongation or aging.<sup>61</sup> Steidl and Pruett<sup>64</sup> reported that eyes with a shallow staphyloma had the high frequency of CNV. They suggested that it is possible that eyes with a shallow staphyloma may be healthier and more metabolically active with well-perfused chorioretinal tissue and good capacity to respond to injury by neovascular ingrowth. It appears that the influence of aging and mechanical factors is rather complicated and different lesions of course may have different pathogenetic influences.

## Histopathology

### The Sclera

Scleral thinning and localized ectasia of the posterior sclera are characteristic changes of the eyes with pathologic myopia. Vurgese and Jonas reported that in axially elongated eyes, scleral thinning occurred at and posterior to the equator, being more marked closer

to the posterior pole in human eyes.<sup>65</sup> Microscopically, the normal sclera consists of interwoven bands or bundles of collagen fibers.<sup>58</sup> These are usually well integrated and in longitudinal section present a relatively homogeneous appearance throughout their extent. The architectural changes in the longitudinal fibers in pathologic myopia consist of thinning of the collagen bundles, a reduction in refringence of the bundle edges, and the loss of longitudinal fiber striations. The cross-sectional fibers demonstrate dissociation such that the individual fibers separate from one another. There is also a reduction in the size of the individual dissociated fibers. The more advanced examples of architectural disorganization are found in and about the regions of the posterior pole and peripapillary sclera. It has also been reported that the elastic fibers within the sclera showed a definite decrease in the number of fibers.

Electron microscopic analyses showed that a predominance of collagen fibrils of small diameter, usually averaging below 60–70 nm, was found.<sup>58</sup> Fibrils of a very fine diameter were also observed. Also, the cross-sectioned fibrils showed a marked increase in the prevalence of fissured or “star-shaped” forms. Most of the ultramicroscopic alterations seen in the myopic sclera indicate a derangement of the growth and organization of the fibrils. These may be products of defective fibrillogenesis. These aspects of development are thought to be under the control of the acidic glycosaminoglycan composition of the interfibrillar substance. It is also conceivable that this picture corresponds to abnormal fibril growth in the presence of an accentuated breakdown or catabolism of the sclera.

Ohno-Matsui et al. analyzed the scleral thickness and scleral curvature in a large series of highly myopic patients using swept-source OCT.<sup>66</sup> The entire thickness of the sclera was observed in most of the highly myopic eyes, and the mean subfoveal scleral thickness was 227.9  $\mu\text{m}$  in the highly myopic eyes. The curvatures of the inner scleral surface of highly myopic eyes could be divided into curvatures that sloped toward the optic nerve, those that were symmetric and centered on the fovea, those that were asymmetric, and those that were irregular (Fig. 71.1). Irregular scleral curvature was associated with the frequency of myopic macular

complications.

**FIG. 71.1** Different curvature patterns of the sclera in highly myopic eyes. (A) The curvature is sloped toward the optic nerve. The curve of inner scleral surface is straight (*arrowhead*), and the optic disc is at the bottom of the posterior segment of the eye. Scale bar: 1 mm. (B) The curvature is symmetric around the fovea. The sclera is strongly bowed posteriorly; however, the curve is symmetric around the fovea (*arrowhead*), and the fovea is situated on the bottom of posterior segment of the eye. (C) Asymmetric curvature around the fovea. The sclera is strongly bowed posteriorly, and the most protruded point is away from the central fovea. The fovea (*arrowhead*) is on the slope. (D) Irregular curvature. The sclera is irregular and does not have a smooth curvature. The *arrowhead* indicates the fovea. (With permission from Ohno-Matsui K, Akiba M, Morigi T, et al.

Association between shape of sclera and myopic retinochoroidal lesions in patients with pathologic myopia. Invest Ophthalmol Vis Sci 2012;53(10):6046-61.)

## Choroid and Retinal Pigment Epithelium

The degenerative changes found in pathologic myopia initially appear to involve the choriocapillaris–Bruch's membrane–retinal pigment epithelium (RPE) complex. The changes subsequently

affecting the choroid were essentially degenerative and atrophic. Thinning of the choroid and loss of the choriocapillaris were reported (Fig. 71.2). Choroidal vascular occlusions are a prominent feature of the disease, and this process appears to affect the smaller-diameter vessels initially. The choroidal vessels appear to be fewer and to have thinner walls than seen normally. There is a generalized loss of the normal connective tissue framework of the choroid with some degree of compaction of the vessels. Although the large-sized choroidal vessels tend to be most resistant, these, too, may undergo occlusion in the late stages of the disease. Recent studies using enhanced-depth imaging of optical coherence tomography (EDI-OCT) or high penetrance OCT also showed significant thinning of the choroid in highly myopic eyes.<sup>67</sup>

**FIG. 71.2** Choroidal thinning in pathologic myopia. In comparison with emmetropic eyes (top), the choroid is extremely thinned in eyes with pathologic myopia (bottom). Large choroidal vessels sporadically remain and indent the overlying retinal pigmented epithelium.

The RPE cells are seen to be flatter and larger than usual, a

possible consequence of passive expansion. Hyperpigmentation, hypopigmentation, and multilayered clumping of the RPE cells may also be seen. Bruch's membrane may show a variety of changes, including thinning, splitting, and rupture.

## Animal Models

Rhesus monkeys, chickens, fish, tree shrews, marmosets, and guinea-pigs have long been used as animal models of experimental myopia by inducing form-deprivation myopia by lid suture or by wearing plastic goggles.<sup>68-70</sup> Chicks have long been the main animal model for experimental myopia because myopia accompanying a dramatic increase of the axial length can be induced easily by wearing plastic goggles in about 2 weeks.<sup>71</sup> Therefore, many studies were performed using chick models of experimental myopia. These studies identified responsible factors that cause excessive eye growth. However, the sclera of chickens differs from that of humans. The chicken has the classic vertebrate sclera, consisting of a layer of cartilage surrounded by layers of fibrous connective tissue, whereas in most mammals, including primates and rodents, the cartilage has been lost.

Based on the benefit of having similar scleral components, mice have commonly been used as experimental myopia,<sup>72,73</sup> although there is some drawback that the induced myopia is not as severe as in the chickens because mice are not "visual animals." Mouse model advantages also include the availability of numerous knockout mutants, more advanced gene microarrays for screening the transcriptome, and a completely sequenced genome. Moreover, Olivier et al. reported that mice with conditional inactivation of *Lrp2* in eyes demonstrated congenital high myopia. In addition to an excessive elongation of the posterior chamber, the *Lrp2*-deficient eye had normal intraocular pressure and developed chorioretinal atrophy and staphyloma resembling human pathologic myopia.<sup>74</sup>

In general, animal models of experimental myopia do not develop retinal complications. This might be due to a short lifespan of animals and short duration of myopia. As an exception, Hirata and Negi<sup>75</sup> reported the development of lacquer cracks in chicks with experimental myopia (Fig. 71.3). This result is interesting

because it suggests that lacquer cracks are purely caused by mechanical stretching of the globe and less affected by aging.

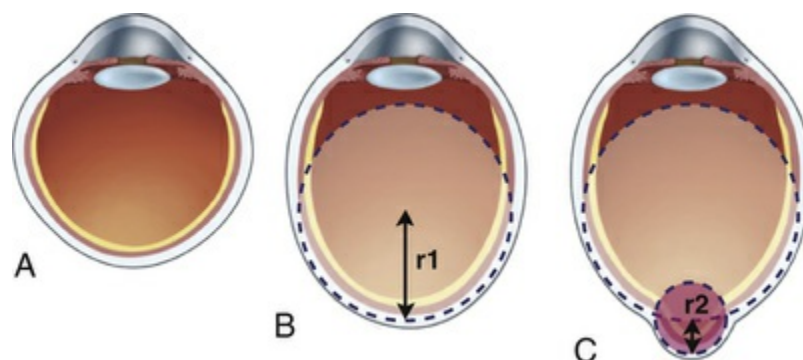

**FIG. 71.3** Development of lacquer cracks in chick models of experimental myopia. In the posterior fundus (left), lacquer cracks are observed to course as linear streaks. Electron microscopic photograph at the area of lacquer cracks shows a disruption of choriocapillaris (right). Large choroidal vessels across the lesion are observed. (With permission from Hirata A, Negi A. Lacquer crack lesions in experimental chick myopia. *Graefes Arch Clin Exp Ophthalmol* 1998;236(2):138-45.)

The transcriptome of neurosensory retina without RPE was analyzed with Affymetrix GeneChip Mouse Genome 430 2.0 arrays after unilateral retinal image degradation by use of frosted goggles in mice,<sup>76</sup> and identified some genes altered including a downregulation of the early growth response 1 (*Egr-1*) gene. The refractions of homozygous *Egr-1* knockout mice were some 4–5 diopters less hyperopic relative to the wild-type.<sup>77</sup> Zebrafish have also been considered as a model of experimental myopia. Downregulation of zebrafish lumican gene expression manifested ocular enlargement resembling axial myopia due to disruption of the collagen fibril arrangement in the sclera and resulted in scleral thinning.<sup>78</sup> The lumican gene, which encodes one of the major keratan sulfate proteoglycans in the vertebrate cornea and sclera, has been linked to axial myopia in humans. Veth and colleagues<sup>79</sup> have used zebrafish to identify a genetically complex, recessive mutant that shows risk factors for glaucoma including adult-onset severe myopia, elevated intraocular pressure, and progressive retinal ganglion cell pathology. Positional cloning and analysis of a

noncomplementing allele indicated that non-sense mutations in low-density lipoprotein receptor-related protein 2 (lrp2) underlie the mutant phenotype.

## Posterior Staphyloma

A posterior staphyloma is an outward protrusion of all layers of the posterior eye globe and is considered a hallmark lesion of pathologic myopia. Until recently there has not been a uniformly accepted definition of a posterior staphyloma; thus, it has been common for authors to refer to abnormalities in the posterior pole of myopic eyes, even those that do not involve an outpouching, as being “staphylomas.” Spaide<sup>80</sup> recently proposed a clear definition of a staphyloma as “an outpouching of the wall of the eye that has a radius of curvature that is less than the surrounding curvature of the wall of the eye” (Fig. 71.4) in pathologic myopia.

**FIG. 71.4** Definition of a posterior staphyloma. (A) Normal eye shape. (B) Axial length elongation occurring in the equatorial region that does not induce any alteration in the curvature of the posterior part of the eye. This eye would have axial myopia but no staphyloma. (C) A second curvature develops in the posterior portion of the eye, and this second curvature has a shorter radius ( $r_2$ ) of curvature than the surrounding eye wall ( $r_1$ ). This secondary curve is due to a staphyloma. (With permission from Spaide RF, Ohno-Matsui K,

Yannuzzi LA. Pathologic myopia. New York: Springer; 2014.)

There are 10 different types of staphyloma according to Curtin (Fig. 71.5).<sup>62</sup> Types I through V are basic staphylomas, and types VI

through X are compound staphylomas. A posterior staphyloma is not common in children with pathologic myopia, and the incidence of staphyloma is significantly higher in older patients (96.7% in those  $\geq 50$  years of age) than in younger patients (80.7% in those  $< 50$  years).<sup>46</sup>

**FIG. 71.5** Curtin's classification of posterior staphyloma. (With permission from Curtin BJ. The posterior staphyloma of pathologic myopia. *Trans Am Ophthalmol Soc* 1977;75:67†86.)

However, this classification was made from the ophthalmoscopic appearances and fundus drawings that made the classification subjective. Also, some of the types are rare, and recent studies using OCT showed that there are more complex irregularities of the scleral curvature<sup>66,81–86</sup> within the area of a staphyloma than Curtin<sup>87</sup> had noted. To overcome these problems, we<sup>88</sup> used three-dimensional magnetic resonance imaging (3D MRI) of the globe and ultrawide-field fundus imaging to analyze the presence and types of the posterior staphyloma based on Spaide's definition. Ohno-Matsui reported that in about a half of highly myopic eyes (mean axial length; 30 mm), the staphyloma was not observed and the eyes were simply elongated (Fig. 71.6). The most frequent type of staphyloma was the wide, macular type (Fig. 71.7), followed by the narrow, macular type. The types of staphyloma have been renamed according to the area: wide-macular, narrow-macular, peripapillary, nasal, inferior, and others to facilitate memorization

(Fig. 71.8).

**FIG. 71.6** Axially elongated highly myopic eye without having a posterior staphyloma. Wide-field fundus photo (left) shows diffuse chorioretinal atrophy in the posterior fundus. In three-dimensional magnetic resonance imaging (3D MRI) of the globe, the eye is simply elongated and does not have a clear outpouching suggestive of staphyloma in the images viewed from nasally (middle) as well as in the image viewed from inferiorly (right). (With permission from Ohno-Matsui K. Proposed classification of posterior staphylomas based on analyses of eye shape by three-dimensional magnetic resonance imaging. *Ophthalmology* 2014;121(9):1798-1809.)

**FIG. 71.7** Highly myopic eye with wide, macular staphyloma. Wide-field fundus photo (left) shows macular atrophy and large conus. The upper edge of wide, macular staphyloma is clearly observed. In three-dimensional magnetic resonance imaging (3D MRI) of the globe, an outpouching of wide area of posterior

segment is seen in the image viewed from nasally (middle) as well as that viewed from inferiorly (right).

(With permission from Ohno-Matsui K. Proposed classification of posterior staphylomas based on analyses of eye shape by three-dimensional magnetic resonance imaging. *Ophthalmology* 2014;121(9):1798-1809.)

**FIG. 71.8** Renaming of types of posterior staphyloma. Curtin's Type I to wide-macular, Type II to narrow-macular, Type III to peripapillary, Type IV to nasal, Type V to inferior, and others.

## Classification of Myopic Maculopathy

Various kinds of macular lesions develop in eyes with pathologic myopia, such as diffuse chorioretinal atrophy, patchy chorioretinal atrophy, lacquer cracks, myopic choroidal neovascularization (myopic CNV), CNV-related macular atrophy (Fig. 71.9).<sup>1,2,58,61,64</sup>

**FIG. 71.9** Various lesions of myopic maculopathy. In the top row, diffuse chorioretinal atrophy (left), patchy chorioretinal atrophy (middle), and lacquer cracks (right). In the bottom row, myopic choroidal neovascularization (myopic CNV; left) and macular atrophy (most frequently, CNV-related macular atrophy; right).

Based on the long-term data of natural progression of lesions of myopic maculopathy (Fig. 71.10),<sup>39</sup> Ohno-Matsui and META-PM study group investigators<sup>89</sup> proposed an international classification (Table 71.1). According to the main path of natural progression, five categories were proposed (category 0, no macular lesions; category 1, tessellated fundus; category 2, diffuse chorioretinal atrophy; category 3, patchy chorioretinal atrophy; category 4, macular atrophy). The lesions that develop independently from the main progression pattern were considered “plus lesions,” and they included lacquer cracks, myopic CNV, and Fuchs' spot (scar phase of myopic CNV). The eyes with lesions more severe than or equal to category 2 or with “plus lesions” are considered “pathologic myopia.”

**FIG. 71.10** Pattern of natural progression of myopic maculopathy. (With permission from Hayashi K, Ohno-Matsui K, Shimada N, et al. Long-term pattern of progression of myopic maculopathy: a natural history study. *Ophthalmology* 2010;117(8):1595-1611.)

**TABLE 71.1**

**International Photographic Classification and Grading System for Myopic Maculopathy**

	Myopic Maculopathy	"Plus" Lesions
<b>Category 0</b>	No macular lesions	
<b>Category 1</b>	Tessellated fundus	
<b>Category 2</b>	Diffuse chorioretinal atrophy	Lacquer cracks (Lc)
<b>Category 3</b>	Patchy chorioretinal atrophy	Myopic choroidal neovascularization
<b>Category 4</b>	Macular atrophy	Fuchs' spot (Fs)

## Myopic Chorioretinal Atrophy

Two types of myopic chorioretinal atrophy develop in the posterior fundus. According to Tokoro, there is diffuse chorioretinal atrophy

and patchy chorioretinal atrophy.<sup>6</sup> Diffuse chorioretinal atrophy is observed as yellowish-white and ill-defined chorioretinal atrophy. Diffuse chorioretinal atrophy is characterized by marked thinning of the choroid in OCT images. Due to the disappearance of most of the choroid, only large choroidal vessels sporadically remain. Patchy chorioretinal atrophy is observed as grayish-white and well-defined chorioretinal atrophy. The areas of patchy atrophy develop within an area of diffuse atrophy (Fig. 71.11). The entire choroid does not exist in the area of patchy atrophy accompanying with a loss of retinal pigment epithelium and photoreceptors, the inner retina directly sits on the sclera in OCT images.

**FIG. 71.11** Patchy chorioretinal atrophy. Left fundus (top left) shows multiple areas of whitish, patchy atrophy. Fluorescein angiogram (top right) shows choroidal filling defect in the area of patchy atrophy. Optical coherence tomographic (OCT) image shows a lack of the entire choroid, retinal pigment epithelium, and photoreceptors. The inner retina directly sits on the sclera.

## Lacquer Cracks

Lacquer cracks are considered to represent linear ruptures of Bruch's membrane in the macular area of highly myopic eyes and are observed as yellowish linear lesions in the macula. The presence of Bruch's membrane defects has been reported in histopathologic studies.<sup>90</sup> However, due to a lack of clinicopathologic studies, it is not clear whether the yellowish linear lesions observed in highly myopic eyes truly represent rupture of Bruch's membrane. In addition, it is still difficult to detect such a narrow lesion by using OCT.

Lacquer cracks are more easily detected by fluorescein angiography, fundus autofluorescence imaging, and indocyanine green angiography.<sup>64,65</sup> With time, lacquer cracks increase in number and also increase their width (Fig. 71.12).<sup>66</sup> When new lacquer cracks develop, the choriocapillaris is also damaged and subretinal bleeding may occur.<sup>67</sup> Subretinal bleeding without CNV is a visible sign of new lacquer crack formation, and after absorption of bleeding, lacquer cracks appear as yellowish linear lesions. Lacquer cracks are known as precursor lesions of myopic CNV.<sup>65,68</sup> Often, CNV tends to develop along the foveal edge of chorioretinal atrophy that was formed by increased width of lacquer cracks.

**FIG. 71.12** Progression from lacquer cracks to patchy chorioretinal atrophy. Right fundus shows vertically linear lacquer cracks temporal to the fovea (left). Fifteen years later, the width of lacquer cracks has

widened and has progressed to patchy atrophy (right).

As linear lesions that need to be differentiated from lacquer cracks, myopic stretch lines (Fig. 71.13) were reported by Shinohara et al.<sup>91</sup> Myopic stretch lines are considered to represent the proliferation of RPE cells indented by large choroidal vessels in the area with severe diffuse atrophy.

**FIG. 71.13** Myopic stretch lines. In fluorescein angiogram (A), the lesions are observed as radial hypofluorescence. In fundus autofluorescence (B), the lesions are seen as a mixture of hyper- and hypoautofluorescence.

## Myopic Choroidal Neovascularization

Macular CNV is one of the most frequent complications that reduce the central vision in patients with pathologic myopia (Fig. 71.14). Myopic CNV develops in 10% of highly myopic patients,<sup>68</sup> and 30% of the patients who have a CNV in one eye eventually develop CNV in the other eye. Due to a thin, stretched fundus, the bleeding does not usually overlie the CNV, and therefore CNV is easily observed ophthalmoscopically. Myopic CNV is almost always so-called classic CNV, and CNV shows distinct hyperfluorescence throughout the entire angiographic phase. Especially for small CNV, fluorescein angiography is a powerful tool to detect CNV.

**FIG. 71.14** Myopic choroidal neovascularization (CNV) treated with anti-vascular endothelial growth factor. At onset (A,B) small CNV is observed temporal to the fovea in fundus photo (A) and in fluorescein angiogram (B). The best corrected visual acuity (BCVA) is 0.7. Six years after a single injection of intravitreal bevacizumab (C–E), the CNV is barely detectable in fundus image (C) and in optical coherence tomography image (E). Fundus autofluorescence does not show a

development of CNV-related macular atrophy (D). The BCVA is 1.0.

Due to the low activity of the CNV, myopic CNV does not show hyperfluorescence by indocyanine green angiography in most cases. OCT shows CNV as an elevated lesion in the subretinal space; however, most eyes with myopic CNV do not show exudative changes like retinal edema or retinal detachment. Thus, OCT does not differentiate subretinal bleeding with or without CNV in eyes with pathologic myopia.

## Natural Course of Myopic CNV

Myopic CNV is not intensely active, and thus has a tendency to regress spontaneously, and progresses from an active phase to a scar phase. In the scar phase, the CNV is covered by proliferated RPE cells and is observed as a dark pigmented spot (Fuchs' spot). After CNV regression, well-defined chorioretinal atrophy gradually develops and enlarges around the Fuchs' spot, and this causes a progressive visual decrease in the long term. This phase is called atrophic CNV.

The prognosis of myopic CNV is poor. A natural history study with 10-year follow-up showed that, at the onset of CNV, 70% had a visual acuity better than 20/200 and 22% had a visual acuity better than 20/40. Three years after the onset of CNV, 56% retained a visual acuity of better than 20/200. At 5 and 10 years after onset, however, visual acuity dropped to 20/200 or less in 89% and 96%, respectively.<sup>37,77</sup> The mechanism by which chorioretinal atrophy develops and enlarges around the regressed CNV in eyes with pathologic myopia is not clear. Because chorioretinal atrophy around the CNV affects the final visual outcome of eyes with myopic CNV, we need to determine the effect of treatment against myopic CNV on chorioretinal atrophy development.

## Current Treatment of Myopic CNV

Anti-vascular endothelial growth factor (VEGF) therapy has recently been used as the first-line therapy to treat myopic CNV. Large clinical trials examining the effectiveness and the safety of

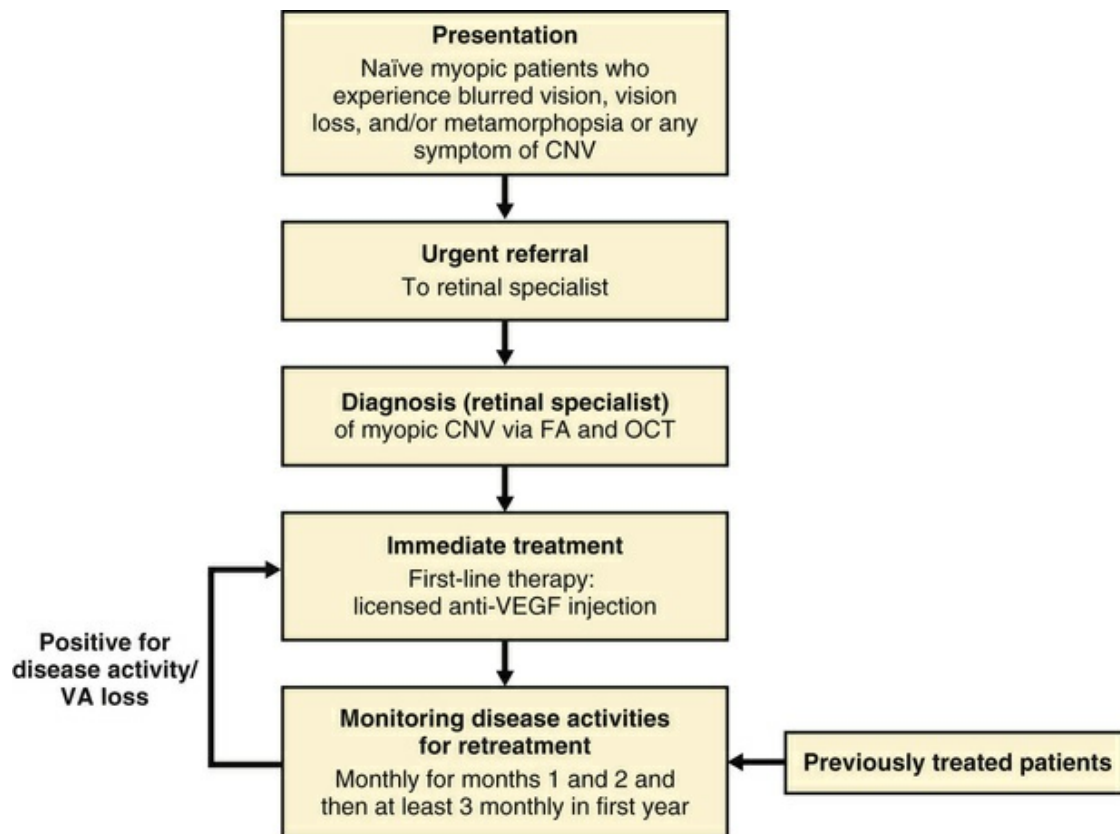

ranibizumab and aflibercept have been reported in the REPAIR study,<sup>92</sup> the RADIANCE study,<sup>9</sup> and the MYRROR study.<sup>5</sup> In the REPAIR study,<sup>92</sup> 65 patients with myopic CNV treated with ranibizumab were enrolled across 12 sites. At 12 months, 86% of patients showed improvement in mean score of the best corrected visual acuity (BCVA) and 37% of patients achieved a BCVA gain of  $\geq 15$  letters. In the RADIANCE study,<sup>9</sup> 277 patients with visual impairment due to myopic CNV were enrolled and showed that ranibizumab treatment (either guided by vision stabilization or guided by disease stability) was superior to photodynamic therapy on mean average BCVA change from baseline to month 3 through month 12. In the MYRROR study,<sup>5</sup> a total of 122 patients with myopic CNV were assigned either to aflibercept or sham injection. The patients in the intravitreal aflibercept group gained significantly more vision at week 24 and 48 than those in the sham injection group.

Anti-VEGF therapies are especially effective for nonsubfoveal CNV.<sup>93</sup> Some patients with nonsubfoveal myopic CNV show a complete disappearance of CNV over the long term without developing CNV-related macular atrophy (see [Fig. 71.13](#)). However, some patients show a development and enlargement of CNV-related macular atrophy with time ([Fig. 71.15](#)). The long-term visual outcome of anti-VEGF therapies need to be clarified, since some studies showed a decreased vision in the long term.<sup>6,94</sup> The influence of anti-VEGF therapies on the development of chorioretinal atrophy around myopic CNV also needs to be evaluated. The treatment guideline for myopic CNV has been proposed by Wong et al. ([Fig. 71.16](#)).<sup>95</sup>

**FIG. 71.15** Long-term development of macular atrophy in the eyes treated with anti-vascular endothelial growth factor. At onset (left), the choroidal neovascularization (CNV) accompanying with hemorrhage is observed. The best corrected visual acuity (BCVA) is 0.2. Six years after a single injection of intravitreal bevacizumab (right), the CNV has shrunken and is seen as a tiny Fuchs' spot. However, a large chorioretinal atrophy has developed, and the BCVA has decreased to 0.08.

**FIG. 71.16** Treatment algorithm for myopic choroidal neovascularization (myopic CNV). *FA*, fluorescein angiography; *OCT*, optical coherence tomography; *VA*, visual acuity; *VEGF*, vascular endothelial growth factor. ## Other Macular Lesions

### Dome-Shaped Macula (Fig. 71.17)

The dome-shaped macula (DSM) was first described by Gaucher et al.<sup>92</sup> as a convex protrusion of the macula in highly myopic eyes detected in OCT images. Imamura and Spaide<sup>84</sup> used EDI-OCT and showed that the DSM resulted from a relative localized thickening of the sclera under the macula in highly myopic eyes. Caillaux et al.<sup>82</sup> classified DSM into round dome; horizontal oval-shaped dome; and vertical oval-shaped dome.

**FIG. 71.17** Dome-shaped macula (DSM). In optical coherence tomographic images, the dome-shaped protrusion is obvious in vertical section across the macula (bottom image) due to the subfoveal scleral thickening. DSM is not obvious in horizontal section (top image). The choroidal neovascularization is observed at the top of the dome.

Liang, Ohno-Matsui, and coworkers<sup>96</sup> examined a large series of highly myopic patients and showed that DSM was found in about 20% of highly myopic eyes, suggesting that DSM was a common complication of pathologic myopia. Macular complications such as serous retinal detachment and macular retinoschisis have been reported to occur in eyes with DSM.<sup>96</sup>

## Myopic Traction Maculopathy

Myopic macular retinoschisis (also known as myopic foveoschisis<sup>69</sup> or myopic traction maculopathy<sup>70</sup>) was first identified in 1999.<sup>8</sup> Myopic macular retinoschisis is found in 9% of highly myopic eyes

with posterior staphyloma,<sup>71</sup> and 50% of patients progress to more serious complications such as full-thickness macular hole or macular retinal detachment within 2 years.<sup>72</sup> Myopic macular retinoschisis is considered to be caused by various factors. The rigidity of the internal limiting membrane (ILM) can induce significant traction on the retina.<sup>4</sup> OCT examinations of serial sections along the entire posterior vascular arcade showed that the paravascular abnormalities, such as paravascular lamellar holes,<sup>73</sup> vascular microfolds,<sup>73-75</sup> and paravascular retinal cysts,<sup>73</sup> are frequently found in eyes with myopic macular retinoschisis. Although the mechanism of the development of this condition is not fully clear, the glial cells such as astrocytes, which exist abundantly around the retinal vessels, can migrate and proliferate through the paravascular lamellar holes. These cells can produce collagen and facilitate the proliferative and contractile response of ILM. Studies have shown that vitrectomy is useful to treat myopic macular retinoschisis in some patients.<sup>69,76</sup> The development of postoperative or intraoperative full-thickness macular holes is a serious complication. To avoid the mechanical damage to the fovea by ILM peeling, nonfoveolar peeling<sup>15</sup> or foveal-sparing ILM peeling<sup>11</sup> (Fig. 71.18) have been used with a good surgical outcome.

**FIG. 71.18** Schematic drawings of fovea-sparing internal limiting membrane (ILM) peeling. Start ILM peeling away from the central fovea. Proceed with the ILM peeling. When the peeled ILM flap comes close to the central fovea, stop and start ILM peeling from a new site. Proceed with ILM peeling from the new site with special attention not to peel the ILM around the central fovea. Start the ILM peeling from several new sites and proceed to peel ILM from the entire macular area away from the central fovea. Trim the ILM that remains on and around the fovea with a vitreous cutter.

(With permission from Shimada N, Sugamoto Y, Ogawa M, et al. Fovea-sparing internal limiting membrane peeling for myopic traction maculopathy. *Am J Ophthalmol* 2012;24:24.)

## Conclusion

Pathologic myopia is a major cause of visual impairment worldwide, and associated visual loss is due to various lesions of myopic macular degeneration that develop secondary to posterior staphyloma formation and progressive thinning of the RPE-choroid with age in addition to an increase of axial length. Among various lesions of myopic macular degeneration, myopic CNV can be treated by application of anti-VEGF therapy or photodynamic therapy. Also, the advance of OCT technology has enabled the evaluation of pathogenic mechanism of myopic macular retinoschisis, and vitrectomy has been proven useful to treat this condition. Further studies evaluating the long-term outcome of anti-VEGF therapy for myopic CNV and vitrectomy to manage myopic macular retinoschisis are expected.

## Introduction

The appearance of angioid streaks was initially described by Doyne in 1889 as irregular and radiating lines extending from the optic nerve to the peripheral retina found in an eye with retinal hemorrhages after blunt trauma.<sup>1</sup> The term “angioid streaks” originated as the ophthalmoscopic appearance of the lines was similar to that of blood vessels.<sup>2</sup> Histopathologic studies found that angioid streaks represent irregular dehiscences in the collagenous and elastic portion of Bruch's membrane.<sup>3,4</sup> Associations have been found between angioid streaks and systemic conditions such as pseudoxanthoma elasticum (Grönwald–Strandberg syndrome),<sup>5-7</sup> osteitis deformans (Paget disease),<sup>5,8-10</sup> blood dyscrasias such as sickle-cell anemia,<sup>5,11-13</sup> fibrodysplasia hyperelastica (Ehlers–Danlos syndrome),<sup>5,14</sup> and acromegaly.<sup>5,15</sup> However, angioid streaks may also occur in patients without associated systemic disease.<sup>16</sup> Patients with angioid streaks usually are asymptomatic unless complications such as macular choroidal neovascularization (CNV) develop.<sup>5,16</sup> In cases of macular involvement the prognosis is often poor, with most eyes progressing to legal blindness without treatment.<sup>5,6,16</sup> Multiple therapeutic strategies have been used to treat CNV secondary to angioid streaks, including argon laser photocoagulation,<sup>17-19</sup> transpupillary thermotherapy,<sup>20</sup> photodynamic therapy,<sup>21-23</sup> surgical intervention,<sup>24-26</sup> intravitreal anti-vascular endothelial growth factor (VEGF) treatments with pegaptanib,<sup>27</sup> bevacizumab,<sup>28-34</sup> or ranibizumab,<sup>35-40</sup> aflibercept,<sup>41</sup> and combination therapy.<sup>42-44</sup>

## Histopathology

Angioid streaks represent discrete irregular breaks in Bruch's membrane and are often associated with atrophic changes of the overlying retinal pigment epithelium (RPE) and calcific degeneration.<sup>4</sup> Klien proposed a dual mechanism for the development of angioid streaks, including (1) a primary abnormality in the fibers of Bruch's membrane and (2) increased deposits of metal salts or an increasing tendency for their pathologic position.<sup>3</sup> The deposition of calcium may cause Bruch's membrane to be more brittle and to develop choroidal rupture.<sup>4</sup> Immunohistochemical studies show significant calcium deposition and infiltration of vascularized tissue above the RPE from Bruch's membrane in the area of CNV in an eye with angioid streaks.<sup>45</sup>

Tissue metalloproteinase, specifically MMP-9, was found in high concentrations in the excised Bruch's membrane in an area of CNV in an eye with angioid streaks. MMP-9 is known to induce basement membrane destruction and angiogenesis.<sup>45</sup>

In the early stages, angioid streaks are partial breaks of the thickened and calcified Bruch's membrane with thinning of the RPE, events that do not cause anatomic changes in the overlying retinal layers.<sup>46</sup> Subsequently, a full-thickness defect of the Bruch's membrane may occur followed by atrophy of the choriocapillaris, RPE, and photoreceptors. Fibrovascular proliferation from the choroid may occur through the Bruch's membrane break, resulting in CNV and subsequent development of a disciform scar.<sup>4,10,46</sup> This process usually results in slowly progressive macular changes and vision loss. Sudden vision loss can result from a serous or hemorrhagic detachment around the CNV or after mild trauma leading to choroidal rupture and submacular hemorrhage resulting from the brittleness of Bruch's membrane.<sup>4,10</sup>

## Systemic Associations

Angioid streaks have been most commonly associated with systemic conditions such as pseudoxanthoma elasticum (Grönwald–Strandberg syndrome),<sup>5–7</sup> osteitis deformans (Paget disease),<sup>5,8–10</sup> fibrodysplasia hyperelastica (Ehlers–Danlos syndrome),<sup>5,14</sup>

acromegaly,<sup>5,15</sup> Marfan syndrome,<sup>6</sup> and blood dyscrasias such as sickle-cell anemia,<sup>11,12</sup> thalassemia,<sup>6</sup> and spherocytosis.<sup>6</sup> Angioid streaks have also been described in patients with the following conditions: alpha-beta-lipoproteinemia, acquired hemolytic anemia, hemochromatosis, hypertension, diabetes, hypercalcinosis, hyperphosphatemia, diffuse lipomatosis, Sturge–Weber syndrome, tuberous sclerosis, neurofibromatosis, microsomia, epilepsy, senile **Box 72.1** ~~Box 72.1~~ cutaneous calcinosis, and trauma<sup>5,6,16</sup> (**Box 72.1**).

## Systemic Conditions Associated With Angioid Streaks

- Pseudoxanthoma elasticum (Grönwald–Strandberg syndrome)
- Osteitis deformans (Paget disease)
- Fibrodysplasia hyperelastica (Ehlers–Danlos syndrome)
- Acromegaly
- Marfan syndrome
- Sickle-cell anemia
- Thalassemia
- Spherocytosis
- Acquired hemolytic anemia
- Hemochromatosis
- Alpha-beta-lipoproteinemia
- Hypertension
- Diabetes
- Hypercalcinosis
- Hyperphosphatemia

- Diffuse lipomatosis
- Sturge–Weber syndrome
- Neurofibromatosis
- Tuberous sclerosis
- Microsomia
- Epilepsy
- Cutaneous calcinosis
- Trauma

In a large study examining associated systemic diagnosis in 50 patients with angioid streaks, half of the patients were found to have a related systemic condition.<sup>5</sup> Seventeen of the 25 patients were diagnosed also with pseudoxanthoma elasticum (PXE), 5 patients with Paget disease, and 3 patients had sickle-cell disease.<sup>5</sup> The remaining half of the patients with angioid streaks did not demonstrate associated systemic disease.<sup>5</sup>

The most common systemic association of angioid streaks is PXE, an inherited disorder associated with degeneration of the elastic fibers in the dermatologic, gastrointestinal, cardiovascular, and ocular tissues. PXE accounts for 59–87% of cases with angioid streaks.<sup>7</sup> In PXE, the primary finding is elastic fiber degeneration in connective tissue, followed by a secondary calcium deposition.<sup>4,10</sup> In addition to angioid streaks, eyes also demonstrate a so-called “peau d'orange” pigmentary change, reticular pigmentary dystrophy affecting the macula, atrophic lesions of the RPE, crystalline bodies, and optic disc drusen (in 21% of patients with PXE and angioid streaks).<sup>4,7</sup> By 20 years after first diagnosis, angioid streaks develop in almost all patients with PXE.<sup>16</sup>

In patients with Paget disease, extensive Bruch's membrane calcification and angioid streaks followed by CNV and disciform scarring may develop.<sup>9,10</sup> About 10% of patients with advanced Paget disease develop angioid streaks.<sup>9,10</sup>

Similar significant calcium depositions at Bruch's membrane have been identified using histochemical and electron microscopic studies in patients with sickle-cell hemoglobinopathies.<sup>13</sup> The presence of iron–calcium complexes at the level of Bruch's membrane was previously suggested as an etiology for angioid streaks in patients with hemoglobinopathy; however, histopathologic studies demonstrate no increased iron deposition at the Bruch's membrane.<sup>47</sup> Compared to PXE, a smaller proportion of patients develop CNV and subsequent visual loss.<sup>6</sup>

## Ocular Manifestations and Clinical Course

Angioid streaks usually originate from the optic nerve and may either radiate out or surround it concentrically and appear as irregular lines of varying width.<sup>6</sup> The subretinal lines can range in diameter from 50 to 500  $\mu\text{m}$ .<sup>16</sup> The color of angioid streaks varies based on the fundus pigmentation and tends to be reddish in light-colored individuals and brown-colored in darker-pigmented individuals<sup>16</sup> (see [Figs. 72.1A–D](#)).

**FIG. 72.1** A 63-year-old Asian woman with pseudoxanthoma elasticum and angioid streaks. Wide-field imaging of the right (A) and left (B) eyes shows angioid streaks (darker lines) radiating out from the optic disc. A hyperpigmented scar just nasal to the fovea developed after laser photocoagulation (A). The laser treatment was given prior to the use of intravitreal anti-VEGF therapy. Fundus autofluorescence imaging demonstrates the angioid streaks in the right (C) and left (D) eye. Spectral domain optical coherence tomography in this patient is shown in [Fig. 72.3](#).

Angioid streaks have not been reported in newborns, and few cases have been described in individuals under 10 years of age.<sup>6</sup> Angioid streaks remain over time and do not regress, and the streaks may increase in length and width over time.<sup>48</sup> New streaks may form adjacent to old lesions. Over time, the adjacent RPE and choriocapillaris may develop atrophy.<sup>48</sup>

Most patients with angioid streaks are asymptomatic unless the macula is involved, with the development of traumatic rupture of

the Bruch's membrane or CNV (Figs. 72.1B and 72.2A–B). If the macula is involved, patients may report metamorphopsia or blurred vision.

**FIG. 72.2** An 86-year-old Caucasian woman with angioid streaks. Extensive disciform scar is found in the macula in both eyes (A,B), with new choroidal neovascularization and subretinal hemorrhage in the peripheral nasal retina in the left eye (B). Fluorescein angiography demonstrates extensive pigmentary changes and disciform scarring in the right eye (C). She underwent multiple intravitreal bevacizumab injections in the right eye, and her visual acuity had improved from 20/100<sup>-2</sup> to 20/60. In the left eye the visual acuity was 20/400.

Patients may demonstrate breaks of Bruch's membrane after mild head or eye injuries, due to the brittleness of the calcified Bruch's membrane. Rupture of Bruch's membrane after trauma may be followed by subretinal hemorrhages. Up to 15% of patients with

angioid streaks develop significant visual loss after mild head injury.

The most common and significant complication of angioid streaks is the development of CNV, which is often bilateral and occurs in 72–86% of eyes with angioid streaks.<sup>16</sup> CNV is usually bilateral but asymmetric, with an interval of approximately 18 months between the development of CNV in initial and fellow eye.<sup>7</sup> Patients with PXE have a higher risk of CNV development compared to patients with other systemic diseases. By age 50, the majority of patients with PXE demonstrate reduced vision less than 20/200. Geographic chorioretinal atrophy (GA) independent of CNV is another cause of visual loss in eyes with PXE.<sup>49</sup> In one series, 8 of 41 (20%) eyes examined with PXE demonstrated GA, with growth of the GA similar to that of atrophic age-related macular degeneration.<sup>49</sup> Pattern dystrophy was found in 46–59% of eyes with PXE.<sup>49</sup>

## Ocular Imaging and Diagnosis

### Fluorescein Angiography (FA)

Usually the diagnosis of angioid streaks is made on fundoscopic examination, but FA may be helpful to detect the streaks and associated CNV when the findings are subtle. Irregular hyperfluorescence of the angioid streaks occurs during early phase angiography followed by varying degrees of staining during the later phases.<sup>4</sup> In some individuals with deeply pigmented choroidal tissue, the angioid streaks may be difficult to detect angiographically; whereas in lightly pigmented individuals, FA may aid in the identification of the angioid streaks before ophthalmoscopic detection<sup>4</sup> (Fig. 72.2C).

### Fundus Autofluorescence (FAF)

Autofluorescence imaging uses light emission from lipofuscin in RPE cells and is considered to reflect RPE metabolic activity. Angioid streaks can show increased or decreased fundus autofluorescence. Autofluorescence often demonstrates RPE

atrophy more extensive than that seen on fundus ophthalmoscopy or FA; therefore, FAF may be a useful noninvasive tool to monitor the progression of the RPE changes related to angioid streaks and CNV (see [Figs. 72.1C–D](#)). FAF in eyes with angioid streaks has also been similar to the FAF images from eyes with pattern dystrophy. FAF demonstrated large areas of confluent hypoautofluorescence, demonstrating widespread loss of RPE cells in eyes with PXE.<sup>50</sup>

## Indocyanine Green Angiography (ICGA)

A study incorporating the use of multiple modalities (FA, ICGA, FAF, and confocal near-infrared reflectance) in patients with angioid streaks and PXE has suggested a centrifugal spread of progressive calcification of Bruch's membrane that begins at the posterior pole and progresses toward the retinal periphery.<sup>51</sup> A central area of decreased fluorescence centered on the posterior pole on late-phase ICGA, while eccentric areas demonstrated a normal fluorescence on late-phase ICGA.<sup>51</sup>

## Spectral Domain Optical Coherence Tomography (SD-OCT)

In eyes with advanced fundus pathology, such as large areas of atrophy and fibrosis, the underlying Bruch's membrane breaks cannot be detected on fundus photography, fluorescein angiography, or fundus autofluorescence imaging.<sup>46</sup> SD-OCT can detect abnormalities in Bruch's membrane as well as subretinal fibrosis and deposits that can be difficult to discern in areas of atrophy on FAF, FA, or ICGA<sup>52</sup> ([Fig. 72.3](#)).

**FIG. 72.3** Same patient as Fig. 72.1. Spectral domain optical coherence tomography demonstrates chorioretinal atrophy corresponding to the laser scar nasal to the fovea in the left eye, which has a best corrected visual acuity of 20/25. Visual acuity in the right eye was 20/25.

## Swept Source OCT

A prospective case series showed similar mean choroidal thickness in eyes with angioid streaks without CNV compared to normal age-matched controls.<sup>53</sup> However, in those eyes with angioid streaks and CNV, the choroid was much thinner.<sup>53</sup> The degree of choroidal

thinning was found to be independent of CNV treatment history: no difference was found in choroidal thickness in treatment-naïve eyes with CNV versus those previously treated with anti-VEGF or PDT.<sup>53</sup> The small sample size in the study may be insufficient to detect a difference.

## Therapy

There is no known prophylaxis except perhaps eye protection to reduce trauma. Current treatment strategies are directed to the eyes with CNV. Untreated CNV results in an average visual acuity of 20/200 by age 50, which was found by pooling data from several studies totaling 147 eyes.<sup>54</sup> One study found a final visual acuity of 20/640 in a group of 26 untreated eyes with either active CNV or disciform scar secondary to angioid streaks.<sup>19</sup> Untreated CNV results in poor visual outcomes in the majority of published reports.

## Laser Photocoagulation

Results from laser photocoagulation in the treatment of macular CNV demonstrate a high recurrence rate of up to 77% and poor overall visual outcomes.<sup>17-19</sup> Thermal laser was one of the first therapies used for the treatment of macular CNV (see [Fig. 72.1B](#)). In one case series, the eyes treated with laser for macular CNV developed further CNV growth and vision loss.<sup>8</sup> However, other studies suggested that laser treatment for extrafoveal CNV related to angioid streaks resulted in better visual outcomes than untreated eyes.<sup>17</sup> Prophylactic treatment of angioid streaks prior to development of CNV is not recommended.<sup>47</sup> Laser photocoagulation achieves short-term cessation of CNV growth, but given the scotoma created and the early recurrences, other treatment regimens such as anti-VEGF therapy should be considered as first-line therapy.<sup>54</sup> Laser photocoagulation treatment for extrafoveal CNV still remains controversial given the availability of better treatment regimens.

## Transpupillary Thermotherapy

Using a diode laser beam with 810 nm wavelength, transpupillary thermotherapy (TTT) may have better penetration to the choriocapillaris and may be less damaging to the RPE. TTT employs a diode with a lower threshold to avoid producing a thermal burn. However, a retrospective study investigating the use of TTT in treatment of subfoveal choroidal neovascularization found no significant long-term benefit in reducing the growth of the CNV or in visual improvement.<sup>20</sup>

## Photodynamic Therapy

Data from both retrospective and prospective case series of eyes treated with photodynamic therapy (PDT) demonstrate variability in visual outcomes after treatment.<sup>55</sup> Several early reports investigating PDT use in eyes with angioid streaks suggest a reduction of CNV progression compared to natural history alone.<sup>21,55</sup> A retrospective, placebo-controlled case series found a greater reduction in mean visual acuity over the mean follow-up period of 18 months in untreated (from 20/160 to 20/640) versus PDT-treated eyes (from 20/126 to 20/500).<sup>21</sup> However, another study found mean visual acuity decreased after PDT treatment from 20/400 to 20/600.<sup>56</sup> Extension of an initial study with two additional years of follow-up identified progressive decrease in visual acuity following PDT treatment.<sup>57</sup> In a recent pooled retrospective analysis examining PDT outcomes, the lesion size was found to be increased after PDT treatment and may be indicative of persistent disease activity despite PDT.<sup>54</sup> When compared to natural history, the outcome post-PDT treatment is similar.<sup>23</sup>

## Surgical Therapies

Prior to the use of anti-VEGF treatments for CNV, macular translocation and CNV removal were treatment options. Translocation is a surgical technique used to move the macular neuroretina to lie on top of an area of RPE without previous choroidal neovascularization. Varying short-term visual acuity improvement has been reported in a few studies employing macular translocation for CNV-related angioid streaks, but the number of eyes treated (less than 10) was limited.<sup>25,26</sup> Both macular

translocation and CNV removal were associated with frequent complications, such as proliferative vitreoretinopathy, retinal detachment, and hemorrhage. Currently, surgical treatment of CNV is not recommended.<sup>25,26</sup>

## Anti-VEGF Treatment

Laser photocoagulation, TTT, and PDT have not been as successful in reducing the degree of visual loss compared with the visual outcomes following anti-VEGF therapy. Treatments with anti-VEGF therapies, such as with bevacizumab,<sup>28–34</sup> ranibizumab,<sup>34–40</sup> and aflibercept,<sup>41</sup> have demonstrated a marked reduction in the rate of visual acuity loss in the treated eyes compared with that in untreated eyes, but again, follow-up is short and randomized trials are lacking. Overall, no obvious difference in efficacy between bevacizumab and ranibizumab was found for CNV therapy in angioid streaks; however, the small number of eyes in each study was insufficient to detect differences in safety or effectiveness.<sup>28–39</sup> Variability in the treatment regimen, with pro re nata (prn) dosing used predominantly in bevacizumab studies, while a monthly regimen was more likely used in ranibizumab-treated eyes, was noted.<sup>54</sup> Currently there is inadequate evidence to show superiority of a prn versus fixed-dosing regimen in CNV treatment in angioid streaks.<sup>54</sup>

### Bevacizumab

The majority of eyes with CNV secondary to angioid streaks treated with intravitreal bevacizumab demonstrated an improvement or stabilization in mean visual acuity on long-term follow-up ranging from 12 to 28 months.<sup>28–34</sup> Several retrospective case series reported stabilization or improvement of visual acuity after bevacizumab treatment in 87–100% of eyes with a follow-up ranging from 12 to 28 months.<sup>28–32</sup> Mean visual acuity improved by 3 or more lines in 44–62% of eyes by 12 months after bevacizumab treatment.<sup>29,31</sup>

In a study involving patients with angioid streaks secondary to PXE, the mean visual acuity improved from 20/80 to 20/40 with an average of 6.5 injections over a mean follow-up of 28 months.<sup>28</sup> In the same study, eyes with early disease demonstrated better visual

outcomes, with a mean visual acuity of 20/25 compared to a final mean visual acuity of 20/63 in eyes with advanced disease.<sup>28</sup> Eyes with CNV were initially treated with intravitreal bevacizumab and were followed every 4–6 weeks.<sup>28–32</sup> Retreatment with another bevacizumab injection was given if CNV activity was found.<sup>28,31</sup>

Multiple studies with at least 12-month follow-up reported a mean of approximately four bevacizumab injections (1.25–1.5 mg) given over 12–18 months.<sup>29,30,31</sup> Recurrent CNV is common, occurring in 33% of eyes by 19 months in one case series.<sup>32</sup> Not only can CNV recur at the same location, but new CNV can also develop in a different location requiring retreatment.<sup>32</sup>

Angiographic resolution of the CNV was found in 67% of the eyes by 19 months.<sup>32</sup> At final follow-up between 12 and 19 months, several studies have shown a reduction of central retinal thickness by 67–103  $\mu\text{m}$  after bevacizumab treatment.<sup>29,31</sup>

Despite a majority of eyes demonstrating stable or improved visual acuity at the final follow-up in studies using bevacizumab to treat CNV secondary to angioid streaks, 8–13% of eyes demonstrate further decreased visual acuity.<sup>28,31,32</sup> In the eyes with visual loss after undergoing bevacizumab treatment, the visual decline is postulated to be related to atrophic macular changes and not from active choroidal neovascularization.<sup>28,31</sup>

## **Ranibizumab**

Similar to the visual outcomes in bevacizumab trials, the majority of eyes treated with intravitreal ranibizumab demonstrated improved or stable visual outcomes at final follow-up, ranging from 3 months to 24 months.<sup>35–39</sup> In several prospective and retrospective case series reports, final visual acuity outcomes were stable or improved in 66–93% of eyes treated with ranibizumab (0.3–0.5 mg).<sup>35,36,38,39</sup> While the majority of eyes treated with intravitreal ranibizumab maintained or improved vision, 7–33% of eyes treated with ranibizumab lost vision by the end of the study.<sup>35–39</sup>

In two prospective studies, all eyes were given either three- or four-monthly loading doses of ranibizumab.<sup>38,39</sup> Then an “as needed” treatment protocol was used: another ranibizumab injection was given if CNV activity was detected. An average of 5–7 ranibizumab injections was given in two prospective trials with a

follow-up of 14–16 months, respectively.<sup>38,39</sup> One prospective trial found that 78% of eyes needed retreatment after the first three loading doses of ranibizumab.<sup>39</sup> Angiographic resolution of the CNV after ranibizumab treatment was reported in 66% of eyes.<sup>36</sup> On OCT testing, a mean decrease of 107  $\mu\text{m}$  was shown in one prospective study at one year.<sup>38</sup> Vision loss secondary to retinal degeneration despite CNV resolution has been reported in eyes after treatment with ranibizumab.<sup>40</sup>

## **Aflibercept**

To date, one case report documented aflibercept use in two patients treated with a single injection.<sup>41</sup> Vision improved from 20/25 to 20/20 in one patient at 12 months, whereas the other patient showed a gain of 20/200 to 20/50 after one injection at 9 months.<sup>41</sup>

## **Combination Therapy**

Several studies examined whether combination therapy may be superior to monotherapy.<sup>42–44</sup> One prospective trial investigated the outcomes using reduced fluence PDT (25 J/cm<sup>2</sup>) and intravitreal ranibizumab (0.5 mg) for treatment-naïve eyes with CNV related to angioid streaks.<sup>42</sup> At 12 months of follow-up, 9 of the 10 eyes demonstrated stable or improved vision, with 6 eyes showing gains of two or greater lines. One eye had more than 3 lines of decreased vision.<sup>42</sup> A diminished recurrence rate was found, but the visual outcome was similar to that with ranibizumab alone.<sup>42</sup> Another study examining the effect of PDT plus bevacizumab versus bevacizumab alone found similar outcomes with either therapy regimen.<sup>43</sup> One report with 5 eyes noted fewer PDT treatments needed when combined with intraocular triamcinolone injection.<sup>44</sup> Given the small sample size of these studies, further investigations involving combination therapies are needed before determining if added benefit exists over monotherapy with anti-VEGF treatment alone.

## **Conclusion**

Calcification and degeneration in Bruch's membrane account for the

fundus and histopathologic appearance of angioid streaks. Angioid streaks are associated with multiple systemic conditions, including PXE, Paget disease, Ehlers–Danlos syndrome, and various blood dyscrasias such as sickle-cell anemia. Angioid streaks may not significantly affect vision if they remain extramacular or if choroidal neovascularization does not develop. However, choroidal neovascularization has been reported to occur in the majority of eyes with angioid streaks and is often bilateral. Treatments with laser photocoagulation, photodynamic therapy, and surgical interventions have not resulted in sustained visual improvement. However, significant improvement in visual outcomes has been found after using anti-VEGF therapy. Whether the early favorable results are sustained with longer follow-up will require further study. Geographic atrophy also is a contributing factor in visual loss in PXE patients with angioid streaks, and future therapies that inhibit GA progression may be beneficial.

## Historical Perspective

In 1942 Reid provided the first description of histoplasmosis-associated ophthalmic abnormalities from a patient with acute disseminated histoplasmosis.<sup>1</sup> Following Reid's description, additional reports surfaced of atrophic chorioretinal lesions associated with positive histoplasmin skin testing.<sup>2-4</sup> In 1959 Woods and Wahlen<sup>4</sup> published a series of 62 patients with granulomatous uveitis. Nineteen of these patients “showed a peculiar and consistent pattern of ocular lesions” that included both discrete atrophic, sparsely pigmented or unpigmented, peripheral lesions (frequently referred to as “histo spots”) and later cystic lesions in the macula. Skin testing for histoplasmin was positive in all of these 19 patients. Woods and Wahlen concluded that previous benign systemic histoplasmosis was responsible for the ocular findings in these 19 patients.<sup>4</sup> A few years later Schlaegel and Kenney<sup>5</sup> demonstrated that atrophic lesions around the optic nerve were also part of the clinical spectrum of ocular histoplasmosis syndrome (OHS), often called ocular histoplasmosis or presumed ocular histoplasmosis syndrome (POHS).

## Clinical Features of Ocular Histoplasmosis

The symptoms associated with ocular histoplasmosis are wide-

ranging and are dependent on the pathology present. Atrophic lesions are typically asymptomatic. The presence of choroidal neovascularization (CNV) often results in variable vision loss and metamorphosia. Recently, an updated review of ocular histoplasmosis outlined many of the clinical features of ocular histoplasmosis, as well as recent shifts in treatment paradigms.<sup>6</sup>

A clinical diagnosis of ocular histoplasmosis is based on the presence of at least two of the following fundus lesions in one or both eyes in the absence of ocular inflammation:<sup>7,8</sup>

- Discrete, focal, atrophic (i.e., punched-out) choroidal scars in the macula or the periphery, smaller in size than the optic disc (histo spots) (Fig. 73.1).

**FIG. 73.1** Chorioretinal scars (i.e., “histo spots”) characteristic of ocular histoplasmosis. (A) Peripheral histo spots. (B) Macular histo spots. Larger lesion with pigment proliferation may represent spontaneously regressed choroidal neovascularization (CNV). (C) Histo spots and peripapillary scarring. The peripapillary lesion superotemporal and within the peripapillary scarring probably represents spontaneously regressed CNV.

- Peripapillary chorioretinal scarring (i.e., peripapillary atrophy) (Fig. 73.2).

**FIG. 73.2** (A,B) Two examples of peripapillary scarring.

- CNV or associated sequelae (hemorrhagic retinal detachment, fibrovascular disciform scar) (Figs. 73.3–73.5).

**FIG. 73.3** (A) Choroidal neovascularization (CNV) secondary to ocular histoplasmosis with subretinal fluid in the macula. (B) Early frame of fluorescein angiogram shows extrafoveal CNV. (C) Late frame of fluorescein angiogram shows increased leakage of fluorescein dye. (D) Color photograph taken 1 day after laser photocoagulation shows whitening of retina from treatment. (E) Treatment scar 2 years after laser photocoagulation; no evidence of recurrent CNV.

**FIG. 73.4** (A) Choroidal neovascularization (CNV) secondary to ocular histoplasmosis with subretinal fluid in the macula. (B) Extrafoveal CNV is visible on this early frame of a fluorescein angiogram. (C) Late frame of fluorescein angiogram shows increased leakage of fluorescein dye from the CNV. (D) Color photograph taken 1 day after laser photocoagulation shows whitening of retina from treatment. (E) Atrophic treatment scar 2.5 years after laser photocoagulation; no evidence of recurrent CNV.

**FIG. 73.5** The Macular Photocoagulation Study Group demonstrated that laser treatment of eligible choroidal neovascular lesions was better than no treatment with respect to delaying or preventing loss of visual acuity. However, some CNV regresses spontaneously. These two patients did not have laser treatment of their choroidal neovascularization (CNV), which involuted spontaneously. (A) Juxtafoveal CNV in first patient. (B) Disciform scar 4 years later. (C) This patient had extrafoveal CNV with a rim of hemorrhage visible on the photograph. (D) CNV, hemorrhage, and fluid are all visible on this early frame of a fluorescein angiogram. (E) A small scar with pigment proliferation is visible 4 years later. Visual acuity returned to 20/20 3 months after enrollment and remained at 20/20 throughout the 5-year follow-up period.

Most often both eyes have typical lesions, although the appearance may not be symmetric at initial presentation. The early granulomatous stage of ocular histoplasmosis, as described by Woods and Whalen, is rarely seen clinically.<sup>4,7</sup> The initial focal scars are probably too small to be seen with the ophthalmoscope. Gass<sup>7</sup> has postulated that lymphocytic infiltration of the surrounding tissue produces enlargement of the lesion over a period of years and thus allows it to become clinically detectable.

## Differential Diagnosis

The differential diagnosis of ocular histoplasmosis includes a wide spectrum of disorders:

- **Multifocal choroiditis with panuveitis.** Characterized by multiple chorioretinal scars with similar findings to ocular histoplasmosis. Significant anterior and/or posterior inflammation present in the active phase, and there may be associated CNV. One study examined distinguishing features of multifocal choroiditis compared to ocular histoplasmosis.<sup>9</sup> Findings that were more characteristic of multifocal choroiditis included progressive growth of lesions, bridging scars, progressive proliferation of pigment, myopic disc changes, clustering of lesions (e.g., macula, equator), disc swelling, subretinal fibrosis, and narrowed/sheathed

vessels.<sup>9</sup> These features may be particularly important in distinguishing quiescent multifocal choroiditis from ocular histoplasmosis (see [Chapter 79](#), White spot syndromes and related diseases).

- **Myopic degeneration.** Peripapillary atrophy and CNV may be seen in patients with myopic degeneration. Small white focal areas of chorioretinal atrophy along with linear atrophic areas (e.g., lacquer cracks) may also be present in the posterior pole (see [Chapter 71](#), Myopic macular degeneration).
- **Multiple evanescent white dot syndrome (MEWDS).** White lesions of the retinal pigment epithelium (RPE)/outer retina may be present with associated granularity of the fovea. Often the vision is transiently decreased with an associated enlarged blind spot. Mild inflammation may be present. Scarring and permanent chorioretinal lesions are not usually observed (see [Chapter 79](#), White spot syndromes and related diseases).
- **Idiopathic CNV.** A diagnosis of exclusion. Particularly in younger individuals, idiopathic CNV is seen in the absence of other signs of ocular histoplasmosis, age-related macular degeneration (AMD), angioid streaks, and other CNV-related conditions.
- **Choroidal rupture with CNV.** A history of trauma is usually present. A partially circumferential concentric chorioretinal macular scar is typically present and is associated with the CNV. Peripapillary atrophy and associated peripheral chorioretinal atrophy is not present (see [Chapter 94](#), Traumatic chorioretinopathies).
- **Punctate inner choroidopathy.** Minimal to mild inflammation may be present. Atrophic scars may be associated with CNV. Spots are usually smaller than those seen with ocular histoplasmosis. Predominantly seen in women. Peripapillary atrophy is usually not present. Acute symptoms (e.g., photopsias) are usually associated with the initial diagnosis of the white lesions and may correlate with location of lesions (see [Chapter 79](#), White spot syndromes and related diseases).
- **Neovascular AMD.** Typically in older patients (i.e., >50 years). Drusen present. Areas of focal atrophy may be present in the

macula, but the atrophy is not usually seen in the periphery. Peripapillary atrophy is often not present (see [Chapter 69](#), Neovascular (exudative or “wet”) age-related macular degeneration).

- **Sarcoidosis.** Scattered active inflammatory choroidal lesions may be present. Usually accompanied by anterior/posterior inflammation. CNV and peripapillary atrophy not typically present. Elevated angiotensin-converting enzyme may be seen. Often associated with hilar adenopathy on chest radiograph or CT scan of the chest (see [Chapter 81](#), Sarcoidosis).

## Relationship of Ocular Disease to Systemic Infection

Systemic infection with *Histoplasma capsulatum* via the respiratory tract is thought to be the initial event prior to the development of ocular histoplasmosis. Although a definitive causal relationship between *H. capsulatum* and the ocular disorder has not been demonstrated to satisfy Koch's postulates completely,<sup>10,11</sup> continuing experimental work with primates<sup>12,13</sup> may eventually satisfy this requirement.

Several observations support a causal relationship between *H. capsulatum* and the ocular histoplasmosis syndrome:

- Almost all patients diagnosed as having ocular histoplasmosis in the United States have lived some or all of their lives in an endemic area.<sup>14,15</sup>
- Positive histoplasmin skin testing occurs more frequently in patients with ocular histoplasmosis compared with controls.<sup>15-17</sup>
- Activation of lesions of ocular histoplasmosis has been reported following histoplasmin skin testing.<sup>2-4,17-19</sup>
- DNA from *H. capsulatum* has been isolated from an enucleated eye previously diagnosed with ocular histoplasmosis.<sup>20</sup>
- DNA from *H. capsulatum* has been isolated from the peripheral blood of a patient diagnosed with acute ocular histoplasmosis associated with a systemic illness also consistent with histoplasmosis.<sup>21</sup>

Other observations can be used to question the causal relationship between *H. capsulatum* and the ocular syndrome. In the UK and Europe, a clinical syndrome nearly identical to ocular histoplasmosis may occur.<sup>22-26</sup> These patients have never lived in or visited an endemic area, however, and only a small proportion of Europeans are positive reactors to histoplasmin skin testing.<sup>22-27</sup> Additionally, *H. capsulatum* has not been identified in the UK.<sup>27</sup> Certainly, the possibility exists that an alternate organism may result in a similar ocular syndrome in these areas.<sup>24</sup> Systemic antifungal treatment with amphotericin B has not been shown to be effective for the treatment of the ocular disorder.<sup>28</sup>

## Clinical Features of Systemic Infection

Goodwin<sup>29</sup> classified systemic infection based on the immune status of the host and exposure type. The usual histoplasmosis infection is a relatively mild illness with flu-like respiratory symptoms. Most patients do not seek medical care. Studies in Tennessee have demonstrated that almost 90% of children of 13 years of age had positive reactions to histoplasmin skin tests.<sup>30</sup> A great deal of variation has been observed in the distribution of positive reactors by neighborhood of residence.<sup>31,32</sup> Rarely, more severe, even fatal cases of disseminated infection may occur, but these are usually associated with immune system deficiencies, such as acquired immunodeficiency syndrome (AIDS). Occasionally, epidemics of systemic disease outbreak may occur that are often associated with high levels of environmental exposure (e.g., excavations, construction projects in old buildings, work in chicken or other fowl habitats, or exposure in bat-inhabited caves).<sup>33-48</sup>

## Epidemiology of Ocular Histoplasmosis

### Geographic Distribution of *H. capsulatum* in the United States

The Ohio and Mississippi river valleys make up the largest part of

the “histo belt,” where 60% or more of lifelong residents have positive histoplasmin skin testing.<sup>49</sup> Comstock described the major endemic histoplasmosis area as a triangle with its apices in Eastern Nebraska, Central Ohio, and Southwestern Mississippi.<sup>31</sup>

## Prevalence and Incidence

The prevalence of asymptomatic ocular histoplasmosis in endemic areas (e.g., Ohio, Maryland) within the United States ranges from 1.6 to 5.3%.<sup>15,16,50</sup> The disciform lesion prevalence rates in the same areas were 0.0–0.1% of the endemic populations.<sup>15,16,50</sup> In those eyes that had atrophic spots, the prevalence of disciform lesions was 4.5%.<sup>50</sup>

The incidence rate of neovascular disciform lesions and atrophic lesions is largely unknown. The development of initial neovascular disciform lesions has been reported at around 2 per 100,000 population per year.<sup>51</sup> Studies examining the incidence rate of neovascular lesions in fellow eyes have shown a rate of 0.0–12% per year.<sup>52–56</sup>

## Age

The median age of patients with vision-threatening disciform lesions has typically been reported to be in the fourth and fifth decade, with an age range of 10–81 years old.<sup>14,18,51,57–60</sup> The median age of persons who have atrophic scars has been reported to be in the fourth, fifth, and sixth decades of life by various investigators.<sup>16,61</sup> These reports are of the age at detection, however, and not necessarily the age of development of the atrophic lesion. It is likely that these lesions develop earlier in life and are only coincidentally discovered during ophthalmic examinations for causes of visual symptoms that may or may not be related to ocular histoplasmosis.

## Gender and Race

There is no gender predilection for ocular histoplasmosis. The vast majority of disciform lesions occur in Caucasians with only around a dozen cases reported among African Americans.<sup>62</sup> Interestingly,

histo spots and positive skin tests have been reported in some studies to have similar prevalence among Caucasians and African Americans.<sup>16,63</sup> Other studies have found a much higher prevalence in Caucasians (i.e., nearly 100% of all cases) as compared to Hispanics or African Americans.<sup>15,17,50,57</sup>

## Histocompatibility Antigens and Genetic Predisposition

In disciform lesions, both human leukocyte antigen (HLA)-B7 and HLA-DRw2 have been reported to be two to four times more common among cases than controls.<sup>64-66</sup> For histo spots, HLA-DRw2 was twice as common among cases as among controls, but less difference was seen between the groups in regards to HLA-B7.<sup>66,67</sup> These findings suggest an underlying genetic susceptibility or predisposition for development of ocular histoplasmosis. It is unclear whether this genetic predisposition specifically reflects the susceptibility to ocular histoplasmosis or to infection by *H. capsulatum*. Although these associations exist, routine testing for HLA typing in connection with ocular histoplasmosis is not typically performed owing to the lack of significant positive and negative predictive values.

A recent analysis of patients with ocular histoplasmosis identified several genes that confer increased risk of CNV in age-related macular degeneration, including ARMS2, C3, MT-NDH2, and CFH.<sup>68</sup> In this report of 93 patients, 62 eyes had CNV secondary to ocular histoplasmosis and 31 patients had no evidence of CNV. Genetic testing detected no association with CNV risk. Though small, this study suggests alternate genetic risk factors may be at play for CNV secondary to ocular histoplasmosis compared to age-related macular degeneration.

## Pathogenesis

Numerous theories regarding the pathogenesis of ocular histoplasmosis have been proposed. The most widely accepted theory involves focal infection of the choroid at the time of systemic infection. The focal inflammatory/infectious process results in an

atrophic scar that disrupts Bruch's membrane. Alternatively, the infection may involve the retinal pigment epithelium and choriocapillaris and may progress rapidly to subretinal hemorrhage, exudation, and a fibrovascular disciform scar (Fig. 73.6).

**FIG. 73.6** Hypothesized mechanism of the pathogenesis of disciform lesions of ocular histoplasmosis. Focal choroiditis (A) damages the choriocapillaris, retinal pigment epithelium (RPE), and Bruch's membrane and produces an exudative detachment of the retina (B) or hemorrhage into the subretinal space (C). Any of these three stages may resolve, leaving either a focal area of atrophy of the

retinal pigment epithelium, Bruch's membrane, and choroid (D) or, in the case of subretinal hemorrhage, a disciform scar (G). Either in the absence of further inflammation or under the influence of recurrent episodes of inflammation, the choroidal blood vessels surrounding an atrophic chorioretinal scar (D) may decompensate and cause serous exudation, choroidal neovascularization, and transient serous detachment of the retina (E). This process in turn may result in a hemorrhagic detachment of the retina (F) that resolves as a disciform scar (G). (Reproduced with permission from Gass JDM. Stereoscopic atlas of macular diseases, vol. 1: Diagnosis and treatment. St. Louis: Mosby; 1987. p. 6.)

CNV formation may be promoted by multiple factors at the site of the atrophic scar. Disruption of Bruch's membrane provides access to the subretinal space for neovascularization.<sup>69</sup> The fragile vessels are prone to hemorrhage and exudation, often ultimately resulting in disorganization of the RPE and neurosensory retina and, ultimately, a fibrovascular scar.

The initiator for CNV development is unknown. The results from HLA typing suggest a possible genetic predisposition for progression from atrophic scars to disciform lesions in ocular histoplasmosis.<sup>64–67</sup> Other hypotheses have attributed these phenomena to a larger initial inoculum of the fungus,<sup>12,70</sup> reinfection,<sup>4,71</sup> hypersensitivity,<sup>4,15</sup> and the presence of other factors that compromise the vascular system<sup>15,72,73</sup> or the immune system.<sup>74</sup> CNV development has also been associated with proangiogenic factors such as vascular endothelial growth factor.<sup>75</sup>

One recent study examined 568 patients with ocular histoplasmosis, and of those patients, 142 patients were diagnosed with associated CNV.<sup>76</sup> In this study, logistic regression analysis identified age, education level, and smoking as significant risk factors for CNV development. Level of education was inversely associated (weak) with CNV risk (OR 0.95; 95% CI 0.92–0.98). Smoking was the most significant risk factor, with an OR of 2.83 (95% CI 1.8–4.31).<sup>76</sup>

Studying ocular histoplasmosis with animal models has been difficult. Histoplasmosis is known to occur in many species of animals.<sup>77–81</sup> However, efforts to develop an animal model for

ocular histoplasmosis have been hampered by two major factors: (1) nonprimates do not have a macula with its special anatomic, physiologic, and neurologic characteristics; and (2) decades are believed to elapse between initial infection with *H. capsulatum* and the development of characteristic macular lesions. The most promising animal models are primates, in which systemic infection and ocular lesions have been produced.<sup>12,13</sup>

## Natural History of Ocular Histoplasmosis and Public Health Implications

Histo spots outside the macular area are typically asymptomatic, although visual symptoms occasionally have been reported that correlate with the location of the atrophic scars.<sup>82</sup> Active CNV may result in sudden decrease in vision secondary to hemorrhage or exudation. The vision loss in this disease often occurs in middle-aged individuals who are in the most active and productive stage of their life.<sup>14,18,51,57-60</sup> Spontaneous recovery of central vision has been reported in the Macular Photocoagulation Study (MPS)<sup>53,58</sup> and by other investigators.<sup>83-85</sup>

Two studies have addressed the public health importance of ocular histoplasmosis as a cause of visual impairment. One study in Tennessee found that ocular histoplasmosis was responsible for 2.8% of visual impairment among applicants for aid for the blind.<sup>51</sup> In Maryland a study comparing the 15-year incidence of visual impairment in those persons with histo spots to those persons without histo spots found that there was no difference in the rates of visual impairment.<sup>52</sup> The Submacular Surgery Trials Research Group found that individuals with unilateral and bilateral CNV cases had significant deficits in visual function, similar to patients with neovascular age-related macular degeneration (AMD).<sup>86</sup> Not surprisingly, the study showed that patients with bilateral CNV had significantly worse functional impairment of all groups, but those with unilateral involvement also had significant functional deficits.<sup>86</sup>

## Treatment

Numerous approaches for ocular histoplasmosis management have been suggested, including avoidance of stress, avoidance of aspirin, avoidance of the Valsalva maneuver, hyposensitization to histoplasmin, use of immunosuppressive agents, and photocoagulation.<sup>10</sup> Histoplasmin desensitization,<sup>87</sup> amphotericin B,<sup>18,28</sup> and other prophylactic interventions<sup>88,89</sup> have been tried by many investigators and discarded. No treatment is known to prevent inactive lesions from giving rise to exudative or hemorrhagic neovascular complexes that typically end in disciform macular scars. Systemic corticosteroids also have been suggested, particularly in cases of “active” histo spots and subfoveal CNV.<sup>7</sup> In the era of anti-vascular endothelial growth factor (VEGF) and photodynamic therapy (PDT), however, the use of systemic corticosteroids even in subfoveal cases is now mainly of historic interest. Whether there is a role to manage active histo spots is unclear since many or perhaps most spontaneously involute.

## Laser Photocoagulation

Initiated in 1979, the Macular Photocoagulation Study (MPS) Group demonstrated the effectiveness of laser treatment in comparison to no treatment in two randomized clinical trials for patients with well-defined extrafoveal or juxtafoveal CNV.<sup>58,59,90,91</sup> The first trial enrolled 262 patients with well-demarcated extrafoveal CNV.<sup>59,90</sup> The posterior border of these lesions could not be closer than 200  $\mu\text{m}$  from the center of the foveal avascular zone; initial best corrected visual acuity of the affected eye was 20/100 or better. Eligible eyes were randomly assigned to argon laser treatment or to no treatment. The eyes were reexamined twice each year, at which time best corrected VA was measured and color photographs were taken. Fluorescein angiograms were taken at time of study entry, 6 and 12 months after enrollment, and annually thereafter.

In 1983 the MPS Data and Safety Monitoring Committee halted enrollment after concluding that argon laser photocoagulation was beneficial in preventing or delaying large loss of visual acuity compared to observation without treatment. From 18 months

through 5 years, a loss of 6 or more lines of VA was experienced in 10% of treated eyes compared to 40% of untreated controls. Median VA at baseline was 20/25 and after 5 years dropped to 20/40 in the treated group compared to 20/80 in controls.<sup>90</sup> In the laser-treated group, 26% of eyes had persistence of CNV or recurrence of CNV at the scar edge, and 7% developed a new CNV not contiguous with the laser scar.<sup>90</sup>

In 1981 a second trial was initiated by the MPS Group for patients with juxtafoveal CNV.<sup>91</sup> In this trial, best corrected VA at entry was permitted to be as poor as 20/400 in the study eye. A total of 289 eyes were randomized between krypton laser treatment and no treatment. Five years after the trial began, the MPS Data and Safety Monitoring Committee again halted enrollment after concluding that eyes treated with krypton laser were less likely to lose visual acuity than untreated eyes. A loss of 6 or more lines was seen in 11% of the treated eyes compared to about 30% of the controls.<sup>91</sup> Approximately one-third of treated patients had persistent or recurrent CNV contiguous with the zone of laser treatment; and new, noncontiguous areas of CNV developed in 2% of treated eyes.<sup>91</sup> A subgroup analysis by the MPS group of CNV located between the fovea and optic nerve showed that there was no contraindication to treatment of these lesions in the papillomacular bundle with laser.<sup>92</sup> A subset of the MPS Group piloted laser photocoagulation for subfoveal CNV secondary to ocular histoplasmosis but observed no short-term benefit compared to observation.<sup>93</sup>

In view of the very good results with extrafoveal CNV and even juxtafoveal CNV from the MPS studies, laser photocoagulation therapy may be considered for these lesions. Additionally, when compared to anti-VEGF therapy, laser photocoagulation is not as expensive and avoids many of the ocular and possible systemic risks of intravitreal injections with anti-VEGF agents. If subfoveal recurrence or primary subfoveal disease develops, PDT and/or anti-VEGF treatment should be considered (see below).

## Photodynamic Therapy

The treatment of subfoveal CNV secondary to ocular

histoplasmosis with PDT was first suggested in 2002.<sup>94</sup> Since that small study, numerous studies have been published examining the use of PDT for ocular histoplasmosis. In fact, PDT is now approved by the United States Food and Drug Administration (FDA) for the treatment of subfoveal CNV secondary to ocular histoplasmosis.

Most of the studies performed for PDT with ocular histoplasmosis have been retrospective case series. In a 2003 retrospective review of 38 eyes with juxtafoveal CNV treated with PDT, treated eyes were more than twice as likely to have visual improvement or stabilization compared to the natural history group in the corresponding MPS clinical trial. Visual acuity improved or stabilized in 69% of eyes, with 44% of eyes improving at least 2 lines. Nearly 40% of eyes had undergone submacular surgery prior to PDT.<sup>95</sup> In 2004 a retrospective review of 11 eyes, of which five had juxtafoveal CNV and six had subfoveal CNV, documented similar findings. Eighty percent of eyes showed vision stabilization or improvement in the juxtafoveal group. Sixty percent of eyes with juxtafoveal lesions achieved a final visual acuity of 20/40 or better. Eyes with subfoveal lesions had similar results, with 83% of eyes having stabilization or improvement in vision. Fifty percent of eyes with subfoveal CNV also had a final visual acuity of 20/40 or better.<sup>96</sup> In 2005 a retrospective review of 23 eyes with juxtafoveal CNV associated with ocular histoplasmosis found that approximately 82% of eyes had visual stabilization (less than 2 line loss) or improvement. Thirty percent of eyes gained more than 2 lines of vision. Approximately 60% of patients required only a single PDT session. Following PDT, submacular surgery was performed in 16% of patients due to CNV progression.<sup>97</sup>

In 2006 a retrospective review of young patients undergoing PDT for CNV secondary to etiologies other than AMD included 6 patients with ocular histoplasmosis with subfoveal CNV. The mean pretreatment acuity in these eyes was 20/50, and the mean final visual acuity was 20/50. Three of these eyes (50%) required at least one retreatment session with PDT. One of 6 patients improved by more than 1 line of VA. Four eyes (67%) maintained their visual acuity (i.e., less than 2 lines lost or gained), one eye gained more than 2 lines of VA, and one eye lost 2 lines.<sup>98</sup>

An uncontrolled prospective trial evaluating PDT for subfoveal

CNV secondary to POHS included 26 eyes. Examination of 22 eyes 2 years following initial treatment revealed that 45% of eyes had gained 1.5 lines or more. Eighteen percent of eyes lost 1.5 lines or more, including 9% of eyes that lost 3 or more lines of VA. The mean number of treatments was 2.9 during the first year and 1 during the second year. After 2 years, only 15% of eyes had persistent angiographic leakage.<sup>99</sup>

## Anti-VEGF Therapy

Over the last several years, the use of anti-VEGF agents has transformed the landscape in the treatment of CNV-related disease, particularly neovascular AMD. Case reports and case series suggest that anti-VEGF agents may also be effective in the treatment of CNV secondary to ocular histoplasmosis (Fig. 73.7). In 2007 the first case report was published documenting a 23-year-old female with sudden vision loss to 20/200 with subfoveal CNV. After a single intravitreal injection of bevacizumab, the visual acuity improved to 20/30 by 6 months follow-up.<sup>100</sup> Of course, the control arms of the MPS studies discussed above show that spontaneous involution can occur, but following this case report, retrospective consecutive case series were published examining the use of the intravitreal bevacizumab for the treatment of CNV in ocular histoplasmosis. One study examined intravitreal bevacizumab in 24 treatment-naïve eyes. The mean age was 43 years and the average number of injections was 6.8 per year. After 3 months, visual acuity improved from a mean baseline visual acuity of 20/114 to 20/55 (i.e., approximately 3 lines). Fifty-eight percent of eyes had 20/40 or better vision at final follow-up compared to 21% at baseline. Nine patients had 12 month follow-up and improved from a mean baseline visual acuity of 20/150 to 20/45 (i.e., approximately 6 lines). No significant complications were reported.<sup>101</sup>

**FIG. 73.7** Optical coherence tomography images of subfoveal choroidal neovascularization (CNV). CNV is visible in the subfoveal area with overlying subretinal fluid (A). Following intravitreal bevacizumab therapy, the subretinal fluid is significantly improved although the CNV remains (B).

A second study examined the use of bevacizumab in 28 eyes with CNV secondary to histoplasmosis. All patients included had active CNV with subfoveal fluid and either juxtafoveal or subfoveal CNV. Previous or concurrent PDT was allowed in this study. Seven patients were treatment naïve, 16 were PDT failures, and 5 patients were treated with combination PDT/bevacizumab therapy. The mean age was 46 years and mean follow-up was 5 months. Overall, the mean initial visual acuity was 20/88 and the mean final visual acuity was 20/54. Stability of visual acuity (<1.5 line loss) was seen in 93% of patients. Additionally, 43% of eyes experienced a 3 or more line gain. Both of the studies examining bevacizumab were retrospective, with significant methodologic shortcomings, and the results should be interpreted with caution.<sup>102</sup>

An additional retrospective review reported 54 eyes of 52 patients treated with either bevacizumab or ranibizumab for CNV secondary to histoplasmosis. The mean patient age was 47.6 years. Mean baseline visual acuity was 20/53, and the final mean visual acuity was 20/26 ( $p < .005$ ). Previous treatment, including PDT, was allowed. Visual acuity improvement was noted in 81% of eyes, stability of visual acuity was recorded in 13% of eyes, and vision loss was reported in 6% of eyes.<sup>103</sup>

A phase I randomized 12-month clinical trial evaluated ranibizumab for the treatment of CNV secondary to conditions other than AMD has been conducted. This study randomized eyes to monthly ranibizumab or 3-monthly injections followed by an as needed (prn) dosing schedule at monthly visits. Nine eyes (of 30)

with ocular histoplasmosis were included in this trial, four in the monthly arm and five in the prn arm. Prior treatment with other therapeutic modalities was allowed. Subgroup analysis was not performed for each diagnosis included. As a group, mean lines of change from baseline was +7.4 in the monthly injection arm and +5.0 in the prn group. A 3-line or more gain in visual acuity was seen in 66.7% of the monthly arm patients and in 57% in the prn arm. There were no statistically significant differences between the groups at any time point. No serious ocular or systemic adverse events were observed, but larger sample sizes are needed to detect infrequent severe adverse events.<sup>104</sup>

Further research is needed to define better the role of anti-VEGF therapy in the management of CNV secondary to ocular histoplasmosis. Early research suggests that it may have an important role in the management of this condition.

## Combination Therapy

Similar to AMD, combination therapy is also being considered for the treatment of CNV secondary to ocular histoplasmosis. Combination therapy may reduce the need for ongoing intravitreal injections. PDT or laser photocoagulation may provide a more enduring effect, compared to anti-VEGF therapy alone. Adding anti-VEGF therapy may reduce the required spot size needed for either laser modality. In 2010, a small retrospective case series examining combination anti-VEGF agents with PDT included three eyes with CNV secondary to ocular histoplasmosis. Treatment consisted of PDT and intravitreal bevacizumab initiated concurrently with retreatment with PDT every 10–12 weeks and with bevacizumab every 4–6 weeks. Retreatments were based on persistent edema or subretinal fluid. Three of 3 (100%) eyes improved 2 lines or more at final follow-up.<sup>105</sup> As outlined in the previous section, a retrospective case series utilizing bevacizumab for CNV secondary to ocular histoplasmosis included five eyes that were treated with concurrent PDT therapy. Subgroup analysis of these five patients revealed that all five eyes experienced stabilization or improvement in visual acuity with a mean gain of 2.4 lines.<sup>102</sup>

In 2012 a retrospective comparative case series was published that examined intravitreal bevacizumab compared to combined intravitreal bevacizumab and PDT. A total of 151 eyes were included in the study, and 104 eyes had at least a 12-month follow-up period. The mean follow-up was 21.1 months. There was no difference in visual acuity at 12 months or 24 months between the bevacizumab monotherapy and combination groups.<sup>106</sup>

## Intravitreal Triamcinolone

Given the possible underlying inflammatory pathogenic mechanisms of ocular histoplasmosis, the use of intravitreal steroids may be of use in the treatment of CNV secondary to ocular histoplasmosis. A retrospective case series examined the use of intravitreal triamcinolone in 10 eyes with CNV secondary to ocular histoplasmosis (5 subfoveal and 5 juxtafoveal) was conducted with a median follow-up of 17 months. Visual acuity improved or stabilized in 80% of eyes, including 30% that gained 1 line or more. Twenty percent of eyes lost 1–3 lines of visual acuity, and no eyes lost more than 3 lines of vision. Cataract progression and increased intraocular pressure were concerning ocular side-effects.<sup>107</sup>

## Submacular Surgery and Macular Translocation

Prior to PDT and anti-VEGF therapy, submacular surgery for CNV secondary to ocular histoplasmosis was an important treatment alternative for many patients with significant vision loss.<sup>108–110</sup> As with many treatment modalities for CNV, recurrence of CNV is a major issue. In fact, the recurrence rate after submacular surgery is higher than recurrence following laser photocoagulation.<sup>111</sup> In 1997 the National Eye Institute and the National Institutes of Health initiated the Submacular Surgery Trials group H trial in order to compare functional outcomes and quality of life between patients assigned to surgery versus those assigned to observation (Fig. 73.8). The trial included 225 patients non-AMD with subfoveal CNV and visual acuity of 20/50 to 20/800. Of the 225 patients, 192 patients had ocular histoplasmosis. At 2 years, vision had improved or remained

stable in 20% more patients treated with surgery than with observation.<sup>112</sup> This outcome difference was not statistically significant. Subgroup analyses revealed that nearly all of the benefit seen with surgery was in those eyes with 20/100 or worse baseline visual acuity. In this subset of 92 eyes, 76% of surgery eyes remained stable or improved compared to 50% of eyes that were observed. Additionally, quality-of-life scores improved more with surgery.<sup>113</sup>

**FIG. 73.8** Eye with subfoveal choroidal neovascularization (CNV) treated with submacular surgery in the Submacular Surgery Trials (group H trial). Color photograph (A) and early frame of fluorescein angiogram (B) shows subfoveal CNV in an eye with characteristic lesions of ocular histoplasmosis. Color photograph (C) and early frame of fluorescein angiogram (D) taken 6 months after submacular surgery show a well-demarcated postoperative disturbed area of the retinal pigment epithelium.

Macular translocation has also been utilized for the treatment of

patients with bilateral vision loss associated with ocular histoplasmosis.<sup>114</sup> One report described three cases of ocular histoplasmosis treated with 360° macular translocation. Two of the three eyes showed improvement in visual acuity. Two of the three cases developed recurrent CNV, and two of the three cases developed chronic cystoid macular edema.<sup>114</sup> Limited macular translocation for ocular histoplasmosis has also been reported, but the specific visual acuity results were not separated from the larger study which included predominantly AMD cases so that conclusions cannot be drawn regarding the effectiveness of limited translocation for ocular histoplasmosis.<sup>115</sup> Although surgical intervention remains a viable option in select situations, anti-VEGF therapy and PDT are now the mainstays of treatment for subfoveal and juxtafoveal CNV secondary to ocular histoplasmosis and laser photocoagulation is often advised for extrafoveal CNV.

Anti-VEGF Therapy

### Introduction

Polypoidal choroidal vasculopathy (PCV) is an exudative maculopathy with features similar to neovascular age-related macular degeneration (AMD) with pigment epithelial detachment (PED), and neurosensory detachment, some with hemorrhage. The pathogenesis of PCV is largely unknown, but it is now recognized widely as a subtype of neovascular age-related macular degeneration.

PCV is more common in non-white populations (including blacks, Hispanics, and Asians).<sup>1</sup> The incidence of PCV in Chinese and Japanese patients in exudative AMD has been reported to be much higher than in Caucasians.<sup>2-7</sup> The true prevalence and consequences may be underestimated if indocyanine green angiography (ICGA) is not performed. The widespread availability of ICGA has improved the diagnosis of PCV.

Polypoidal choroidal vasculopathy was first described as polypoidal, subretinal, vascular lesions associated with serous and hemorrhagic detachments of the retinal pigment epithelium (RPE) in a series of patients (10/11 were women) by Yannuzzi et al. at the Annual Meeting of the American Academy of Ophthalmology in 1982.<sup>8</sup> The entity was initially called idiopathic polypoidal choroidal vasculopathy (IPCV). Kleiner et al. in 1984<sup>9</sup> described a peculiar hemorrhagic disorder of the macula, characterized by recurrent subretinal and subretinal pigment epithelium bleeding in middle-aged black women, which they termed posterior uveal bleeding syndrome (PUBS).<sup>10</sup> Later, a study from the same group of authors showed an expanded clinical spectrum for PCV, affecting various ages, both genders, and several racial populations.<sup>11</sup> This chapter will use the PCV nomenclature; the IPCV and PUBS terms are mentioned for historical benefit.

The past decade has witnessed dramatic improvements in the understanding of exudative maculopathy and recognition of the importance of PCV, especially in the Asia-Pacific regions. A PCV Roundtable meeting panel of experts suggest that PCV is defined

angiographically as the presence of single or multiple focal nodular areas of hyperfluorescence arising from the choroidal circulation within the first 6 minutes after injection of indocyanine green, with or without an associated choroidal interconnecting vascular network. The presence of orange–red subretinal nodules with corresponding indocyanine green hyperfluorescence is pathognomonic of PCV.<sup>12</sup> The implication of the definition is obvious but bears repetition. The definition of PCV relies on ICGA. Retina specialists who do not generally utilize ICGA tend not to diagnose PCV. Later in the chapter there is also clinical definition of PCV.

## Pathogenesis

PCV is regarded as a primary abnormality of the choroidal vessels, characterized by an inner choroidal vascular network of vessels ending in an aneurysmal bulge or outward projection, often visible as a reddish-orange, spheroid, polyp-like structure. PCV primarily involves the inner choroidal vasculature that is well differentiated from the middle and larger choroid vessels by histology.<sup>13</sup>

Histopathological features have been reported by Kuroiwa from surgically excised specimens from five patients with PCV, who had been diagnosed by ICGA. The results indicated that arteriosclerosis appears to be an important pathologic feature in the choroidal vessels of PCV subjects.<sup>14</sup> In another histopathologic report, by Nakashizuka et al., who examined specimens surgically extracted from five eyes of five PCV patients, the pathologic findings revealed little granulation tissue formation in any of the specimens; on the other hand, all the specimens exhibited a massive exudative change and leaking, all the vessels exhibited hyalinization, and choriocapillaris had disappeared, even in the cases in which RPE had been preserved.<sup>15</sup> This group also demonstrated by immunohistochemistry that PCV is not the same as choroidal neovascularization (CNV). CD-34 is a marker of vascular endothelial expression, and CD-34 staining revealed discontinuity in the vascular endothelium, smooth muscle actin (SMA) was negative in hyalinized vessels, and there was disruption and injury of smooth-muscle cells causing dilation of vessels. VEGF antibody

was negative in vascular endothelial cells. These histopathologic findings indicated that hyalinization of choroidal vessels, like arteriosclerosis, was characteristic of PCV.<sup>15</sup>

The genetic studies with CNV and PCV have been controversial in published papers.<sup>16,17</sup> Recently, we investigated the relationship between CNV of AMD and PCV by performing a series of meta-analyses. We found that many genes have common associations with PCV and CNV. For example, the pooled odds ratio (OR) between SNP rs10490924 (TT : GG, within the *ARMS2* gene, previously identified as LOC387715<sup>18</sup>) and CNV is 4.23 (95% CI 3.535-06), while the pooled OR between this SNP and PCV is 5.13 (95% CI 3.40–7.75) (data unpublished). SNP rs9332739 within complement factor 3 (*C3*) gene also have a common association with CNV (GG : CC, pooled OR 2.12, 95% CI 1.81–2.47) and PCV (pooled OR 3.52, 95%CI 1.43–8.69). Moreover, a similar trend was found in complement factor H (*CFH*, rs1061170, CC : TT) and *SERPING1* (C1 inhibitor, rs2511989 GG : AA). The elastin gene identified by Kondo et al. in 2008 was shown to disrupt the elastic area of the Bruch's membrane. He found that a common elastin gene (*ELN*) variant was significantly associated with susceptibility to PCV.<sup>19</sup> With the increased knowledge about the genetic determinants for AMD, researchers have tried to find genetic evidence to determine the association between neovascular AMD and PCV. Single-nucleotide polymorphisms (SNP) of *CFH*, replicated in multiple cohorts, have been proved to be associated with both neovascular AMD and PCV, which demonstrates major genetic evidence to support the similarity between neovascular AMD and PCV. One study reported a strong association with PCV ( $p < .0005$ , with or without adjustment for age and sex). All of the 11 SNPs tested at the *CFH* locus were significantly associated with PCV, and 8 of 11 SNP markers tested showed significant evidence of heterogeneity between AMD and PCV ( $p < .05$  for all comparisons) after adjusting for age and sex.<sup>20</sup>

Furthermore, a series of meta-analyses was performed to investigate the pooled OR between the risk factors for CNV and PCV. We found that CNV and PCV have many common risk factors, such as smoking and diabetes. For example, the pooled OR between smoking and CNV is 1.78 (95%CI 1.52–2.09),<sup>21</sup> while the

pooled OR between smoking and PCV is 1.51 (95% CI 1.06–2.16, data unpublished). The pooled OR between diabetes and CNV is 1.66 (95% CI 1.05–2.63),<sup>21</sup> while the pooled OR between diabetes and PCV is 1.94 (95% CI 1.29–2.92, data unpublished). However, the pooled OR between hypertension and CNV is 1.02 (95% CI 0.77–1.35),<sup>21</sup> while the pooled OR between hypertension and PCV is 1.60 (95% CI 1.17–2.18, data unpublished). Therefore, hypertension is only associated with PCV. This is consistent with pathology findings: the PCV lesion has thickened and hyalinized vessel walls, which is similar to that seen in hypertension.<sup>22</sup>

## Clinical Features

### Demographics

The prevalence of PCV in presumed neovascular AMD was reported as 7.8% in US,<sup>1</sup> 4.0% in Belgian,<sup>23</sup> 9.8% in Italian,<sup>24</sup> 8.2% in Greek<sup>25</sup>, 23.0–54.7% in Japanese,<sup>26</sup> 22.3–49% in Chinese,<sup>7,27</sup> and 24.6%<sup>28</sup> in Korean populations. The prevalence varies with age.<sup>29</sup> In summary, PCV is more prevalent in blacks, Japanese, Chinese, and other Asians than in whites, while the incidence of AMD is very high in whites and low in blacks. The incidence of both diseases is high in Asians.

Although early reports suggested that PCV was a condition predominantly of middle-aged women,<sup>11</sup> and that typically PCV presents one to two decades earlier than classical AMD, it is most commonly diagnosed in patients between the ages of 50 and 65.<sup>30</sup> However, the age of the subjects reported with a mean of 66.1± 9.6 years in Chinese population.<sup>29</sup> Caucasian patients usually present with PCV at an older age.<sup>31</sup> It has subsequently been established that PCV occurs in both genders (and more commonly in Asian men than women).<sup>28</sup> Although women are involved more often than men in some reports, more men still have manifestations of the disorder among Chinese patients.<sup>7,29,31,32</sup> PCV is usually a bilateral disease. The majority of the patients with evidence of PCV in one eye eventually develop similar lesions in the fellow eye.

The natural course of PCV is variable: it may be relatively stable, or there may be repeated bleeding and leakage with vision loss and

chorioretinal atrophy, with or without fibrotic scarring. Reddish-orange nodules alone, or nodules and small subretinal hemorrhage and absence of hard exudates, may still allow a benign clinical course and stable vision.<sup>33,34</sup>

The association of PCV with other conditions is not certain. PCV with severe thrombocytopenia and massive hemorrhage has been reported,<sup>35</sup> and PCV has also been associated with sickle-cell disease and irradiation.<sup>36</sup> Some experts believe it is advisable to screen PCV patients for hypertension and platelet count, but hypertension is common in older patients and is already monitored during medical visits, and the platelet data are not firmly established. The role of hereditary and environmental factors in its etiology is inconclusive and needs further study.

## Clinical Findings

Clinically, PCV is characterized by protruding orange-red elevated lesions, often with nodular elevations of the RPE, that can be seen during routine fundus examination using ophthalmoscopy and contact lens slit-lamp biomicroscopy. The nodular elevations of the RPE are easily visible by optical coherence tomography (OCT). PCV is also characterized by nodular lesions only observed when using ICGA. The nodular lesions appear as polyp-like or grape-like clusters (Fig. 74.1).<sup>11,15</sup> The nodular lesions are associated with serous exudation and hemorrhage that may lead to detachment of the RPE and sometimes the neurosensory retina.<sup>34</sup> Associated features are recurrent subretinal hemorrhage and vitreous hemorrhage (Fig. 74.2).

**FIG. 74.1** (A) Color photograph of an 53-year-old male with blurred vision in the right eye for 2 years; visual

acuity was 20/200. There are protruded orange–red elevated lesions (*arrows*) in the superior area of the macular. (B) Fluorescein angiogram of the same fundus showing occult choroidal neovascularization. (C) Indocyanine green angiogram at 6 minutes 3 seconds reveals a branching vascular network in the central macular and polypoidal lesions (*arrows*) connecting to a branching vascular network (*dashed arrows*) and corresponding to the orange–red subretinal nodules.

**FIG. 74.2** (A) Color photograph of a 65-year-old man with blurred vision for 18 months. There is a large area of protruding orange–red elevated lesion on the temporal side of the fovea. (B) Indocyanine green angiogram from the same fundus. (C) One month later the vision dropped to hand motions and the color photograph showed hemorrhagic retinal detachment inferior to the fovea. (D) One week later subretinal

hemorrhages and bleeding into the vitreous cavity was demonstrated on B-scan ultrasonography.

Nodular lesions are located mainly in the macula area, although this may be ascertainment bias since ICGA tends to look at that area. In one report, 69.5% nodular lesions were located in the macular area, 15% PCV lesions were located under the temporal retinal vascular arcade, and 4.5% PCV lesions were located peripapillary (within one disc diameter of the disc edge). PCV lesions were also located in the midperipheral area.<sup>29</sup>

PCV lesions may be active or inactive (Fig. 74.3). PCV is considered as active if there is clinical, OCT, or fluorescein angiography (FA) evidence of any one of the following: vision loss of 5 or more letters (ETDRS chart); subretinal fluid with or without intraretinal fluid; pigment epithelial detachment; subretinal hemorrhage; or fluorescein leakage (Box 74.1). There are currently no universally recognized criteria for defining disease activity in PCV; treatment should be initiated for active and symptomatic PCV and can be considered for active, asymptomatic PCV.<sup>12</sup>

**FIG. 74.3** Indocyanine green angiogram of a 73-year-old man with polypoidal choroidal vasculopathy and a 7-month history of decreased visual acuity in his left eye. There are two polyps in the macular region. *Yellow arrowhead* identifies an inactive polyp; *red arrowhead* points to an active polyp with surrounding hypofluorescence.

### **Box 74.1**

## **Characteristics of Active Polypoidal Choroidal Vasculopathy**

- Neurosensory detachment
- Pigment epithelium detachment
- Subretinal lipid exudation
- FA evidence of activity is leaking hyperfluorescence, mostly in an “occult” pattern
- Subretinal haemorrhage
- Polyp surrounded by fluid (hypofluorescent halo in ICGA)

FA, fluorescein angiography; ICGA, indocyanine green angiography.

Choroidal vascular hyperpermeability, reportedly a characteristic finding in central serous chorioretinopathy (CSC), might play a role in the pathogenesis of PCV. PCV with angioid streaks secondary to pseudoxanthoma elasticum has also been reported in one patient.<sup>37,38</sup>

Some authors reported PCV combined with CNV.<sup>31</sup> PCV theoretically can induce ischemic changes, inflammation, sick RPE, and breaks in Bruch's membrane. These changes could contribute to the development of CNV, and fibrosis and scarring may ensue. The fibrotic scarring can be caused by subretinal bleeding.

## **Angiographic Features**

PCV is better visualized by ICGA than by FA because indocyanine green absorbs and emits near-infrared light, which readily penetrates the RPE, enhancing viewing of choroidal lesions. Also, the higher binding affinity of indocyanine green to plasma proteins means that it does not leak rapidly from the choriocapillaris in the same way as fluorescein.<sup>39</sup> In recent years, ICGA has been accepted as the gold standard for the diagnosis of PCV, and as one of the specific criteria to distinguish PCV from retinal angiomatous proliferation by the angiogram in stereo.<sup>6</sup> The ICGA characteristics of PCV include a branching network of inner choroidal vessels,<sup>2,6,22,40–42</sup> and nodular polypoidal aneurysms or dilations at the edge of these abnormal vessel networks, which correspond to orange subretinal nodules;<sup>2,6,11,21,32,34,40,42</sup> and the presence of single or multiple focal nodular areas of hyperfluorescence (hypofluorescent halo) arising from the choroidal circulation within the first 6 minutes (Box 74.2). Pulsation in polyps and/or associated vasculature has been less extensively reported and can be observed using video ICGA.<sup>43,44</sup>

## ICGA Characteristics of Polypoidal Choroidal Vasculopathy

- Polypoidal lesions shown on ICGA as typical nodular hyperfluorescence, and one of the following angiographic criteria:
- A branching network of inner choroidal vessels, nodular polypoidal aneurysms or dilations at the edge of these abnormal vessel networks, presence of hypofluorescent halo (in first 6 minutes)
- Pulsation in polyps can be observed only using video ICGA

ICGA, indocyanine green angiography.

ICGA should be considered to assist the diagnosis of PCV when routine ophthalmoscopic examination indicates a serosanguineous maculopathy with one of the following features: clinically visible orange–red subretinal nodules, spontaneous massive subretinal

hemorrhage (if not so severe as to preclude all ICG views), and in some cases with notched or hemorrhagic pigment epithelium detachment (PED), or a lack of response to anti-VEGF therapy. The total lesion area for PCV is the area of all polyps and the branching vascular network (BVN) as viewed by ICGA. This is important for laser and photodynamic treatment modalities.

## Classification

PCV was initially classified by the Japanese Study Group on PCV.<sup>2</sup> PCV roundtable meeting panel of experts proposed three categories to subclassify PCV:<sup>12</sup>

1. Quiescent: polyps in the absence of subretinal or intraretinal fluid or hemorrhage
2. Exudative: exudation without hemorrhage, which may include sensory retinal thickening, neurosensory detachment, PED, and subretinal lipid exudation
3. Hemorrhagic: any hemorrhage with or without other exudative characteristics

There are additional classifications for discussion. Akiyuki Kawamura classified PCV into two types: Type 1, both feeder and draining vessels are visible on ICGA and network vessels are numerous; Type 2, neither feeder nor draining vessels are detectable and the number of network vessels is small.<sup>45</sup> Based on the presence of a branching vascular network on ICGA and presence of late leakage from the PCV lesion on FA, Tock Han Lim classified into three types: Type A (interconnecting channels on ICGA) – 22.4%; Type B (branching vascular network with no leakage of FA) – 24.3%; Type C (branching vascular network with late leakage of FA) – 53.3% from 107 patients. The highest rate of moderate visual loss (loss of  $\geq 3$  lines) occurred in Type C PCV (57.7% vs. 0% for Types B and A at 5 years,  $p < .001$ ).<sup>46</sup>

## Differential Diagnosis

## Neovascular Age-Related Macular Degeneration

Some authors categorize PCV as a subtype of neovascular AMD.<sup>6</sup> PCV has been considered to be part of or similar to occult CNV due to similar features (Fig. 74.4A), elevated levels of vascular endothelial growth factor (VEGF), similar histology, and expression of growth factors and receptor antibodies. We view PCV as a distinct condition. It has been documented that the increased levels of VEGF in PCV are lower compared with AMD CNV or myopic CNV. The increase in VEGF levels in PCV is mild to moderate. The clinical features of the PCV are different from those of neovascular AMD. PCV is associated with polyp-like structures projecting from the plane of the inner choroid towards the outer retina or RPE; the RPE is mostly intact, while in neovascular AMD the neovascular tufts arising from the choroid may either invade and perforate Bruch's membrane or grow through defects in Bruch's membrane and proliferate in either sub-RPE space (type I CNV) or in the subsensory retinal space (type II CNV).<sup>47</sup> The ingrowth of new vessels extending from the choroid into the sub-RPE space is the most important histopathologic change of occult CNV (Fig. 74.4B).

**FIG. 74.4** (A) Color photograph of 72-year-old man

with visual acuity 20/20. (B) Indocyanine green angiography (ICGA) demonstrates choroidal neovascularization (CNV) superior to fovea. (C) Optical coherence tomography (OCT) of the same fundus; *arrow* points to the CNV component above the retinal pigment epithelium (RPE) band and the RPE band is broken. (D) Color photograph of 66-year-old woman with visual acuity 20/100, with orange–red subretinal nodules in the macular area (*arrow*). (E) ICGA of the same fundus showed polyps corresponding to the orange–red lesions. (F) OCT of the same fundus showed a detached RPE in a “bent back” form corresponding to the polypoidal lesion with subretinal fluid and a large area RPE detachment.

OCT findings (Figs. 74.4C and F) can assist in understanding the differences in the retinal structures that are affected by these two clinical entities and also may help in the differential diagnosis of PCV and neovascular AMD.<sup>13</sup>

## Central Serous Chorioretinopathy

Central serous chorioretinopathy (CSC) is characterized by accumulation of transparent fluid and round, serous detachment of the macular retina. It has been thought to be due to a focal leakage from one or more defects at the level of the RPE, which allow serous fluid from the choriocapillaries to diffuse into the subretinal space. It has been hypothesized that a protracted disturbance in the microcirculation of the choriocapillaries leads to leakage of fluid into the sub-RPE space. A combination of choroidal hyperpermeability and impaired RPE function leads to pooling of fluid in the sub-RPE space with eventual leakage through the RPE into the subretinal space. ICGA has expanded our knowledge of CSC. A consistent finding is the hyperpermeability of the choroid during ICGA in CSC. The multifocal choroid hyperfluorescence patches in the ICG demonstrate multifocal choroid vascular hyperpermeable areas.<sup>42</sup>

PCV masquerading as CSC was reported in CSC with persistent and/or recurrent exudation; a myriad of retinal pigment epithelial changes may evolve that make it difficult to differentiate it from

PCV. In such patients, ICGA is useful in differentiating these two entities. An accurate clinical diagnosis is important since CSC and PCV differ in terms of their risk factors, natural course, visual prognosis, and treatment.<sup>48</sup>

## Treatment

### Thermal Laser Photocoagulation

Laser photocoagulation has been suggested to be beneficial, albeit with short-term follow-up. The greatest benefit may be for extrafoveal PCV.<sup>49</sup> In some studies that analyzed reported vision outcomes, ICGA-guided laser photocoagulation was successful in stabilizing or improving vision in 55–100% of eyes; however, vision loss occurred in 13–45% of eyes.<sup>32,49–51</sup> Photocoagulation of the whole lesion, compared with polyps only, appears to be more efficacious.<sup>51</sup>

### Photodynamic Therapy

Verteporfin photodynamic therapy (PDT) causes regression or resolution of polyps by its angio-occlusive mechanism of action. In the Everest trial, 71.4% achieved complete occlusion of polyps<sup>12</sup> with resolution of exudative changes after less than three treatments, reduces loss of letters on the ETDRS chart to less than 15, with improved vision in 80–100% of patients after 1 year<sup>52,53</sup>. For treatment-naïve patients the entire PCV lesion as indicated by ICGA (polyps plus the branching vascular network) should be treated.

Common complications reported with verteporfin-PDT therapy are subretinal hemorrhage, recurrence of PCV with leakage from the branching vascular network (BVN), RPE damage or tear, and fibrous scarring. Subretinal hemorrhage is common and can lead to vitreous hemorrhage and consequently a poor outcome.<sup>52–54</sup> Larger lesion size and a leaking vascular net<sup>53</sup> are risk factors for bleeding after PDT.

### Anti-VEGF Therapy

Increased VEGF levels have been observed in PCV patients.<sup>43</sup> Recent studies have demonstrated the usefulness of anti-VEGF therapy for PCV. Reduction in the number of polypoidal complexes was low, achieved in 4/12 (33%) eyes treated with intravitreal ranibizumab<sup>55</sup> and 1/11 (9.09%) eyes with intravitreal bevacizumab.<sup>56</sup>

LAPTOP study is a phase IV prospective multicenter randomized clinical trial with two arms for 12 months: PDT versus ranibizumab, which demonstrated intravitreal ranibizumab is superior to PDT monotherapy in achieving visual gain.<sup>54</sup> The use of intravitreal conbercept has been reported for the management of PCV: 53 patients with PCV were identified at baseline. At month 12, mean changes in best corrected visual acuity (BCVA) from baseline were  $14.4 \pm 14.1$  letter scores for the pooled 0.5 mg group ( $n=25$ ,  $p < .001$ ) and  $14.2 \pm 21.0$  letter scores for the 2.0 mg group ( $n=18$ ,  $p = .011$ ). A gain of  $\geq 15$  letters was observed in 48.0% (12/25) and 44.4% (8/18) of patients receiving 0.5 and 2.0 mg conbercept, respectively.<sup>57</sup> A similar outcome was reported in aflibercept: 48 % and 27% of PCV patients had completely or partially regressed polyps after aflibercept monthly for 3 months.<sup>58</sup>

## Combination Therapy

EVEREST is a multicenter, double-masked, ICGA-guided randomized controlled trial studying patients with symptomatic PCV. Eyes were treated with verteporfin PDT monotherapy, 0.5 mg ranibizumab monotherapy, or a combination of these treatments.<sup>1</sup> Both combination therapy and verteporfin PDT monotherapy were superior to ranibizumab monotherapy in achieving complete polyp regression at month 6. Improvements in BCVA and central retinal thickness (CRT) also favored combination therapy.<sup>12</sup>

The authors of a recent relatively large comparative case series reported that with combination verteporfin PDT plus bevacizumab there were better early BCVA outcomes than with verteporfin PDT alone ( $p = .0016$  for the difference between treatments in mean BCVA change from baseline at 3 months and  $p = .048$  at 12 months).<sup>31</sup> Combination therapy also decreased the rate of PDT-related hemorrhages compared with verteporfin PDT monotherapy (3/61

[4.9%] vs. 15/85 [17.6%], respectively), but did not impact the resolution and recurrence of lesions.<sup>31</sup>

These trials support the selection of ICGA-guided verteporfin PDT with or without combination with ranibizumab as standard preferred treatment options.

## **Introduction**

Albrecht von Graefe first described a disease causing recurrent serous macular detachment and coined the term “central recurrent retinitis” in 1866.<sup>1,2</sup> One hundred years later, Bennet used the term “central serous retinopathy.”<sup>3</sup> In 1967, Gass provided the classic description of the pathogenesis and clinical features of this condition and called it idiopathic central serous choroidopathy (CSC).<sup>4-6</sup> Currently, this chorioretinal disorder is known as central

serous chorioretinopathy (CSCR).

CSCR is a disorder with multifactorial etiology and complex pathogenesis. It typically affects middle-aged men and is characterized by serous neurosensory detachment (NSD) of the retina at the posterior pole. Most cases of CSCR are idiopathic and regress spontaneously within 3–4 months with good visual prognosis.<sup>7</sup> However, some patients suffer from a chronic form of the disease with persistent or recurrent serous macular detachment with progressive visual loss. Advances in indocyanine green angiography (ICGA) and optical coherence tomography (OCT) have led to greater understanding of the pathophysiology and treatment for CSCR. Photodynamic therapy (PDT) using lower doses and reduced fluence has revolutionized the treatment of symptomatic CSCR. Recently, evolving treatment options in the form of antivascular endothelial growth factor (anti-VEGF) and mineralocorticoid receptor (MR) antagonists appear to be promising, but more support from randomized controlled trials (RCTs) is needed before incorporating them into regular clinical practice.

## Definition, Pathogenesis, Risk Factors, and Epidemiology

### Definition

Central serous chorioretinopathy (CSCR or CSC) is a disease characterized by localized and serous detachments of the neurosensory retina with or without focal pigment epithelial detachments (PEDs) and altered retinal pigment epithelium (RPE). The disease causes central visual symptoms due to the presence of serous retinal detachments (SRDs) in the macular area. There are reports of asymptomatic patients presenting with one or multiple episodes of extramacular SRDs, as observed in the contralateral eye of an active CSCR patient or when examining the eyes of relatives of CSCR patients.<sup>8,9</sup>

The disease termed “CSCR” is classically divided into two forms, i.e., acute and chronic. This distinction to some extent depends upon the duration of the SRD and on the presence of extended RPE

changes. The acute form usually resolves within 3–4 months, leaving mostly color discrimination defects in a few patients.<sup>7</sup> The chronic form, which was initially termed as “diffuse retinal epitheliopathy” by Yannuzzi et al. in 1992,<sup>10</sup> is characterized by widespread tracks of RPE atrophy showing reduced fundus autofluorescence (FAF) with or without SRD.<sup>11,12</sup> In this chronic form of disease, in addition to chronic SRD and multifocal RPE atrophic areas, there can be irregular RPE detachments and longstanding intraretinal cystoid cavities, usually seen with disease duration longer than 5 years.<sup>13,14</sup>

## Pathogenesis

The pathophysiology of CSCR is thought to involve multiple etiologies and mechanisms that ultimately lead to widespread choroidal circulatory abnormalities and subsequent RPE disturbances.<sup>15</sup> The hyperpermeability of the choroid can be due to stasis, ischemia, or inflammation, which is evident with the staining of the inner choroid in mid-phase ICGA.<sup>16–19</sup> This is further supported by the enhanced-depth imaging (EDI-) OCT finding of a thickened choroid in both eyes of patients with CSCR.<sup>20</sup> These hyperpermeable choroidal vessels, hypothesized to cause increased tissue hydrostatic pressure, overcome the barrier function of the RPE and lead to the formation of PEDs. This phenomenon is supported by areas of choroidal staining contiguous with the foci of RPE leakage on fluorescein angiography (FA).<sup>16,21,22</sup> Further increases in hydrostatic pressure in the choroid cause breaches in the RPE that allow fluid to enter into the subretinal space. Choriocapillary nonperfusion, as revealed by areas of hypofluorescence on ICGA in patients with CSCR, leading to choroidal venous dilation and congestion, has also been identified as one of the possible causes.<sup>16–18</sup> Focal loss of polarity of RPE cells has also been attributed to causing CSCR by actively pumping fluid into the subretinal space.<sup>23</sup>

Recently, new research has demonstrated the potential involvement of the aldosterone/mineralocorticoid receptor pathway in the pathogenesis of CSCR. In preclinical animal models, intravitreal injection of aldosterone provoked vasodilation,

thickening, and leakage of the choroidal vessels with elongation of RPE cells and accumulation of subretinal fluid, mimicking CSCR.<sup>24</sup>

## Risk Factors

In 1927, Horniker suggested that psychiatric disturbances were linked to CSCR.<sup>25</sup> However, it was Yannuzzi in 1987 who observed a definite association between CSCR and the “type-A” personality pattern.<sup>26</sup> Subsequently, antipsychotic medication use, psychologic stress, and depression were described as independent risk factors for CSCR.<sup>27,28</sup> Recently, a possible association between narcissistic personality and CSCR has been suggested by Carlesimo et al.<sup>29</sup> Patients receiving corticosteroid therapy are at higher risk of developing CSCR.<sup>30-32</sup> Though systemic intake of steroids (both oral and intravenous) is an independent risk factor for CSCR,<sup>27,32,33</sup> it has also been described after local administration of steroids via inhaled, intranasal,<sup>34,35</sup> epidural,<sup>36</sup> intraarticular,<sup>37,38</sup> topical dermal,<sup>39</sup> and periocular<sup>40</sup> routes. Furthermore, there are two reports suggesting the aggravation of preexisting CSCR and the induction of CSCR after vitrectomy with intravitreal triamcinolone injection.<sup>41,42</sup> Steroid-induced CSCR is probably an idiosyncratic response in selected individuals, with less male predilection, frequent bilaterality, and commonly atypical presentation.<sup>43,44</sup> Steroid-induced SRD during corticosteroid treatment for posterior uveitis can be deceptive, and prompt discontinuation of steroid therapy should be advocated once the diagnosis is confirmed.<sup>43</sup> CSCR has also been reported following kidney, bone marrow and heart transplantations.<sup>45-48</sup> Conditions that are associated with increased endogenous cortisol production, such as Cushing disease and pregnancy, increase the risk of having CSCR. In pregnancy, the risk is greatest during the third trimester and usually resolves after delivery.<sup>33,49-51</sup> Patients with hypertension and obstructive sleep apnea also have a higher risk of developing CSCR.<sup>52</sup> Abnormalities in coagulation and platelet aggregation have been proposed as risk factors in the pathogenesis of CSCR.<sup>53</sup> Aqueous sample analysis in patients with CSCR showed lower levels of platelet-derived growth factor (PDGF). This suggests PDGF may play a role in the pathogenesis of CSCR.<sup>54</sup> The role of VEGF in CSCR has not been

proven in studies.<sup>55</sup> Gastroesophageal reflux and *Helicobacter pylori* infection have been separately reported to be associated with CSCR and treatment of the above conditions has been shown to accelerate the rate of subretinal fluid resolution.<sup>56–58</sup> Smoking, antihistamines, alcohol consumption, and allergic respiratory diseases are known to increase the risk of CSCR.<sup>59</sup> Recently, oral MEK inhibitors (binimetinib) used for metastatic cancer were shown to produce transient bilateral SRDs in 65% of patients.<sup>60,61</sup> Though use of phosphodiesterase-5 inhibitors (sildenafil, tadalafil, vardenafil) was shown to cause CSCR, there is conflicting evidence in different studies regarding resolution of the disease after their discontinuation.<sup>62,63</sup>

So far, cases of familial CSCR have been reported in the literature, but no clear transmission pattern or genotype has been found to be associated with the disease.<sup>64–66</sup> In a recent analysis of five families, 50% of the eyes from relatives of CSCR patients had a choroid thicker than 395 nm, suggesting that pachychoroid could be one of the phenotypical indicators and that CSCR may be inherited with a possible dominant transmission pattern.<sup>8</sup>

## Epidemiology

At present, CSCR ranks after age-related macular degeneration (AMD), diabetic retinopathy (DR), and retinal vein occlusion (RVO) as the most common vision-threatening disease.<sup>67</sup> Men are mostly affected in 72–88% of cases,<sup>68</sup> and the annual incidence in a population-based study was six times higher in men than in women.<sup>69</sup> Recent epidemiologic data confer a higher mean age of affected patients than generally assumed, ranging between 39 and 51 years.<sup>69,70</sup> CSCR has rarely been reported in children.<sup>71</sup> The epidemiology of CSCR in older patients (i.e., older than 50 years of age) shows more bilaterality, features of chronic CSCR, female prevalence, and risk of developing choroidal neovascularization (CNV).<sup>69,72</sup> In this age group one should always consider and exclude other differential diagnoses, such as AMD and polypoidal choroidal vasculopathy (PCV).<sup>73</sup>

# Clinical Features

## Demographics

The incidence of CSCR varies among different ethnic groups. A suspected higher frequency is noted among Asians and whites as compared to blacks, and in the latter group CSCR behaves more aggressively with poor visual outcome.<sup>73,74</sup> In Asian populations, CSCR is common and both bilateral and multifocal forms are seen more frequently in this population compared to other ethnic groups.<sup>75</sup> Highly elevated SRD and large pigment epithelial detachments (PED) are also noticed in Asian populations, which often get misdiagnosed as Harada's disease.<sup>76</sup>

## Symptoms

Acute CSCR patients usually complain of symptoms related to the localization of SRD in the macular area (Fig. 75.1). These are mostly blurred vision, relative central scotoma, metamorphopsia, mild to moderate dyschromatopsia, hypermetropization, micropsia, and reduced contrast sensitivity. The anteriorly displaced neurosensory retina causes the eye to become hyperopic and patients often gain benefit from the addition of hyperopic corrective lenses.

**FIG. 75.1** Color fundus of a young male patient with typical central serous chorioretinopathy presenting with circular neurosensory detachment at the posterior pole (*encircled by white ring*).

## Signs

The hallmark of acute CSCR is a well-demarcated round or oval-shaped area of NSD over the posterior pole. This can be associated with one or multiple serous PEDs. Though indirect ophthalmoscopy is sufficient to diagnose SRD, sometimes minimal subretinal fluid or small PEDs can be better detected by slit-lamp biomicroscopy using a 78 D lens. In those patients, the loss of foveal reflex provides a clue for diagnosis. Due to increased visibility of xanthophyll pigments, these patients often have a yellow discoloration of the fovea.<sup>4,50,68,77</sup> Phagocytosed photoreceptor outer segments from the outer retina can sometimes appear as tiny yellow dots at the inner surface of the RPE<sup>78</sup> (Fig. 75.2). The subretinal fluid in acute CSCR is usually transparent but occasionally can become turbid due to subretinal or sub-RPE fibrin deposition<sup>4,68</sup> (Fig. 75.3). This fibrin usually dissolves over time but sometimes coalesces to cause subretinal fibrosis leading to a

permanent decrease in vision. Patients with CSCR can also present with inferior bullous exudative retinal detachment.<sup>79,80</sup> In chronic cases there are areas of RPE change and typical RPE atrophic tract in the fundus, which are located inferiorly due to the gravitational effect of longstanding subretinal fluid. They can also present with chronic cystoid macular edema, subretinal lipid deposition, and secondary CNV.

**FIG. 75.2** Color fundus photograph of a patient with central serous chorioretinopathy showing neurosensory detachment of the parafoveal region, with yellow dots on the posterior surface of the detached retina (*white arrows*).

**FIG. 75.3** This patient with chronic central serous chorioretinopathy showed organized subretinal fibrin with subretinal fluid temporal to the macula. Fluorescein angiography showed areas of retinal pigment epithelial atrophy with multiple pinpoint leaks adjoining the fibrin.

## Differential Diagnosis

### Age-Related Macular Degeneration

CSCR, CNV, and PCV can be grouped together on the spectrum of “pachychoroid” conditions.<sup>81</sup> AMD is the most important differential diagnosis in CSCR patients aged 50 years or older.<sup>18</sup> Secondary CNV (mostly type 2) can develop in patients with chronic CSCR during follow-up or after laser photocoagulation. Although each of the diseases has its own characteristic FA and ICGA features, it might be difficult to differentiate between the two because of diffused and ill-defined leakage. OCT may be helpful in those cases by showing the neovascular complex in AMD.

### Polypoidal Choroidal Vasculopathy

Because of serous macular detachment, RPE alteration, and choroidal hyperpermeability on ICGA, it can be difficult to

distinguish PCV from chronic CSCR. The important points that favor the diagnosis of polyps are subretinal hemorrhage, branching vascular network, and leaking polyps on ICGA. OCT typically shows serosanguineous, notched or hemorrhagic PED and higher optical density of subretinal fluid.<sup>82</sup>

## Optic Disc Pit

Optic disc pits are focal excavations located in the temporal aspect of the optic nerve head creating communication between the vitreous cavity, the subretinal space, and to some extent the subarachnoid space. They have been seen to produce chronic or recurrent serous retinal detachment following schisis of the inner retina in around 45% of cases with variable intraretinal cystoid edema. The diagnosis can be confirmed clinically by careful peripapillary examination and the absence of leakage on FA of optic disc pits.

## Inflammatory and Infectious Diseases

Vogt–Koyanagi–Harada (VKH) disease is a multisystemic disorder with bilateral granulomatous panuveitis, which often presents with multiple serous retinal detachments mimicking CSCR. Apart from its systemic, neurologic, and dermatologic signs, the presence of vitritis, increased choroidal thickening on ultrasound, and pinpoint multifocal leaks on FA readily distinguish it from CSCR. Posterior scleritis can also present with serous retinal detachment. In this case, however, patients frequently experience pain on ocular movement and ultrasound B-scans demonstrate thickening of the suprachoroidal space with the characteristic T-sign. Hence, differentiation for these conditions is of utmost importance, as unlike CSCR, systemic steroids are the mainstay of treatment. Other inflammatory conditions causing SRD include sympathetic ophthalmia, uveal effusion syndrome, and benign reactive lymphoid hyperplasia of the choroid. Presumed ocular histoplasmosis syndrome (POHS) is an infectious disease that may cause SRD like CSCR, but it has characteristic punched-out peripheral chorioretinal lesions and peripapillary atrophy.

## Autoimmune and Vascular Disorders

Autoimmune diseases such as systemic lupus erythematosus, polyarteritis nodosa, and scleroderma produce fibrinoid necrosis of the choroidal vessels. The disease process itself and sometimes systemic steroid therapy can lead to SRD, complicating the outcome. A few nonautoimmune conditions like malignant hypertension, toxemia during pregnancy, and disseminated intravascular coagulopathy can also present with NSD secondary to choroidal arterial occlusion.

## Intraocular Tumors

Various types of choroidal tumors, including choroidal hemangioma, choroidal melanoma, choroidal osteoma and choroidal metastasis, can cause exudative macular detachment mimicking CSCR. It is important to differentiate a malignant and potentially lethal condition from CSCR. Most of the time, large tumors are detected clinically, but sometimes small tumors, especially choroidal hemangiomas, are difficult to discern in the presence of subretinal fluid. Ultrasonography is useful in detecting and differentiating the nature of the tumor. In hemangiomas, ICGA shows a classical “wash-out” phenomenon in late phases of angiography and EDI-OCT shows increased caliber of medium and large choroidal vessels in the tumor with normal choriocapillaries.<sup>83</sup>

## Dome-Shaped Macula

Dome-shaped macula is a forward bulge of the macula within a posterior pole staphyloma in myopic eyes; fluctuating serous foveal detachment is observed in around 50% of these eyes.<sup>84</sup> This condition can be associated with pinpoint leakage on FA, small PEDs, and greater subfoveal choroidal thickness on OCT, making it difficult to differentiate from CSCR.<sup>85</sup> SRDs resolve spontaneously in most cases. In chronic and persistent SRDs there are studies reporting good results with half-fluence PDT and oral spironolactone.<sup>86,87</sup>

# Ancillary Testing

## Optical Coherence Tomography (OCT)

Spectral domain (SD-OCT) and recently, enhanced-depth imaging and swept-source technologies, have made the understanding of CSCR better by allowing better full-depth visualization of the neurosensory retina, RPE, choroid, and choroidal vessels.

Hyperreflective dots on SD-OCT seen in the subretinal space and within retinal layers correspond with the hyperautofluorescent area on FAF.<sup>88–90</sup> Throughout the disease process, an increased number of dots tends to correlate with worse final visual acuity.<sup>91</sup>

Elongation of photoreceptor outer segments in the area of a macular SRD is a frequent SD-OCT finding in CSCR. Frequently, erosion of photoreceptor outer segments is visible on SD-OCT at the site of leakage, suggesting mechanical abrasion from active flow through the RPE break. Serous PED is seen in 50–100% of CSCR-affected eyes.<sup>92,93</sup> In active CSCR cases, a combination of SD-OCT with FA identified an elevation of the RPE or a PED at the leakage sites in most or all cases<sup>94</sup> (Fig. 75.4). Compared to healthy subjects, increased choroidal thickness has been reported in both affected and fellow eyes of CSCR patients.<sup>94,95</sup> Localization of PEDs in the areas of dilated, large choroidal vessels and thickened choroid on SD-OCT, (Fig. 75.5) and with vascular hyperpermeability on ICGA, suggests the role of choroidal flow deregulation in the pathogenesis of PED.<sup>94</sup> In chronic CSCR, there can be hyperreflective content over the Bruch membrane, creating a “double layer sign” on OCT.<sup>93</sup>

Quantitative measurement and thickness maps taken serially can be used to assess disease progression and response to treatment.

Treatment response to photodynamic therapy (PDT) when evaluated with EDI-OCT has shown a 20% reduction in subfoveal choroidal thickness one year after half-fluence treatment.<sup>96</sup> Thinning of the outer nuclear layer, chronic cystoid degeneration, and disruption of the ellipsoid zone (junction of the inner and outer segments of the photoreceptors) on OCT are associated with poorer visual outcome.<sup>89</sup>

**FIG. 75.4** This 45-year-old male presented with a right eye relative scotoma for 3 weeks. (A) Clinical examination showed subretinal fluid together with a pigment epithelium detachment (PED) in the macula. Optical coherence tomography (OCT) shows PED with subretinal fluid. Fluorescein angiogram (FA) showed initial pooling of dye in the PED followed by leakage. (B) Left eye showed PED in fundus photo and OCT with pooling of dye on FA.

**FIG. 75.5** Enhanced-depth imaging spectral domain optical coherence tomography showed an increase of subfoveal choroidal thickness in a patient with acute central serous chorioretinopathy.

## Fundus Autofluorescence

FAF mostly originates from the RPE lipofuscin and reflects RPE health. It allows for noninvasive detection of the changes seen at different phases and forms of CSCR. Focal areas of hypoautofluorescence corresponding to the leakage points in acute CSCR are observed in 70–100% of eyes. This supports the hypothesis of a focal RPE defect or detachment<sup>90</sup> (Fig. 75.6). The SRD in acute CSCR also shows hypoautofluorescence due to the masking effect of SRF and elongated photoreceptors. As the disease progresses to become persistent or chronic, with the resolution of subretinal fluid, there is increasing hyperautofluorescence due to the accumulation of non-shed fluorophores. The pattern of this

change in FAF has been shown to correlate with visual acuity.<sup>97</sup> FAF can be pathognomonic in chronic CSCR by multiple hypoautofluorescent “gravitational tracks” with a thin border of surrounding hyperautofluorescence<sup>98,99</sup> (Fig. 75.7).

**FIG. 75.6** This 38-year-old man with central serous chorioretinopathy was treated with ill-defined laser for submacular fluid before he presented to us with active pinpoint leakage on fluorescein angiography of the left eye. Fundus autofluorescence showed increased autofluorescence suggestive of longstanding subretinal fluid with point hypoautofluorescence (*black arrow*) corresponding with the leak on angiography.

**FIG. 75.7** The left eye of a patient after renal transplant on long-term systemic steroids showing multifocal pinpoint leaks in central serous chorioretinopathy. Note the hypoautofluorescent patches (*white arrow*) with surrounding hyperautofluorescence (*black arrow*) suggestive of the chronic nature of the disease.

## Fluorescein Angiography (FA)

FA in acute CSCR classically shows leakage in either an inkblot or smokestack pattern. In the former, the leakage starts as a pinpoint in the early phase and then concentrically enlarges in the late phase to appear as an inkblot (Fig. 75.8). In smokestack appearance, the leakage again starts as a pinpoint in the early phase, but gradually the hyperfluorescence ascends and expands to form a mushroom

cloud or umbrella-like appearance. The smokestack pattern (Fig. 75.9) is less frequent and appears in only about 10–15% of patients with acute CSCR, especially in the very early stage.<sup>100</sup> It is caused by an increased protein concentration in the subretinal fluid. Chronic CSCR shows diffuse RPE window defect and patchy hyperfluorescence due to RPE atrophy (Fig. 75.3). Multifocal CSCR would show multiple sites of leakage (Fig. 75.7). FA is also useful in differentiating CSCR from other conditions such as CNV and VKH and helps in diagnosing unnoticed extramacular leaks in the affected or fellow eye.

**FIG. 75.8** Inkblot leakage (fluorescein angiogram). The hyperfluorescence starts as a pinpoint and then enlarges circumferentially to produce intense

hyperfluorescence in the late phase similar to the appearance of a drop of ink on a piece of paper.

**FIG. 75.9** Smokestack appearance (fluorescein angiogram). The hyperfluorescent spot starts as a pinpoint and then diffuses upward and laterally to give a mushroom cloud or umbrella-like appearance.

## Indocyanine Green Angiography

ICGA is one of the most important investigations in CSCR because it demonstrates the choroidal vascular changes that contribute to the disease process and can act as a guide to treatments such as photodynamic therapy (PDT). ICGA in CSCR shows delay in choroidal filling in the early phase with hypofluorescent areas resulting from nonperfusion of choriocapillaries. This leads to choroidal venous dilatation that results in geographic areas of

hyperfluorescence, which indicates choroidal hyperpermeability in the mid phase (Fig. 75.10). In the late phase there is either washout or persistent hyperfluorescence. In addition, punctate hyperfluorescent spots are often seen in the mid- and late phases in 80–90% of active CSCR patients.<sup>101</sup> The area of choroidal vascular abnormality seen in ICGA is frequently bilateral and usually much more widespread than the leakage seen on FA.

**FIG. 75.10** Confocal scanning laser ophthalmoscope allows for simultaneous scanning and provides more information on macular changes in central serous chorioretinopathy patients. (A) Multicolor imaging showing dome-shaped neurosensory detachment (NSD); (B) hypoautofluorescence of NSD; (C) pinpoint leak on fluorescein angiography; and (D) dilated choroidal vessels on indocyanine green angiography.

## Multifocal Electroretinography

Multifocal electroretinography (mfERG) can indicate widespread retinal dysfunction in CSCR beyond what is appreciated on clinical examination. First- and second-order kernel mfERG response amplitudes are reduced in patients with CSCR.<sup>102</sup> First-order kernel mfERG amplitudes are reduced in the center and the second-order responses are predominately reduced in the peripheral retina. This suggests that, though outer retinal dysfunction is localized in the center, inner retinal dysfunction might extend beyond the border of visible SRD and can be seen in the fellow eye also. Unlike OCT, mfERG response amplitudes were found to correlate with visual acuity.<sup>102,103</sup> The amplitude of mfERG improves markedly after resolution of subretinal fluid but does not return to baseline.

## Microperimetry

Microperimetry allows functional assessment of macular sensitivity in patients with CSCR. In acute CSCR, presence of subretinal fluid causes reduced macular sensitivity in both the central and paracentral areas. It has been shown to improve; however, the condition never reverts to normal after resolution of subretinal fluid with or without treatment.<sup>104,105</sup> More often there are residual focal areas of reduced sensitivity, which correspond to RPE irregularities or defects at the ellipsoid layer on OCT. Moreover, macular sensitivity demonstrated correlation with central macular thickness on OCT and visual acuity, suggesting the existence of structural and functional correlation in CSCR.<sup>106</sup>

## Natural History

Most acute CSCR patients show spontaneous visual recovery within 3–4 months. However, some patients may progress to chronic or recurrent diseases, which lead to areas of RPE atrophy and pigmentation in the macular area with subsequent visual loss. Poor visual acuity on presentation and long-standing macular detachment suggest worse prognosis. Up to 50% of patients with CSCR develop recurrence within the first year of presentation.<sup>107</sup> A

history of psychiatric illness, especially depression, is associated with a higher rate of recurrence. A small proportion of patients develop irreversible visual loss due to gross RPE atrophy, subretinal fibrosis, development of CNV (0.3–2% per patient per year)<sup>108</sup> or chronic cystoid macular degeneration (CMD) (Fig. 75.11). According to the study by Ooto et al., eyes with resolved CSCR with 20/20 or better visual acuity had reduced cone density with preserved ellipsoid zone when analyzed with adaptive optics scanning laser ophthalmoscope, compared to controls.<sup>109</sup> This explains the presence of residual symptoms like metamorphopsia, scotoma, reduced contrast and color sensitivity even in patients with well recovered vision after resolution of acute CSCR. Thus, the loss of photoreceptors in eyes with good acuity emphasizes the subclinical functional loss that patients can experience after even a single episode of CSCR.

**FIG. 75.11** This 52-year-old woman on oral steroids for a long duration presented with longstanding dimness

of vision in both eyes. Her right eye showed gross retinal pigment epithelial defects and chronic cystoid macular degeneration on optical coherence tomography suggestive of chronic central serous chorioretinopathy. Indocyanine green angiography demonstrated dilated choroidal vasculature in the early phase and late diffuse patchy hyperfluorescence.

## Treatment

### Observation With or Without Removal of Risk Factors

Acute CSCR is a self-limiting disease, with reattachment of the neurosensory retina occurring within 3–4 months in the majority of cases.<sup>19</sup> Because of this favorable natural history, observation has been considered as an appropriate first-line approach. As high levels of endogenous or exogenous corticosteroids have been implicated as an etiology for CSCR, discontinuation of steroids in any form (i.e., systemic, nasal sprays, intraarticular injections, topical ointments) is advocated. Correction of corticosteroid level, when possible, can lead to resolution of detachment in 90% of cases. Lifestyle modification, treatment of sleep apnea, and psychosocial therapies also help in affected CSCR patients prone to psychologic stress.<sup>110,111</sup> In CSCR, recurrences occur in approximately 20–50% of patients within one year. Patients with frequent recurrences or chronic neurosensory retinal detachment for around 4 months may develop foveal attenuation, cystoid macular degeneration, and widespread RPE atrophy, resulting in permanent loss of visual functions.<sup>112</sup> Therefore, though observation is the standard initial management in most cases of acute or classic CSCR, active treatment should be initiated when symptoms persist for more than 3 months.<sup>113</sup> Treatment usually accelerates visual recovery but no treatment can maximize final visual gain.<sup>111</sup> In this situation, any treatment other than observation should be applied judiciously in susceptible patients with persistent serous macular elevation and RPE atrophic areas with subtle leaks on FA.<sup>10,68</sup> Early treatment is recommended in cases where rapid recovery of vision is required

for vocational or other reasons, and also when untreated CSCR has previously resulted in a poor visual outcome in the fellow eye.<sup>114</sup>

## Historical Thermal (Argon) Laser Photocoagulation and Micropulsed Diode Laser

Laser photocoagulation, when applied to the RPE leakage points, causes direct thermal sealing effects on focal RPE defects that promote a healing response and favor stimulation of surrounding RPE cells.<sup>115</sup> This often hastens the resolution of NSD but rarely alters final visual outcome or rate of recurrence.<sup>28</sup> This may be due to the fact that zonal hyperperfusion and hyperpermeability of the choriocapillaries, the presumptive pathophysiology in CSCR, are not amenable to laser photocoagulation therapy.<sup>96</sup> This promising treatment method has become less favored in recent years because of significant adverse effects such as permanent scotoma, enlargement of RPE scar, secondary laser-induced CNV formation, and, rarely, inadvertent foveal photocoagulation in cases of subfoveal or juxtafoveal leak.<sup>115-117</sup> Thermal laser photocoagulation is now indicated in the management of CSCR with discrete, solitary extrafoveal leakage points with persistent NSD (Fig. 75.12). Situations with multiple leaks, subfoveal or juxtafoveal leak, and bullous exudative RD are better managed by safety-enhanced PDT rather than argon laser photocoagulation.

**FIG. 75.12** Resolved subretinal fibrin and subretinal fluid in longstanding central serous chorioretinopathy following focal laser to extrafoveal leakage.

There has been a renewed interest in using micropulse diode laser, instead of conventional argon laser photocoagulation, to treat CSCR.<sup>118–122</sup> The diode laser with ultrashort 810-nm micropulsed emissions enables subthreshold therapy to the RPE and choroid without a visible burn endpoint, reducing the risk of structural and functional retinal damage. In a series of 30 patients, the diode group had faster visual recovery and better final contrast sensitivity than the argon laser group without any persistent scotoma.<sup>123</sup> A small case series has also demonstrated the beneficial effect of using indocyanine green dye-enhanced micropulse diode laser photocoagulation at the end of 1-year follow-up.<sup>122</sup> Nevertheless, the efficacy and safety of micropulse diode laser in instances involving more than one leakage point, as commonly encountered in chronic CSCR, are not proved and RCTs are necessary to fully substantiate the treatment efficacy and safety of micropulse diode laser in the management of CSCR.

## Photodynamic Therapy (PDT)

The results of the TAP and VIP studies in the management of age-related macular degeneration with PDT encouraged some researchers to use PDT in selected CSCR patients.<sup>73,124</sup> There are confirmed reports showing the efficacy and favorable visual outcomes of ICGA-guided PDT to treat CSCR in a majority of cases.<sup>22,125–129</sup> The analyzed mechanism of action of PDT that causes narrowing of choriocapillaries, choroidal hypoperfusion, and choroidal vascular remodeling supports its use as treatment for CSCR, which is thought to be primarily a choroidal vascular disorder; success of PDT has also been shown to depend upon the degree of hyperpermeability on ICGA.<sup>128–132</sup> However, in AMD the use of conventional PDT has revealed RPE atrophy, choriocapillaris ischemia, and secondary CNV as potential vision-threatening complications.<sup>127,128</sup> Therefore, in recent years there has been a constant effort to apply PDT in the safest form to reduce the risk of iatrogenic adverse effects in symptomatic CSCR patients.

### Conventional PDT With Normal Dosage and Fluence

The standard PDT for treatment of neovascular AMD is performed using 6 mg/m<sup>2</sup> infusion of verteporfin (Visudyne, Novartis AG, Bülach, Switzerland). A 30-mL infusion of verteporfin is administered for 10 minutes, followed by delivery of laser at 689 nm 15 minutes after the commencement of infusion. A total light energy of 50 J/cm<sup>2</sup>, intensity of 600 mW/cm<sup>2</sup>, and photosensitization time of 83 seconds is delivered, with a spot size diameter of 1000 µm larger than the greatest linear dimension of the lesion. There has been normalization in calibers of the congested choroidal vasculature with a decrease in extravascular leakage in cases treated with PDT in a few pilot studies.<sup>128</sup> In a recent meta-analysis, all 10 studies that met standard STROBE criteria<sup>133</sup> showed significant improvement in best corrected visual acuity (BCVA) after conventional PDT treatment.<sup>134</sup> However, the possible posttreatment visual loss, potential choroidal ischemia, RPE atrophy, and risk of developing CNV have restricted clinicians from the widespread application of standard dose PDT in CSCR patients.<sup>111,127,135,136</sup>

## Safety-Enhanced PDT With Reduced Verteporfin Dosage

As conventional PDT treatment poses certain potential iatrogenic hazards to patient's vision, many studies of CSCR have tried to modify the dosage of verteporfin or reduce the fluence of laser application to enhance the efficacy of PDT while minimizing its side-effects.<sup>111,135</sup> It has been demonstrated that after 10 minutes of infusion, the concentration of verteporfin is greatest in the choroidal circulation and least at the retinal outer segment.<sup>137</sup> In PDT, photochemical response in the choroid is dose–response-dependent and the aims of these studies were to lower the risk of retinochoroidal complications without compromising the vascular remodeling ability of PDT.<sup>96</sup> Safety-enhanced PDT was performed using half the normal dose of verteporfin at 3 mg/m<sup>2</sup> with 10 minutes of infusion, followed by a delivery of 689 nm laser after 5 minutes. A total light energy of 50 J/cm<sup>2</sup> was delivered within 83 seconds.<sup>135</sup> The well-known safety issues, such as impairment of retinal function associated with full-dose PDT, were alleviated in this half-dose regimen.<sup>135,138</sup> In a RCT, Chan and associates showed complete resolution of fluid in 79.5% and 94.9% of the half-dose PDT-treated eyes at 1 and 12 months, respectively, with only 1 recurrence.<sup>135</sup> Recently, one study reporting the long-term results of half-dose PDT in chronic CSCR patients without posterior cystoid retinal degeneration showed a dry macula at 12 months' follow-up for all 27 eyes<sup>139</sup> (Fig. 75.13). Eyes without PED, duration of CSCR for less than 6 months, and age younger than 45 years were more likely to achieve better visual outcome after treatment. Though studies have tried lower doses of verteporfin, it is the 3-mg group that had the best results in terms of BCVA and central foveal thickness (CFT) reduction at 6 months' follow-up<sup>135,140–142</sup> (Fig. 75.14). In spite of the encouraging results on the safety of half-dose PDT in the management of CSCR, it is essential to individualize management plans due to the absence of a large RCT to document treatment complications. The role and limitations of PDT in CSCR should be clearly emphasized to patients, as most of them will have good visual potential, and there have been sporadic observations of transient impairment of multifocal ERG response and development of juxtafoveal CNV with the use of half-dose PDT.<sup>143</sup>

**FIG. 75.13** This 33-year-old male presented with a right eye relative scotoma for more than 3 months. (A) Optical coherence tomography (OCT) showed neurosensory detachment of the macula. (B–D) Resolution of subretinal fluid and restoration of normal architecture of the macula after photodynamic treatment (PDT) shown on OCT. On longitudinal follow-up the choroidal thickness has also decreased after PDT.

**FIG. 75.14** This 42-year-old male presented with a left eye persistent central scotoma for more than 4 months. (A) Optical coherence tomography showed mild neurosensory detachment of the macula (B). (C,D) Resolved subretinal fluid after photodynamic treatment and restoration of relatively normal architecture of the choroid.

### **Safety-Enhanced PDT With Reduced Laser Fluence**

Similar to drug dosage, another parameter that can be modified to enhance the safety of PDT is the intensity of the laser fluence. For instance, improved efficacy and safety profiles of low fluence PDT have been documented in the management of chronic CSCR.<sup>144-146</sup>

An RCT by Bae et al.<sup>146</sup> compared half-fluence PDT with intravitreal ranibizumab (0.05 mL) in 16 eyes of chronic CSCR patients and found complete resolution of SRF at 6 months in 75% of the half-fluence group compared to 25% in the ranibizumab group. The low fluence PDT group also showed significant CFT reduction at the

end of 9 months. In two other studies, Shin et al.<sup>145</sup> and Reibaldi et al.<sup>144</sup> compared standard versus half-fluence PDT and both authors reported better BCVA in the half-fluence group at the end of 12-month follow-up compared to the standard group. A recent retrospective study of 56 chronic CSCR patients treated with half-dose and half-fluence PDT divided in equal numbers showed a complete resolution of SRF in 19 (61.3%) and 26 (83.9%) half-fluence-treated eyes at 1 and 12 months, respectively. The corresponding values were 25 (86.2%) and 29 (100%) in the half-dose-treated eyes without any statistical difference in BCVA between the groups. There were 15 and 5 recurrences overall in the half-fluence PDT and half-dose PDT groups, respectively.<sup>147</sup> The meta-analysis by Erikitola et al. also concluded that 100% of the subjects in the reduced fluence group and 42.9% of the subjects in the half-dose group had recurrence within the 1-year follow-up period.<sup>134</sup> Therefore, half-dose PDT can be more cost-effective and superior to half-fluence in keeping the macula dry for a longer period with fewer retreatments. However, the lack of quality RCTs to discern either short-term or long-term safety, coupled with reports of complications, is sufficient to remind clinicians of the importance of caution and individualization when managing CSCR with reduced dose or lowered fluence PDT.

## Anti-Vascular Growth Factor (VEGF) Injections

The favorable results of anti-VEGF treatment in macular diseases have led to several studies on anti-VEGF in patients with CSCR. Although CSCR is not associated with increased VEGF aqueous or plasma levels,<sup>148</sup> anti-VEGF therapy was proposed in CSCR to reduce choroidal hyperpermeability.<sup>149</sup> A limited number of interventional case series have reported beneficial effects of bevacizumab in terms of visual acuity improvement and SRF reduction without significant complications.<sup>150-152</sup> Of the two randomized studies, the first by Lim et al. showed no difference in terms of visual acuity gain, CFT reduction, or duration of SRD between the bevacizumab and control groups.<sup>153</sup> The second study by Bae et al. showed a superior effect of half-fluence PDT over

ranibizumab.<sup>146</sup> More recently, aflibercept was used in a pilot study of 12 patients with persistent fluid over 6 months, which showed a moderate effect on SRF and CFT reduction.<sup>154</sup> A recent meta-analysis of 4 studies including acute and chronic CSCR showed no significant improvement with intravitreal bevacizumab compared to observation, PDT, or laser photocoagulation in terms of final visual acuity and central macular thickness.<sup>149</sup> Though the role of bevacizumab,<sup>155</sup> ranibizumab,<sup>156</sup> and aflibercept<sup>157</sup> in CSCR-related CNV is accepted, the long-term benefit and safety issues in different types of CSCR still warrant further study.

## Miscellaneous Treatments

### Transpupillary Thermotherapy

Transpupillary thermotherapy (TTT) is a long-pulse, low-energy, 810-nm near infrared laser, which causes choroidal vascular thrombosis and is used in the treatment of choroidal tumors. A few people have expressed their preference for performing TTT at the site of focal juxtafoveal leakage instead of using thermal laser.<sup>158</sup> Wei and colleagues were the first to report the use of TTT for CSCR, describing the complete resolution of subretinal fluid 4 weeks after TTT in a case of chronic CSCR with no observed visual improvement.<sup>159</sup> In a large unmasked, nonrandomized, prospective cohort study with unmatched control of 15 eyes, 96% of the 25 treated with TTT experienced complete resolution of neurosensory retinal detachment and focal leakage on FA at 3 months. Visual acuity improved significantly in 92% of cases compared with 33% of the control group.<sup>160</sup> Because of the longer duration of disease in the control group, it is difficult to confidently accept the outcomes in this study. Therefore, well-controlled, properly matched RCTs are warranted to determine the precise role and efficacy of TTT in the management of CSCR.

### Systemic Medications

#### Anticorticosteroid Therapy.

Patients with CSCR commonly have endogenous hypercortisolism, which has resulted in trials of medications targeting cortisol

pathways.<sup>161</sup> These include ketoconazole, mifepristone (RU486), finasteride, rifampin, and antiadrenergic drugs. Ketoconazole interferes with endogenous glucocorticoid production in part by inhibiting the conversion of 11-b-deoxycortisol to cortisol. Two groups have investigated ketoconazole as a treatment for CSCR without any significant benefit.<sup>162</sup> Nielsen and colleagues investigated oral mifepristone, an abortifacient with glucocorticoid receptor antagonist properties, in 16 chronic CSCR subjects with varied response.<sup>163</sup> Finasteride, an inhibitor of 5-alpha-reductase that converts testosterone to the potent androgen dihydrotestosterone, has been investigated in CSCR.<sup>164</sup> Packo et al. found that rifampicin, a semisynthetic antituberculosis antibiotic with an inhibitory effect on endogenous steroid production, caused resolution of macular edema and subretinal fluid in a CSCR patient initially suspected to have tuberculosis. Rifampicin has been investigated in a small series<sup>165</sup> but further research into using corticosteroid antagonists in the treatment of CSCR is warranted. The rationale for adrenergic blockade to treat CSCR is the glucocorticoid-mediated increased expression of adrenergic receptors.<sup>166</sup> Yoshioka's monkey model prevented the development of experimental CSCR by blocking alpha-adrenergic receptors.<sup>167</sup> In a recent retrospective consecutive case series, patients received oral eplerenone, a competitive antagonist to the mineralocorticoid receptor (MR), for chronic CSCR. MR activation in choroidal vessels has been shown to be involved in the pathogenesis of CSCR. A total of 17 eyes of 13 patients treated with 25 and 50 mg of oral eplerenone per day showed an improvement of logMAR visual acuity from 0.42 at baseline to 0.29 and decreased subfoveal thickness from 339.5  $\mu\text{m}$  to 270  $\mu\text{m}$  at 6 months.<sup>168</sup> Though these studies provide hope for the medical management of CSCR, there is a need for extensive research with longer follow-up before these drugs can be accepted as primary oral therapy in CSCR.

### **Carbonic Anhydrase Inhibitors.**

Oral acetazolamide was tried as a treatment for CSCR on the basis that the inhibition of carbonic anhydrase in the RPE seemed to promote resorption of SRF and retinal adhesion.<sup>169</sup> Patients treated with acetazolamide had faster subjective improvement in vision,

but it did not alter final visual outcome or recurrence rates.<sup>170</sup>

### **Aspirin.**

A report showing increased levels of plasminogen activator inhibitor in CSCR patients compared to controls led to the hypothesis that hypercoagulability can play a role in CSCR pathogenesis.<sup>171</sup> In a nonrandomized, open-label case series, 109 patients had more rapid visual recovery, reduced rates of recurrence, and slightly better visual outcome than the control group after an aspirin regimen of one 100-mg tablet daily for 1 month followed by 100-mg on alternating days for 5 months.

### **Anti-*Helicobacter pylori* Treatment.**

A prospective study of 25 *H. pylori*-positive CSCR patients treated with the standard *H. pylori* eradication regimen (metronidazole and amoxicillin 500 mg three times per day for 2 weeks and omeprazole once per day for 6 weeks) demonstrated complete subretinal fluid reabsorption compared to 25 controls, without any effect on final visual outcomes or recurrence rate.<sup>172</sup> The exact pharmacopeia of the above-mentioned systemic treatments for CSCR is not clearly understood and will require well-designed studies to establish their long-term efficacy and safety.

## **Conclusion**

The pathophysiology of CSCR remains uncertain. It is a multifactorial disease and seems to result from a complex interaction of both known and unknown environmental and genetic factors. The role of choroidal vascular hyperpermeability related to the deranged mineralocorticoid pathway in the pathogenesis of CSCR is interesting but needs more scientific support. Though the natural history of CSCR has been thought to be favorable, frequent reports of significant anatomical and functional loss even from a mild course of the disease and the risk of frequent recurrences require early effective treatment. Advances in imaging techniques have not only resulted in more accurate diagnosis and management but have also broadened the horizons for the development of new treatments. To date, we do not have appropriate guidelines for the

management of CSCR and new modes of therapy are being developed regularly. We have tried to emphasize a simple evidence-based diagnostic and treatment algorithm, which can be beneficial for handling CSCR patients in everyday practice (Fig. 75.15). Of the described treatment options, safety-enhanced PDT using lower doses, oral corticosteroid antagonists, intravitreal anti-VEGF therapy, and micropulse diode laser do merit further research. Combination therapies involving the above treatment modalities may have a role in preventing permanent visual loss in this so-called benign disease and thus warrant additional studies in the form of large-scale randomized trials.

AR = Autorefraction; Anti-VEGF = Anti-vascular endothelial growth factor; BCVA = Best corrected visual acuity; BIO = Binocular indirect ophthalmoscope; CME = Cystoid macular edema; CSCR = Central serous chorioretinopathy; Dx = Diagnosis; FA = Fluorescein angiography; ICGA = Indocyanine green angiography; IV = Intravitreal; OCT = Optical coherence tomography; PDT = Photodynamic therapy; Tx = Treatment

# Uveal Effusion Syndrome and Hypotony Maculopathy

---

*Cagri G. Besirli, Mark W. Johnson*

## **Uveal Effusion Syndrome Hypotony Maculopathy**

The clinical observation of abnormal serous fluid accumulation in the outer layer of the ciliary body and choroid is called uveal effusion. This exudative detachment of the choroid and the ciliary body is also known as ciliochoroidal effusion, ciliochoroidal detachment, choroidal effusion, or choroidal detachment. These names are used interchangeably in this chapter. Uveal effusion does not refer to a specific entity, but this name is used as the common term to describe a pathoanatomic condition caused by several ocular and systemic disorders. Uveal effusion is frequently associated with nonrhegmatogenous retinal detachment, secondary to the chronic accumulation of protein-rich fluid in the choroid and

the breakdown of the retinal pigment epithelial fluid barrier. The term “idiopathic uveal effusion syndrome” or “uveal effusion syndrome” in short refers to the presence of ciliochoroidal effusion in an eye with no other known associated ocular or systemic disorder. Uveal effusion syndrome typically occurs spontaneously in an otherwise healthy middle-aged man.

Hypotony maculopathy refers to the structural changes in the macular region and related visual dysfunction that may develop in an eye with low intraocular pressure. In addition to the changes in the macular region, hypotony may be associated with other posterior-segment abnormalities, including optic nerve swelling, vascular tortuosity, and chorioretinal folds. The vision loss may be profound in the setting of persistent ocular hypotony, but visual improvement is typical after intraocular pressure is restored.

## Uveal Effusion Syndrome

### Introduction

Spontaneous exudative detachment of the choroid and ciliary body was first reported by Schepens and Brockhurst in 1963;<sup>1</sup> these authors used the term “uveal effusion” in their description of this disorder. Almost two decades later, Gass and Jallow in 1982 coined the term “idiopathic uveal effusion syndrome” to describe idiopathic serous detachment of the choroid, ciliary body, and retina.<sup>2</sup> Uveal effusion syndrome is a rare ocular disorder that typically manifests itself in an otherwise healthy middle-aged male. In their original report, Schepens and Brockhurst described 17 patients, only one of whom was female. The diagnosis of uveal effusion syndrome is based on characteristic clinical findings and exclusion of other known causes of uveal effusion. Bilateral involvement is common, and unilateral cases tend to occur in older males. In addition to the accumulation of serous fluid in the ciliary body and choroid, nonrhegmatogenous retinal detachment with marked shifting of the subretinal fluid is commonly observed in patients with uveal effusion syndrome. Retinal detachment often begins inferiorly, as in other causes of exudative retinal detachment. Other ocular findings include dilation of the episcleral

blood vessels, blood in Schlemm's canal, normal intraocular pressure, mild vitreous cells, leopard-spot retinal pigment epithelial alterations, elevation of the subretinal fluid protein levels, and elevation of the cerebrospinal fluid protein. Without treatment, a protracted clinical course with remissions and exacerbations over many months to years may cause significant visual decline and morbidity. Unlike other causes of ciliochoroidal effusion, patients with idiopathic uveal effusion syndrome respond poorly to nonsurgical treatment, including corticosteroids or antimetabolites. Similarly, surgical treatment of nonrhegmatogenous retinal detachment in uveal effusion syndrome using conventional techniques, including scleral buckling or pars plana vitrectomy, fails to reattach the neurosensory retina secondary to persistent serous exudation. In most cases, successful reattachment of the nonrhegmatogenous retinal detachment requires a scleral-thinning procedure, including quadrant partial-thickness sclerectomies and sclerostomies.

## Pathophysiology of Ciliochoroidal Effusions

### General Mechanisms

Since idiopathic uveal effusion syndrome represents only a small percentage of ciliochoroidal effusions, it is important to discuss the general mechanisms of serous accumulation in the ciliary body and choroid. Most cases of ciliochoroidal effusion can be classified into one of the following pathophysiologic categories: (1) hydrodynamic; (2) inflammatory; (3) neoplastic; or (4) associated with abnormal sclera.<sup>3</sup> Under physiologic conditions, a normal eye has equilibrium between the transmural hydrostatic pressure gradient, defined as the difference between the intravascular blood pressure and intraocular pressure, and the colloid osmotic pressure gradient of the choriocapillaris (Fig. 76.1). Albumin is the most abundant protein in the choroidal capillaries and is the primary driver of the colloid osmotic pressure. This pressure gradient draws fluid into blood vessels and maintains relative dehydration of the suprachoroidal space due to a low extravascular colloid concentration.<sup>4</sup> Fenestrated capillaries of the choroid allow albumin to escape into the extravascular space. To maintain the colloid

osmotic gradient, albumin leaves the choroid across the sclera, and this transscleral protein flow is facilitated by intraocular pressure.<sup>5-7</sup>

**FIG. 76.1** In normal choroidal capillaries, the transmural hydrostatic pressure gradient is in equilibrium with the colloid osmotic pressure gradient. Colloids escaping the fenestrated capillaries move across the sclera by bulk flow, driven by intraocular pressure (*IOP*). *BP*, blood pressure. (From Johnson MW. Uveal Effusion. In: Guyer DR, Yannuzzi, L.A., Chang, S., Shields, J.A., Green, W.R., editor. *Retina-Vitreous-Macula*. Philadelphia: W.B.Saunders.)

The fluid equilibrium across the layers of the choroid may be disturbed by several factors affecting one or more components of this intricate system.<sup>3</sup> Ocular hypotony decreases the driving force for transscleral protein flow and increases the transmural hydrostatic pressure gradient. These changes then facilitate the accumulation of protein and fluid in the suprachoroidal space. Elevated uveal venous pressure increases the transmural hydrostatic pressure gradient and leads to increased fluid movement into the extravascular space. Vascular competence may be compromised by inflammation, which then increases capillary protein permeability and accumulation of protein in the extravascular space. This reduces the colloid osmotic pressure gradient and the absorption of extravascular fluid into the capillaries. Abnormal scleral composition or thickness may increase resistance to transscleral protein outflow and accumulation of protein-rich fluid in the suprachoroidal space.<sup>8</sup> These alterations are more likely to affect the choroidal fluid dynamics when two or

more are present simultaneously. Indeed, the creation of ciliochoroidal effusion in animal models requires experimental alteration of two or more pathophysiologic factors.<sup>9,10</sup>

## **Idiopathic and Nanophthalmic Uveal Effusion**

In patients with uveal effusion syndrome or the closely related condition of nanophthalmos, abnormal sclera, referred to here as scleropathy, is the most likely primary ocular anomaly affecting choroidal fluid dynamics. In nanophthalmos, scleropathy is congenital in origin and associated with other ocular abnormalities. Acquired scleropathy may be secondary to a systemic disorder, such as the accumulation of amyloid in systemic amyloidosis or mucopolysaccharide in Hunter syndrome.<sup>11,12</sup> In uveal effusion syndrome, scleropathy appears to be secondary to the abnormal accumulation of glycosaminoglycan-like deposits and thickening of the sclera in the absence of any known systemic disorder.<sup>13-15</sup> Ward et al. reported that electron microscopy of excised sclera showed increased glycosaminoglycan-like deposits between the scleral fibers.<sup>15</sup> In a following report, Forrester and colleagues performed histochemical studies on scleras excised from patients with uveal effusion syndrome and showed deposition of the glycosaminoglycan proteodermatan sulfate and a smaller amount of proteochondroitin sulfate, indicating a primary defect in scleral proteodermatan metabolism and representing a form of ocular mucopolysaccharidosis.<sup>13</sup> Histologic similarities between scleras isolated from eyes with uveal effusion syndrome and nanophthalmos were demonstrated by Uyama et al., who found disorganized scleral fibers and proteoglycan deposits in 6 nanophthalmic eyes and 11 non-nanophthalmic eyes with uveal effusion syndrome.<sup>14</sup> As discussed above, abnormal scleral composition increases resistance to transscleral protein outflow, which in turn leads to the accumulation of protein, mostly albumin, in the extravascular space of the choroid and higher colloid osmotic pressure.<sup>8</sup> This results in reduced movement of fluid from the suprachoroidal space into the choroidal capillaries and leads to serous ciliochoroidal effusion. In vitro experimental evidence is consistent with this model, as chondroitinase ABC digestion, which removes glycosaminoglycans, improves scleral transport in human

cadaver eyes.<sup>16</sup>

Ciliochoroidal effusion and nonrhegmatogenous retinal detachment can be successfully treated in patients with uveal effusion syndrome by quadrant partial-thickness sclerectomies.<sup>17,18</sup> The disappearance of serous fluid after partial-thickness sclerectomies is consistent with the hypothesis that abnormally thickened sclera prevents outflow of protein and suggests that the removal of excess extravascular protein may be improved by reducing scleral thickness and resistance. Under normal conditions, eyes with congenital or acquired scleropathies may have enough redundancy in choroidal protein transport mechanisms to achieve physiologic fluid equilibrium and dehydration of the suprachoroid. However, when choroidal fluid dynamics are further stressed by additional pathologic factors, such as compression of the vortex veins, these compensatory mechanisms may no longer be sufficient to overcome the effect of increased colloids in the suprachoroidal space, which may then lead to increased extravascular fluid retention and ciliochoroidal detachment.

Vortex vein compression was first suggested by Schaffer in 1975 as a possible mechanism of uveal effusion in nanophthalmic eyes following glaucoma filtration surgery.<sup>19</sup> Relative obstruction of venous outflow secondary to compressed vortex veins may cause congestion of the choriocapillaris and alter the transmural hydrostatic pressure gradient, favoring increased retention of fluid in the suprachoroidal space. Brockhurst reported successful reattachment of the retina and resolution of ciliochoroidal effusion in nanophthalmic eyes after surgical decompression of the vortex veins.<sup>20</sup> Additional evidence for the role of increased intravascular pressure secondary to reduced ocular venous drainage in uveal effusion was provided by Casswell and colleagues, who reported resolution of retinal detachment after vortex vein decompression in patients with uveal effusion syndrome.<sup>21</sup> As proposed by Gass, compression of the vortex veins by an abnormally thickened sclera may contribute to increased fluid retention and serous exudation in the choroid and ciliary body in uveal effusion syndrome.<sup>17</sup>

## Clinical Features

Ciliochoroidal detachments in uveal effusion syndrome are brown–orange, solid-appearing elevations with smooth, convex surfaces (Fig. 76.2). Transillumination of the globe confirms the serous nature of the exudation. Choroidal detachments do not undulate appreciably with ocular movements, and this helps to distinguish them from rhegmatogenous retinal detachments. In early or mild cases, the diagnosis is suggested when the ora serrata is visible without the use of scleral depression secondary to shallow elevation of the pars plana and peripheral choroid (Fig. 76.3). As the effusion progresses, annular or lobular choroidal detachment may be seen. The characteristic four-lobed configuration results from the attachment of the choroid to the sclera at the vortex vein ampullae. The fluid accumulation is always greater anteriorly, as the anterior connecting fibers attaching choroid to the sclera are long and tangentially oriented, unlike the posterior fibers that are short and run more directly from uvea to sclera.<sup>22</sup>

**FIG. 76.2** Ciliochoroidal effusion demonstrating the characteristic solid-appearing choroidal elevation with a smooth, convex surface.

**FIG. 76.3** Visible ora serrata without the use of scleral depression secondary to shallow elevation of the pars plana and peripheral choroid in an eye with ciliochoroidal effusion.

Long-standing uveal effusion causes decompensation of the retinal pigment epithelial fluid barrier, resulting in increased protein and fluid accumulation in the subretinal space and development of nonrhegmatogenous retinal detachment (Fig. 76.4). There is greater absorption of fluid from the subretinal space compared with protein outflow, which results in rising protein concentration and marked shifting of subretinal fluid with changes in head position. Progressive subretinal fluid accumulation may lead to total retinal detachment. Chronic serous effusion and subretinal fluid accumulation may result in diffuse depigmentation and multifocal hyperplasia of the retinal pigment epithelium, forming the characteristic clinical finding of leopard spots in the fundus (Figs. 76.4 and 76.5).

**FIG. 76.4** Nonrhegmatogenous retinal detachment in a patient with uveal effusion. Location of the subretinal fluid is dependent on gravity. Leopard-spot retinal pigmentation is apparent superiorly.

**FIG. 76.5** Leopard-spot retinal pigmentation in uveal

effusion syndrome.

Anterior-segment examination in a patient with uveal effusion syndrome may reveal dilation of the episcleral blood vessels. Blood may be present in the Schlemm's canal on gonioscopy. The anterior chamber is free of any signs of inflammation, and the presence of anterior-chamber cell should increase suspicion of another ocular disorder with secondary uveal effusion. Mild vitreous cells may be present. Intraocular pressure is normal in patients with uveal effusion syndrome, and hypotony would indicate the presence of an alternative etiology. Elevation of subretinal fluid protein levels has been documented.<sup>2,23,24</sup> Although not commonly tested today, earlier studies of patients with uveal effusion syndrome demonstrated increased cerebrospinal fluid pressure and protein levels in some cases.<sup>1,2</sup>

## Diagnostic Studies

In addition to the clinical examination, ancillary studies are important for the diagnosis of uveal effusion syndrome and, more importantly, for the exclusion of other more common etiologies of ciliochoroidal effusion.

### Ophthalmic Ultrasound

B-scan ultrasound examination typically shows a smooth, thick, dome-shaped membrane with little aftermovement.<sup>25</sup> Ciliochoroidal effusion may be distinguished from retinal detachment by extension of the detachment anterior to the ora serrata. Highly bullous ciliochoroidal detachments may extend posteriorly and insert near the edge of the optic nerve. A-scan evaluation demonstrates a thick, 100% spike at tissue sensitivity, which at low sensitivity can often be seen to be double-peaked.<sup>25</sup> In early presentations of uveal effusion syndrome, the only evidence for ciliochoroidal effusion may be subtle degrees of supraciliary effusion on high-frequency ultrasound biomicroscopy. Diffuse, high-reflective thickening of the posterior choroid may be seen (Fig. 76.6). Low-reflective choroidal thickening should raise the suspicion for an infiltrative process secondary to an inflammatory

or neoplastic condition.<sup>25</sup>

**FIG. 76.6** B-scan ultrasound of an eye with uveal effusion syndrome shows choroidal thickening and inferior nonrhegmatogenous retinal detachment.

## Angiography and Optical Coherence Tomography

The diagnostic value of fluorescein and indocyanine green angiography and optical coherence tomography is limited in uveal effusion syndrome and serves mostly to exclude other etiologies. Angiography may demonstrate a leopard-spot appearance of hyperfluorescence and hypofluorescence (Fig. 76.7). The presence of focal fluorescein leaks and focal pigment epithelial detachments should increase the suspicion for idiopathic central serous chorioretinopathy as the underlying diagnosis. Multiple pin-point leaks may indicate the presence of an inflammatory or neoplastic choroidal infiltration. Indocyanine green angiography shows diffuse granular choroidal hyperfluorescence in the early phase, indicating marked hyperpermeability of the choroidal vessels.<sup>14</sup>

This choroidal hyperfluorescence persists into the late-phase angiogram and becomes more diffuse, demonstrating increased accumulation of fluid in the choroid. Spectral-domain optical coherence tomography may show focal thickening of the retinal pigment epithelium layer corresponding to the areas of leopard spots.<sup>26</sup>

**FIG. 76.7** Fluorescein angiogram of a patient with uveal effusion syndrome demonstrating leopard-spot appearance of hyperfluorescence and hypofluorescence.

## Differential Diagnosis

Uveal effusion syndrome is a diagnosis of exclusion. The differential diagnosis may be categorized by primary pathogenic factors causing ciliochoroidal effusion ([Box 76.1](#)). As discussed above, serous effusions in the ciliary body and choroid generally require the simultaneous presence of multiple pathogenic factors.

## Differential Diagnosis of Ciliochoroidal Effusions

## **Scleropathies**

### Congenital

- Uveal effusion syndrome
- Nanophthalmos

### Acquired

- Amyloidosis
- Mucopolysaccharidosis

## **Hydrodynamic factors**

### Ocular hypotony

- Wound leak
- Overfiltration
- Cyclodialysis
- Penetrating ocular trauma
- Rhegmatogenous retinal detachment
- Ciliary body dysfunction

### Elevated uveal venous pressure

- Arteriovenous fistula
- Sturge–Weber syndrome

- Idiopathic prominent episcleral vessels
- Vortex vein compression
- Valsalva maneuver

Malignant hypertension

#### **Inflammatory factors**

- After trauma or surgery
- After photocoagulation or cryotherapy
- Drug reaction
- Uveitis
- Scleritis
- Orbital cellulitis
- Idiopathic orbital inflammation

#### **Neoplastic conditions**

- Metastatic carcinoma
- Malignant melanoma
- Lymphoproliferative and melanocytic choroidal infiltration

### **Congenital and Acquired Scleropathies**

As discussed above, congenital or acquired scleropathy with abnormal thickening of the sclera significantly alters the choroidal fluid dynamics and may cause uveal effusion, especially in the presence of other pathogenic factors such as vortex vein compression with reduced venous outflow and elevated uveal venous pressure. Uveal effusion syndrome and nanophthalmos can be considered in the same spectrum of diseases with a congenital primary scleral abnormality. Secondary scleral abnormalities are seen in association with systemic disorders, including amyloidosis or mucopolysaccharidosis.<sup>11,12</sup>

Uveal effusion in patients with nanophthalmos is remarkably similar to that seen in the idiopathic uveal effusion syndrome. Nanophthalmos is a pure form of microphthalmia characterized by small eyes and extremely thick sclera with no other identifiable ocular or systemic abnormalities. The axial length is generally less than 20 mm, and high hyperopia (>+7.00 D) is typical. Other findings include small corneal diameter, shallow anterior chamber, high lens-to-eye volume ratio, and strong predisposition to develop angle closure glaucoma.<sup>27</sup> Uveal effusion and nonrhegmatogenous retinal detachment may occur spontaneously and are frequently induced by intraocular surgery in nanophthalmic eyes.<sup>27,28</sup> The detection of nanophthalmos is important prior to any planned intraocular procedure since prophylactic use of sclerectomies may prevent significant postoperative complications secondary to uveal effusion.

## **Hydrodynamic Effusions**

Hydrodynamic factors associated with ciliochoroidal effusion include ocular hypotony, elevated uveal venous pressure, and malignant hypertension. Long-standing low intraocular pressure induces uveal effusion and may in turn be worsened by ciliary body detachment. The most common reason for hypotony is glaucoma filtering or drainage device surgery, especially in the early postoperative period. Resuturing the scleral flap, scleral patch grafting, autologous blood injection, and other methods have been described in the literature to reverse postoperative hypotony.<sup>29-31</sup> Hypotony and uveal effusion complicating anterior-segment surgery are usually secondary to a wound leak or inadvertent

filtering bleb. Other ocular disorders that may lead to hypotony and secondary ciliochoroidal effusion include cyclodialysis, penetrating ocular trauma, rhegmatogenous retinal detachment, and ciliary body dysfunction.

Elevated uveal venous pressure and increased transudation from choroidal vessels may be seen in the setting of carotid–cavernous sinus fistula or dural arteriovenous fistulas. When an intracranial fistula is suspected in a patient with uveal effusion, nonrhegmatogenous retinal detachment, and other associated findings, neuroimaging should be obtained. Patients with idiopathic prominent episcleral vessels or Sturge–Weber syndrome have elevated episcleral venous pressure and likely secondary increase in choriocapillaris pressure, which predisposes them to a higher risk of significant ciliochoroidal effusion during intraocular surgery when the intraocular pressure drops to zero.<sup>32</sup> Compression of the vortex veins and reduction of ocular venous outflow may lead to uveal effusion after scleral buckling surgery.

Malignant hypertension secondary to severe renal disease or pregnancy may lead to ciliochoroidal effusion and nonrhegmatogenous retinal detachment, which usually resolve with blood pressure control.

## **Inflammatory Factors**

In addition to causing hypotony, penetrating trauma may induce marked intraocular inflammation, which leads to increased vascular permeability. Chronic low-grade inflammation with increased permeability of the choriocapillaris may also be seen after intraocular surgery. Transient vascular leakage and serous ciliochoroidal fluid accumulation may be seen after thermal injury from panretinal photocoagulation or transscleral cryotherapy. Inflammation of the uveal tract secondary to autoimmune or infectious etiologies may be complicated by ciliochoroidal effusion and nonrhegmatogenous retinal detachment. A uveitic syndrome is usually suspected in these patients based on other ocular findings. A painful or red eye in a patient with uveal effusion may be secondary to scleritis, idiopathic orbital inflammation, or orbital cellulitis. Careful examination is required to differentiate idiopathic uveal effusion from uveitis, especially if there is no response to

high-dose corticosteroid treatment.<sup>33</sup> A buckle infection should always be in the differential diagnosis of uveal effusion in a patient with scleral inflammation after scleral buckling surgery.

## **Neoplastic Effusions**

Choroidal metastatic tumors or malignant melanoma may infrequently present with ciliochoroidal effusion and nonrhegmatogenous retinal detachment. The diagnosis may only be apparent after an ophthalmic ultrasound in cases with extensive choroidal and subretinal fluid accumulation. In addition to solid tumors of the eye, neoplastic infiltrations and secondary uveal thickening may cause nonrhegmatogenous retinal detachment and occasional serous uveal effusion in lymphoproliferative disorders or melanocytic proliferation.

## **Treatment of Idiopathic Uveal Effusion Syndrome**

Most patients with idiopathic uveal effusion syndrome become symptomatic of their disease when the subretinal fluid from the inferior nonrhegmatogenous retinal detachment progresses superiorly and causes macular detachment. Macular damage can also occur from repeated episodes wherein subretinal fluid shifts into the macula while the patient is lying down. Some patients may initially be misdiagnosed and treated medically for other causes of exudative retinal detachment, which fails to restore vision. Surgical treatment is required to prevent further macular damage by facilitating the resolution of subretinal fluid. In patients with known idiopathic uveal effusion syndrome and an otherwise asymptomatic eye (e.g., fellow eye of a patient with a unilateral presentation), prophylactic treatment with a scleral-thinning procedure should be considered prior to any intraocular surgery in order to prevent postoperative ciliochoroidal effusion and nonrhegmatogenous retinal detachment.

## **Scleral Thinning Procedures**

Gass first described sclerectomy with sclerostomy for the treatment

of uveal effusion syndrome in 1983.<sup>17</sup> The idea of using this procedure in patients with uveal effusion syndrome arose after an unsuccessful attempt at vortex vein decompression in another patient. Gass operated on both eyes of a patient with thick sclera and uveal effusion and amputated or ruptured the vortex veins during attempted decompression. Despite the occurrence of suprachoroidal hemorrhage in both eyes, ciliochoroidal and nonrhegmatogenous detachment resolved in both eyes postoperatively. This observation led him to hypothesize that the excision of large scleral flaps at the sites of vortex veins was responsible for the successful outcome. To test this hypothesis, he performed quadrant partial-thickness sclerectomies and sclerostomies without vortex vein decompression or drainage of subretinal fluid in both eyes of a patient with long-standing uveal effusion and bullous nonrhegmatogenous retinal detachment. Complete resolution of ciliochoroidal and subretinal fluid occurred 10–12 weeks after surgery.<sup>17</sup> In 1990, Johnson and Gass expanded on this initial result in a retrospective study of 23 eyes of 20 patients with uveal effusion syndrome who underwent a scleral-thinning procedure without vortex vein decompression.<sup>18</sup> The investigators observed complete resolution of subretinal and supraciliochoroidal fluid in 96% of eyes after one or two procedures. The mean time for resolution of uveal effusion and nonrhegmatogenous retinal detachment was 2.4 months. Other investigators reported similar results using scleral-thinning procedures for treatment of uveal effusion and nonrhegmatogenous retinal detachment associated with Hunter syndrome, nanophthalmos, and uveal effusion syndrome.<sup>12,14,21,34,35</sup>

The surgical procedure for scleral thinning involves the creation of 5×7 mm, one-half to two-thirds thickness sclerectomies in each quadrant, centered 1–2 mm anterior to the equator and placed outside the meridian of each vortex vein to avoid its intrascleral course (Fig. 76.8).<sup>17,18,36</sup> The long axis of the sclerectomy is oriented circumferentially. An approximately 2-mm linear sclerostomy may be created in the center of each sclerectomy bed and enlarged with a 1–2-mm scleral punch. Similar scleral-thinning techniques have been reported by others treating nanophthalmic or idiopathic uveal effusion.<sup>14,37</sup> Persistent or recurrent uveal effusion and

nonrhegmatogenous retinal detachment following surgery may be secondary to the fibrosis and scarring of sclerectomies and sclerotomies. An antimetabolite, such as mitomycin-C (MMC), may reduce the risk of recurrent fibrosis following repeat scleral thinning procedure.<sup>38</sup> A novel approach using Ex-PRESS shunt to drain choroidal fluid without sclerotomies has recently been reported.<sup>39</sup>

**FIG. 76.8** Scleral-thinning procedure for uveal effusion syndrome. Borders of the sclerectomy are outlined with partial-thickness scleral incisions (top left). One-half to two-thirds thickness lamellar scleral dissection is performed (top right), creating a scleral window (bottom left) and an excised section of abnormally thick sclera (bottom right).

## **Pars Plana Vitrectomy**

The extent of visual improvement after scleral-thinning procedures

may be limited by photoreceptor and retinal pigment epithelial damage secondary to chronic retinal detachment. In the series reported by Johnson and Gass, visual acuity improved by 2 or more Snellen lines in 56% of eyes, remained stable in 35% of eyes, and worsened in 9% of eyes.<sup>18</sup> Overall visual acuity was 20/400 or better in 96% of eyes and 20/40 or better in 35% of eyes. Among the 12 of 23 eyes whose final visual acuity was worse than 20/40, the primary vision-limiting factor was atrophic photoreceptor and retinal pigment epithelial damage due to chronic retinal detachment. The mean time for retinal reattachment following scleral-thinning surgery in this series was 2.4 months. To facilitate rapid retinal reattachment and prevent ongoing damage to photoreceptors and the retinal pigment epithelium, Schneiderman and Johnson performed pars plana vitrectomy and internal drainage of subretinal fluid at the time of quadrantic partial-thickness sclerectomies in a 73-year-old man with uveal effusion syndrome and total retinal detachment.<sup>40</sup> This patient's vision improved from hand motions to 20/70 1 year postoperatively. This combined approach of sclerectomies and pars plana vitrectomy for macula-off nonrhegmatogenous retinal detachment in uveal effusion syndrome allows immediate approximation of the photoreceptors and the retinal pigment epithelium and prevents further photoreceptor cell death. An alternative approach is external drainage of the subretinal fluid,<sup>24</sup> which presents significant risk of subretinal hemorrhage, profound ocular hypotony, and difficulty accessing the posteriorly shifting subretinal fluid.

## **Vortex Vein Decompression**

In 1980, Brockhurst reported successful use of scleral-thinning procedure with vortex vein decompression in the treatment of nanophthalmic ciliochoroidal effusion.<sup>20</sup> He described the isolation of the intrascleral portion of the vortex vein and decompressing all four veins. Since scleral-thinning procedures alone are successful in the treatment of uveal effusion syndrome, vortex vein decompression for the treatment of ciliochoroidal effusion in uveal effusion syndrome or nanophthalmos is no longer performed by most vitreoretinal surgeons.

## Conclusion

Idiopathic uveal effusion syndrome is a rare condition that typically presents in otherwise healthy middle-aged males with spontaneous detachment of the ciliary body and the peripheral choroid. This condition is frequently associated with nonrhegmatogenous retinal detachment with marked shifting of subretinal fluid due to its exceptionally high protein content. Other ocular findings include dilation of the episcleral blood vessels, blood in Schlemm's canal, normal intraocular pressure, mild vitreous cells, and leopard-spot pigment epithelial alterations. Current evidence indicates that congenital scleropathy manifesting with abnormal accumulation of glycosaminoglycan-like deposits and thickening of the sclera is the primary pathologic anomaly in patients with uveal effusion syndrome. The diagnosis of uveal effusion syndrome is based on characteristic clinical findings and exclusion of the other known causes of ciliochoroidal effusion and nonrhegmatogenous retinal detachment. The natural course is usually prolonged with remissions and exacerbations, and without treatment, patients may experience permanent loss of vision. Treatment is primarily surgical and requires quadrantic partial-thickness sclerectomies and sclerostomies.

## Hypotony Maculopathy

### Introduction

Loss of central vision may develop in patients with reduced intraocular pressure following trauma or ocular surgery. One of the causes of reduced vision in the setting of hypotony is significant folding of the choroid, neurosensory retina, and retinal pigment epithelium in the posterior pole, termed hypotony maculopathy by Gass in 1972.<sup>41-44</sup> The initial description of fundus changes associated with hypotony dates back to the 1950s, when Dellaporta described patients with reduced vision following glaucoma procedures or perforating eye injuries.<sup>41</sup> He noted that hypotony was associated with several fundus abnormalities, including optic nerve swelling, vascular tortuosity, and chorioretinal folds.<sup>41</sup> The incidence of hypotony maculopathy significantly increased after the

introduction of antimetabolites in glaucoma-filtering surgery.<sup>45-47</sup> Younger age, myopia, and male gender are significant risk factors for the development of hypotony maculopathy after glaucoma procedures.<sup>46-48</sup>

## Clinical Features

Posterior-segment examination in patients with hypotony maculopathy shows irregular folding of the neurosensory retina, retinal pigment epithelium, and choroid (Fig. 76.9). These folds are initially broad and indistinct and tend to radiate outward in a branching fashion from the optic disc temporally and appear concentric or irregular nasally. Around the center of the fovea, retinal folds may be arranged in a stellate pattern. The elevated crests of the folds appear yellow with dark narrow troughs in between. Reduction of the ocular anteroposterior diameter causes relative hyperopia. Marked optic disc edema may be present. Retinal vasculature is typically tortuous and may be engorged in some eyes. Anterior-segment examination may show a shallow anterior chamber if there is ciliochoroidal effusion. As the intraocular pressure returns to the normal range, the choroidal folds flatten and may disappear. If the hypotony was chronic, permanent retinal pigment epithelial changes may cause pigmented lines in the fundus.

**FIG. 76.9** Chorioretinal folds and optic disc edema in a patient with hypotony maculopathy.

## Diagnosis

### Fluorescein Angiography

Fluorescein angiography is useful in demonstrating chorioretinal folds, especially in mild cases with a normal-appearing fundus examination. In the initial stages of hypotony, fluorescein angiography demonstrates an irregular increase in background choroidal fluorescence corresponding to the crest of the choroidal folds (Fig. 76.10). This produces hyperfluorescent streaks that may be seen in the early arterial phase. The hyperfluorescence of these streaks is multifactorial: (1) thinning of the retinal pigment epithelium on the crest of the folds; (2) pooling of the choroidal fluorescein under the crest; and (3) shorter course of the incident blue and reflected yellow-green light during angiography. The troughs of the folds are occupied by compressed retinal pigment epithelial cells, which reduce the transmission of the background choroidal fluorescence and cause hypofluorescence on angiography. Leakage of fluorescein may be seen in the capillaries of the optic nerve and there is typically no leakage in the retinal

capillaries.<sup>49</sup> In long-standing hypotony, angiography may show permanent alterations in the retinal pigment epithelium. The chorioretinal folds may be differentiated from the folds of the neurosensory retina, which do not alter the background fluorescence.

**FIG. 76.10** Fluorescein angiogram in hypotony maculopathy demonstrates hyperfluorescent streaks corresponding to the crest of the chorioretinal folds.

## Ocular Ultrasound

B-scan ultrasonography typically shows flattening and thickening of the sclera and choroid in the posterior pole<sup>50</sup> (Fig. 76.11).

Anterior-segment evaluation with ultrasound biomicroscopy may be useful for the identification of the underlying etiology of hypotony. The presence of a cyclodialysis cleft or anterior ciliary detachment may only be apparent on ultrasound biomicroscopy.<sup>51,52</sup>

**FIG. 76.11** B-scan ultrasonography in a patient with low intraocular pressure showing characteristic flattening and thickening of the sclera and choroid in the posterior pole.

## Optical Coherence Tomography

In patients with low intraocular pressure and reduced visual acuity, optical coherence tomography (OCT) imaging of the posterior pole can help to demonstrate subtle chorioretinal folds of the macula that may otherwise be difficult to detect on biomicroscopy<sup>53-55</sup> (Fig. 76.12). High-resolution OCT may detect chorioretinal folding in early hypotony, which may not show any changes in the background choroidal fluorescence during fluorescein angiography.<sup>54</sup> However, the clinical significance of subtle chorioretinal folds detected only by OCT in a patient with unchanged vision is unclear. OCT in a patient with symptomatic hypotony maculopathy and stereotypical biomicroscopic findings typically shows prominent chorioretinal folds (Fig. 76.12).

**FIG. 76.12** High-resolution optical coherence tomography may demonstrate subtle (top panel) or prominent (bottom panel) chorioretinal folding in hypotony maculopathy.

## Pathogenesis

### Hypotony

The reduction of intraocular pressure may be secondary to decreased aqueous production or increased aqueous outflow. In most cases, both a reduction in aqueous production and an increase in aqueous outflow are present in a hypotonous eye. [Box 76.2](#) lists various etiologies of decreased intraocular pressure, some of which [Box 76.2](#) briefly discussed below.

### Causes of Hypotony

#### Postoperative

- Wound leak

- Overfiltration

#### **Ocular trauma**

- Cyclodialysis
- Perforating injury

#### **Inflammatory**

- Iridocyclitis

#### **Retinal detachment**

#### **Ciliochoroidal detachment**

#### **Ciliary body hypoperfusion**

- Carotid occlusion
- Giant cell arteritis

#### **Photocoagulation or cryoablation of the ciliary body**

#### **Excessive reduction of intraocular pressure by pharmacologic agents**

#### **Systemic**

- Hyperosmotic agents
- Dehydration
- Uremia
- Diabetic ketoacidosis

- Myotonic dystrophy

## Decreased Aqueous Production

Reduced aqueous production is an uncommon etiology of hypotony. The factors that lead to decreased aqueous production may be inflammatory, vascular, or structural. Ciliary body inflammation may compromise the production of aqueous in patients with uveitis. Severe intraocular inflammation in the immediate postoperative period following intraocular surgery may decrease aqueous secretion. Trauma may be associated with significant iridocyclitis and hypotony, which may be worsened by increased aqueous outflow due to a cyclodialysis cleft or globe rupture. Decreased ocular perfusion in patients with vasculitis or arterial occlusion may cause ciliary body ischemia. Other causes of decreased aqueous production include ciliary body detachment secondary to ciliochoroidal effusion, trauma, or proliferative vitreoretinopathy.

## Increased Aqueous Outflow

When the aqueous production is no longer sufficient to match the increased outflow, hypotony develops. Most cases of ocular hypotony are secondary to increased aqueous outflow. Under physiologic conditions, the aqueous leaves the eye primarily through the trabecular meshwork and Schlemm's canal in a pressure-dependent manner, with much smaller amounts exiting through uveoscleral outflow. Several factors may increase aqueous outflow, including wound leak after anterior-segment surgery and excessive aqueous filtration after glaucoma filtering or drainage device surgery. After the introduction of antimetabolites in glaucoma-filtering procedures, the incidence of hypotony increased.<sup>45</sup> Antimetabolites inhibit subconjunctival healing and scarring, which would otherwise limit the overfiltration rate. With the introduction of sutureless small-gauge vitrectomy technology, vitreoretinal surgeons encounter ocular hypotony with increasing frequency in their postoperative patients.<sup>56</sup> Ocular trauma may be associated with scleral rupture and wound leak. Postoperative or traumatic cyclodialysis creates a free communication between the

anterior chamber and the suprachoroidal space, increasing the uveoscleral outflow.

## Mechanism of Maculopathy

Chorioretinal folds form in the hypotonous eye due to scleral shrinkage and reduction of the inner surface area of the sclera. This loss of surface area then leads to folding of the inner portion of choroid and the outer retina.<sup>57-60</sup> Maculopathy develops when the neurosensory retina is thrown into a series of stellate folds around the center of the fovea. This central stellate retinal wrinkling is caused by the thickened posterior scleral wall and the choroid displacing the normally thick retina surrounding the thin foveola.<sup>49</sup> The folding of the neurosensory retina is the primary cause of vision loss in hypotony maculopathy. The risk of hypotony maculopathy is highest in young myopic patients, and this may indicate that the sclera is more vulnerable to swelling and contraction in young patients.

## Mechanism of Optic Disc Edema

Reduced intraocular pressure may lead to broad areas of choroidal swelling and retinal folding around the optic nerve, and this may cause disc edema.<sup>49</sup> Another proposed mechanism is the anterior bowing of the lamina cribrosa and constriction of axonal bundles in the lamina scleralis, causing reduced orthograde and retrograde axoplasmic transport and swelling of the optic nerve.<sup>61</sup> Disc edema may be less impressive in eyes with preexisting optic nerve disease and loss of axons.

## Differential Diagnosis

The finding of chorioretinal folds may be seen in any condition that reduces the inner surface area of the sclera secondary to thickening of the sclera (Box 76.3).

## Differential Diagnosis of Hypotony Maculopathy

- Idiopathic chorioretinal folds

- Retrobulbar mass lesions
- Scleral inflammation
- Scleral buckle
- Choroidal tumors
- Choroidal neovascularization
- Focal chorioretinal scars
- Optic nerve head disorders
- Retinal folds

### **Idiopathic Chorioretinal Folds**

Horizontal macular chorioretinal folds, as well as folds radiating from the optic nerve, may be seen in young hyperopic patients on routine evaluation.<sup>58,62</sup> These idiopathic chorioretinal folds are usually confined to the area around the macula and optic nerve, but may at times involve most of the posterior pole. Patients usually do not report any visual dysfunction. The appearance of the folds is usually symmetric in both eyes, but may occasionally be seen unilaterally. As the name indicates, the etiology of these chorioretinal folds is unknown and may be secondary to the shrinkage of the fibrous tunic of the eye after an inflammatory process during early years of life.<sup>49</sup>

### **Retrobulbar Mass Lesions**

Any space-occupying mass in the orbit may cause scleral edema, choroidal congestion, and chorioretinal folds.<sup>63,64</sup> A mass in the extraconal space may induce astigmatism, whereas intraconal location of a tumor may lead to acquired hyperopia.<sup>63</sup> Both benign and malignant tumors have been reported to present with chorioretinal folds.

### **Scleral Inflammation**

Scleral inflammation with edema, thickening, and choroidal congestion may lead to the development of chorioretinal folds. Thyroid eye disease, idiopathic orbital inflammation, and other autoimmune or infectious uveitic diseases presenting with scleritis may have associated chorioretinal folds.<sup>49,65,66</sup>

### **Scleral Buckle**

Thickening of the sclera in the posterior slope of a scleral buckle may cause occasional chorioretinal folds in patients who underwent rhegmatogenous retinal detachment repair.

### **Choroidal Tumors**

Malignant melanoma or metastatic lesions of the choroid may cause vascular congestion, choroidal edema, and scleral thickening, leading to chorioretinal folds surrounding the tumor.<sup>49</sup>

### **Choroidal Neovascularization**

Spontaneous or laser-induced contraction of subretinal pigment epithelial choroidal neovascular membrane may induce the formation of chorioretinal folds that radiate away from the membrane.<sup>67</sup>

### **Focal Chorioretinal Scars**

Focal scars of the choroid and the retina may sometimes cause contraction and induce chorioretinal folds radiating towards the center of the scar.<sup>68</sup>

### **Optic Nerve Head Disorders**

Idiopathic intracranial hypertension and papilledema may be associated with chorioretinal folds. These folds are usually horizontal in the macula and converge on the nasal side of the swollen optic nerve.<sup>69,70</sup> Chorioretinal folds have also been seen in patients with unexplained optic atrophy.<sup>71</sup> In some patients with increased intracranial pressure, chorioretinal folds may present in the absence of any detectable papilledema and a lumbar puncture with an opening pressure may need to be performed to rule out idiopathic intracranial hypertension.<sup>72</sup>

## Retinal Folds

Retinal folds may be mistaken for chorioretinal folds in some eyes. Usually, folds of the neurosensory retina are narrow and seen radiating away from a focal inner retinal contraction caused by macular pucker or outer retinal contraction secondary to a chorioretinal scar (Fig. 76.13).<sup>49</sup> Fluorescein angiography is helpful in differentiating retinal folds from chorioretinal folds, since folds of the neurosensory retina do not change the fluorescence pattern and are not seen on angiography.

**FIG. 76.13** Red-free photo of the posterior pole (top panel) and high-resolution optical coherence tomography (bottom panel) demonstrate fine, subtle

retinal folds associated with an epiretinal membrane.  
Fluorescein angiogram shows no fluorescence  
changes associated with these folds (middle panel).

## Treatment

The effective treatment of hypotony maculopathy requires correcting the underlying ocular abnormality and restoring normal intraocular pressure. Since postoperative hypotony accounts for a significant portion of hypotony maculopathy patients, treatment is typically managed by an anterior-segment surgeon. Injection of viscoelastic or fluid into the anterior chamber to increase intraocular pressure produces short-lived effects. Wound leaks after anterior-segment surgery need to be addressed immediately with a bandage contact lens or suturing the wound to prevent further aqueous loss. Ocular inflammation requires treatment with a topical or oral corticosteroid. Posttraumatic cyclodialysis cleft may require laser or surgical closure to normalize intraocular pressure. Overfiltration after glaucoma surgery may require resuturing the scleral flap, donor scleral patch graft placement, or autologous blood injection.<sup>29-31,73</sup>

Chorioretinal folds may resolve following the restoration of normal intraocular pressure. In cases of chronic hypotony, the retinal pigment epithelium will show permanent changes, including hyperpigmentation at the troughs of the folds, causing irregularly dark, pigmented lines in the posterior pole detected by fluorescein angiography.<sup>49</sup> The choroid and the sclera return to normal thickness, and the tortuosity and engorgement of the retinal vessels disappear.

Early detection of hypotony maculopathy is important for implementing the necessary measures to restore normal intraocular pressure and recovery of vision. The prognosis for visual recovery depends on the duration of the hypotony and the chronicity of the chorioretinal folds. Prolonged folding of the choroid and the neurosensory retina may cause irreversible structural changes in the macula and poor visual recovery after normalization of the intraocular pressure. However, significant visual improvement may still occur in some patients after treatment of chronic hypotony.<sup>74</sup>

Duker and Schuman reported that pars plana vitrectomy and mechanical flattening of the posterior pole with intraoperative instillation of perfluorocarbon liquid significantly improved visual acuity in a patient who had minimal visual recovery after increasing the intraocular pressure with previous bleb revision.<sup>75</sup> The efficacy of this approach has not been confirmed in larger patient cohorts. Others have advocated internal limiting membrane peeling with gas tamponade in myopic patients with hypotony maculopathy.<sup>76</sup>

## Conclusion

Hypotony maculopathy is characterized by folding of the choroid, neurosensory retina, and retinal pigment epithelium in the posterior pole in an eye with low intraocular pressure. The folding of the neurosensory retina is believed to be the primary cause of vision loss. In addition to chorioretinal folds, acquired hyperopia, optic disc edema, and tortuous retinal vasculature may be associated with hypotony maculopathy. Fluorescein angiography demonstrates an irregular increase in background choroidal fluorescence corresponding to the crest of the chorioretinal folds. B-scan ultrasonography shows flattening and thickening of the sclera and choroid in the posterior pole. High-resolution optical coherence tomography allows early detection of chorioretinal folding that may be difficult to diagnose on clinical examination. Early detection and treatment are important for preventing permanent structural changes in the retina and maximizing visual recovery.

## Introduction

Sympathetic ophthalmia, also known as sympathetic ophthalmitis and sympathetic uveitis, is a rare bilateral diffuse granulomatous uveitis that occurs a few days to several decades after penetrating accidental or surgical trauma to an eye. Both the traumatized eye,

commonly referred to as the “exciting” eye, and the fellow eye, referred to as the “sympathizing” eye, are affected. Injury to and/or incarceration of uveal tissue has been a feature of nearly all cases of sympathetic ophthalmia. The clinical signs and symptoms are usually detected in the sympathizing eye within the first 3 months after trauma to the fellow eye.<sup>1,2</sup>

The notion that injury to one eye may have repercussion in the contralateral eye probably dates back to ancient times, with Hippocrates (460–370 BC), but has also been reported by Agathias, in a compilation from Constantius Cephalis (1000 AD).<sup>1,3</sup> However, it was William Mackenzie, in 1830, who provided the first comprehensive clinical description and pioneered the use of the term “sympathetic ophthalmia” to describe this entity.<sup>1,3</sup> Ernst Fuchs, in 1905, thoroughly detailed the characteristic histopathologic features.<sup>4</sup> The pathogenesis of sympathetic ophthalmia has, however, remained an enigma despite years of study. There is now some experimental evidence implicating an autoimmune delayed hypersensitivity reaction to melanocytes or tyrosinase peptide antigen as a possible pathogenetic mechanism.

## Epidemiology

Sympathetic ophthalmia is a relatively rare disease, although exact figures are difficult to determine because the onset or the diagnosis, or both, are often delayed for months to years after the initial injury. In addition, definite histopathologic confirmation is achieved in around only one-third of suspected cases, but may be established histopathologically in others not suspected clinically.<sup>2</sup> In 1972, Liddy and Stuart<sup>5</sup> reported an incidence of sympathetic ophthalmia of 0.19% following penetrating injuries and 0.007% following intraocular surgery. Among the general population, sympathetic ophthalmia has been estimated to affect 0.03 per 100,000 persons per year<sup>6</sup> and possibly corresponds to 1–2% of all uveitis cases.<sup>7</sup> Surgical procedures that may lead to sympathetic ophthalmia include cataract extraction, iridectomy, paracentesis, cyclodialysis, synechialysis, retinal detachment repair, keratectomy, vitrectomy, evisceration, laser cyclophotocoagulation, proton-beam irradiation, and others.<sup>2,3,8</sup>

Although advances in modern surgical techniques may be contributing to a lower incidence of sympathetic ophthalmia, this is probably being partially offset by more aggressive surgical management of severely traumatized eyes, which in the past would have been promptly enucleated. In fact, the epidemiology of sympathetic ophthalmia has been changing, and more cases are now being associated with intraocular surgery,<sup>6,7,9,10</sup> in contrast to accidental penetrating trauma.<sup>3</sup> Pars plana vitrectomy is now one of the leading surgical procedures associated with sympathetic ophthalmia<sup>11</sup> with an estimated risk of around 0.01%,<sup>12</sup> cases have been recently reported even after the advent of small-gauge sutureless vitrectomy surgery.<sup>13,14</sup> For these reasons, sympathetic ophthalmia should not be considered a disappearing disease and thus should not be neglected.

Some studies have shown a male preponderance, but this is believed to be a reflection of the higher incidence of accidental trauma in males. Indeed, when only cases of surgical trauma are considered, the ratio is similar.<sup>15</sup> In Winter's series of 257 cases of sympathetic ophthalmia, there was no difference in age incidence.<sup>16</sup> Other authors have reported relative peaks in childhood and early adult years, thought to reflect a higher incidence of accidental trauma in these ages, and an additional peak in the sixth and seventh decades, thought to represent an increased incidence of surgical procedures among persons in this age group.<sup>17</sup>

## Pathogenesis

The exact cause of sympathetic ophthalmia is unknown. Clinical studies have shown that the predominant predisposing factors are accidental penetrating trauma, accounting for approximately 60–70% of cases, and penetrating surgical trauma, accounting for nearly 30%. Recent studies have pointed to an inversion of this proportion, with many cases now being associated with surgical rather than accidental trauma.<sup>6,7,10,11</sup> A small percentage of cases are the result of contusion injuries with occult scleral rupture and perforating corneal ulcers. The common denominator in the overwhelming majority of cases is the presence of a penetrating injury in which wound healing is complicated by incarceration of

the iris, ciliary body, or choroid.<sup>2</sup>

Historically, the pathogenesis of sympathetic ophthalmia had been suspected to be infectious. However, no organisms have ever been isolated from cases of sympathetic ophthalmia, and infective agents have not induced the disease in laboratory animals. Sympathetic ophthalmia may also develop in the setting of posttraumatic or postoperative infectious endophthalmitis, and it is possible that such infection may potentiate the development of sympathetic ophthalmia in these cases<sup>18</sup> and not prevent it, in contrast to what had previously been suggested.<sup>1,19,20</sup> Most cases of sympathetic ophthalmia, however, develop in the absence of intraocular infection.<sup>17</sup>

Several investigators have proposed an immunologic basis for sympathetic ophthalmia, in which a T-cell-mediated autoimmune response against an antigenic protein from the uvea, particularly a uveal tyrosinase peptide, may be involved.<sup>21-25</sup> Marak<sup>26,27</sup> and Wong and colleagues<sup>21</sup> demonstrated enhanced transformation of peripheral lymphocytes from patients with histologically confirmed sympathetic ophthalmia when exposed to homologous uveal-retinal extracts in tissue culture, suggesting that these patients have lymphocytes that are sensitized to some component(s) of uveal-retinal antigen. When antigens extracted from the retina are injected into guinea-pigs, intraocular inflammation similar to sympathetic ophthalmia develops in these animals.<sup>27</sup> Some studies indeed suggest that sympathetic ophthalmia may result from altered T-cell response to one of the soluble proteins associated with the retinal photoreceptor membranes, particularly the retinal S antigen, or to other retinal or choroidal melanocyte antigens.<sup>22-24,27,28</sup> However, recent studies reveal that T-cell immune response to tyrosinase peptide may play a role in the development of sympathetic ophthalmia, as in Vogt-Koyanagi-Harada disease.<sup>23,29-31</sup>

There may be a genetic predisposition to the development of sympathetic ophthalmia. Human leukocyte antigen (HLA) association has been reported in sympathetic ophthalmia, including HLA-A11, HLA-B40, HLA-DR4/DRw53, and HLA-DR4/DQw3 haplotypes.<sup>32,33</sup> Studies from Asia and Europe found a significant correlation between HLA-DRB1\*4 and HLA-DQB1\*04 and the development of sympathetic ophthalmia.<sup>34-36</sup> A similar association

was also seen in patients with Vogt–Koyanagi–Harada disease. Finally, genetic background may also correlate to disease severity, either through some of those predisposing HLA haplotypes such as HLA-DRB1<sup>34</sup> or through cytokine polymorphisms such as in interleukin (IL)-10, modifying the immune response and the risk of disease recurrence.<sup>37</sup>

## Immunopathology

In sympathetic ophthalmia the immunopathologic alterations are similar in both the exciting and sympathizing eyes and typically consist of a diffuse granulomatous inflammation of the uveal tract, made up of lymphocytes, plasma cells, and nests of epithelioid histiocytes; pigment is often present within these epithelioid cells and also within giant cells (Fig. 77.1). In the majority of cases, the inflammatory process does not involve the choriocapillaris or the retina. Absence of necrosis is another characteristic feature. The choroid is diffusely involved and thickened by an infiltration of predominantly lymphocytes, collections of epithelioid cells, and a few giant cells; neutrophils are rarely seen. Plasma cells may be present, particularly in patients treated with corticosteroids. Eosinophils can also be found and are frequently concentrated in the inner choroid, particularly in heavily pigmented individuals. Nodular clusters of epithelioid cells containing pigment are often seen lying between the retinal pigment epithelium (RPE) and Bruch's membrane; these appear clinically as the drusen-like, yellow-white dots known as Dalen–Fuchs nodules (Fig. 77.2).<sup>1,2,4,16,17,38,39</sup> Inflammatory cell infiltration in the iris may result in the clinical appearance of a thickened iris.

**FIG. 77.1** Histopathologic aspects of sympathetic ophthalmia. (A) Note granulomatous inflammation of the choroid with focal serous detachment of the retina (hematoxylin and eosin,  $\times 130$ ). (B) Multinucleated giant cells and epithelioid histiocytes have pigment in their cytoplasm (hematoxylin and eosin,  $\times 565$ ).

**FIG. 77.2** Histopathologically, the Dalen–Fuchs nodule is characterized by focal collections of epithelioid cells at the level of Bruch's membrane (hematoxylin and eosin,  $\times 250$ ).

The retina is usually free of inflammatory infiltrates. However, few enucleated eyes of sympathetic ophthalmia show collections of mononuclear cells around the blood vessels, and occasional involvement in the areas overlying the Dalen–Fuchs nodules, and in the pars plana region. Other pathologic changes include scleral involvement with inflammatory infiltrates around the emissary veins and extension of the granulomatous process into the optic

nerve and surrounding meningeal sheaths, the sites where melanocytes are also present.<sup>1,4,17,40,41</sup> Some of the eyes with characteristic histologic features of sympathetic ophthalmia but also with breaks in the lens capsule may additionally reveal features of phacoanaphylaxis, with zonal granulomatous inflammation around the lens material.<sup>40</sup> Even though typical features of sympathetic ophthalmia include non-necrotizing granulomatous uveitis, there are cases exhibiting atypical features such as nongranulomatous choroiditis, and enucleated eyes with long-standing intraocular inflammation may show chorioretinal adhesions with the inflammatory process involving the choriocapillaris, as seen in chronic Vogt–Koyanagi–Harada disease.<sup>16,40</sup>

Immunohistochemical studies have revealed infiltration of predominantly T lymphocytes in the uveal tract.<sup>38,42</sup> B lymphocytes may also be present, especially in long-standing disease, as well as in individuals receiving corticosteroids.<sup>41,43,44</sup> Among the T lymphocytes, both helper (CD4<sup>+</sup>) and suppressor/cytotoxic (CD8<sup>+</sup>) cells have been observed,<sup>38,42</sup> driving a Th1 response with secretion of proinflammatory cytokines such as interferon- $\gamma$  and IL-2.<sup>45</sup> M1 macrophages have been reported to predominate in the granulomas, with significant expression of IL-23, CCL19, and CXCL11. IL-17 has also been detected in relatively high levels in the inflammatory infiltrate of eyes with SO.<sup>46</sup> Inflammatory cells are probably recruited to the eye by the selective expression of intercellular adhesion proteins in the uveal tract (particularly some integrins),<sup>47</sup> as well as some other molecules in macrophages and RPE cells, including chemokines, such as monocyte chemoattractant protein-1 (CCL2/MCP-1) and stromal cell-derived factor-1 (CXCL12/SDF-1), and metalloproteinases, such as gelatinase-B.<sup>44</sup> Relative preservation of the choriocapillaris in the acute phase of the disease process may be associated with secretion of anti-inflammatory cytokines by the RPE.<sup>28</sup> A recent study has shown CD4<sup>+</sup> T lymphocytes and melanin-laden macrophages expressing HLA-DR underneath the conjunctiva in the exciting eye, suggesting that antigen processing and presentation may initially take place at that site, further leading to activation of lymphocytes and to the granulomatous response.<sup>48</sup>

Even though the retina seems to be relatively spared in the

pathologic process of sympathetic ophthalmia, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ )-mediated mitochondrial oxidative stress has been localized in the outer retina of enucleated human globes with the disease (Fig. 77.3). This was associated with apoptosis of photoreceptors, and such photoreceptor damage could be an early mechanism leading to vision loss in sympathetic ophthalmia.<sup>49,50</sup> Interestingly, overexpression of a heat shock protein,  $\alpha$ -A-crystallin, has also been identified in the outer retina of these eyes, being associated with protection against oxidative damage and decreased photoreceptor apoptosis.<sup>51</sup>

**FIG. 77.3** Mitochondrial oxidative stress and apoptosis in the human retina with sympathetic ophthalmia. Cytochrome C and nitrotyrosine are immunolocalized in the inner segments (*IS*) of the photoreceptors. Apoptotic neurons marked by terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (*TUNEL*) assay are detected primarily in the outer nuclear layer (*ONL*), and also in the inner nuclear layer (*INL*), but not in the ganglion cell layer (*GCL*). The corresponding hematoxylin and eosin-stained section is seen on the left.

A recent study<sup>52</sup> has also implicated microRNA (small noncoding RNA that negatively regulate gene expression) in the coordination of the immune response in sympathetic ophthalmia. Downregulation of four microRNA (hsa-miR-1, hsa-let-7e, hsa-miR-9, and hsa-miR182) has been associated with the expression of proinflammatory cytokines, particularly TNF- $\alpha$  and nuclear factor-kappa B1 (NF- $\kappa$ B), crucial to the pathogenesis of the disease.<sup>52</sup>

## Clinical Findings

The clinical onset of sympathetic ophthalmia is typically heralded by the development of an apparently mild intraocular inflammation in the sympathizing eye and worsening of inflammation in the exciting eye. The interval between the time of injury and the onset of inflammation in the sympathizing eye has been reported to be as short as 5 days and as long as 66 years after trauma.<sup>1,3,53</sup> In general, however, sympathetic ophthalmia rarely develops sooner than 2 weeks after trauma, with 80% of cases occurring within 3 months and 90% within 1 year of the penetrating injury.<sup>2,7,11</sup> The peak incidence occurs between 4 and 8 weeks after accidental trauma, while cases following surgical trauma may have a more delayed onset.<sup>54</sup>

Symptoms in the sympathizing eye include mild pain, photophobia, and increased lacrimation, blurring of vision, visual fatigue, or even paresis of accommodation. The exciting eye may have a decrease in vision and an increase in photophobia. Moreover, both eyes may show ciliary injection and a partially dilated and poorly responsive pupil.<sup>1,2,9,11</sup>

The clinical signs are variable and can be either insidious or fairly rapid in onset. Anterior-segment changes are those of an anterior uveitis, with ciliary injection, keratic precipitates, flare, and inflammatory cells in the anterior chamber. Thickening of the iris and even iris nodules may also be seen, and posterior synechiae are common. Posterior-segment findings in sympathetic ophthalmia include inflammatory cell infiltration of the vitreous, hyperemia and edema of the optic disc, diffuse edema and exudative detachment of the retina, as well as small yellow-white deposits beneath the RPE, so-called Dalen–Fuchs nodules.<sup>1,2,9,11,16,17</sup> Bullous

serous detachments may also be seen in the peripheral retina. Occasionally, multiple deep ill-defined yellowish lesions may be present, corresponding to choroidal granulomas (Fig. 77.4). Inflammatory scleral involvement is rarely seen clinically but is a common finding on microscopic examination of enucleated eyes. With time, patients may develop depigmentation of the choroid leading to the so-called sunset glow fundus, as well as RPE changes, as seen in individuals with chronic Vogt–Koyanagi–Harada disease.<sup>55,56</sup> Although less commonly than in Vogt–Koyanagi–Harada disease, extraocular involvement – including meningismus, dysacusis, vitiligo, poliosis, and alopecia – may also be present in patients with sympathetic ophthalmia.<sup>2,55,57,58</sup>

**FIG. 77.4** Multiple choroidal granulomas in sympathetic ophthalmia.

## Diagnosis

The diagnosis of sympathetic ophthalmia is essentially clinical.<sup>1,2,11</sup> No serologic or immunologic tests are available to aid in the diagnosis. Even though there are no systematized diagnostic criteria, the presence of penetrating ocular trauma (either accidental or surgical) is a fundamental feature. Bilateral intraocular inflammation should also be present and may be accompanied by

exudative retinal detachments and/or optic disc edema early in the disease process, or by choroidal depigmentation (sunset glow fundus) and RPE changes in chronic cases, similarly to Vogt–Koyanagi–Harada disease.<sup>59</sup> However, variations in this clinical presentation can challenge or delay the diagnosis. Some imaging studies, such as fluorescein angiography, indocyanine green angiography (ICGA), B-scan ultrasound, as well as optical coherence tomography (OCT), may be helpful to disclose or delineate better some supportive features of sympathetic ophthalmia.<sup>10</sup>

Fluorescein angiography may typically show multiple progressively fluorescent dots at the level of the RPE (pin-point leakage; Fig. 77.5), as well as disc leakage, as also seen in Vogt–Koyanagi–Harada disease. Coalescence of the dye from these foci occurs in the areas of exudative detachment.<sup>2,60,61</sup> Less frequently there may also be early focal blockage of the background choroidal fluorescence, a finding also noted in acute posterior multifocal placoid pigment epitheliopathy.<sup>62</sup> On ICGA numerous hypofluorescent patches may be visible during the intermediate phase, presumably corresponding to the choroidal granulomas. Some of these may become isofluorescent at the later phases.<sup>63–65</sup>

**FIG. 77.5** Fundus and angiographic features of sympathetic ophthalmia following a penetrating scleral injury in the left eye. Foci of exudative retinal detachment are seen in the posterior pole of both eyes. Fluorescein angiography reveals multiple pin-point leaks at the level of the retinal pigment epithelium.

Ultrasound examination may reveal choroidal thickening and also areas of exudative retinal detachment, being particularly useful in the exciting eyes with opaque media.<sup>11,18</sup> Usually the choroidal thickening is more prominent around the optic disc and less in the anterior choroid. OCT can nicely delineate the foci of exudative retinal detachment, their resolution following appropriate therapy (Fig. 77.6), as well as progressive decrease in choroidal thickening, changes in the neurosensory retina and in the RPE.<sup>62,66,67</sup>

**FIG. 77.6** Fundus and tomographic features of sympathetic ophthalmia before (top) and 2 months after (bottom) appropriate treatment with high-dose oral corticosteroid. Complete resolution of the exudative retinal detachment is seen. (Courtesy of Centro Brasileiro de Ciências Visuais, Belo Horizonte, Brazil.)

Especially in those severely traumatized eyes that later require enucleation, histopathologic examination may help to make or confirm the diagnosis.<sup>2,17,18,40,41</sup>

## Differential Diagnosis

Sympathetic ophthalmia must be differentiated from several infectious and also other noninfectious uveitides, including syphilis, tuberculosis, sarcoidosis, multifocal choroiditis, and panuveitis. Other bacterial and fungal infections can also produce a granulomatous anterior and/or posterior uveitis, being usually

differentiated by history and associated clinical findings. Infectious endophthalmitis must always be considered following any penetrating trauma to the eye. In particular, less virulent microorganisms such as *Propionibacterium acnes* and some fungi may lead to a picture of chronic endophthalmitis, which should be distinguished from sympathetic ophthalmia. Reactivation of a preexisting uveitis after injury or the development of a posttraumatic iritis or iridocyclitis can also occur.<sup>2,11</sup>

Phacoanaphylactic endophthalmitis can also closely simulate the clinical picture of sympathetic ophthalmia, and these two entities may even coexist in the same eye. Although unilaterality can be a clue, phacoanaphylaxis may also be bilateral, but such bilaterality is rare. The incidence of phacoanaphylaxis in cases of sympathetic ophthalmia has been estimated to range between 4 and 25%. Unlike sympathetic ophthalmia, in bilateral phacoanaphylaxis the eye first involved is usually quiet by the time inflammation begins in the fellow eye. Moreover, ultrasound examination usually reveals predominant thickening of the anterior uveal tract in phacoanaphylactic endophthalmitis, in contrast to sympathetic ophthalmia, in which such thickening is more pronounced in the posterior uveal tract. A careful slit-lamp examination should always be carried out to search for ruptured lens capsule and fragments of lens cortex in the anterior chamber. In phacoanaphylactic endophthalmitis, lens extraction can be curative, thereby avoiding unnecessary enucleation.<sup>18,68</sup>

Vogt–Koyanagi–Harada syndrome is a bilateral granulomatous panuveitis, often associated with a prodrome of meningeal and auditory symptoms. The disease may have clinical and histopathologic features identical to sympathetic ophthalmia in both the acute and in the chronic phase. However, findings such as vitiligo and alopecia are more common in Vogt–Koyanagi–Harada syndrome than in sympathetic ophthalmia. A history of penetrating trauma is helpful in this differential diagnosis.<sup>2,55,56</sup>

## Course and Complications

Untreated sympathetic ophthalmia runs a long, variable, and complicated course, marked initially by episodes of active

intraocular inflammation followed by quiescent periods that can last months to several years. With time, the disease may become chronically active, eventually producing irreversible ocular damage and even phthisis bulbi. Long-term complications of sympathetic ophthalmia include cataract, secondary ocular hypertension or hypotony, glaucoma, persistent cystoid macular edema or retinal detachment, chorioretinal scarring (including epiretinal membrane formation), choroidal neovascularization, subretinal fibrosis, and optic atrophy.<sup>2,17,69</sup> In spite of treatment, the overall risk of developing any of these ocular complications reaches 40% per patient per year, with around half of the patients losing vision to <20/40 and roughly one-fourth eventually becoming legally blind.<sup>54</sup>

## Therapy

Although corticosteroids have not been shown to be effective in the prevention of sympathetic ophthalmia, they do constitute the mainstay of its therapy.<sup>2,6,9</sup> Large doses of corticosteroids should be given early in the course of the disease and continued for at least 6 months. For the first week, 1.5–2.0 mg/kg of body weight of oral prednisone (or equivalent) is given daily and then gradually tapered over several months, following clinical response of the uveitis. Alternatively, pulse therapy with intravenous methylprednisolone (up to 1 g daily for 3 days), as well as supplementation with sub-Tenon injection of triamcinolone acetonide (20–40 mg), may be considered. Topical corticosteroids and mydriatic/cycloplegic agents are used adjunctively as needed. Special care should be taken to monitor side-effects of the systemic corticosteroids, including periodic measurement of blood pressure, body weight, lipids, blood glucose, as well as gastroduodenal protection and prophylaxis of osteoporosis (with calcium and vitamin D supplementation).<sup>70</sup>

In a number of patients, medical problems or systemic or ophthalmologic complications may prevent the long-term use of high doses of steroids. In these patients, supplemental treatment with immunosuppressive agents (azathioprine, 2–4 mg/kg per day; cyclosporine, 2.5–5 mg/kg per day; mycophenolate mofetil, 1–1.5 g b.i.d.; methotrexate, 15–25 mg/week) has been shown to suppress

inflammation effectively, allow reduction of corticosteroid therapy to nontoxic levels (<10 mg/day), and, in some cases, induce disease remission. Careful monitoring of their side-effects every 4–6 weeks, with the supervision of an internist, is recommended. Bone-marrow suppression, renal and/or hepatic toxicity can occur with prolonged use of these agents.<sup>70</sup> The alkylating agents cyclophosphamide (2–3 mg/kg per day) and chlorambucil (0.1–0.2 mg/kg per day) are reserved for more severe and refractory cases.<sup>70,71</sup> These agents require careful monitoring for side-effects, including hemorrhagic urinary bladder inflammation and development of malignancies. A recent study<sup>72</sup> interestingly confirmed that high-dose short-term chlorambucil (median cumulative dose: 1449 mg; median duration: 14 weeks) may lead to sustained remission in most SO patients refractory to conventional therapy, with minimal adverse effects in a median follow-up of 8 years (range: 4–37 years).

Biologicals, particularly anti-TNF agents such as infliximab and adalimumab, may also be used in cases of sympathetic ophthalmia that are unresponsive to conventional immunomodulatory agents and, in this setting, favorable results have been anecdotally reported in the recent literature.<sup>73–75</sup> However the long-term safety of these agents is still uncertain.<sup>76</sup>

Intraocular corticosteroids, either administered as intravitreal injections (triamcinolone acetonide 4 mg) or as slow-release devices, such as fluocinolone or dexamethasone intravitreal implants, may also be used, especially in individuals who cannot tolerate the systemic medications.<sup>77–80</sup> Special concern should be given to the high risk of cataract and secondary glaucoma associated with these intravitreal devices.

## Prevention

The prevention of sympathetic ophthalmia entails careful microsurgical wound toilet and prompt closure of all penetrating injuries. Every attempt should be made to save any eye with a reasonable prognosis for useful vision, but in those eyes with barely discernible or no visual function, and with demonstrable disorganization of the ocular contents, enucleation within 2 weeks after injury is possibly the only way to definitely prevent the

development of sympathetic ophthalmia.<sup>3</sup> At one time it was believed that the use of steroids following penetrating injury would in some instances prevent the development of sympathetic ophthalmia; this has not been proved to be the case.

Enucleation of the exciting eye once sympathetic ophthalmia has commenced has been a topic of considerable controversy. Some studies suggest that early enucleation of the exciting eye may improve the prognosis for the sympathizing eye,<sup>17,81</sup> however, careful review of the data presented in these studies does not support this conclusion.<sup>82</sup> A review by Winter of 257 cases of histologically proven sympathetic ophthalmia indicated no benefit to the sympathizing eye from enucleation of the exciting eye, whether performed briefly before, concomitant with, or subsequent to the development of sympathetic ophthalmia at various elapsed intervals following injury.<sup>16</sup> This was also supported by the results of a prospective study.<sup>6</sup> Indeed, it is possible that the exciting eye may eventually provide the better visual acuity, and its enucleation would therefore deprive the patient of that visual potential.<sup>82</sup>

Another controversy is the possible role of evisceration versus enucleation. Even though evisceration may be technically easier and provides a faster recovery,<sup>83</sup> it may not protect against the development of sympathetic ophthalmia, probably because of retention of uveal remnants in the scleral shell.<sup>84</sup> Cases of sympathetic ophthalmia following evisceration have been described in the older literature.<sup>84,85</sup> Sympathetic ophthalmia after evisceration is rarer nowadays, but recent cases have been anecdotally reported.<sup>86-89</sup> Because this is far less common than in the past,<sup>90,91</sup> and management of sympathetic ophthalmia has significantly improved,<sup>6,9,11</sup> an issue arises whether evisceration should indeed be preferred to enucleation, particularly in blind eyes, after severe trauma and/or infection. Indeed evisceration is increasingly recommended by surgeons in place of enucleation.<sup>10,92</sup> However, this issue is not yet resolved,<sup>65</sup> especially considering the very low incidence of sympathetic ophthalmia and the changing trend from posttraumatic to postsurgical cases.<sup>7,9</sup> An additional complication to this controversy is the risk of inadvertently eviscerating occult tumors,<sup>93</sup> which may even outweigh the risk of sympathetic ophthalmia *per se*. It is advisable that patients with penetrating

ocular injuries, as well as those undergoing intraocular surgeries with an increased risk of sympathetic ophthalmia (such as pars plana vitrectomy), are counseled about the possibility of developing the disease, early or even long after the traumatic or surgical insult.

## Prognosis

Before the use of corticosteroids, the visual prognosis of sympathetic ophthalmia was generally poor. However, after the advent of the corticosteroids and more recently of immunosuppressive agents, outcomes dramatically improved.<sup>9,11</sup> Makley and Azar found that, in patients treated solely with systemic corticosteroids, a visual acuity of 20/60 or better was achieved in most of them, but relapses occurred in 60%, sometimes long after initial disease remission.<sup>69</sup> Chan et al. reported visual acuity of 20/40 or better in 50% of patients treated with steroids and immunosuppressive agents.<sup>94</sup> With prompt and aggressive corticosteroid therapy, and immunosuppressive agents, as needed, many eyes with sympathetic ophthalmia should retain reasonable vision.

In conclusion, sympathetic ophthalmia is a serious ocular inflammatory entity, often with many exacerbations and a relentlessly progressive course that may result in very poor vision. Cases associated with penetrating accidental trauma have been decreasing with improved repair of such globes, but, on the other hand, those following intraocular (particularly vitreoretinal) surgery are on the rise. Long-term follow-up of these patients is essential. It is hoped that, with the prompt and aggressive use of corticosteroids early in the course of the disease, and supplementation with immunosuppressive agents when indicated, the prognosis in these patients need not to be as grim as it had been in the past.

# Introduction and Historical Aspects

Vogt–Koyanagi–Harada (VKH) disease is a bilateral granulomatous uveitis often associated with exudative retinal detachment and with extraocular manifestations, such as pleocytosis in the cerebrospinal fluid and, in some cases, vitiligo, poliosis, alopecia, and dysacusis.<sup>1</sup>

Poliosis associated with ocular inflammation was first described by Ali-ibn-Isa, an Arab physician who lived in the 1st century AD (cited by Pattison).<sup>2</sup> This association was reported by Schenkl in 1873,<sup>3</sup> by Hutchinson in 1892,<sup>4</sup> and by Vogt in 1906.<sup>5</sup> Harada described a primary posterior uveitis with exudative retinal detachments in association with cerebrospinal fluid pleocytosis.<sup>6</sup>

Three years later, in 1929, Koyanagi described six patients with bilateral chronic iridocyclitis, patchy depigmentation of the skin, patchy hair loss, and whitening of the hair, especially the eyelashes.<sup>7</sup> This constellation of findings was termed “uveitis with poliosis, vitiligo, alopecia, and dysacusis.”<sup>7</sup> Babel in 1932<sup>8</sup> and Bruno and McPherson in 1945 combined the findings of Vogt, Koyanagi, and Harada and suggested that these processes represent a continuum of the same disease,<sup>9</sup> thereafter recognized as Vogt–Koyanagi–Harada syndrome.

When a patient presents with the ocular and the extraocular manifestations, the diagnosis of VKH is made with certainty. However, extraocular manifestations such as dysacusis and cutaneous changes are relatively rare, and the dermatologic changes mainly occur late in the course of the disease.<sup>1,10</sup> Because of the variation in clinical presentations of VKH, the American Uveitis Society (AUS) in 1978 recommended the following diagnostic criteria: (1) the absence of any history of ocular trauma or surgery; and (2) the presence of at least three of the following four signs: (a) bilateral chronic iridocyclitis; (b) posterior uveitis, including exudative retinal detachment, forme fruste of exudative retinal detachment, disc hyperemia or edema and “sunset glow” fundus; (c) neurologic signs of tinnitus, neck stiffness, cranial nerve, or central nervous system disorders, or cerebrospinal fluid pleocytosis;

and (d) cutaneous findings of alopecia, poliosis, or vitiligo.<sup>11</sup>

Since VKH manifestations vary depending upon the clinical course, a given patient may not initially present with the features required for the diagnosis of VKH by AUS criteria. Read and Rao evaluated the utility of the existing AUS criteria in 71 consecutive patients with VKH who were diagnosed based on the clinical features and the course of the disease, combined with fluorescein angiography (FA) with or without ultrasonography in selected cases.<sup>12</sup> The authors concluded that AUS criteria for diagnosis of VKH may not be adequate. Taking into account the multisystem nature of VKH and allowing for the different ocular findings present in the early and late stages of the disease, the First International Workshop on VKH proposed revised diagnostic criteria to include clinical manifestations at various stages of disease.<sup>13</sup> The revised diagnostic criteria are summarized in [Box](#)

#### **Box 78.1**

### **Revised Diagnostic Criteria Proposed by the First International Workshop on Vogt–Koyanagi–Harada Disease\***

#### **Complete VKH Disease**

1. Bilateral ocular involvement (a or b must be met, depending on the stage of disease when the patient is examined)
  - a. Early manifestations of disease
    - 1) There must be evidence of a diffuse choroiditis (with or without anterior uveitis, vitreous inflammatory reaction, or optic disc hyperemia), which may manifest as one of the following:
      - a) Focal areas of subretinal fluid, or
      - b) Bullous serous retinal detachments

- 2) With equivocal fundus findings, both of the following must be present as well:
  - a) Focal areas of delay in choroidal perfusion, multifocal areas of pin-point leakage, large placoid areas of hyperfluorescence, pooling within subretinal fluid, and optic nerve staining (listed in order of sequential appearance) by fluorescein angiography, and
  - b) Diffuse choroidal thickening, without evidence of posterior scleritis by ultrasonography
- b. Late manifestations of disease
  - 1) History suggestive of prior presence of findings from 1a, and either both (2) and (3) below, or multiple signs from (3):
  - 2) Ocular depigmentation (either of the following manifestations is sufficient):
    - a) Sunset glow fundus, or
    - b) Sugiura's sign
  - 3) Other ocular signs:
    - a) Nummular chorioretinal depigmented scars, or
    - b) Retinal pigment epithelium clumping and/or migration, or

c) Recurrent or chronic anterior uveitis

2. Neurologic/auditory findings (may have resolved by time of examination)

a. Meningismus (malaise, fever, headache, nausea, abdominal pain, stiffness of the neck and back, or a combination of these factors; headache alone is not sufficient to meet the definition of meningismus, however), or

b. Tinnitus, or

c. Cerebrospinal fluid pleocytosis

3. Integumentary finding (not preceding onset of central nervous system or ocular disease)

a. Alopecia, or

b. Poliosis, or

c. Vitiligo

**Incomplete VKH Disease (Point 1 and Either 2 or 3 Must Be Present)**

1. Bilateral ocular involvement as defined for complete VKH disease

2. Neurologic/auditory findings as defined for complete VKH disease above, or

3. Integumentary findings as defined for complete VKH disease above

## Probable VKH Disease

1. Bilateral ocular involvement as defined for complete VKH disease above

---

\*In all cases there should not be a history of penetrating ocular injury or surgery preceding the initial onset of uveitis and no clinical or laboratory evidence suggestive of other ocular disease criteria.

Modified from Read RW, Holland GN, Rao NA, et al. Revised diagnostic criteria for Vogt-Koyanagi-Harada disease: report of an international committee on nomenclature. *Am J Ophthalmol* 2001;131:647-52.

In the past, constellation of these ocular signs and symptoms warranted the term “syndrome,” but in recent years the entity has been well characterized; thereafter the International Workshop on VKH adopted the term Vogt-Koyanagi-Harada disease.<sup>13</sup>

## Epidemiology

The incidence of VKH is variable. It appears to be more common in Japan, where it accounts for 6.7% of all uveitis referrals.<sup>14</sup> In the United States it accounts for 1–4% of all uveitis clinic referrals.

VKH tends to affect more pigmented races, such as Asians, Hispanics, American Indians, and Asian Indians.<sup>1,15</sup> In the United States there appears to be variability in the racial distribution of patients with VKH disease.<sup>1,11,16,17</sup> In northern California, VKH was seen mainly in Asians (41%), followed by whites (29%), Hispanics (16%), and blacks (14%).<sup>17</sup> In contrast, reports from southern California show that 78% of VKH patients were Hispanic while 3% were white, 10% were Asian, and 6% were black.<sup>1</sup> A series reported from the National Institutes of Health (NIH) showed that 50% of VKH patients were white, 35% were black, and 13% were Hispanic.<sup>17</sup> However, most of those patients reported in the NIH series had remote American Indian ancestry. Most studies report that women tend to be affected more frequently than men; however, Japanese investigators have not found such a female predilection.<sup>15</sup> Most patients are in their second to fifth decades of

life, but children may also be affected.<sup>1,18</sup> According to the university hospital-based national survey conducted twice in Japan in the past 10 years, the frequency of VKH disease among all uveitis patients has been stable at about 7%.<sup>19</sup>

## Clinical Description

Typical clinical features of VKH include bilateral panuveitis associated with exudative retinal detachment, meningismus associated with headache and pleocytosis of cerebrospinal fluid, tinnitus or hearing loss, and cutaneous changes, such as alopecia, poliosis, and vitiligo. However, all of the cutaneous changes are rarely seen during the initial presentation, and the clinical features vary depending upon the stage of the disease as well as the effect of medical treatment. Presence of ocular and two or more extraocular features is considered as a complete form of VKH disease.<sup>13</sup>

Incomplete VKH disease includes bilateral typical ocular involvement plus either neurologic/auditory or cutaneous changes, whereas probable VKH disease is composed of just ocular manifestations.<sup>13</sup> However, some of these probable VKH patients can develop cutaneous manifestations during the chronic or chronic recurrent stage of the disease.

## The Prodromal Stage

Initial manifestations of VKH disease may include nonspecific viral-like illness, commonly referred to as a prodromal stage. This stage may last only a few days and may be limited to headaches, nausea, dizziness, fever, orbital pain, and meningism. Light sensitivity and tearing may occur 1–2 days following the above symptoms. These neurologic signs include cranial nerve palsies and optic neuritis. Cerebrospinal fluid analysis usually reveals pleocytosis.

## The Acute Uveitic Stage

This stage follows the prodromal phase and presents with blurring of vision in both eyes. One eye may be affected first, followed a few days later by the second eye. Despite a delay in symptoms, careful

examination will reveal bilateral posterior uveitis. This uveitis consists of thickening of the posterior choroid with elevation of the peripapillary retinochoroidal layer, multiple serous retinal detachments (Fig. 78.1), hyperemia, and edema of the optic nerve head.

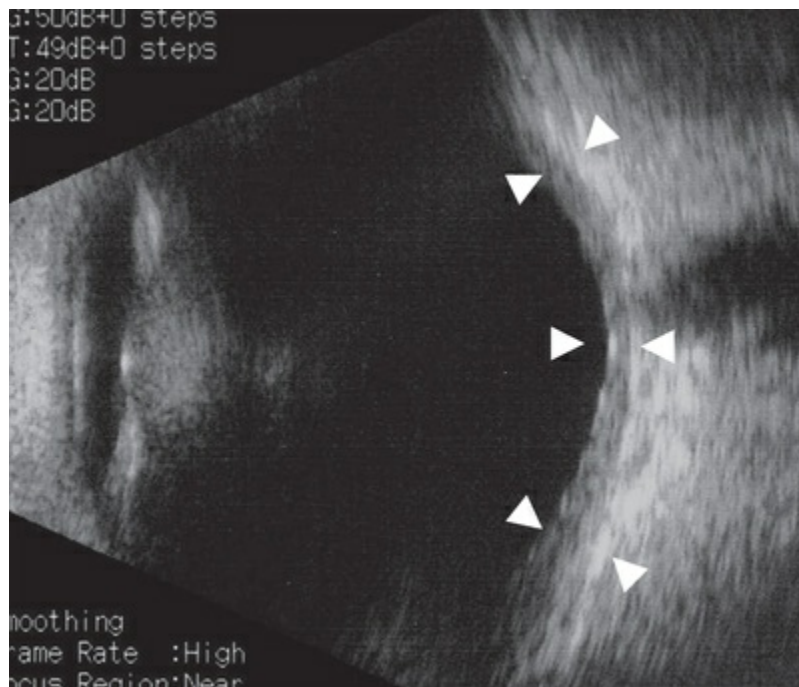

**FIG. 78.1** Bilateral multiple serous retinal detachments at the acute uveitis stage of Vogt–Koyanagi–Harada disease.

Rarely VKH disease can present with optic disc hyperemia and edema without serous retinal detachments (Fig. 78.2). VKH patients with optic disc swelling without typical serous retinal detachment are more likely to be female, older individuals, and they develop chronic disease more frequently than patients with the typical VKH presentations.<sup>20</sup>

**FIG. 78.2** Bilateral hyperemia and edema of the optic disc at the acute uveitis stage of Vogt–Koyanagi–Harada disease without serous retinal detachment.

Thickened choroid can be detected by ultrasonography (Fig. 78.3). Alteration in the retinal pigment epithelium (RPE) associated with multifocal choroidal inflammation is easily observed with FA, which reveals hypofluorescent dots at the early phase followed by multiple focal areas of leakage and subretinal fluid accumulation at the late phase (Fig. 78.4).

**FIG. 78.3** Ultrasonography showing thickened choroid (*arrowheads*).

**FIG. 78.4** (A) Early arteriovenous phase of fluorescein angiogram exhibiting multiple hypofluorescent dots with irregular hyperfluorescent background. (B) Subsequently, multiple hyperfluorescent dots at the retinal pigment epithelium level are noted. (C) Dye leakage during midphase of the angiogram. (D) Subretinal dye pooling at the area of serous retinal detachment during the late phase.

Indocyanine green angiography (ICGA) (Fig. 78.5) could be useful to evaluate choroidal inflammatory changes, such as early choroidal stromal vessel hyperfluorescence and leakage, and hypofluorescent dark dots at the level of the choroid.<sup>21,22</sup>

**FIG. 78.5** (A) Early phase of the indocyanine green angiogram showing vascular leakage in the choroid. (B) Late phase of angiogram showing multiple hypofluorescent dots.

The inflammation eventually becomes diffuse, extending into the anterior segment and revealing the presence of flare and cells in the anterior chamber. Less commonly, mutton-fat keratic precipitates, small nodules on the iris surface and pupillary margin, may be observed;<sup>1</sup> however, these anterior inflammatory changes are more common in the recurrent phase. The inflammatory infiltrate in the ciliary body and choroid may cause forward displacement of the lens iris diaphragm (Fig. 78.6), leading to acute angle closure glaucoma or annular choroidal detachment.<sup>23,24</sup> These intraocular changes are typically bilateral; rarely, however, the process can be restricted to one eye.<sup>25</sup>

**FIG. 78.6** Shallow anterior chamber caused by the anterior displacement of the lens associated with inflammatory infiltrates at the ciliary body.

## The Chronic Uveitic Stage

The chronic or convalescent stage occurs several weeks after the acute uveitic stage and is characterized by development of vitiligo (Fig. 78.7), poliosis, and depigmentation of the choroids. Perilimbal vitiligo, also known as Sugiura's sign (Fig. 78.8), may develop at this stage among the patients who have melanosis at the palisade of Vogt, such as Japanese patients.<sup>1,13</sup>

**FIG. 78.7** Bilateral upper-eyelid vitiligo.

**FIG. 78.8** Chronic stage of Vogt-Koyanagi-Harada disease showing extensive posterior synechiae and loss of pigment at the limbus (Sugiura's sign).

Choroidal depigmentation occurs a few months after the uveitic phase. This leads to the characteristic pale disc with a bright red-orange choroid known as sunset glow fundus (Fig. 78.9). In Hispanics, the sunset glow fundus may show foci of RPE changes in the form of hyperpigmentation or hypopigmentation. The juxtapapillary area may show marked depigmentation. At this stage, small, yellow, well-circumscribed areas of chorioretinal

atrophy may appear, mainly in the inferior midperiphery of the fundus. This convalescent phase may last for several months.

**FIG. 78.9** Chronic stage of Vogt–Koyanagi–Harada disease revealing sunset glow fundus with juxtapapillary depigmentation and oval retinal pigment epithelium atrophic lesions in an Asian patient (A) and in a Hispanic patient (B).

## The Chronic Recurrent Stage

The chronic recurrent stage consists of a smoldering panuveitis with acute episodic exacerbations of granulomatous anterior uveitis. Recurrent posterior uveitis with exudative retinal detachment is uncommon. The anterior uveitis may be resistant to local and systemic corticosteroid therapy. Iris nodules may be seen during this phase (Fig. 78.10). The most visually debilitating complication of the chronic inflammation during this stage appears to be the development of subretinal neovascular membranes.<sup>26</sup> Posterior subcapsular cataract, as well as glaucoma, either angle closure or open angle, and posterior synechiae, may also be seen.<sup>27,28</sup> Recurrence of the intraocular inflammation may lead to extensive chorioretinal atrophy.

**FIG. 78.10** Multiple iris nodules at the iris in chronic recurrent stage.

## Frequency of Distinguishing Clinical Features

Clinical features of ocular and extraocular manifestations of 180 patients with VKH disease and 967 patients with non-VKH disease analyzed by stepwise logistic regression models are listed in [Table 78.1](#).<sup>29</sup> In the acute stage, exudative retinal detachment was most likely to be found, whereas in the chronic stage, sunset glow fundus was most common. Prevalence of sunset glow fundus can be low (67.5%) in patients treated with systemic corticosteroid from the initial acute uveitic stage.<sup>27</sup>

**TABLE 78.1**  
Distinguishing Clinical Features of Acute and Chronic Vogt–Koyanagi–Harada Disease<sup>26</sup>

Dependent Variable = VKH	Odds Ratio Estimate (95% CI)	<i>p</i> Value
<b>ACUTE DISEASE</b>		
Exudative retinal detachment	>999 (48.02, >999)	<0.0001
Alopecia	81.23 (2.47, >999)	0.01
Disc hyperemia	5.28 (1.02, 27.42)	0.05
Asian	24.48 (2.38, 251.9)	0.007
Hispanic	59.76 (3.77, 948.2)	0.004
<b>CHRONIC DISEASE</b>		
Sunset glow fundus	141.66 (54.65, 367.2)	<0.0001

Vitiligo	11.73 (3.59, 38.33)	<0.0001
Alopecia	3.20 (1.40, 7.31)	0.0005
Nummular chorioretinal scars	2.83 (1.34, 5.98)	0.01
Vitreous cells	0.39 (0.18, 0.83)	0.02
Asian	3.48 (1.60, 7.60)	0.002

## Pathology and Pathogenesis

VKH is a non-necrotizing diffuse granulomatous inflammation involving the uvea. Although a granulomatous process is the primary feature of the disease, the histopathologic changes vary depending on the stage of the disease.<sup>30</sup> Uvea is thickened by diffuse infiltration of lymphocytes and macrophages, admixed with epithelioid cells and multinucleated giant cells containing melanin granules. The neural retina is detached from the RPE, and the subretinal space contains proteinaceous fluid exudates (Fig. 78.11). Dalen–Fuchs nodules, which represent focal aggregates of epithelioid histiocytes admixed with RPE, are located between Bruch's membrane and the RPE.<sup>31</sup> In the convalescent stage, the choroidal melanocytes decrease in number and disappear (Fig. 78.12), resulting in the sunset glow appearance of the fundus.<sup>31</sup> During the chronic stage, the numerous focal yellowish oval or round lesions seen in the inferior peripheral fundus by ophthalmoscopy histologically display a focal loss of RPE cells and the formation of chorioretinal adhesions.<sup>31</sup> In the longstanding chronic recurrent stage, the RPE and neural retina show degenerative changes (Fig. 78.13). The RPE may reveal hyperplasia and fibrous metaplasia with or without associated subretinal neovascularization.<sup>31</sup>

**FIG. 78.11** Acute uveitic stage of Vogt–Koyanagi–Harada disease shows serous detachment of the retina, preservation of choriocapillaris from inflammatory cell infiltration, and thickening of choroid from granulomatous inflammatory cell infiltration (hematoxylin and eosin). (Courtesy of Professor H. Inomata.)

**FIG. 78.12** Convalescent stage of Vogt–Koyanagi–Harada disease, exhibiting loss of choroidal melanocytes and infiltration of lymphocytes and plasma cells in the choroid. Note relatively intact retinal pigment epithelium and neurosensory retina

(hematoxylin and eosin). (Courtesy of Professor H. Inomata.)

**FIG. 78.13** Chronic recurrent stage of Vogt–Koyanagi–Harada disease shows choroidal inflammation, retinal pigment epithelium proliferation, and degeneration of overlying retina (hematoxylin and eosin). (Courtesy of Professor H. Inomata.)

Although the exact cause for the inflammation directed at the melanocytes remains unknown, current evidence suggests that it involves an autoimmune process driven by T lymphocytes against an as-yet unidentified antigen(s) associated with melanocytes.<sup>1,32,33</sup>

The antigenic peptides to induce autoimmune response in the uveal tract may include tyrosinase or tyrosinase-related proteins.<sup>34,35</sup> Experimental animal studies, as well as T-cell clones raised specific to tyrosinase family protein from the peripheral blood of patients with VKH, suggest that autoreactive T cells against tyrosinase and/or tyrosinase-related proteins may play a role in the development of VKH in a genetically susceptible individual.<sup>35</sup>

Cytokines are known to play an important role in the pathogenesis of VKH disease. Interleukin (IL)-21, a member of the IL-2 family exerting pleiotropic effects on the immune system, could be involved in the pathogenesis of VKH disease, possibly by promoting IL-17 secretion.<sup>36</sup>

CD4<sup>+</sup>CD25<sup>high</sup> T-regulatory (Treg) cells have been shown to be involved in the pathogenesis of autoimmune diseases. Reduction of number or impaired function of CD4<sup>+</sup>CD25<sup>high</sup> Treg cells has been reported in patients with VKH.<sup>37</sup>

There is a strong association with the human leukocyte antigen (HLA) DR4 in Japanese patients with VKH disease, and these patients and individuals from Korea showed predominant alleles of DRB1\*0405 and HLA-DRB1 \*0410.<sup>38</sup> Significant difference in the prevalence of HLA-DRB1 \*0405 between the VKH patients and control subjects was also demonstrated in the Middle East.<sup>39</sup> However, in other racial groups, such as mixed Hispanic individuals from southern California, either HLA-DR1 or HLA-DR4 was found in 84% of patients with VKH disease.<sup>40</sup> Indeed, there was a higher relative risk with HLA-DR1 than HLA-DR4 (4.11 vs. 1.96, respectively). Similar HLA-DR1 and HLA-DR4 subtypes were noted in 89% of mixed Mexican patients.<sup>41</sup> These studies indicate that specific HLA genes may confer risk for development of VKH disease.

## Investigations

### Imaging Studies

In the vast majority of cases, the diagnosis of VKH disease is a clinical one when the patient presents with ocular and extraocular manifestations. However, when the disease presents without extraocular changes, FA is essential for the diagnosis. ICGA is also useful to evaluate choroidal inflammatory changes.

In patients with inadequate pupillary dilation caused by posterior synechiae or dense vitritis that obscures the view of the fundus, ultrasonography may help to establish the diagnosis.<sup>42</sup> Ultrasound biomicroscopic examination and other recent ophthalmic viewing systems during the uveitic stage may reveal shallow anterior chamber, ciliochoroidal detachment, and thickened ciliary body.

In addition to angiography and ultrasonography, optical coherence tomography (OCT) and scanning laser ophthalmoscopy (SLO) have been found useful for substantiating the diagnosis.

Serous retinal detachment can be clearly observed by OCT (Fig. 78.14). Thickened choroid can be demonstrated by OCT with enhanced depth imaging (Fig. 78.15). OCT has been used not only for supporting diagnosis but for monitoring resolution of the serous retinal detachment<sup>43,44</sup> and choroidal thickness<sup>45,46</sup> with corticosteroids and immunomodulatory therapy. Choroidal undulation and bulging inward in the acute stage are also clearly demonstrated by OCT.<sup>47</sup> In the chronic stage, changes of the RPE can be clearly depicted as decreased fundus autofluorescence<sup>48,49</sup> (Fig. 78.16).

**FIG. 78.14** Optical coherence tomography showing serous retinal detachment at the acute uveitic stage. Note the multiple serous retinal detachment with septa (A), presence of fibrin in subretinal space (*arrow*) (B), wavy of retinal pigment epithelium (C), and choroidal excavation (D).

**FIG. 78.15** Optical coherence tomography 9 days after systemic corticosteroid therapy showing thickened choroid at the macular area (*arrowheads*).

**FIG. 78.16** Fundus autofluorescence imaging shows decreased autofluorescence at the atrophic nummular scars.

## Lumbar Puncture

Although lumbar puncture is not necessary for the diagnosis of VKH disease with typical ocular and extraocular manifestations, this procedure is a useful adjunctive test in cases with atypical features. Ohno et al. found that more than 80% of patients with VKH disease had cerebrospinal fluid pleocytosis, consisting mostly of lymphocytes.<sup>17</sup> In their study, the pleocytosis was present in 80% of patients within 1 week and in 97% of patients within 3 weeks of the onset of uveitis. The cerebrospinal fluid pleocytosis, however, is

transient and resolves within 8 weeks even in patients who develop recurrences of intraocular inflammation. Cytologic analysis may reveal melanin-containing histiocytes in patients with pleocytosis.<sup>50</sup>

## Differential Diagnosis

The differential diagnosis of VKH disease includes sympathetic ophthalmia, uveal effusion syndrome, posterior scleritis, acute posterior multifocal placoid pigment epitheliopathy (APMPPE), and sarcoidosis.<sup>1</sup> Sympathetic ophthalmia can present with bilateral panuveitis associated with retinal detachment and meningismus. However, a history of penetrating ocular injury is the rule in this disorder. Extraocular manifestations, such as dysacusis, vitiligo, poliosis, and alopecia, can occur in sympathetic ophthalmia, but they are rare.<sup>51</sup>

Uveal effusion syndrome may clinically mimic VKH disease. Angiographically, the effusion syndrome may reveal numerous fluorescent blotches in the subretinal space during the serous detachment phase. The syndrome can involve both eyes, although not simultaneously. Unlike VKH disease, the effusion syndrome lacks intraocular inflammation. Posterior scleritis affects predominantly women and is often bilateral. Patients may present with pain, photophobia, and loss of vision, and the vitreous often reveals cells. Exudative retinal detachment and choroidal folds may be noted. Ultrasonography can help to differentiate posterior scleritis from VKH disease. The former reveals flattening of the posterior aspect of the globe, thickening of the posterior coats of the eye, retrobulbar edema, and high internal reactivity of the thickened sclera. Other entities, such as sarcoidosis and APMPPE, can be differentiated based on their clinical features, ultrasonography, and FA.

## Treatment

Although data from randomized trials are lacking, early and aggressive use of systemic corticosteroids followed by slow tapering over 3–6 months is the acceptable treatment of choice to suppress the intraocular inflammation and to prevent the

development of complications related to the ocular inflammation.<sup>1</sup> Such treatment may prevent progression of the disease to the chronic recurrent stage and may also reduce the incidence and/or severity of extraocular manifestations. If the ocular inflammation relapses after tapering of systemic corticosteroids, the relapse may reflect too-rapid tapering of the corticosteroids. Such recurrences become increasingly steroid-resistant, and cytotoxic or immunosuppressive agents are usually required to control the inflammation. Patients with inflammatory cell infiltration in the anterior chamber require topical corticosteroids and cycloplegics to reduce ciliary spasm and prevent posterior synechiae formation.

High-dose oral corticosteroids, 1–2 mg/kg per day of prednisone or 200 mg of intravenous methylprednisolone for 3 days, followed by oral administration of high-dose corticosteroids with a slow taper, are the mainstay of therapy for VKH disease.<sup>52,53</sup> The use of intravenous corticosteroids, up to 1 g/day for 3 days, followed by a slow taper has been recommended by some. However, Sasamoto et al. found a similar beneficial effect of decreased intraocular inflammation with either 1 g or 200 mg per day of intravenous corticosteroids.<sup>53</sup> Of course, as is always the case when corticosteroids are prescribed, careful attention to possible risks and side-effects is warranted. The route of systemic administration of corticosteroids includes oral and intravenous injection followed by an oral taper. However, the International VKH Study Group concluded that route of administration had no significantly detectable effect on visual acuity outcome nor on the development of visually significant complications.<sup>54</sup>

Although the initial episode of uveitis can be managed successfully in the majority of cases with intravenous and/or oral corticosteroids, few patients may require additional immunomodulatory agent such as cyclosporine, methotrexate, or mycophenolate mofetil. In contrast, recurrences do not respond as well to systemic corticosteroid treatment.<sup>1</sup> Such patients may show some initial response to sub-Tenon injections of triamcinolone acetonide, but they usually require immunomodulatory agents, such as cyclosporine, methotrexate, azathioprine, mycophenolate mofetil, cyclophosphamide, and chlorambucil.<sup>55–58</sup> Sustained release steroid such as the fluocinolone acetonide intravitreal implant may

provide control of intraocular inflammation and reduce dependency on systemic corticosteroids and/or immunosuppressive agents in patients with the chronic stage of VKH disease.<sup>59</sup>

Cyclosporine 2.5–5 mg/kg per day is generally preferred when the intraocular inflammation is corticosteroid-resistant or when the patient experiences intolerable side-effects from the long-term use of corticosteroids. Recently, biologic agents, rituximab and anti-TNF- $\alpha$  antibody, infliximab have been reported in the management of VKH disease.<sup>60</sup>

Administration of the immunomodulatory agents and biologics requires a careful pretreatment evaluation and careful subsequent evaluations during the follow-up examinations for any side-effects associated with the therapy. Various immunosuppressive and cytotoxic agents used in the treatment of VKH disease are

**Box 78.2** summarized in [Box 78.2](#).

## **Immunosuppressive/Cytotoxic Agents Used in the Treatment of Vogt–Koyanagi–Harada Disease**

- Corticosteroids<sup>1,53</sup>
- Oral prednisone 1–2 mg/kg per day initially, followed by gradual taper over 3–6 months
- Pulse dose of methylprednisolone 1 g/day for 3 days, followed by gradual tapering of oral prednisone over 3–6 months
- Intravenous methylprednisolone 100–200 mg/day for 3 days, followed by gradual tapering of oral prednisone over 3–6 months
- Immunosuppressive agents<sup>1</sup>
- Cyclosporin 2.5–5 mg/kg per day
- FK506 0.1–0.15 mg/kg per day
- Cytotoxic agents<sup>1</sup>

- Azathioprine 1–2.5 mg/kg per day
- Mycophenolate mofetil 1–3 g/day
- Cyclophosphamide 1–2 mg/kg per day
- Chlorambucil 0.1 mg/kg per day; dose adjusted every 3 weeks to a maximum of 18 mg/day
- Anti-TNF- $\alpha$  monoclonal antibody<sup>59</sup>

## Complications and Management

A retrospective analysis of the records of 101 patients with VKH disease followed at the Doheny Eye Institute revealed the development of at least one complication in 51% of eyes.<sup>61</sup> Cataract occurred in 42%, glaucoma in 27%, choroidal neovascularization in 11% (Fig. 78.17), and subretinal fibrosis in 6% (Fig. 78.18). The patients who developed these complications had a significantly longer median duration of disease and significantly more recurrences than did those patients who developed no complications. Moreover, eyes possessing a better visual acuity at presentation had better visual acuity at final follow-up, and patients who developed VKH at a more advanced age had a worse visual acuity.<sup>61</sup>

**FIG. 78.17** Submacular choroidal neovascular membrane and hemorrhage during the chronic recurrent stage (A); the fluorescein angiogram shows a

typical neovascular membrane (B).

**FIG. 78.18** Subretinal fibrosis in a patient with chronic recurrent stage of Vogt–Koyanagi–Harada disease.

There is general agreement that cataract surgery should be delayed until the intraocular inflammation has subsided, at which time safe cataract extraction with posterior-chamber intraocular lens implantation can be successfully accomplished. Occasionally, patients with significant vitreous opacities and debris may require a combined procedure of pars plana vitrectomy and lensectomy.

Angle closure due to peripheral anterior synechiae and posterior synechiae may cause glaucoma.<sup>27</sup> Acute angle closure with elevated intraocular pressure has been reported as a presenting sign of VKH disease. Although sustained elevated intraocular pressure can be controlled by medical therapy alone, most patients require surgical intervention in the form of iridectomy, trabeculectomy with 5-fluorouracil or mitomycin C, and tube-shunt surgery.

Chronic recurrent anterior uveitis and fundus pigmentary disturbances seem to predispose patients to the development of choroidal neovascularization<sup>26</sup> (Fig. 78.18). These subretinal neovascular membranes present with raised masses, which may be associated with subretinal hemorrhage. Fluorescein angiography, ICGA, OCT angiography, and OCT are useful for detecting the

neovascular membranes, and photocoagulation may help with the management. Photodynamic therapy with verteporfin for subfoveal choroidal neovascularization has been attempted with some success.<sup>62</sup> Intravitreal injection of an anti-vascular endothelial growth factor (VEGF) may be an option to treat CNV in eyes with VKH.<sup>63</sup>

## Prognosis

In general those VKH patients who are treated with initial high-dose systemic corticosteroids followed by gradual tapering will usually have a fair visual prognosis; nearly two-thirds of these patients retain 20/40 or better visual acuity.<sup>1,53</sup> On average, most patients require treatment for 4–6 months. The complications of chronic recurrent VKH disease include cataract, glaucoma, choroidal neovascularization, subretinal fibrosis, and optic atrophy.<sup>1,52,61,64</sup>

Jap et al. reported that patients treated with low-dose prednisolone (less than 1 mg/kg) had a higher incidence of peripapillary atrophy with increase in recurrences and more frequent episodes.<sup>65</sup>

## Conclusion

VKH is a bilateral granulomatous panuveitis typically associated with exudative retinal detachment that can present initially with posterior uveitis associated with focal or multifocal serous retinal detachment, with signs of meningeal irritation and with or without extraocular manifestations such as poliosis, vitiligo, and auditory disturbances. However, in general the cutaneous extraocular manifestations develop during the chronic phase of the disease. In most cases the diagnosis is a clinical one, but the diagnosis of atypical cases may require the use of FA, lumbar puncture, and ultrasonography. VKH is treated initially with high-dose systemic corticosteroids. Successful outcome requires a gradual tapering of the corticosteroids over a 3–6-month period. Complications of this disease include cataract, glaucoma, choroidal neovascularization, and subretinal fibrosis. The overall prognosis for adequately

managed cases is fair, with nearly 60–70% of patients retaining vision of 20/40 or better.

## **Introduction**

The white spot syndromes (WSS) are a group of diseases characterized by inflammation and dysfunction of the outer retina, retinal pigment epithelium, choroid, or a combination of these. They often present a diagnostic and therapeutic challenge for

clinicians and researchers. The etiologies of WSS remain unknown. This chapter discusses birdshot chorioretinopathy (BCR), acute posterior multifocal placoid pigment epitheliopathy (APMPPE), serpiginous choroiditis, relentless placoid chorioretinitis, persistent placoid maculopathy, multifocal choroiditis (MFC)/punctate inner choroidopathy (PIC), multiple evanescent white dot syndrome (MEWDS), acute zonal occult outer retinopathy (AZOOR), and acute macular neuroretinopathy (AMN). Many entities are included in the differential diagnosis of these diseases. These include granulomatous diseases, such as sarcoid, tuberculosis, and sympathetic ophthalmia; masquerade syndromes like syphilis and intraocular lymphoma; infectious etiologies including toxoplasmosis and pneumocystis choroidopathy; and other entities such as presumed ocular histoplasmosis and Behçet disease.<sup>1</sup> In addition, in some cases, degenerative processes such as drusen may appear similar to the whitish-yellow lesions of WSS.

The WSS each have distinct features, but do share some characteristics. Blurred vision, photopsias, visual field changes, floaters, and changes in contrast sensitivity can occur. Although these entities are thought to be inflammatory in nature, vitritis and iritis are not a necessary finding. The white spots themselves may be subtle or a prominent finding. Inflammatory multifocal chorioretinopathies may actually be a more descriptive term.

The white spot syndromes may present in one or both eyes. When bilateral, they may be asymmetric. The age of onset is generally greater than 50 (other than MEWDS and MFC/PIC) but can range from the second to the sixth decade of life.

An autoimmune etiology has been hypothesized<sup>2</sup> and proposed specifically for birdshot chorioretinopathy, acute zonal occult outer retinopathy (AZOOR), and multiple evanescent white dot syndrome (MEWDS).<sup>3</sup> Infectious causes have been postulated. As yet, no characteristic pattern of antiretinal antibodies has been found. These entities need to be distinguished from entities with known neoplasias such as cancer-associated retinopathy (CAR) or melanoma-associated retinopathy (MAR). There are similar features, including panretinal dysfunction, rapid progression, ERG changes, family history of autoimmune disease, retinal antibody activity on Western blot, and improvement in symptoms with

immunosuppression. It has been shown that there is an increased prevalence of systemic autoimmunity in both patients with WSS and their first- as well as second-degree relatives.<sup>4</sup> This suggests that this group of diseases occurs in families with inherited immune dysregulation that predisposes to autoimmunity.

It has also been suggested that several of these entities may be “related” or even represent a spectrum of the same process. Multifocal choroiditis (MFC), punctate inner choroiditis (PIC), MEWDS, acute macular neuroretinopathy (AMN), and AZOOR share commonalities, and Gass referred to them as the AZOOR complex.<sup>5</sup> These include female preponderance, zones of visual field loss that are usually contiguous to the blind spot, enlarged blind spot, photopsias, and ERG changes such as reduced amplitudes. These diseases are rarely overlapping, and clear distinctions can be made with multimodal imaging techniques. Acute idiopathic blind spot enlargement (AIBSE) was previously described by Fletcher and colleagues in 1988<sup>6</sup> and sometimes included with the white spot syndromes. In previous case series characterizing this entity,<sup>7</sup> there were many patients that today could be distinguished as having other distinct WSS. We believe enlarged blind spots may be a feature of the white spots syndromes and other diseases mentioned in this chapter and are not a specific entity.

## **Birdshot Chorioretinopathy**

The term birdshot retinochoroidopathy was first used in 1980 by Ryan and Maumenee.<sup>8</sup> It was a descriptive term for patients with multiple small, cream-colored fundus findings. These lesions are scattered around the optic disc and radiate to the equator in a “shotgun” pattern. Other terms such as vitiliginous chorioretinitis have been used.<sup>9</sup> It has come to be known as birdshot chorioretinopathy (BCR) due to the histopathologic evidence that the primary lesions of the disease are in the choroid.<sup>10</sup> It is a bilateral, chronic process with vitritis, retinal vasculitis, and cystoid macular edema (CME). Furthermore, it demonstrates the strongest link between any disease and any HLA class I antigen.<sup>11</sup>

## Clinical Course

### Clinical Symptoms.

Patients present with complaints of blurred vision, floaters, and photopsias. Most have vision of 20/40 or better.<sup>10</sup> The eye is generally not red or painful. Severe nyctalopia despite normal visual acuity may also be a presenting symptom.<sup>12</sup> Individuals also may describe an alteration in color vision<sup>13</sup> or visual fields.<sup>14</sup> Although Gass described a few patients who concurrently had vitiligo of the skin,<sup>9</sup> BCR is thought to be a purely ocular disease.

### Epidemiology.

BCR is a rare chronic posterior uveitis. Shah and colleagues did an extensive review of English literature in 2005 and reported the following epidemiologic characteristics.<sup>10</sup> Birdshot chorioretinopathy accounts for 0.6–1.5% of patients referred to tertiary centers for uveitis, or 6–7.9% of patients with posterior uveitis. There is a slight female predominance in the literature, at 54.1–58%.<sup>10,15</sup> The mean reported age at the onset of disease is 53 years. It is generally not a disease of children. The oldest reported age at onset was 79 years. Patients are predominantly white. Finally, the HLA-A29 allele (which is present in about 7% of Caucasians) is strongly associated with BCR.<sup>16</sup> The presence of this allele has been associated with a risk factor of 50–224 to develop BCR. Ninety percent or more of patients with BCR are HLA-A29-positive. Further sequencing of this allele has uncovered 11 subtypes. The HLA-A29\*02 subtype is 20 times more prevalent in Caucasians than the HLA-A29\*01 type, and the rest are exceedingly rare.<sup>17</sup> HLA-A29\*02 subtype is most commonly associated with BCR.

### Fundus Findings.

It is important to recognize that symptoms can precede the onset of the classic fundus findings by several years.<sup>18</sup> There is a range of presentations of the lesions associated with BCR. These birdshot lesions can be oval or round in shape, typically about one-half or one-quarter disc diameter in size. They appear deep to the retina (Fig. 79.1). They can be subtle and be asymmetric between eyes. The

lesions can be distinct or poorly defined and can occasionally coalesce. They tend to cluster near the nerve and most commonly nasal and inferior to the disc.<sup>19,20</sup> There is a pattern of linear radiation away from the nerve to the periphery<sup>7</sup> (Fig. 79.2). They may appear to follow choroidal blood vessels peripherally. There is no hyperpigmentation or clumping noted. The retinal pigment epithelium (RPE) and overlying retina appear intact. There has been a report of these choroidal lesions preceding symptom onset in BCR, but this is not the norm.<sup>21</sup>

**FIG. 79.1** Fundus photo of the left posterior pole showing a hazy view and the distribution of deep, creamy oval lesions.

**FIG. 79.2** Fundus photo showing the “birdshot” pattern extending linearly from the nerve to the periphery.

### Other Ocular Findings.

The anterior segment generally has minimal inflammation without prominent keratic precipitates. Fine keratic precipitates have been described in some series.<sup>20</sup> Due to the mild nature of anterior segment inflammation, posterior synechiae do not occur. Signs of posterior inflammation include retinal vasculitis, optic disc edema, CME (in about 50% of patients),<sup>22</sup> and epiretinal membrane (ERM) formation. Rhegmatogenous retinal detachment has been reported.<sup>8,23,24</sup> Other common findings include diffuse narrowing of the retinal arterioles, perivascular nerve fiber layer hemorrhages, and tortuosity of retinal vessels. Choroidal neovascularization (CNV) can occur.<sup>11,25,26</sup> It has been postulated that this occurs due to the uveitic component causing CNV rather than ischemic factors.<sup>27,28</sup>
