## Choroidal Neovascular Membranes

### Introduction

The growth of choroidal neovascular membranes (CNV) beneath the macula usually causes significant disturbance of central visual function. Prior to the advent of photodynamic therapy and anti-vascular endothelial growth factor (anti-VEGF) agents, the only therapy of proven benefit compared with observation was thermal photocoagulation of the CNV.<sup>1</sup> During that era, surgical removal of subfoveal CNV of various etiologies was an alternative method of eradicating the CNV and improved visual function was achieved in a variety of etiologic settings. Even with current anti-VEGF agents, on occasion extensive submacular hemorrhage (SMH) occurs and surgical intervention may be warranted (Fig. 122.1A). Rarely, surgical removal of CNV without hemorrhage is indicated. This chapter presents current concepts regarding the use of vitreoretinal

surgical techniques as treatment of CNV with or without SMH.

**FIG. 122.1** (A) Thick fovea-involving submacular hemorrhage of 1-day duration in the left eye of an 82-year-old man with exudative macular degeneration who was treated with vitrectomy, subretinal tPA, and sulfur hexafluoride pneumatic displacement. Color fundus photograph on the day of presentation; visual acuity was 3/200, and the area of the hemorrhage was 26.98 mm<sup>2</sup>. (B) Color fundus photograph at 2 weeks after surgery with complete displacement of hemorrhage inferiorly. Visual acuity was 20/400 at postoperative month 1 and 20/80 at 1 year postoperatively after two total anti-VEGF injections.

## Surgical Technique

De Juan and Machemer first reported vitrectomy for the removal of macular CNV through large temporal retinal incisions.<sup>2</sup> Thomas and Kaplan subsequently modified the technique to utilize an eccentric, small retinotomy. Fluid was injected through the retinotomy, and manipulation and extraction of the CNV were achieved.<sup>3,4</sup> Face-down positioning overnight proved adequate to close the small retinotomies without laser photocoagulation.<sup>5</sup> Complications with this technique were minimal.

## Early Results

These surgical techniques were applied to macular CNV, and favorable visual outcomes were reported for CNV of a variety of etiologies.<sup>6-17</sup> It was soon recognized that although some eyes regained excellent central visual function following removal of subfoveal CNV, others did not. Gass hypothesized that some CNV proliferate within Bruch's membrane and beneath the retinal pigment epithelium (RPE), as well as beneath the neurosensory retina (type I CNV – typical of AMD). Removal of such CNV would be expected to leave defects in the RPE and thus poor vision. In other eyes, he postulated that CNV grow through relatively discrete defects in Bruch's membrane and proliferate anterior to native RPE in the subneurosensory retinal space (type II CNV – typical of presumed ocular histoplasmosis syndrome [POHS]).<sup>18</sup> Eyes with CNV associated with POHS, other chorioretinal inflammatory conditions, and idiopathic CNV indeed often demonstrate preserved central RPE and good foveal function after surgical extraction. Eccentricity of the choroidal ingrowth site was found to be an important prognostic factor for good vision in these cases with focal ingrowth sites.<sup>19</sup> Recurrent CNV proved to be a major obstacle to good vision following surgery, as is the case with essentially all other therapies for choroidal neovascularization.<sup>20</sup>

## Submacular Surgery Trials

The Submacular Surgery Trials (SST) were four NIH-sponsored, multicenter, randomized, prospective trials conducted to compare outcomes of submacular surgery versus then-current standard therapy.<sup>21</sup> The SST Pilot Trial found no advantage to surgery over laser photocoagulation for recurrent choroidal neovascularization secondary to age-related macular degeneration (AMD).<sup>22</sup>

The SST Group N enrolled 454 patients with new subfoveal choroidal neovascularization secondary to AMD and randomly assigned patients to surgery or observation. Both groups declined in visual acuity (VA) from 20/100 at baseline to 20/400 by month 24, and the investigators concluded that surgery should not be recommended for these patients.<sup>23</sup>

The SST Group H enrolled 225 patients, 18 years or older with new or recurrent subfoveal choroidal neovascularization that was

either idiopathic or associated with POHS. At all time points, median VA was better in the surgery group than in the observation group, but the difference did not reach statistical significance. At 24 months, median VA was 20/250 for observation eyes and 20/160 for surgery eyes. Only those eyes with acuity worse than 20/100 at baseline achieved a significantly better outcome with surgery than observation at 24 months. The study concluded that submacular surgery may be considered in similar eyes with poor vision (worse than 20/100).<sup>24</sup>

## Current Indications for Surgical Removal of CNV

In the era of anti-VEGF therapy, surgical removal of CNV is rarely necessary. Possible indications would include large peripapillary CNV unresponsive to anti-VEGF agents and/or photodynamic therapy and too large for thermal laser photocoagulation.<sup>25</sup> In such extrafoveal lesions, the CNV can be removed to produce a small, quiet, atrophic scar around the nerve. If the fovea is involved in the neovascular process, then surgical extraction results in loss of foveal RPE and a poor visual outcome. However, in CNV due to POHS, central RPE and reasonable VA may be preserved.<sup>26-31</sup>

## Submacular Hemorrhage

### Introduction

Subretinal hemorrhage, defined as blood located in the potential space between the neurosensory retina and the RPE, is a common manifestation of several diseases of the retina and choroid. The natural history of untreated, thick SMH is generally poor due to a combination of iron toxicity, blockage of nutrient exchange between photoreceptors and the RPE, and mechanical shearing forces of clot retraction.<sup>32</sup> Over the past two decades, a variety of treatment options have been proposed for the treatment of fovea-involving SMH. However, data from large randomized comparative studies are lacking, and the ideal management of SMH remains controversial.

## Etiology

Subretinal hemorrhage involving the macula is most often caused by CNV. Therefore any macular condition that causes growth of CNV can lead to SMH. In a series of 47 consecutive cases of SMH reported by Ibanez et al., over 80% of cases were due to AMD. The remainder of cases were due to CNV from POHS, angioid streaks, and idiopathic SMH.<sup>33</sup> Pathologic myopia and polypoidal choroidal vasculopathy (PCV) have also been reported as causes of SMH.<sup>34,35</sup> Trauma is another possible cause of SMH, and this may occur either at the time of trauma due to localized choroidal rupture or remotely due to the development of CNV at the edge of the rupture site.<sup>36</sup> Aside from ruptured retinal arterial macroaneurysms, other non-CNV related sources of subretinal hemorrhage in the macula are rare.

## Natural History

The natural history of untreated SMH has been described by several authors. Bennet et al.<sup>36</sup> described 29 eyes with SMH and found that the etiology was the most important factor in predicting the final visual outcome. In this series of 12 patients with AMD as the cause of the hemorrhage, 67% of the patients had unimproved or worsened VA at the end of the follow-up period. The final mean VA was 20/1700. Another study, by Scupola et al.,<sup>37</sup> examined 60 eyes with SMH due to AMD and confirmed this poor prognosis, with 80% of the eyes having a worse mean VA of 20/1250. In contrast to this, in Bennet's series, the five patients with traumatic choroidal rupture with SMH fared much better. All five eyes improved, with mean VA of 20/35.<sup>36</sup> Likewise, in a case series of 11 patients with SMH due to Best disease, 10 of the 11 patients experienced improvement, with a final mean VA of 20/50.<sup>38</sup>

The largest natural history study of AMD-associated SMH to date is the observation arm of the Submacular Surgery Trials Group B in which 168 eyes with subfoveal choroidal neovascular lesions composed of at least 50% blood involving the foveal center and with initial VA between 20/100 and light perception (LP) were followed for 2–3 years. Only 19% of eyes gained 2 or more lines of vision during follow-up, while loss of 2 or more lines occurred in

59%, and 36% experienced severe vision loss of 6 lines or more. At 2 years, only 10% of eyes had VA of 20/200 or better.<sup>39</sup>

These natural history studies demonstrate that thicker hemorrhages portend a poorer prognosis due to scar tissue formation and photoreceptor loss and are less likely to clear spontaneously. Duration of the SMH is also an important factor, and most studies recommend intervention within the first 2 weeks, if intervention is undertaken. In the rabbit eye, Glatt and Machemer demonstrated that subretinal blood caused irreversible photoreceptor loss in less than 24 hours.<sup>40</sup> In this animal model, severe damage to the outer retina was seen at 7 days, with scant photoreceptors detected on electron microscopy, and the photoreceptor and outer nuclear layers were completely absent at 2 weeks after injection of autologous blood into the subretinal space.

## Management Options

Given the generally poor natural history of SMH, especially when caused by AMD, various treatment modalities have been explored.

### Surgical Removal of Blood and CNV

Although small retrospective reviews of surgical extraction of clots and associated CNV appeared encouraging compared to the poor natural history of SMH, these early attempts were limited by intraoperative and postoperative complications, including retinal detachment, proliferative vitreoretinopathy (PVR), and recurrent hemorrhage.<sup>33,39,41-43</sup> The SST Group B was a randomized, prospective, multicenter trial comparing surgical extraction of the clot and CNV to observation for patients with hemorrhagic lesions (AMD-associated lesions >3.5 MPS [Macular Photocoagulation Study] disc areas in size in which blood comprised >50% of the lesion).<sup>39</sup> Surgery entailed vitrectomy, optional use of subretinal tissue plasminogen activator, and manual extraction of the clot and any apparent CNV beneath the foveal center through a single retinotomy. Of 168 eyes randomized to surgery, only 18% had VA of 20/200 or better after 2 years and there was no statistically significant difference between the surgery and observation arms in terms of stabilization of vision at any point during 24–36 months'

follow-up. However, at 2 years, fewer surgery eyes (21%) compared with observation eyes (36%) had experienced severe vision loss of 6 lines or more ( $p=.004$ ). This benefit of surgery was most evident in eyes with relatively better vision at presentation (20/100 to 20/160). A high rate of retinal detachment was seen in the surgical arm (16% of all eyes), and these were more common in eyes with very poor vision and very large hemorrhagic lesions on presentation. Progression of cataract was the most common complication of surgery. The study concluded that surgical removal of hemorrhagic AMD lesions was generally not beneficial, although the data would support considering the procedure for lesions that were neither very large nor had very poor vision.<sup>39</sup>

### **Vitreotomy, Injection of Subretinal Tissue Plasminogen Activator, and Aspiration of Liquefied Blood**

The disappointing results obtained with direct surgical extraction of clot led investigators to study possible adjuvants to assist in the removal of subretinal blood. Experimental models of subretinal hemorrhage in animals suggested that the subretinal injection of tissue plasminogen activator (tPA) was safe in doses up to 50  $\mu\text{g}/\text{mL}$ .<sup>44</sup> Proponents of subretinal tPA injection hypothesized that it could decrease the thickness of hemorrhage,<sup>45</sup> improve the rate of clearance,<sup>44</sup> and potentially reduce outer retinal damage during surgical removal of subretinal clots.<sup>46</sup>

In 1991, Peyman et al. first reported their experience with five patients treated for SMH using a standard pars plana vitrectomy, followed by tPA (12.5  $\mu\text{g}/\text{mL}$ ) injected into the subretinal space. After dissolution of the clot, the subretinal hemorrhage was removed with presumed minimal trauma via gentle irrigation of balanced salt solution.<sup>41</sup> Despite this approach, VA results in cases of AMD were disappointing. In 1994, Lew<sup>42</sup> published a pilot study involving 24 consecutive eyes with recent SMH secondary to AMD treated with tPA followed by surgical drainage. This study demonstrated improved final visual outcome when causative CNV was eccentric to the fovea. Factors predictive of good postoperative VA in this study included duration of hemorrhage <7 days, hemorrhage limited to the temporal arcades, and the absence of sub-RPE hemorrhage. In 1995, Lim et al.<sup>43</sup> reported retrospectively

18 patients managed with a similar surgical technique and final VA improved 2 or more lines in only 28% of patients.

## **Intravitreal Tissue Plasminogen Activator With Pneumatic Displacement**

In 1997, Heriot initially described a novel method for the management of SMH using intravitreal tPA injection and pneumatic displacement of blood.<sup>47</sup> The potential benefits of this treatment modality are that it is minimally invasive and can be performed in the office.

Hesse et al. reported their experience with this technique in 11 eyes with SMH due to AMD.<sup>48</sup> The method described by these investigators involved intravitreal injection of 50 µg or 100 µg of tPA and injection of a long-acting gas bubble (C<sub>3</sub>F<sub>8</sub> or SF<sub>6</sub>), either immediately or 24 hours after the tPA injection, followed by 24-hour face-down positioning. A typical clinical outcome with this technique was partial but not total displacement of SMH, leading to asymptomatic exudative inferior retinal detachment. Complications included breakthrough vitreous hemorrhage, which occurred in all four eyes treated with 100 µg of tPA and only one of the seven eyes (14.3%) treated with the 50 µg dose.<sup>48</sup> Hassan et al. reported similar results in their case series of 15 patients, with 10 of 15 patients having improved final VA. Vitreous hemorrhage was the common complication, and there was one case of postoperative endophthalmitis in this group.<sup>49</sup> In a large series of 43 consecutive eyes treated with this in-office technique, Hattenbach et al. found that 30% of eyes gained 2 or more lines of VA at the final visit and that SMHs of ≤14 days duration had the most favorable outcomes.<sup>50</sup>

Animal models show conflicting data on whether tPA injected intravitreally penetrates into the subretinal space in a concentration sufficient for dissolution of a subretinal blood clot.<sup>51-53</sup> At a molecular weight of 70 kD, tPA is similar in size to albumin (68 kD), which has been shown to diffuse across intact retina into the subretinal space.<sup>54</sup> However, in the rabbit eye model, Kamei and coauthors demonstrated that intravitreal radiolabeled tPA did not diffuse through intact retina compared to radiolabeled dextran (20 kD) at a dose of 50 µg/0.1 mL.<sup>53</sup> They found that the fluorescence-labeled tPA accumulated at the internal limiting membrane,

vitreous cortex, or both. Based on their findings, the authors concluded that there was no scientific rationale for giving intravitreal tPA for SMH. Other authors have modified this in-office technique to include pneumatic displacement without the use of intravitreal tPA.<sup>55</sup> Ohji et al. reported a series of five patients with SMH treated with this modified approach, and anatomic and visual improvement were noted in all eyes in their small series. Because subretinal hemorrhage will undergo some degree of gradual spontaneous liquefaction 7–10 days after onset, maximum displacement of SMH using this technique may be achieved with the use of a long-acting gas bubble such as C<sub>3</sub>F<sub>8</sub> and repeated overnight sessions of prone positioning for 7–10 days for as long as the gas bubble persists.

### **Subretinal Injection of Tissue Plasminogen Activator With Pneumatic Displacement**

A novel surgical procedure of vitrectomy with subretinal tPA injection and pneumatic displacement without clot extraction was first described by Hauptert et al. in 2001.<sup>56</sup> Using a bent 36-gauge needle, the authors injected tPA (25–50 µg/mL) into the subretinal space. Instead of waiting for clot lysis and attempting to remove the hemorrhage as in previous subretinal techniques, the authors performed a fluid–air exchange followed by air–gas exchange for nonexpansile 20% sulfur hexafluoride (SF<sub>6</sub>). Postoperatively the patients were instructed to maintain a prone position. In their series of 11 patients with thick SMH secondary to AMD, anatomic inferior displacement of the clot was achieved in all eyes, while final postoperative VA was improved in eight (73%) cases.<sup>56</sup>

This technique was then slightly modified by Olivier et al. and others.<sup>57</sup> Using a 39- or 40-gauge cannula, they injected tPA into the subretinal space at a concentration of 12.5 µg/0.1 mL. The tPA was slowly injected at a steady infusion rate to “balloon up” the retina, creating a neurosensory retinal detachment in the macula and bathing the entire subretinal hemorrhage. The subretinal blood collected in this potential space and was pushed inferiorly by an intraocular air bubble injected at the end of the vitrectomy surgery. Following postoperative prone positioning, the macula was

generally cleared of subretinal hemorrhage (Fig. 122.1B), permitting fluorescein angiography and possible treatment of the underlying CNV. They reported total subfoveal blood displacement in 86% of 29 eyes treated with this technique, and 59% of patients gained 2 or more lines of vision at 3 months after surgery.<sup>57</sup> In a large retrospective series, Chang et al. reported complete displacement of hemorrhage from the fovea in 83 of 101 eyes (82%) using this technique.<sup>58</sup> Furthermore, 40% of patients in that study continued to receive anti-VEGF therapy after vitrectomy and maintained improved VA for 6 months compared to those who did not receive postvitrectomy anti-VEGF treatment and experienced a regression in treatment effect.

The advantages of this technique are maximal chemical lysis of the clot via subretinal injection of tPA, which minimizes the risk of mechanical trauma to the retina and RPE from manual clot extraction. In addition, vitrectomy surgery allows for a larger gas bubble to be placed in the vitreous cavity compared to in-office gas injection, allowing for more complete displacement of blood from the submacular space. Sandhu et al. reported that vitrectomy with subretinal tPA and air–fluid exchange displaced subretinal hemorrhage in three of four patients who failed expansile gas injection in the office.<sup>59</sup> Also, Hillenkamp et al. compared vitrectomy with intravitreal tPA injection to vitrectomy with subretinal tPA injection, with both groups receiving nonexpansile SF<sub>6</sub>. Hemorrhage was displaced completely in only 22% of the intravitreal tPA group compared to 55% of the subretinal tPA group.<sup>60</sup>

## **Subretinal tPA Plus Subretinal Air and/or Subretinal Anti-VEGF**

As vitreoretinal instrumentation and surgical techniques continue to improve, novel procedures involving additional subretinal injections of anti-VEGF and/or subretinal air have been reported.

Shah et al. reported the successful displacement of AMD-related SMH in two patients treated with vitrectomy and subretinal injection of both tPA and an anti-VEGF agent followed by intraocular SF<sub>6</sub>.<sup>61</sup> Both patients received continued intravitreal anti-

VEGF treatments after surgery and maintained functional VA (20/70 to 20/80) during 1-year follow-up. In a larger retrospective series, Treumer et al. reported successful complete displacement of SMH in 35 of 41 eyes treated with vitrectomy, combined subretinal tPA, and subretinal bevacizumab, and intraocular SF<sub>6</sub>.<sup>62</sup> Twenty-six patients with at least 12 months follow-up received postoperatively an average of 4.5 intravitreal bevacizumab injections, and BCVA improved in 22 patients. Although the optimal concentration and pharmacokinetics of subretinally injected anti-VEGF agents are unknown, neither study found any evidence of toxicity to the retina or RPE.

Martel and Mahmoud first reported the successful displacement of SMH using injection of subretinal air in addition to subretinal tPA and bevacizumab.<sup>63</sup> The authors used a 41-gauge extendable cannula to inject a combination of 0.4 mL of tPA at a concentration of 12.5 µg/0.1 mL (50 µg total), 0.1 mL of bevacizumab (2.5 mg), and 0.2 mL of filtered air. At the end of the vitrectomy, 20% SF<sub>6</sub> is injected to about 50% of the vitreous cavity to keep the subretinal air within the macular space, and the patient is positioned upright in the postoperative period. The authors hypothesize that based on Archimedes' principal, the addition of subretinal air dramatically lowers the buoyancy force of red blood cells in the subretinal space and allows for a more effective and immediate inferior displacement of the hemorrhage.<sup>63</sup> In another recent case series, Kadonosono et al.<sup>64</sup> described a similar procedure in which 0.4 mL of tPA at a concentration of 62.5 µg/0.1 mL (250 µg total) was injected into the subretinal space followed by 0.4 mL of filtered air. Following additional subretinal air injection to displace the dissolved clot inferiorly, there was no fluid–air exchange. The eyes in this study also did not receive subretinal anti-VEGF injection. Although they reported total blood displacement in all 13 eyes, this study was limited by its short 3-month follow-up and also included hemorrhages due to PCV.

## **Anti-VEGF Agents**

Intravitreal anti-VEGF injections have become the standard of care for patients with exudative AMD following several large randomized clinical trials. However, patients with predominantly

hemorrhagic lesions were excluded from these landmark trials, and it is therefore difficult to apply the results of these studies to patients with AMD-related SMH. A recent report on a subgroup of patients in the CATT trial with hemorrhage comprising >50% of lesion size<sup>65</sup> found a similar percentage of 3-line gainers at 2 years between the predominantly hemorrhagic and nonhemorrhagic groups (33.3% vs. 29.4%, respectively). However, the baseline VA in the hemorrhagic group was 20/80, and only 59.5% of those patients had subfoveal hemorrhage. Other studies have also reported on the outcomes of treating AMD-related SMH with anti-VEGF monotherapy alone.<sup>66-71</sup> Stifter et al. reported a  $\geq 3$  line VA gain at 4 months in 9.5% of 21 eyes with SMH treated with bevacizumab monotherapy.<sup>67</sup> In a small prospective series of 7 eyes, Chang et al. reported that nearly half of ranibizumab-treated eyes gained 2 or more lines of VA with a median gain of 7 ETDRS letters at 12 months.<sup>66</sup> In a recent retrospective study by Shienbaum et al.,<sup>69</sup> 19 eyes with AMD-related SMH received an average of 4.7 anti-VEGF injections over 12 months, at which time 60% gained  $\geq 3$  lines of VA.<sup>69</sup> In a large retrospective study using anti-VEGF monotherapy for SMH, Kim et al.<sup>70</sup> reported 91 eyes with fovea-involving SMH treated with ranibizumab only, bevacizumab only, or a combination of the two drugs. However, only 26% of their patient population had typical neovascular AMD, whereas 48% had polypoidal choroidal vasculopathy (PCV) on indocyanine green angiography, and the remainder could not be definitively classified due to the large hemorrhage. In their study, 59.3% of eyes had  $\geq 3$  lines of VA improvement at 6 months and 64.8% improved  $\geq 3$  lines at 12 months. Unlike typical neovascular AMD, PCV has relatively good visual prognosis with higher rates of spontaneous hemorrhage resolution.<sup>34,70</sup> In a prospective study of ranibizumab monotherapy in 23 patients with AMD-related SMH, Iacono et al. found that only 34.7% of their patients gained  $\geq 3$  lines of VA at 12 months of follow-up.<sup>71</sup> However, only 26% of hemorrhages in this study involved the fovea, and similar to the other anti-VEGF monotherapy studies, their cohort had a better baseline VA compared to studies using intravitreal or subretinal tPA.

One retrospective study compared patients with combination anti-VEGF and expansile gas versus anti-VEGF monotherapy and

found that vision improved in 80% of patients with both agents compared to 60% with the anti-VEGF agent alone. This study was retrospective, and the duration of hemorrhage was not well matched between the groups.<sup>72</sup> To date, there are no prospective data to guide the clinician in the use of anti-VEGF agents alone or in combination with expansile gas displacement or with vitrectomy and tPA injection.

## Conclusion

SMH is a potentially devastating complication of many macular disorders. The natural history is especially poor in patients with the underlying diagnosis of AMD. Other factors that portend a poor visual prognosis include increasing size, thickness, and duration of submacular blood.

In an attempt to improve upon the natural history of the disease, several investigators have attempted to remove the blood from the submacular space. Initial efforts and those of the SST showed disappointing visual results with limited complications. The use of anti-VEGF agents either alone or in combination with expansile gas or with vitrectomy and tPA use seems more promising than the natural history. However, there is no large randomized study comparing anti-VEGF monotherapy to intravitreal or subretinal tPA for the treatment of SMH, and there is no consensus on the preferred management strategy. Although there are no set criteria for which patients would benefit from tPA-assisted displacement of SMH versus anti-VEGF monotherapy, the authors believe that eyes with thicker hemorrhages of less than 7 days' duration, located within the vascular arcades, and without a large hemorrhagic pigment epithelial detachment, benefit the most from displacement of SMH out of the macula. Because successful displacement has been reported with both intravitreal injection of tPA and expansile gas, and vitrectomy and subretinal tPA injection with intraocular gas, the technique chosen will ultimately depend on the surgeon's comfort level and experience with the procedure. After either procedure, face-down positioning should be strongly encouraged to help facilitate displacement of the hemorrhage out of the macula, and close follow-up with continued anti-VEGF treatment of the

underlying CNV is ideal. Regardless of which treatment modality is used, the functional outcome in AMD-driven SMH will largely depend on the location and extent of the underlying CNV.

## Background and Rationale

Preservation of the integrity and function of the foveal photoreceptors is vital to visual outcome in patients with macular disease, including diseases such as age-related macular degeneration (AMD), myopic degeneration, and pattern dystrophies. Many of these disorders initially affect subretinal layers, including the retinal pigment epithelium (RPE), Bruch's membrane, and the choriocapillaris. These layers provide critical support for overlying outer retina, including the foveal photoreceptors.<sup>1</sup> Ultimately, disruption of these tissues results in structural and functional deterioration of the photoreceptors with subsequent vision loss. Macular translocation surgery moves the fovea from over a severely diseased subretinal bed to a new location with healthier subretinal tissues to allow for improved function and ideally restoration of functional central vision.

## Animal Studies

Machemer and Steinhorst utilized a rabbit model to demonstrate the feasibility of purposeful retinal detachment with subretinal infusion via a transscleral approach.<sup>2</sup> Electron microscopy confirmed preservation of photoreceptor nuclei and mitochondria in the inner segments with some disruption of the outer segments, suggesting this technique was reasonably atraumatic and may be well tolerated. In addition, successful retinal translocation around the axis of the optic nerve following 360-degree (360°) peripheral retinectomy was also demonstrated. Additionally, maximal shaving of the vitreous base was found to be critical for creation of the retinectomy. Residual vitreous resulted in increased difficulty and less predictability during creation of the retinectomy.<sup>2</sup>

The rabbit model has also been used to demonstrate the utility of calcium- and magnesium-free infusate in reducing retinal adhesion to the RPE without creating cellular toxicity.<sup>3,4</sup> Collateral damage to photoreceptor outer segments was also reduced by using calcium- and magnesium-free solutions. Although transient electroretinogram (ERG) depression of b-wave amplitude was noted on postoperative day 1, subsequent recovery was observed.<sup>3</sup> Animal studies have also revealed that dark adaptation results in easier retinal detachment with reduced retinal damage. In model surgery, a red-free intraocular light source was used during the surgical procedure to prevent reversal of dark adaptation.<sup>4</sup>

## Historical Perspective and Evolution of Technique

In 1983 Lindsey first proposed translocation of the retina.<sup>5</sup> Tiedeman et al. published their proposal for retinal translocation in 1985.<sup>6</sup> Machemer published the first human surgical cases in 1993. All three subjects had AMD and were treated with 360° peripheral retinectomy and translocation (MTS360, MT360).<sup>7</sup> The original MTS360 technique involved pars plana vitrectomy with transscleral injection of subretinal fluid with 360° retinectomy, removal of subretinal blood and choroidal neovascularization (CNV), partial fill with silicone oil, retinal translocation, complete silicone oil fill, and finally laser retinopexy. All surgeries were performed under general anesthesia. One of the original patients had significant

improvement in central acuity (1/200–20/80).<sup>7</sup>

The original procedure has gone through multiple evolutionary iterations with major developments by Eckardt et al., Toth and Freedman, and Tano.<sup>8–10</sup> Changes to technique have focused on facilitating retinal detachment, effectively translocating the macula, reducing complications (e.g., proliferative vitreoretinopathy [PVR]), and decreasing the duration of surgery.<sup>8–18</sup> Because retinal rotation results in significant cyclotorsion,<sup>8,9,12,14,17,19</sup> extraocular muscle surgery to counter-rotate the globe is used routinely to manage the cyclotropia.<sup>8</sup> Attempts at reducing the extent of the retinectomy (e.g., <360°) have not been widely adopted due to very high rates of PVR.<sup>10,11,20,21</sup>

Variations on MTS360 also included the development of limited macular translocation, which shifted the macula a shorter distance than with MTS360. De Juan developed a technique to shorten the sclera following detachment of the superotemporal retina across the macula. This resulted in redundant retina that allowed the foveal center to be relocated downward by gravity after surgery, by positioning the patient upright with a partially gas-filled eye. Because of the variable and limited distance of macular displacement, this procedure has become much less popular.<sup>22–24</sup>

Macular translocation has been used to describe all of these surgical displacement procedures. The terms retinal rotation, full macular translocation, macular translocation surgery with 360° peripheral retinectomy, MTS360, and MT360 have been used to describe the Machemer technique.

## Principles of Foveal Relocation

The primary goal of macular translocation surgery is to relocate the fovea to a new location of healthier subretinal tissues in order to preserve and maintain foveal function to maximize visual acuity. Thus the fovea should be relocated to an area outside that of the subfoveal lesion.<sup>1</sup> The distance from the preoperative foveal center to the edge of the lesion is the minimum desired translocation. The distances of postoperative foveal displacement versus the minimum desired translocation have been found to be predictors of anatomic success following macular translocation.<sup>25</sup> The distance of

translocation is limited by the resistance of retinal tissue to twist around the optic nerve, by potential for both axonal injury and retinal folds with extreme rotation around the nerve, and by the maximum amount of ocular counter-rotation that is possible.

Characteristics of the underlying lesion (e.g., shape, size) determine the minimum desired translocation. Most surgeons move the retina further than the minimum distance in order to have a reasonable margin between the lesion edge and the new foveal location. Lesion location is also critical to required translocation distance. Central larger lesions may require the same displacement distance as smaller eccentric lesions (Fig. 123.1). The postoperative foveal location in MTS360 is highly predictable since the new foveal location is determined intraoperatively and the retina is reattached at the new location. MTS360 has an average foveal displacement of 3500  $\mu\text{m}$  and the capacity to translocate the macula upward or downward.<sup>8-11</sup>

**FIG. 123.1** Schematic diagram of left fundus where *F*

is the foveal center,  $D$  is a point on the temporal edge of the optic disc, and  $I$  is a point on the superior border of the subfoveal lesion such that  $DF = DI$ . (A) The distance  $FI$  is the minimum desired translocation for a superior translocation. (B) The minimum desired translocation for a superior translocation is the same for three subfoveal lesions of different sizes (A–C). The typical translocation would be to point  $X$ , which leaves a reasonable distance between the old subfoveal lesion and the new foveal location.

In MTS360, advantages to translocating the macula upward off the subretinal abnormality are to position the blind spot from the subretinal lesion site in the superior visual field; to position the macula in an optimal superior location for silicone oil tamponade; to avoid placing the macula over RPE that has been in an area of chronic exudate or hemorrhage, which is more likely inferior to the macula; and to allow for the most effective surgery for the cyclotropia since advancing the inferior oblique produces more torsional effect than advancing the superior oblique.

## Preoperative Considerations

### Indications

Although clear guidelines for the indications for macular translocation are not established, there are several generally agreed upon principles. Anti-vascular endothelial growth factor (VEGF) therapy is clearly the first-line treatment for subfoveal neovascular disease.<sup>26,27</sup> Because of the potential to induce postoperative torsional diplopia even after extraocular muscle surgery for correction, MTS360 surgery is only considered in patients who already also have central vision loss or low vision in the other eye. The surgical eye is typically the eye with better visual potential, more recent vision loss, and greater preservation of retinal architecture. MTS360 may be considered in nonresponders to anti-VEGF treatment, eyes with extensive subretinal fibrosis, selected cases of massive subretinal hemorrhage, retinal pigment epithelial tears, or submacular diseases that are not VEGF-driven.<sup>8,9,12,15,17,28–35</sup> Although macular translocation has been reported in numerous

diseases including neovascular AMD, non-neovascular AMD with geographic atrophy, myopic degeneration with CNV, ocular histoplasmosis with CNV, adult-onset foveomacular vitelliform dystrophy, punctate inner choroidopathy with subfoveal CNV, angioid streaks with CNV, North Carolina macular dystrophy, and central serous chorioretinopathy, there are cases in which it has a lower likelihood of success.<sup>8,9,12,15,17,28,29,32-35</sup> In cases of central geographic atrophy with AMD, the atrophy has often recurred in the new foveal location, and many would consider this a contraindication to surgery.<sup>32,36,37</sup> Underlying ocular inflammatory diagnoses (e.g., punctate inner choroidopathy, ocular histoplasmosis) may also be associated with worse outcome.<sup>29</sup> General inclusion and exclusion criteria for patients being assessed **Box 123.1** are outlined in [Box 123.1](#).

## Inclusion and Exclusion Criteria for Macular Translocation With 360° Peripheral Retinectomy

### Inclusion Criteria

Bilateral disease

Severe loss of central vision in second affected eye for no more than 6 months<sup>a</sup>

Best corrected Snellen visual acuity between 20/50 and 20/400 in the surgically treated eye

May have a previous photodynamic therapy, anti-VEGF therapy, or intravitreal steroid

Caution if there was previous extrafoveal or juxtafoveal thermal laser treatment with retinal thinning on optical coherence tomography or retinal angiomatous proliferation or choroidal anastomosis

### Exclusion Criteria

Surgical eye characteristics:

No light perception visual acuity

Previous thermal laser treatment of fovea

Other ocular disease such as:

Diabetic retinopathy

Retinal vascular occlusive disease

Uncontrolled glaucoma

Optic neuropathy

Fellow eye characteristics:

Visual acuity of no light perception

Other ocular disease causing severe peripheral visual field loss

---

<sup>a</sup>Duration of vision loss determined by patients' reports of when they were unable to perform vision-related daily activities such as reading and driving.

## History and Ocular Examination

Information regarding the history of progression and duration of vision loss is useful before surgery. The longer the duration of vision loss, the greater the likelihood of atrophy or scarring of the neurosensory retina with permanent dysfunction, and thus the lower likelihood of benefitting from MTS360. Unfortunately, the duration of significant vision loss may be difficult to ascertain. Other critical components of the ocular history include previous

strabismus surgery or previous vitreoretinal procedures. Both posterior and peripheral retinal examination are critical prior to performing macular translocation surgery. The posterior examination considers extent of macular chorioretinal scarring, active CNV, retinal atrophy and RPE atrophy, and whether any of these may extend into the site of proposed translocation. Identifying retinal angiomatous lesions and chorioretinal anastomoses aids in planning for dissection of the retina from the subretinal lesion. The peripheral retinal examination with scleral depression is important to identify pathology that may pose issues during the procedure (e.g., peripheral holes, chorioretinal scars that may inhibit retinal detachment). Peripheral retinal vascular disease such as diabetic retinopathy could lead to anterior segment ischemia and neovascularization of the iris after surgery on multiple extraocular muscles. The lens status of the patient is also important. Phakic patients typically undergo phacoemulsification and posterior chamber lens placement prior to or at the time of macular translocation surgery. If the patient is pseudophakic, the type of intraocular lens and the status of the posterior capsule are important given the planned infusion of silicone oil.

## Diagnostic Testing

Preoperative evaluation for macular translocation may include fundus photography, fluorescein angiography, optical coherence tomography (OCT), fundus autofluorescence (FAF), fixation capability, and microperimetry. These tests may be useful to identify eyes that are poor candidates for MTS360, such as eyes with severe macular chorioretinal scarring, extensive neurosensory retinal atrophy, widespread RPE atrophy, CNV in the site of proposed translocation, retinal angiomatous lesions, chorioretinal anastomoses, or unexpected retinal vascular disease. Unfortunately, overall these tests, including fixation and microperimetry, have been shown to be poor predictors of 1 year visual outcomes in patients who were considered eligible for MTS360.<sup>38</sup> As noted in ocular examination above, however, these details have been very useful in surgical planning.

Spectral domain or swept source (SD- or SS-) OCT imaging of the

ultrastructure of the retina can be helpful in identifying outer retinal atrophy, which may limit the utility of macular translocation. Histologic evidence has shown significant photoreceptor atrophy overlying disciform scars.<sup>39</sup> If outer retinal atrophy is present in the entire macula on OCT, patients are probably unlikely to realize improvement in visual function after macular translocation. Surprisingly, a thinner retina on time domain OCT before surgery was associated with good visual outcomes in one study.<sup>38</sup> However, time domain OCT lacks the resolution of SD-OCT imaging; therefore, resolution was not sufficient to identify photoreceptor layer details. In some cases, perhaps the more compact retina was healthier than the edematous retina before MTS360. Additionally, OCT may be helpful in identifying other structural abnormalities that are important to preoperative planning (e.g., large intraretinal cysts, areas of adhesion).

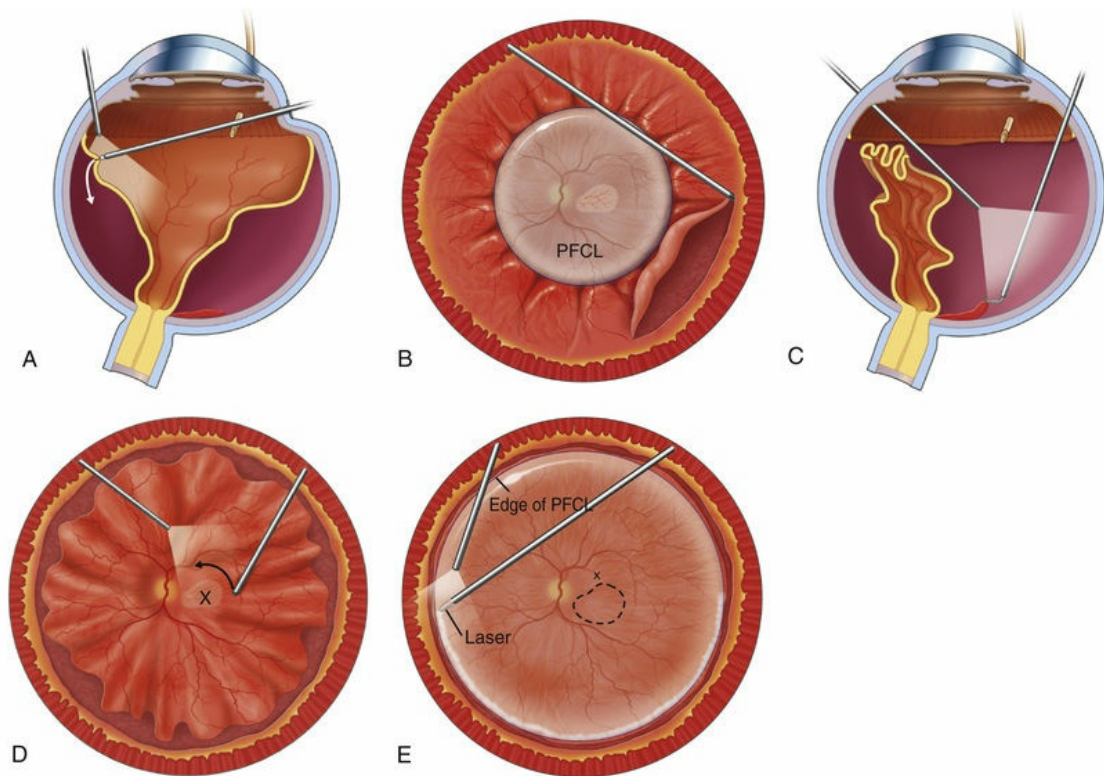

Fluorescein and/or indocyanine green angiography are utilized to assess the extent, location, and activity of the CNV and/or submacular disease process. Additionally, preoperative fluorescein angiography can be helpful in identifying retinal angiomatous proliferation or chorioretinal anastomosis, which should be considered in surgical planning, as these can result in a retinal tear or significant intraoperative hemorrhage during the separation of the retina from the RPE and choroid.<sup>40,41</sup> Additionally, the RPE integrity and perfusion status of the choroid and retina can be assessed. FAF can be useful for evaluation of the RPE health of the future subfoveal RPE bed. Hyper- or hypofluorescence in the area of the future foveal location should be considered before committing to surgery.

## **Surgical Technique for Macular Translocation**

### **MTS360**

MTS360 is performed under general or local anesthesia. If the patient has the muscle surgery at the start of the translocation surgery, then this is typically under general anesthesia. If a patient

is phakic, cataract extraction and intraocular lens placement are performed at the time of macular translocation. Complete pars plana vitrectomy with elevation of the posterior hyaloid, if attached, is the first step of MTS360. Careful, close shaving of the vitreous base with the vitreous cutter and 360° of scleral depression is performed. Retinal detachment is induced with subretinal fluid injection through a retinotomy that is typically located peripherally within the vitreous base. Posterior retinotomies have been associated with greater epiretinal membrane formation. Different specialized cannulas have been utilized to infuse the subretinal fluid to detach the retina.<sup>8-11,14,15</sup> Fluid is typically either infused into the subretinal space through a 41-gauge cannula posteriorly,<sup>42</sup> or at the ora serrata through a silicone-tipped cannula larger than a very small retinotomy made with the vitreous cutter, and marked using endodiathermy (Fig. 123.2A).<sup>9</sup> A fluid–air exchange facilitates subretinal fluid displacement from areas of detached retina to areas of attached retina. Although animal models have shown that calcium- and magnesium-free solutions may facilitate retinal detachment, prolonged use of these solutions in humans may result in higher postoperative keratopathy and the use of these solutions is not common.

**FIG. 123.2** Diagrams showing the steps involved in macular translocation with 360° peripheral retinectomy. (A) The retina is detached by subretinal injection of fluid through a retinotomy that may be located posteriorly or peripherally. (B) After the retina is totally detached, it is then cut at the ora serrata using the vitreous cutter (retinectomy) or retinal scissors (retinotomy). (C) When the retina has been completely cut free at the ora serrata, it is reflected and the subretinal lesion is removed. (D) The neurosensory retina is then translocated off the subfoveal abnormality usually in a superior direction. While a number of instruments can be used to manipulate the retina, a modified diamond-dusted silicone-tipped needle that is connected via short tubing to a syringe containing perfluorocarbon is shown here. (E) At completion of the surgery the retina is typically rotated 40–45° displacing the fovea (X) off the bed of choroidal neovascularization (*dotted line*). PFCL, perfluorocarbon liquid.

Once the retina is totally detached, the retina is cut at the ora serrata with the vitreous cutter (peripheral retinectomy)<sup>9–11</sup> or retinal scissors (peripheral retinotomy) (Fig. 123.2B).<sup>8,10,11,15</sup>

Perfluorocarbon liquid (PFCL) is temporarily placed over the posterior pole of the retina to stabilize the retina if performing a peripheral retinectomy; once the retina is completely free from the periphery, the PFC is removed. The retina is reflected allowing removal of the subfoveal lesion, if present, and diathermy of feeding vessels as required (Fig. 123.2C). The retina is then translocated into the new position. Most commonly, the retina is translocated superiorly (Fig. 123.2D). A small bubble of preretinal PFCL is utilized to stabilize the retina while the translocation is performed. Multiple instruments have been utilized for the retinal manipulation during translocation, including retinal forceps<sup>8,10,11</sup> and a silicone-tipped needle,<sup>14</sup> although the diamond-dusted silicone-tipped needle is excellent for atraumatically snagging the retinal surface with very gentle pressure over an arcade, and then sliding the retina. The tip may be connected to a syringe containing PFCL.<sup>9</sup> Once appropriate displacement has been achieved (typically approximately 45° off the CNV bed, which equates to positioning the center of the old CNV bed under the inferotemporal arcade), additional PFCL is added to reattach the retina in the manner of a giant retinal tear. Laser photocoagulation is then applied to the retinectomy margins under PFCL tamponade. A direct PFCL/silicone oil exchange is performed to avoid retinal slippage (Fig. 123.2E).

## Early Postoperative Management

### Positioning

Positioning following MTS360 is based on the surgeon's preferences. Approaches include face-down positioning or alternating side-to-side positioning thought to diminish pooling of factors for PVR in aqueous medium at the 6 o'clock position.

### Extraocular Muscle Surgery for Macular Translocation

Given the extensive translocation that occurs during MTS360, often 30–45° in an upward direction, the amount of torsion exceeds the

maximum amplitude of cyclofusion (typically around 15°).<sup>43</sup> Translocation results in both horizontal and vertical strabismus. In order to alleviate the symptoms associated with excess cyclotorsion, extraocular muscle surgery is performed to strengthen the inferior oblique and weaken the superior oblique. Rectus muscle transposition is also often performed to increase excyclorotation.<sup>8,43</sup> Two major techniques have been described.

The Freedman technique involves performing the extraocular muscle surgery 8 weeks after the MTS360 procedure. Because of separate and thus shorter procedures, general anesthesia is not needed for the extraocular muscle surgery or the MTS360. The number of operated muscles is determined by the measured posttranslocation torsion. The inferior oblique is advanced to the temporal border of the superior rectus muscle with the anterior and posterior edges 13 and 15 mm posterior to the limbus, respectively, and a complete superior oblique tenotomy is performed. If an eye has between 20 and 35° of torsion, superior transposition of the lateral rectus muscle is also performed adjacent to the superior rectus, 7 mm from the limbus. For the majority of cases, more than 35° of torsion is present and thus the medial rectus is also transposed to the nasal edge of the inferior rectus muscle (Fig. 123.3).<sup>43</sup>

**FIG. 123.3** Drawing of torsional muscle surgery to create an excyclotropia in the right eye using the Eckardt technique. (A) The anterior part of the inferior

oblique muscle is advanced 12 mm and the posterior part, 9 mm, while the anterior and posterior parts of the superior oblique muscles are recessed the same distances. In addition, muscle strips from two opposing rectus muscles are passed beneath the original muscles and transposed in a clockwise direction and attached at the insertion of the adjoining rectus muscles. (B) If more counter-rotation of the eye is required, opposing strips from all four rectus muscles can be moved after the oblique muscle surgery previously described. *LR*, lateral rectus; *SR*, superior rectus.

Simultaneous extraocular muscle surgery may also be performed during the initial MTS360 procedure as demonstrated by Eckardt.<sup>8</sup> General anesthesia is typically utilized when the muscle surgery is combined with MTS360. The muscle surgery may be either the above-described Freedman technique or the Eckardt technique. In the latter, strengthening of the inferior oblique is achieved by advancement or through a 12-mm tuck, and the superior oblique is weakened by recession or tenotomy. Each rectus muscle is split by about one-quarter of the width of the entire muscle for a radial length of 15–17 mm. Each strip is passed under the remaining portion of the rectus, transposing them clockwise (right eye) or counter-clockwise (left eye) to the margins of the adjacent rectus muscle (windmill technique) producing excyclorotation (Fig. 123.4).<sup>8</sup>

**FIG. 123.4** Drawing of torsional muscle surgery to create an excyclotropia in the right eye from the surgeon's view superiorly, using the Freedman technique. (A) The first step is advancement of the inferior oblique muscle. Pen marks on the limbus denote the 6 and 12 o'clock positions of the eye, made prior to beginning strabismus surgery. A muscle hook has been placed beneath the superior rectus insertion. The superior oblique tendon has been transected (not shown). The medial and lateral rectus muscles have each been secured on a 6–0 Vicryl suture and detached from their respective insertions on the globe. The inferior oblique muscle, located on a clamp, is being advanced towards the site on the sclera where partial-thickness scleral bites have been taken with the same 5–0 Dacron suture, which is attached to the inferior oblique behind the clamp. (B) The final positions of the medial and lateral rectus and inferior oblique muscles during strabismus surgery are shown. The lateral rectus muscle has been reattached adjacent to the lateral border of the superior rectus muscle. The inferior oblique muscle, having been advanced as shown previously, is just visible in the superior temporal fornix. The medial rectus muscle has been reattached adjacent to the medial border of the inferior rectus muscle. The pen markings at the limbus demonstrate the excyclorotation of the globe, which has been affected by the surgery. *LR*, lateral rectus; *SR*, superior rectus.

## Postoperative Management of Choroidal Neovascularization

Following MTS360, the previous subfoveal CNV is likely extrafoveal in location (if it has not been removed intraoperatively). If the CNV is active, anti-VEGF therapy, laser photocoagulation, or photodynamic therapy may be used individually or combined to reduce the risk of CNV growth into the new foveal location and to reduce the risk of further vision loss from hemorrhage. Because of the risk of recurrent CNV, postoperative care should include home monitoring and diagnostic testing and examination should seek

evidence of recurrence.

# Functional Outcomes for Macular Translocation Surgery

## Neovascular AMD

Multiple reports have documented functional outcomes after MTS360 for neovascular AMD (Table 123.1).<sup>8–12,14–18,42,44–47</sup> In a prospective randomized clinical trial of MTS360 versus photodynamic therapy with follow-up through 2 years, MTS360 produced superior vision recovery at both 1 and 2 years, with a gain of 0.3 letters in distance acuity and 7 letters in near acuity after MTS360 versus a loss of 12.6 letters in distance acuity and of 9.6 letters in near acuity in the PDT group.<sup>45,48</sup> The subsequent success of anti-VEGF inhibitors in the treatment of CNV has diminished the need for macular translocation surgery and changed the context of these analyses.<sup>26,27</sup>

NA, Information not available; Pro, prospective; Retro, retrospective.

Numerous reviews of the data from clinical series after MTS360 show benefit of treatment and document the potential complications of this surgery.<sup>8–12,14–18,42,44,45,47,49</sup> Duration of follow-up has ranged from 9.6 months to 83 months. Mean preoperative visual acuity varied from 20/125 to 20/260. Mean postoperative visual acuity ranged from 20/80 to 20/260, and some patients achieved a distance visual acuity of 20/40 or better. The percentage of patients with postoperative improvement in distance visual acuity has ranged from 43% to 66%.<sup>8,15,18,44</sup> Gains in visual acuity of three lines or more varied from 13% to 69%, while the percentage of patients in each study who lost three or more lines of visual acuity after MTS360 ranged from 4% to 56.2% (Fig. 123.5).<sup>8–12,14–18,42,44,45,47</sup>

**FIG. 123.5** Color fundus photograph, fluorescein angiogram, fundus autofluorescence, and spectral domain optical coherence tomography (from left to right) documenting macular translocation with 360° retinectomy (MTS360). (A) One month before MTS360 with visual acuity of 20/100, active choroidal neovascularization (CNV), diffuse cystoid macular edema (CME), and atrophy of the retinal pigment epithelium; (B) postoperative year 1 after MT360 with recurrent neovascularization at the edge of the old CNV lesion and CME in the translocated fovea; (C) postoperative year 3 after MT360 with improving visual acuity of 20/80 and regression of CNV and CME after laser and intravitreal antiangiogenic therapy.

MTS360 has also been utilized following photodynamic therapy (PDT) and other nonsurgical treatments. Prior to the anti-VEGF era, eyes treated with a single prior PDT session improved after MTS360 from mean visual acuity of 20/160 to postoperative mean acuity of 20/100, while eyes with more than one previous PDT session generally worsened from 20/200 before MTS360 to a mean postoperative visual acuity of 20/250.<sup>50</sup> In the anti-VEGF era, a study of 43 patients with anti-VEGF therapy or PDT or both,

sustained significant improvement in all measures of visual function at 1 year after MTS360 (mean gain of >9 letters).<sup>38</sup> An additional study examined 38 consecutive patients in the anti-VEGF era and showed that MTS360 resulted in improved visual acuity, particular in those patients with submacular hemorrhage and CNV, secondary to pathologic myopia.<sup>51,52</sup>

Numerous studies have also reported changes in near visual acuity, with near acuity sometimes improving greater than distance acuity.<sup>13,18,45,48</sup> Reported mean preoperative near visual acuity ranged from 20/100 to 20/160, with a significant improvement in mean near visual acuity to 20/63 and 20/55, postoperatively.<sup>8,18</sup> MTS360 has been shown to have better improvement in near visual acuity when compared to PDT (+7 letters versus -9.6 letters).<sup>53</sup> In several studies, over 20% of patients achieved postoperative near visual acuity OF 20/40 or better.<sup>8,18,40,54</sup>

The impact of MTS360 on other visual functions, including reading speed, contrast sensitivity, and color vision, have also been reported. Significant improvements in reading speed have been found following MTS360 with a mean increase of 26–45 words/minute.<sup>18,40,54,55</sup> MTS360 has been shown to not only improve reading speed and fixation quality but also to improve saccades during reading activities.<sup>56</sup> Improved contrast sensitivity has also been documented following MTS360, while color vision has been minimally affected following MTS360.<sup>38,55</sup>

Goldman perimetry studies have shown peripheral field loss but overall good preservation of the visual field following MTS360.<sup>57</sup> Microperimetry studies have shown recovery of central visual sensitivity following MTS360 (Fig. 123.6)<sup>38,56,58</sup> and a new focal scotoma in the superotemporal field due to the translocated CNV bed.<sup>58</sup> Reduction in photopic and scotopic electroretinograms have been documented following MTS360 for up to 5 months after surgery. The mechanism for ERG reduction is not clear, but it may be related to length of surgery, composition of subretinal infusate, and duration of detachment.<sup>59–61</sup> In addition to ERG, electro-oculogram findings have shown a decreased dark trough following MTS360, although the Arden ratio was within normal limits.<sup>62</sup>

**FIG. 123.6** Fundus photographs with superimposed microperimetry (Nidek MP-1) of the left eye of a 76-year-old female with bilateral age-related macular degeneration who had a 4-month history of progressive vision loss in her second affected eye. Photodynamic therapy with Visudyne had been performed 3 months before for predominantly classic subfoveal neovascularization. Microperimetry was performed using a Goldmann III equivalent target and 4–2 threshold testing strategy. Zero (0) signifies the highest-intensity stimulus and 16 the lowest. *Open square*, no response; *filled square*, response to stimulus. (A) Preoperatively best corrected visual acuity on ETDRS testing was 20/250. Microperimetry showed a central dense scotoma with no response to

the brightest stimulus centrally, unstable fixation (inset), and a good response to peripherally stimuli. (B) At 1 year postoperatively, best corrected distance visual acuity on ETDRS testing was 20/64 with resolution of central scotoma, stable fixation (inset), and development of a new peripheral scotoma over the displaced choroidal neovascular membrane bed.

Vision-related quality of life (QOL) has been found to significantly reduce in patients with bilateral severe AMD.<sup>63</sup> Following MTS360, vision-related QOL has been reported to have significant improvement, particularly in relation to distance acuity, near acuity, and reading speed. Near acuity was found to have the greatest impact in vision-related QOL. A 1-line change in near acuity resulted in a 13.7 point change in QOL score, compared with a 1.4–2.1 point change for a 1-line change in distance acuity or an increase in reading speed of 15 words/minute.<sup>63</sup> Vision-related QOL showed significant improvement in vision-related subscores following MTS360 in a prospective randomized study.<sup>53</sup> MTS360 showed significantly higher improvement in QOL scores for general vision, mental health, and dependency compared with treatment with PDT.<sup>53</sup>

## Non-Neovascular AMD

Macular translocation has also been utilized in geographic atrophy (GA) secondary to AMD. Multiple reports have discussed MTS360 for these cases.<sup>32,33,36,37</sup> The first study published included eight eyes undergoing MTS360. Five of eight eyes had visual improvement, one remained stable, and two eyes had worsening visual acuity.<sup>32</sup> A more recent study included four eyes with GA, and in this study the mean preoperative and postoperative visual acuity were unchanged.<sup>36</sup> Recurrent RPE atrophy is a significant concern in patients treated with macular translocation and GA secondary to AMD.<sup>32,36,37</sup>

## Non-AMD Diagnoses

In addition to AMD, multiple other submacular diseases can result in bilateral vision loss. In cases of severe functional limitation,

consideration may be given to macular translocation when other treatment modalities are not effective or a viable option (e.g., anti-VEGF therapy, photodynamic therapy, focal laser photocoagulation). Some of these conditions may not be VEGF-driven and may not respond to intravitreal therapy. Although limited in number, macular translocation has been utilized in many of these non-AMD conditions.<sup>29</sup> One recent study examined 16 subjects treated with MTS360 for conditions other than AMD. Conditions included in this report were adult-onset foveomacular vitelliform dystrophy (AOFVD), myopic degeneration, ocular histoplasmosis, punctate inner choroidopathy (PIC), Best disease, angioid streaks, North Carolina macular dystrophy, and central serous.<sup>29</sup> Of all of these conditions, myopic degeneration has been the most widely studied for macular translocation. A large study of MTS360 for myopic degeneration included 52 eyes with a final visual acuity of 20/40 or better in 39% of subjects.<sup>64</sup> In general, eyes with myopic degeneration had smaller CNVs (e.g., 0.4–1.2 disc diameters) and required less retinal rotation than eyes with neovascular AMD. A study of 15 eyes undergoing MTS360 for myopic degeneration reported that 73% of eyes showed visual improvement, with only 10% of eyes losing vision.<sup>16,34,54</sup> A smaller series of three eyes with myopic degeneration showed a final visual acuity of 20/60 or better in 3/3 eyes, with 2/3 eyes improving  $\geq 3$  lines.<sup>29</sup> An additional series of 17 eyes examined long-term follow-up (5 years or greater) for MTS360 for myopic CNV. Mean preoperative visual acuity was approximately 20/200 and improved to a mean postoperative visual acuity of approximately 20/100.<sup>47</sup> Long-term follow-up has also been reported for an additional group with 60 eyes with myopic CNV and a mean follow-up of 76.3 months. This series reported baseline best corrected visual acuity of approximately 20/125 with improvement to approximately 20/70 that remained stable >5 years after initial intervention.<sup>65</sup>

A case study of MTS360 for idiopathic CNV reported worsening visual acuity from 20/63 preoperatively to 20/100 postoperatively.<sup>16</sup> Comparing inflammatory preoperative diagnoses (e.g., presumed ocular histoplasmosis syndrome [POHS], PIC) with noninflammatory diagnoses (e.g., myopic degeneration, AOFVD, Best disease, North Carolina macular dystrophy, angioid streaks,

and central serous), only 20% of eyes with a preoperative inflammatory diagnosis maintained a visual acuity of 20/100 or better, and the mean final visual acuity in those eyes was 20/209.<sup>29</sup> Three of 5 (60%) eyes with inflammatory disease lost  $\leq 3$  lines of visual acuity, and the mean line change in visual acuity was a loss of 1.4 lines.<sup>29</sup> In eyes with a noninflammatory diagnosis the mean final visual acuity was 20/83 with 73% of eyes maintaining a final visual acuity of  $\geq 20/100$ . Five of 11 eyes maintained a final visual acuity of  $\geq 20/50$ . The mean line change was +1.0 lines.<sup>29</sup> Though this study was retrospective and small, this suggests that increased caution should be used prior to proceeding with MTS360 for inflammatory diagnoses. The most likely cause of worsening final visual acuity appeared to be an increase in postoperative complications for this group.<sup>29</sup> Polypoidal choroidal vasculopathy (PCV) has also been treated with MTS360, with two reported cases showing visual improvement following MTS360.<sup>35</sup>

## Postoperative Surgical Complications Following Macular Translocation

Surgical complications following MTS360 for neovascular AMD are summarized in [Table 123.2](#).<sup>8-12,14-18,42,44,48</sup> Retinal detachment is among the most common complications, with a prevalence of 7.8–42.8%. The higher rates of retinal detachment were reported in studies of early experience of surgeons with MTS360. Recurrence of CNV is also a common complication following MTS360. The prevalence of this complication ranges from 0.0% to 27.8%. Often due to the typical extrafoveal location of the CNV, thermal laser with or without anti-VEGF therapy can be employed. Cystoid macular edema (CME) and epiretinal membrane (ERM) formation are also two frequently reported complications. CME has not been consistently reported; however, studies have given a range of 0.0–44%. Many of these studies were prior to the widespread use of optical coherence tomography (OCT), and subclinical CME may go unrecognized. The studies reporting the highest rate of CME used OCT to examine every patient postoperatively.<sup>18,48</sup> ERM formation has been reported to occur in 6.6–28.2% of patients postoperatively.

However, the lack of uniform definition of ERM and the lack of widespread OCT use should lend caution to the interpretation of these numbers. Other complications such as macular hole, keratopathy, and hypotony tended to be less frequent.

<sup>a</sup>Complications recorded as proportion of 31 patients.

<sup>b</sup>Includes enlargement of CNV that was not removed and recurrence of CNV that was removed.

<sup>c</sup>Includes macular and peripheral epiretinal membranes.

<sup>d</sup>Five patients with recurrent CNV at 24 months follow-up; 10 patients with CME; 1 patient with an epiretinal membrane.

CME, cystoid macular edema; CNV, choroidal neovascularization; ERM, epiretinal membrane; NA, information not available.

Complications following MTS360 for non-AMD diagnoses have also been reported. For myopic degeneration, MTS360 has been reported to have a retinal detachment rate of 34% and recurrent CNV rate of 6%. A small study examining MTS360 for multiple non-AMD conditions showed that eyes with an underlying inflammatory diagnosis had a significantly higher complication rate compared with noninflammatory diagnoses.<sup>29</sup> In that report, the

overall complication rates were 50% for ERM (including mild ERM on OCT); 31% for CME; 13% for retinal detachment; and 13% for CNV. A total of 38% needed an office-based procedure due to a complication (e.g., sub-Tenon injection, laser). Surgical intervention was required in 19% of eyes. In eyes with an underlying inflammatory diagnosis, 100% (5/5) of eyes required some type of intervention for a complication, compared with only 36% (4/11) of eyes with a noninflammatory diagnosis. In eyes with an underlying inflammatory diagnosis, the CNV recurrence rate was 40%.<sup>29</sup>

Given the extensive rotation associated with MTS360, binocular vision is often not recovered and extraocular muscle surgery is required. Almost all patients have a central scotoma in the fellow eye preoperatively, but their peripheral vision is well maintained. The findings regarding binocularity are variable. Using Bagolini glasses, five studies reported findings of postoperative binocular vision in 6.6–28.5% of eyes.<sup>8,10,11,14,17,66</sup> However, one study reported a 0% rate of binocular function in patients.<sup>67</sup>

## Retinal and RPE Changes After Macular Translocation

The positioning of the previously dysfunctional macula over new underlying RPE provides a unique opportunity to study the relationship between photoreceptor and RPE function in humans with macular disease. The status of these tissues has been examined through numerous imaging techniques after MTS360. This has included angiography, autofluorescence imaging, spectral domain optical coherence tomography, and color fundus photography.

A striking finding in patients with GA treated with macular translocation is the recurrence of the RPE atrophy in the new foveal bed, which has now been reported in multiple studies.<sup>32,36,37</sup> In one study, recurrent RPE changes were seen in 75% of eyes treated with MTS360.<sup>36</sup> Similar findings of new RPE atrophy are quite rare in patients with neovascular AMD treated with MTS360.<sup>36</sup> The precipitating factor for RPE atrophy is not clear. Given the rarity of similar findings in MTS360 for neovascular AMD, surgical trauma seems to be an unlikely cause. RPE atrophy may be the primary event, particularly if the increased metabolic activity of the

overlying foveal photoreceptors results in increased stress to the fragile RPE. Alternatively, apoptotic photoreceptors may result in secondary RPE atrophy in the new foveal bed. Additional research is needed to further elucidate the mechanisms involved in this phenomenon.

The reports of recurrence of GA were in the era before more routine autofluorescence imaging. The FAF techniques are useful to monitor the health of the new RPE under the macula. In patients with neovascular AMD and with non-AMD diseases such as myopia, the RPE under the new macula demonstrates hyperautofluorescence that persists with little change over months to years.<sup>42,47,68</sup> This finding is often compatible with good visual acuity. The phenomenon of increased autofluorescence in the area of the new macular location after macular translocation is thought to be related to an unmasking of autofluorescence due to thinning of retina from loss of photoreceptors, though it may also be due to an increase in fluorophores in the RPE due to the metabolic demand of the concentrated central macular photoreceptors.<sup>69</sup> In addition, the RPE that was in the shadow of retinal vessels for the lifetime of the patient, and is now exposed for imaging after translocation, shows increased autofluorescence relative to adjacent RPE, whether after intentional MTS360 or after inadvertent translocation in retinal detachment repair.<sup>70</sup>

Both angiography and OCT imaging are used to monitor for evidence of recurrent CNV, while OCT imaging is also useful to evaluate the photoreceptor layer in the macula after translocation. OCT imaging is also useful for assessment of postoperative CME, which may be chronic and responsive to anti-VEGF therapy or antiinflammatory therapy, including intravitreal steroids.<sup>42</sup>

## **Unintentional Macular Translocation Following Retinal Detachment Repair**

Translocation of the macula is a feared complication during rhegmatogenous retinal detachment repair. Shifting of the retina during surgery may occur during multiple time points. Intraoperatively, as the retina is reattached (e.g., during perfluorocarbon liquid infusion, air–fluid exchange), there is some

risk of shift. However, postoperative positioning is the most likely reason for translocation. Residual subretinal fluid combined with gravitational forces may shift the retina inferiorly (when the patient is upright) or nasally (when the patient is positioned with the nasal side of the surgical eye down). When the detachment involves the superior retina through the macula, this retinal shift can produce a limited macular translocation, resulting in a retinal fold.<sup>71,72</sup> The location of the fold in cases of upright positioning would depend on the location of the inferior border of the detached retina.

In one study, patients with gas-filled eyes after vitrectomy for retinal reattachment were positioned upright for several minutes prior to face-down positioning.<sup>70</sup> This upright positioning was carried out to determine if subtle shifts in the retina occurred inferiorly. Fundus autofluorescence found hyperfluorescent changes corresponding to the preoperative location of the retinal vessels, suggesting an inferior rotation of the retina in 63% (27/43) of eyes. In those eyes with hyperfluorescent changes, a synoptophore measurement revealed that 59% of eyes had excyclotorsion and 49% of eyes had a vertical deviation. Interestingly, none of these eyes had symptomatic diplopia. Risk factors associated with retinal translocation included macula off status and increased size of retinal detachment. The use of perfluorocarbon liquid had no association with risk of retinal rotation.<sup>70</sup>

An increase in cases of partial macular translocation with macular fold was reported after a shift to outpatient surgery, and the fold was associated with patients failing to position face down after leaving the surgical center.<sup>73</sup> Because it is often difficult to assure postoperative prone positioning without inadvertent upright positioning, placing the patient initially on their side with the temporal retina dependent in the early period after surgery may reduce the risk of inadvertent translocation.

## **Advantages of Macular Translocation and Future Directions**

In the anti-VEGF era, the landscape for macular translocation has

changed significantly. The good results achieved with anti-VEGF therapy for neovascular AMD have shifted primary treatment of AMD away from surgical intervention.<sup>26,27</sup> As Zeimssen and Gelisken<sup>74</sup> point out, “Generally, in the presence of highly effective anti-VEGF drugs, FMT can be discussed for second-line treatment, if the fellow eye has poor function and no additional risk factors of the affected eye are known.”

Numerous researchers note that MTS360 may well have a role in the management of bilateral submacular diseases, including AMD. This may be particularly true in cases with early subretinal fibrosis with preservation of the outer retina. If the fellow eye has lost significant visual acuity and anti-VEGF therapy or other modalities have been unsuccessful, consideration may be given to proceeding with macular translocation. Without surgical removal, progressive enlargement of CNV may occur resulting in enlargement of the area of photoreceptor damage.<sup>75,76</sup> Central acuity may not recover even with arrest of CNV leakage, due to underlying fibrosis and loss of RPE. MTS360 may allow recovery of function through the translocation of the foveal photoreceptors off the scarred underlying tissues to an area with improved vitality.<sup>1</sup> Cases of extensive subretinal hemorrhage may also be amenable to MTS360, as the procedure allows for removal of the subretinal blood during the translocation process.<sup>7</sup>

Given that macular translocation is a type of autotransplantation, macular translocation not only provides a service to patients through potentially restoring central vision but has provided the proof that RPE transplants could support central vision and the impetus for surgical trials of transplantation of autologous patches of RPE-choroid beneath the macula (see [Chapter 124, Retinal pigment epithelium and choroid translocation in patients with age-related macular degeneration](#)).<sup>77</sup> In the future, MTS360 could provide a future scenario of neurosensory retina with damaged macular photoreceptors translocated over healthier RPE–Bruch’s–choriocapillaris along with additional growth factors or stem cells to support photoreceptor recovery. Meanwhile, this autotransplantation provides a unique look at the pathophysiology of many submacular diseases that we treat. Findings such as recurrent atrophy in the new RPE bed following macular

translocation for GA but not neovascular AMD provide a window into the possible mechanisms involved in AMD and other disorders. In the future, continued research will hopefully help to answer multiple questions, including photoreceptor damage reversibility, the interactions between photoreceptors and RPE in disease pathogenesis, and the possible role of novel therapies such as growth factors or stem cells in the recovery of function in a new RPE bed.

## **Epidemiology**

In industrialized countries the endstage of age-related maculopathy (ARM) is the principal cause of legal blindness in persons older than 60 years.<sup>1-3</sup> Severe age-related macular degeneration (AMD) occurs in an atrophic (two-thirds) and an exudative form (one-third). While we currently have an effective treatment to manage exudative AMD, there is no equally effective treatment in sight for

geographic atrophy (GA). This situation is likely to increase the relative proportion of blindness through GA compared with exudative AMD in the future, and increasing life expectancy will similarly lead to an increase in the prevalence of GA. (Epidemiology is discussed further in [Chapter 66](#), Epidemiology and risk factors for age-related macular degeneration.)

## Alternative Treatments for AMD

### Exudative AMD

The current 2015 approved treatment for many patients with exudative AMD is anti-vascular endothelial growth factor injections. (This is discussed further in [Chapter 69](#), Neovascular (exudative or “wet”) age-related macular degeneration.)

However, for patients with a retinal pigment epithelium (RPE) tear<sup>4,5</sup> or a large submacular hemorrhage, anti-VEGF therapy is generally less effective in restoring or improving visual acuity (VA), because the underlying anatomy of the outer retina is disrupted. In addition, even with the established anti-VEGF treatments, a substantial percentage of patients fail to respond, especially long term. In the original MARINA study, 10% of patients receiving ranibizumab had lost  $\geq 15$  letters and overall, 15% of patients on ranibizumab were 20/200 or worse by year 2.<sup>6</sup> A recent retrospective analysis of those patients who responded poorly to ranibizumab in both the MARINA and ANCHOR studies by year 2 revealed that these patients may have had disruption of retinal anatomy rather than highly active choroidal neovascularization (CNV).<sup>7</sup> The SEVEN-UP study looked at the long-term (7–8 years) outcomes of patients in the above trials and found a mean loss of VA of 8.6 letters at 7.3 years, with a third (34%) losing vision by 15 lines or more.<sup>8</sup> This highlights the need to consider alternative strategies, such as surgery, to improve the anatomy of the retina–RPE interface in selected patients.

### Dry AMD

Geographic atrophy (GA) is an untreatable advanced form of dry

age-related macular degeneration. However, a number of clinical and animal model studies have evaluated medical treatment approaches, e.g.,

- Growth factors (ciliary neurotrophic factor (see <http://www.clinicaltrials.gov>, NCT00447954, for details)
- Modulation of gene expression (DICER protein)<sup>9</sup>
- Modulation of the visual cycle to decrease toxic by-products (see <http://www.clinicaltrials.gov>, NCT01002950, for details)
- Modulation of inflammation (see <http://www.clinicaltrials.gov>, NCT00766649, for details)
- Plasma filtration (see <http://www.clinicaltrials.gov>, NCT00460967, for details).

Nevertheless, to date, there is no approved treatment regimen for GA.

## Surgical Treatment

As an alternative treatment, five surgical treatment modalities have been described for exudative AMD and to a lesser extent for dry AMD.

1. Removal of the submacular choroidal membrane and/or hemorrhage. This was shown to be of little benefit in the Submacular Surgery Trials (SST), although the percentage of patients with more than 6 lines VA loss was statistically smaller in the subgroup of patients with large submacular hemorrhage (group B) when compared to natural history<sup>10</sup>
2. Macular translocation after 360° retinectomy. This method was first reported by Machemer et al. in 1993.<sup>11</sup> A tilted image in successful cases, complex and time-consuming surgery, and a high percentage of vision-threatening complications such as proliferative vitreoretinopathy (PVR), particularly in the earlier studies, remain drawbacks of this technique<sup>12</sup> (described in more detail in [Chapter 123](#), Macular translocation). In a randomized controlled trial (RCT) in Tübingen in 50 patients, however, with photodynamic therapy (PDT) treatment in the control arm, vision gain was significantly

greater in the surgical arm.<sup>13</sup> The limit to the extent of retinal rotation possible makes it most effective for smaller lesions, particularly classic CNV, but this clinical presentation is also particularly well suited to anti-VEGF treatments, making this surgery less easy to justify in the modern era. Nevertheless, in highly skilled hands, good long-term results can be obtained.<sup>14</sup>

3. Minimal macular translocation by scleral infolding and the induction of retinal detachment (RD) was described by de Juan in 1998.<sup>15</sup> The macular translocation achieved, however, was less than one disc diameter.<sup>16</sup> This has indeed limited its use since the advent of treatments that were particularly effective for small lesions, such as PDT and anti-VEGF (see [Chapter 123](#), Macular translocation).

4. The displacement of an acute hemorrhage by gas and recombinant tissue plasminogen activator, with or without vitrectomy, with subsequent treatment with PDT or anti-VEGF.<sup>17,18</sup> Several case series suggest a clear benefit over natural history.<sup>19–21</sup>

5. Transplantation of an autologous graft of RPE, Bruch's membrane, choriocapillaris, and choroid. This method was first described in a case report by Peyman et al. in 1991.<sup>22</sup> Initially, the graft was harvested from the edge of the macular RPE defect.<sup>23</sup> Later studies utilized midperipheral tissue.<sup>24–29</sup> The most frequent complications of this transplantation technique were recurrent CNV, RD, PVR, failure of the graft to revascularize, macular pucker, and postoperative hemorrhages.

Both macular translocation surgery and the transplantation of a free autologous graft of RPE and choroid will probably achieve a better VA than no intervention. Though macular translocation surgery might produce better outcomes,<sup>30</sup> it has a greater risk of complications and there is a physical limit to the amount of rotation possible (even after 360° retinectomy), which makes it less suited to large CNV.

This chapter focuses on the transplantation of free autologous grafts of retinal pigment epithelium and choroid. It will discuss its history, surgery, published results in patients with exudative and atrophic AMD, and conclude with potential developments.

# Rationale for Reconstitution of Retinal Pigment Epithelium

The spectacular functional restoration achieved in some patients with exudative AMD after macular translocation by rotation proved the principle of reopposing a reversibly compromised fovea to a fresh undersurface of functioning RPE cells.<sup>11,31</sup> Other key discoveries in the concept of restoring the underlayer of the macula have included:

- Showing that functioning RPE cells are essential for the preservation of Bruch's membrane and the underlying choriocapillaris in rabbits.<sup>32</sup>
- Demonstrating that human RPE cells secrete VEGF on their basal side and that the adjoining underlying choriocapillaris has VEGF-receptors.<sup>33</sup>
- Proving the principle that healthy RPE cells can postpone photoreceptor death after subretinal transplantation in a rat model of RPE dysfunction.<sup>34</sup>

Consequently many different surgical approaches to recreate a functioning RPE underlayer of the macula have been tried. These approaches may broadly be defined by several complementary techniques: autografts versus allografts; cells in suspension versus cell sheets or patches; RPE versus iris pigment epithelium (IPE) cells ([Table 124.1](#)).

## Transplantation of a Full-Thickness Patch From the Midperiphery

With the current lack of demonstrable presence or function of RPE or IPE suspension transplants,<sup>38,40,41</sup> the authors decided to pursue the use of a sheet of autologous RPE on its own substratum. Peyman reported a case history on the use of a full-thickness flap with a pedicle. Follow-up was 6 months and stabilization of vision at 20/400 was reported.<sup>22</sup> Aylward, in nine patients, used a full-thickness patch, cut out from a location adjacent to the removed subfoveal membrane. In four patients, some function on microperimetry could be shown over the patch; but the preoperative vision was too low to assess vision in detail using the techniques available at the time.<sup>23</sup> Fibrosis of the patch, however, developed in the second year of follow-up in most patients, and previously documented function on the graft had disappeared.<sup>55</sup> In Aylward's patients the grafted paramacular choriocapillaris appeared sclerotic and damaged by the surgery, and we speculated that it was therefore less likely to be successfully revascularized. Van Meurs<sup>24</sup> sought to improve on Aylward's technique by harvesting a relatively healthy midperipheral full-thickness RPE and choroid patch with the advantage of having easy access to cut out the patch and direct control of bleeding from the donor site. Surgeons in Cologne, Kiel, Liverpool, Vienna, Verona, Beijing,

London, and Rotterdam have published further reports, some with a different surgical approach with a flapover technique to expose the subretinal space. Surgeons have also reported the use of a split-thickness graft, removing most of the choroid with an excimer laser<sup>42</sup> or with a spatula,<sup>43</sup> or using a spontaneously occurring free RPE sheet in patients with a pigment epithelium detachment.<sup>56</sup> The possibility of finding a surgical dissection plane between (layers of) Bruch's membrane and RPE is likely largely dependent on the specific type of exudative AMD. In patients with choroidal polyps, the new vessels grow in that plane and separation along that plane may occur while injecting balanced salt solution (BSS) to detach the retina (personal observation, van Meurs, Jakarta October 2013). This approach, pioneered by Zhizong Ma,<sup>43</sup> is particularly interesting in view of the recent development of free RPE sheets, grown from embryonic stem cells (see below), because this anatomic separation would be most favorable for transplanting an RPE monolayer directly onto host choriocapillaris.

## Surgery

### Keyhole Approach

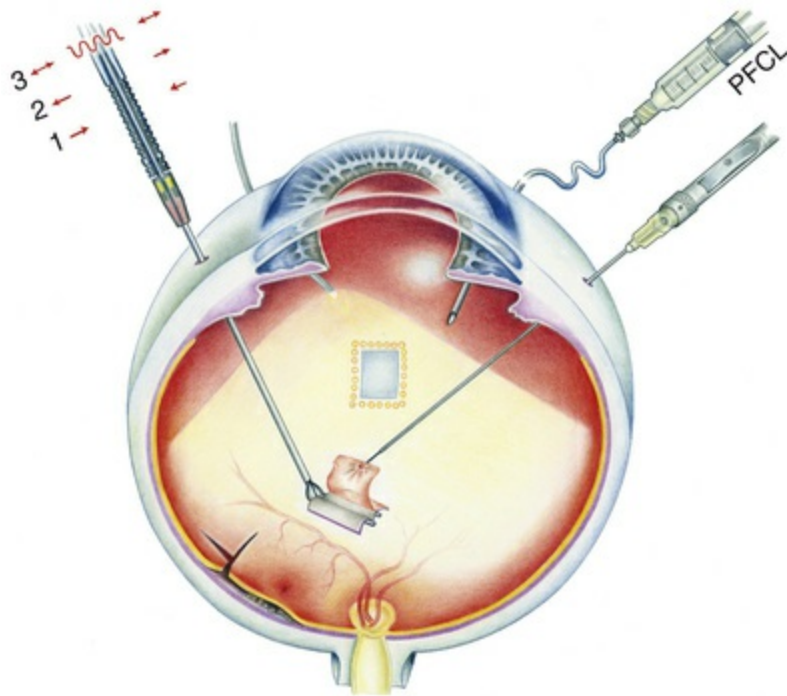

After the induction of a posterior vitreous detachment, a complete vitrectomy is performed (see video under <http://www.eyemoviepedia.com/videos/3971697493/153>). The macular retina can be separated from the RPE and/or blood and/or CNV membrane by injecting a balanced salt solution into the subretinal space through a 28-gauge subretinal cannula. A paramacular temporal retinotomy is made, through which the CNV membrane and/or subretinal hemorrhage is removed from the subretinal space with Thomas subretinal forceps. Remaining hemorrhage is flushed out by irrigation with a 135° bent 32-gauge needle connected by tubing to a syringe filled with BSS and operated by an assistant.

Initially, a small retinotomy was made in the raphe; in later surgeries a radial cut was made along the raphe, from the retinotomy located peripherally. However, a vertical retinotomy temporal to the macula (Fig. 124.1) was found to work best for two

reasons: (1) less tendency to enlarge in the direction of the fovea and (2) easier for later introduction of the flat graft (François Devin, Marseille, personal communication). After circular heavy diathermy or laser in the midperiphery at the 6 or 12 o'clock position, vitreous scissors are used to cut a full-thickness graft of retina, RPE, Bruch's membrane, and choroid of approximately 2.5–3×2.5–4 mm. Initially, the graft was loaded onto an aspiration-reflux spatula. Subsequently the technique was changed so that the graft could be grasped from the choroidal side by fine forceps. The retina is removed from the graft just before it is repositioned under the macula through the existing paramacular retinotomy (Fig. 124.2). Perfluorocarbon liquid is injected over the macula to hold the graft in position during retraction of the instrument. A vibration device attached to the forceps facilitates the release.<sup>57</sup> The midperipheral donor site is then surrounded with laser photocoagulation, followed by silicone oil tamponade.

**FIG. 124.1** A vertical retinectomy (as suggested by F. Devin) is currently preferred because this retinotomy has less tendency to enlarge towards the fovea and the graft is inserted more easily.

**FIG. 124.2** Technique of a free retinal pigment epithelium–choroid transplantation using the keyhole technique. *PFCL*, perfluorocarbon liquid.

In a second procedure, approximately 3 months later, the silicone oil can be removed and the inner limiting membrane (ILM) peeled, which may reduce the risk of macular pucker. In phakic patients, lensectomy and intraocular lens (IOL) insertion can be performed during the first or second procedure.

## Peroperative Course

Bleeding from the choroidal extraction site may pose a serious problem. This can be countered by increasing the infusion pressure up to 180 mmHg and repeated rinsing out of the hemorrhage with a submacular cannula connected to a syringe (operated by an assistant), with or without a perfluorocarbon liquid (PFCL) bubble over the macula. The area of damaged RPE resulting from membrane and hemorrhage removal is generally much larger than the RPE and choroid graft.

## Finding a Cleavage Plane Between Sclera and Choroid

When trying to place the harvested patch under the fovea, remnants of the fibrous connecting tissue between choroid and sclera may jeopardize a clean release. Before cutting out the patch, the authors try to separate the patch from the sclera by introducing and sweeping a sharp spatula in the suprachoroidal space. When we cut out the graft, we leave a slight connection of choroidal tissue at the edge facing the macula, acting as a hinge to fold over and expose the choroidal side. In this manner, the graft is tethered internally so that we can remove loose connective fibers bimanually with intraocular forceps and scissors.

## Positioning the Graft on the Spatula

When all four sides of the rectangular 1.5–3×2.5–4 mm graft are cut clear of the adjoining tissue and the collagenous connections of the choroid to the sclera have been swept away, the graft has the tendency to roll up in a half cylinder with the RPE on the convex side, usually with the half cylinder limbus parallel.

This occurs in BSS (possibly due to the inherent elastic tension of the choroid), and the free floating patch may subsequently become difficult to grasp. Moreover, the infusion bottle should be quite low to minimize turbulence and to prevent the patch being trapped or expelled through a sclerotomy when changing instruments. It is helpful to use a chandelier-style illumination so that the patch can be manipulated bimanually and steadied when changing instruments.

Preparation of the patch under PFCL may help to keep the patch flat on the spatula; while it allows us to keep the bottle raised, thereby decreasing the risk of bleeding from the choroidal or retinal vessels. A concern exists, however, about whether or not a remaining PFCL film/thin layer may interfere with later function. The approach we favor, however, makes use of the observation that an excised choroid-RPE-retina transplant has no tendency at all to curl: the attached retina counteracts any curling forces of the choroid. Thus, while the choroid-RPE plus retina graft is steadied from the choroidal side with horizontal forceps, we peel off the neurosensory retina by means of suction of a flute needle, just before insertion under the macula.

## Positioning of the Graft Under the Fovea

Positioning of the graft under the fovea with a standard vitreoretinal spatula may be difficult. Horizontal forceps, even when designed not to close entirely, proved to be unsuitable because the patch frequently cannot be released easily due to adherence to the forceps. A better instrument to hold and release the patch turned out to be a cannulated spatula with one opening, with an assistant applying aspiration to hold the patch or reflux to release the patch. A single opening appeared better than more openings, since once occlusion is lost over one opening, release can no longer be effected by refluxing. Most recently, the authors rely once more on a wide-opening horizontal forceps, attached to a vibrating device, to facilitate mechanical release of the tissue.<sup>58</sup>

## Tamponade

We have used silicone oil to facilitate examination of the patients in the early postoperative period. A gas tamponade might be possible too in selected cases. It may be speculated that in patients with an inferior donor site, the use of a heavier than water tamponade would decrease the risk of retinal detachment and PVR. This was not confirmed in a study analyzing the occurrence of PVR in 235 patients with either a superior or an inferior donor site with lighter than oil tamponade for all.<sup>59</sup> Indeed, in a prospective randomized study with heavy silicone oil (Densiron, Fluoron, Neu-Ulm, Germany) versus standard silicone oil the rate of PVR was overall unchanged, but the PVR-membranes were shifted from the inferior circumference to the upper.<sup>60</sup>

## Flapover Approach

To obviate the need for a parafoveal and midperipheral retinotomy, to enable better control of choroidal bleeding and to enable the surgeon to fashion the size of the graft to the RPE defect, a technique from macular translocation by retinal rotation can be used.<sup>61</sup> Moreover, this technique allows surgery in patients with more massive hemorrhages.

A temporal retinal detachment is created by subretinal infusion

of BSS through a 41-gauge needle, followed by a retinectomy near the ora serrata in the temporal 13 clock-hours with subsequent folding over of the retina over the disc to expose the temporal subretinal space. While working under BSS for membrane removal and later under PFCL for preparation of the graft, more direct control of obtaining a correctly sized patch is possible. It may be the approach of choice in large lesions and allows direct control of bleeding from the stalk of the CNV. This technique is currently favored by more surgeons, and the best results so far reported are by Pertile in Verona.<sup>48</sup> A specific concern here is that the detached temporal retina may incarcerate in the nasal sclerotomy. Measures to prevent this occurring are the meticulous removal of vitreous base remnants, a low infusion pressure, and a retinectomy that should not be extended too far to the nasal sclerectomy. When incarceration occurs, the incarcerated retina can be manipulated out of the sclerotomy with a ring forceps, after closing the infusion (Gracia Pertile, May 2011, personal communication). With the advent of valved pars plana cannulas, however, the risk of incarceration is much smaller.

## Instruments

Instruments for the keyhole technique were designed and manufactured in close collaboration with Ger Vijfvinkel of the Dutch Ophthalmic Research Center (DORC), Zuidland, The Netherlands. For the flapover technique, standard instruments proved to be adequate.

## Choroidal Rotation

As a further refinement to avoid creating a double layer of choriocapillaris, Lee and colleagues<sup>62</sup> described a novel technique in the nonhuman primates of rotating the choroid beneath the retina. The blood supply to the rotated choroid came from the lateral long posterior ciliary artery (LPCA), at the base of the choroidal flap, which was lasered in a circle extending from the temporal disc to the ora, before being cut and rotated by 180° (Fig. 124.3A). The overlying neurosensory retina was folded over in a similar manner to the “flapover” technique described above, in order to gain access

to the choroid from the transvitreal approach ([Fig. 124.3B](#)).

**FIG. 124.3A** (A) Technique of rotation of autologous translocation using a pedicle of full-thickness choroid. A cast of the human choroidal circulation is shown in panels A and B. *ON*, optic nerve head; *LAT/MED*, lateral and medial posterior choroidal arteries. The location of the lateral long posterior ciliary artery (LPCA) is shown by the *white arrows* in C and the *red line* in D, in a patient with choroideremia in whom the choroidal atrophy has revealed the underlying perforating vessels. (E) An imaginary choroidal new vessel (CNV) complex is seen in red under the fovea. In the era before anti-VEGF treatments, this patient may have been considered for retinal translocation surgery. (F) A peripheral retinectomy allows folding of the retina nasally to expose the underlying choroid. Care is taken to avoid damage to the papillomacular bundle and perfluorocarbon (heavy liquid) is used to stabilise the retina. Under heavy liquid, a circle in the choroid is circumscribed with heavy laser to cauterise choroidal vessels and the choroid is then cut along this line with scissors. The choroid is easily mobilised from the underlying sclera but care is taken to preserve the perforating lateral posterior ciliary vessel which courses laterally across the posterior choroid (red). (G) The mobilised choroidal pedicle is then rotated about 180 degrees to displace the diseased area into the temporal periphery and bring the healthy temporal choroid into the subfoveal zone. (H) The retina is reattached with heavy liquid and peripheral laser applied (yellow). The operation is completed with a heavy liquid silicone oil exchange. (Panels A and B courtesy of Jane Olver MD. Panels E–H reproduced with permission from Lee E, Singh MS, Jones HE, et al. Assessment of 180 degrees rotation of the choroid as a novel surgical treatment for age-related macular degeneration. *Invest Ophthalmol Vis Sci* 2012;53(6):2523-2532.)

**FIG. 124.3B** Choroidal rotation surgery under the retina in the nonhuman primate (*Macaca mulatta*). (A) The retina is detached with balanced salt solution (here using a metal 34 gauge cannula). (B) The detached retina is cut along the periphery, along a

preplaced laser track to reduce retinal bleeding. (C) The retina is folded over under heavy liquid and the circular choroidal laser track can be seen. (D) The choroid is cut along the track to expose the underlying sclera. Note that there is only minimal bleeding under heavy liquid. (E) The choroidal pedicle is rotated carefully around the perforating lateral posterior choroidal artery pedicle. Some shrinkage of the graft is seen, which exposes sclera temporarily. This occurs because the free choroid is an elastic structure. (F) After heavy liquid/oil exchange, the retina is reattached over the choroidal pedicle with no significant subretinal hemorrhage. (Reproduced with permission from Lee E, Singh MS, Jones HE, et al. Assessment of 180 degrees rotation of the choroid as a novel surgical treatment for age-related macular degeneration. *Invest Ophthalmol Vis Sci* 2012;53(6):2523-2532.)

Although the technique was shown to be technically feasible, the revascularization of the rotated choroid was poor, despite the arterial pedicle being present. The choroid has a unique dual blood supply, because while the arteries enter at predefined points penetrating the sclera posteriorly, the veins drain to separate structures (the vortex veins) anteriorly. In a typical vascularized rotational skin graft, the pedicle has both arterial and venous components within it and blood supply is maintained throughout. In the case of the choroidal rotation, however, only the arterial supply is in the pedicle and the venous drainage needs to be reestablished by peripheral vascular networks reconnecting. The researchers speculated that the elastic nature of the choroidal tissue caused peripheral retraction and prevented the venous circulation from being reestablished.<sup>62</sup> These experiments highlight the complex nature of the choroidal circulation, which needs to be explored before progressing to surgical trials in humans.

## Results in Exudative AMD

Reports of free RPE grafts generally have been reported on small groups of patients and have had a follow-up of only 6 months to 3 or 4 years (Table 124.1). MacLaren and Aylward have presented patients with a 5- and 6-year follow-up, but for only four of nine

operated patients.<sup>63</sup>

A recent report followed a cohort of 132 consecutive patients (134 eyes) who underwent RPE–choroid graft surgery; in some patients VA and/or microperimetry results of 4–7 years after surgery were documented (Fig. 124.4).<sup>64</sup> In several patients, clear evidence of retained retinal function on the graft proved in principle the longevity of this technique and at timepoints not yet reached with anti-VEGF treatments (Figs. 124.5 and 124.6).

**FIG. 124.4** Visual acuity (VA) before surgery (preoperative) and each year up to 7 years thereafter. Three groups are depicted. Groups 1 and 2 comprise percentages of patients with a VA of  $>20/200$  or  $\leq 20/200$ . The third group comprises percentages of patients whose last measured VA had been  $>20/200$  before they were lost to follow-up (LFO), and patients who had not able to reach their next yearly follow-up visit yet, while VA was  $>20/200$  at last measurement (LFO while  $>20/200$ ). The data of this third group have been carried forward in this figure.

**FIG. 124.5** A 78-year-old male. Preoperative visual acuity (VA) 20/100, minimally classic choroidal neovascularization. NIDEK MP-1, 5 years postoperatively, with VA 5 20/40.

**FIG. 124.6** Twelve years after RPE and choroid graft transplantation for a 12-week-old submacular hemorrhage with only counting fingers vision in a now 85-year-old woman. Visual acuity 20/40 with preserved retinal sensitivity over the graft on microperimetry (NIDEK MP-2).

The number of patients with preserved macular function remains modest, however, due to several factors: preexisting and surgical damage to the retina; ischemic and surgical trauma to the RPE–choroid graft; revascularization delay; and potential revascularization injury of the graft. Comparison with the results of the submacular surgery trials, however, suggested that it is the RPE graft, rather than simply the removal of the submacular choroidal neovascular scar and blood, that was responsible for the preservation of reasonably good macular function in some patients.<sup>29</sup>

Recently, it was shown that spectral domain optical coherence tomography (SD-OCT), a noninvasive technique, allows the monitoring of revascularization of a RPE–choroid graft (Fig. 124.7A).<sup>29</sup> Indeed, the revascularization steps strongly suggested by SD-OCT<sup>29</sup> have been confirmed by Doppler-OCT, in which flow was demonstrated in the graft's vasculature.<sup>65</sup>

**FIG. 124.7** (A) A rapid and rare fibrotic reaction to a RPE graft in an 83-year-old woman. We removed this graft 8 weeks after its insertion and replaced it with a second one. (B) Microscopic tissue section of the graft removed in Fig. 124.6 ( $\times 100$  magnification, Syrian Red staining for collagen), highlighting the thick fibrotic capsule under the retinal pigment epithelium (RPE) and choroid graft; almost no RPE cells are visible, possibly partly due to preparation artifact. *Bruch*, Bruch's membrane; *Choriocap*, choriocapillaris; *RPE*, retinal pigment epithelium. (Courtesy of Rob Verdijk, MD, PhD.)

SD-OCT may also prove to be an important tool to select patients with a potentially functional retina, by selecting patients with preserved outer retina structures.

## Continuing Concerns

The major concerns with autologous retinal pigment epithelium transplantation that we encounter include the too-frequent development of RD and PVR, and the common fibrosis around or (fortunately rare, three patients out of more than 350) over the graft (Fig. 124.7B). At this moment, in the absence of proven pharmacologic preventive measures, surgery that is as atraumatic as possible remains the key factor. This is exemplified by the low incidence of PVR in a recent report from Verona.<sup>14</sup>

Although an autologous RPE graft is not “foreign,” the surgical procedures to remove the submacular scar and cutting out of the graft certainly produce tissue trauma and elicit an inflammatory reaction with many features of immune involvement (the “danger” model<sup>66,67</sup>).

It is likely that both challenges will remain in future surgery even if RPE grafts are eventually produced in the laboratory from stem cells.

## Retinal Pigment Epithelium Transplantation in Dry AMD

Full macular translocation is usually complicated by rapid onset of RPE atrophy at the new location of the macula.<sup>68</sup> Two prospective nonrandomized studies are available looking at the prognosis after patch translocation in GA.<sup>44,47</sup> A follow-up of more than 2 years is required to be able to discern a therapeutic effect compared to the slow progressive natural course.<sup>47</sup>

## Surgical Aspects in Dry AMD

In patients with dry AMD, several surgical steps are slightly different from those for exudative AMD (see video under <http://www.eyemoviepedia.com/videos/4166636950/67>). After a three-port pars plana vitrectomy, BSS was injected subretinally temporal and adjacent to the macula. In almost all eyes, the macula did not detach, but this was not the case for the retina around the

macula. Additional mechanical separation of the macula proved necessary. An angulated infusion needle was used as spatula and fluid jet. At the same time Bruch's membrane was scratched to create breaks in Bruch's membrane, allowing choroidal vessels to connect to the transplant later on, as graft nonperfusion was observed in our first patients (Cologne, Rotterdam) (Fig. 124.8) when this step was omitted. Access to the subretinal space was through a temporal retinotomy. The excision site of the graft was chosen in the inferior retinal periphery after demarcation by laser photocoagulation. After removal of the overlying retina, the graft was mobilized from the sclera, grasped with angulated forceps from the choroidal side, and inserted under the macula through the temporal retinotomy.<sup>69</sup> Heavy silicone (Densiron, Fluron, Ulm) was used as vitreous tamponade for 3 months.

**FIG. 124.8** One of the first patients with dry age-related macular degeneration (AMD) and a free retinal pigment epithelium–choroid graft, in whom Bruch's membrane was left untouched and no revascularization occurred.

Functional outcomes of 10 patients were as follows: prior to surgery, seven of the 10 patients were able to read compared with five patients being able to read 2–3 years postoperatively. Microperimetry showed central fixation in five eyes prior to surgery and in two eyes 2–3 years after surgery. In all but one eye revascularization of the graft was confirmed by indocyanine green angiography beginning as early as 3 weeks after translocation.

Autofluorescence was present in all eyes throughout the follow-up period, including the patient with no revascularization of the graft and more obvious retinal thinning over the graft than the others.

Recurrent CNV appeared in three eyes at the edge of the graft, not affecting the fovea. Macular pucker was noted in three eyes. PVR retinal detachment outside the posterior pole occurred in three eyes.

## **Conclusions for Patient Benefit in Geographic Atrophy**

In terms of timing of surgery, the insidious onset of changes in the choroid and RPE in atrophic AMD with subsequent atrophic changes in the overlying retina compare unfavorably with the relatively acute-onset changes in RPE and choroid in patients with exudative AMD, with more often some degree of preservation of the overlying retina.

None of our patients with atrophic AMD improved in VA. Stabilization or further visual loss is a more likely long-term outcome. Retinal atrophy could not be reversed by RPE–choroidal grafting. Eccentric preoperative fixation will persist. Tight adhesion of the central neurosensory retina to the choroid is characteristic of GA. This may explain a higher risk of surgical damage to photoreceptors compared to exudative AMD, in addition to preexisting retinal atrophy as part of dry AMD. Only a very small selection of patients with preserved central fixation and an intact junction of inner/outer-segment photoreceptor junction on OCT may profit from grafting, at a considerable risk, however, of losing central vision.

Of interest, we observed no recurrence of RPE atrophy on the graft, as opposed to its rapid recurrence after full macular translocation.

## **Retinal Pigment Epithelium–Choroid Translocation and Future Stem Cell**

## Treatments for AMD

A stem cell is a dividing self-renewing cell also capable of differentiating into a variety of adult differentiated cell types to renew various tissues. While it has always been appreciated that embryonic stem (ES) cells are pluripotent, in that they give rise to a whole embryo and any one of the approximately 220 different cell types that define the adult mammalian organism, it was not until the cloning of Dolly the sheep in 1997 that it became apparent that adult differentiated cells could also have a similar potential. In the case of Dolly, the DNA from a mammary gland cell taken from her genetic mother was extracted and injected into a newly fertilized oocyte, from which the original gamete-fused nucleus was removed.<sup>70</sup> This process, known as somatic cell nuclear transfer (SCNT), led to the development of a clone of ES cells, which was subsequently able to differentiate into the sheep, which was born after implantation into a surrogate mother.

The fact that the sheep was normal proved the principle that any adult somatic cell could potentially be reprogrammed by undefined factors within a newly fertilized oocyte cytoplasm to become an ES cell, and this was subsequently confirmed in primates.<sup>71</sup> Somatic cell nuclear transfer requires a newly fertilized oocyte and so brings with it some ethical considerations and practical limitations. However, a decade after the successful cloning of Dolly the sheep it was discovered that adult differentiated cells could be reprogrammed without the oocyte by manipulating the histones, which are the protein switches that inactivate specific genes, particularly histone H3, or by direct methylation of the DNA promoter sequences.<sup>72,73</sup> Both of these approaches switch specific genes on and off and effectively reprogram the cell to become, for instance, a stem cell.<sup>74</sup> This research identified the transcription factors that facilitate reprogramming of skin cells that were then reimplanted to become a fully differentiated mouse embryo and the reprogramming part (without implantation) has subsequently been achieved in human cells.<sup>75</sup> Hence, current talk about stem cells is not discussing fetal cells or even cells modified via the oocyte; it is believed that induced stem cells may hold the key to regeneration of diseased tissues in future. These could be obtained potentially

from any patient and manipulated into the desired cell type prior to transplantation – referred to as induced pluripotent (iPS) stem cells.

It should be immediately apparent at this stage that since an iPS cell could potentially give rise to a normal mammalian organism, it should by definition be able to give rise to any of the cell types present in that organism. This includes of course the RPE, photoreceptors, retinal ganglion cells, and other components of the visual system. This raises the possibility that we may be able to take adult skin cells from a patient with AMD and reprogram these into RPE cells prior to transplantation. This sounds like an exciting concept, but we need to consider some of the observations learned through two decades of AMD surgery research. We know from the studies mentioned above that suspensions of healthy RPE cells isolated from the retinal periphery in AMD patients are unable to reform a physiologic monolayer underneath the macula. This may in part be due to the fact that these cells need to be fused with the underlying Bruch's membrane and the latter is almost certainly diseased and compromised in the later stages of AMD.<sup>76</sup> The choriocapillaris that gives rise to Bruch's membrane may be derived from the mesoderm germ layer, whereas the RPE originates from the neuroectoderm.<sup>77</sup> This is highly relevant because in studies to date, that have derived RPE cells from both ES cells and iPS cells, it has become apparent that the RPE cell differentiation does not include the creation of a choriocapillaris or Bruch's membrane.<sup>78,79</sup> The key challenge of the application of iPS-derived RPE cells will be to generate these cells not as a suspension, but fused to an underlying substrate of Bruch's membrane, or similar, that can facilitate polarization and hence balanced homeostasis of RPE cells once transplanted into the subretinal space.<sup>80</sup> To address this problem, a trial at the UCL Institute of Ophthalmology in London has recently started that includes support for the transplanted stem cell-derived RPE on a polyester membrane (NCT01691261). In that study, the researchers are also limiting transplantation to AMD patients who have rapid loss of vision, primarily due to tears in the subfoveal RPE. This is helpful as these patients generally do poorly with anti-VEGF treatments and the prospect of a temporarily compromised but otherwise anatomically intact fovea raises the possibility for assessing restored vision on the transplanted

monolayer.

It can therefore be seen that the techniques described above, particularly in relation to RPE–choroid patch graft surgery, are highly relevant to any future stem cell approach because it is almost certain that a very similar surgical technique would be employed to deliver reengineered tissue into the subretinal space. In cases where the retinal degeneration has progressed to the point of photoreceptor loss, any stem cell strategy to transplant photoreceptors back into the fovea would need to be combined with restoration of the underlying RPE, because otherwise the transplanted cells would not survive.<sup>81</sup> It may therefore be possible to use iPS cell-derived RPE engineered on a suitable Bruch's substrate via a standard surgical procedure to restore submacular RPE as the first step, followed by reintroduction of photoreceptors via an alternative stem cell approach at a later stage.<sup>82</sup> It is, however, worth noting that the RPE–choroid patch graft results, described in detail in the section above, suggest that there is no intrinsic problem in using autologous cells harvested from the retinal equator for subfoveal RPE replacement. This would also solve the Bruch's membrane substrate problem because RPE cells would remain adherent to the choriocapillaris throughout the transplantation procedure. While there is no doubt that photoreceptors would almost certainly need to be derived from an alternative possibly stem cell source, the idea of using stem cells or iPS cells to replace the RPE is less clear because the problem of recreating the Bruch's membrane substrate still remains (Fig. 124.9). Furthermore, the concept of introducing genetically modified and potentially teratogenic cells brings with it additional risks that would delay clinical application,<sup>83</sup> whereas autologous grafting techniques are already established in the clinical arena. A clinical trial using iPS cell-derived RPE in a cultured monolayer started in 2014 at the RIKEN Institute in Japan, and one patient has so far been implanted.<sup>84</sup> The trial was, however, suspended in 2015 prior to the second planned surgery due to concerns about possible oncogene activation during the reprogramming process of the harvested autologous cells.

**FIG. 124.9** Ultrastructure of a full-thickness RPE–choroid graft. Scanning electron micrograph showing the regular alignment of retinal pigment epithelium (*RPE*), choriocapillaris, and the continuous Bruch's membrane between (*arrowheads*). The challenge of any stem cell approach will be to recreate a structure similar to this, particularly as autologous tissue can be harvested with minimal risk from the anterior region of the eye and supports foveal vision up to at least 20/30. (Reproduced with permission from MacLaren RE, Pearson RA. Stem cell therapy and the retina. *Eye* 2007;21:1352–9.)

Recently, a phase I clinical trial has shown safety and reported some promising early results transplanting human embryonic stem cells in nine patients with Stargardt disease and nine with AMD.<sup>85,86</sup> This concept has many challenges, not least of which because many patients with Stargardt disease lose vision prior to disruption of the underlying RPE, presumably due to photoreceptor dysfunction.<sup>87</sup> Similarly, it is not clear if these transplanted RPE cells have any capacity to adhere to or polarize on the underlying Bruch's membrane in these patients. Nevertheless, it is likely that observations on the behavior of these ES cell-derived RPE cells will provide useful information on the viability or not of this as a potential future treatment, and there is good evidence from the reports that the transplanted stem cell-derived RPE cells survive after cessation of immune suppression. Moreover, many of the technical challenges relating to surgery with these cells will be overcome, at least in part, as a result of what we have learned to date with the surgical approaches using autologous RPE–choroid grafts.

## **Introduction**

## **Organisms That Cause Endophthalmitis**

## **Experimental Endophthalmitis**

## **Clinical Findings**

## **Therapy**

## **Future Directions**

## **Conclusion**

## **Introduction**

Infectious endophthalmitis is a condition in which the internal structures of the eye are invaded by replicating microorganisms, resulting in an inflammatory response that ultimately may involve all tissues of the eye. Exogenous endophthalmitis occurs when the outer wall of the eye sustains a break as a result of surgical intervention or trauma; only rarely do microorganisms invade through the cornea or sclera without an overt disruption of these tissues. Endogenous endophthalmitis is less common and occurs when the microorganisms spread to the eye from a source

elsewhere in the body, usually through the bloodstream. The most common causative agents are bacteria, but fungi and parasites can also cause endophthalmitis. The time course of the disease may be acute, subacute, or chronic.

The majority of endophthalmitis cases occur after surgery, and over 90% of all cases are caused by bacteria. Each clinical setting of infection has its own characteristics, and as knowledge is refined, various constellations of findings have emerged. In certain clinical settings there is an increased likelihood of infection by certain groups of bacteria. In turn, the clinical condition that is present at the onset of infection and the pathogenicity of the bacteria involved are the primary determinants of the outcome. For example, endophthalmitis following cataract surgery is most often caused by *Staphylococcus epidermidis*, and these eyes have a reasonably good prognosis. Injured eyes, on the other hand, have an increased likelihood of infection with gram-positive *Bacillus* spp., which has a markedly worse prognosis.

## Organisms That Cause Endophthalmitis

Bacteria, fungi, protozoa, and parasites are all capable of producing endophthalmitis (Box 125.1).

### Infective Agents That Commonly Cause Endophthalmitis

#### Bacteria

##### Gram-Positive Cocci

- *Staphylococcus*
- *Staph. aureus*
- *Staph. epidermidis* and related species
- *Streptococcus*

- *Strep. pneumoniae*
- Viridans group
- *Strep. faecalis*

### Gram-Positive Bacilli

- *Bacillus*
- *B. cereus*
- *B. subtilis*
- *Corynebacterium*
- *Listeria monocytogenes*
- *Clostridium* spp.
- *Propionibacterium acnes*

### Gram-Negative Cocci

- *Neisseria*
- *Moraxella*

### Gram-Negative Bacilli

- *Acinetobacter* spp.
- *Haemophilus influenzae*
- *Pseudomonas*
- *P. aeruginosa*

- *Pseudomonas* spp.
- Enterobacteriaceae
- *Escherichia coli*
- *Klebsiella*
- *Proteus*
- *Serratia*
- *Enterobacter*

### Higher Bacteria

- *Nocardia* spp.
- *Actinomyces israelii*
- *Mycobacterium*

### Fungi

- *Candida*
- *Aspergillus*
- *Histoplasma capsulatum*
- *Blastomyces dermatitidis*

### Helminths

- *Onchocerca volvulus*
- *Taenia solium* (*Cysticercus cellulosae*)

- *Toxocara canis* and *T. cati*

## Protozoa

- *Toxoplasma gondii*

## Ectoparasites

- Maggots (myiasis)

## Bacteria

Bacteria are the most common group of organisms causing endophthalmitis. Gram-positive organisms are responsible for 60–80% of acute infections in all large series. These organisms vary widely in their virulence and, therefore, in their effect on the eye.

### Gram-Positive Cocci

#### Staphylococci.

Staphylococci are gram-positive organisms that grow singly, in pairs, in chains, or in clusters. They are members of the family Micrococcaceae, and the individual organisms have a diameter of 0.2–1.2  $\mu\text{m}$ . The main groups of staphylococci producing endophthalmitis are *Staphylococcus aureus* and coagulase-negative staphylococci.

*Staph. aureus* is a nonspore-forming facultative anaerobic organism that colonizes human skin and mucous membranes intermittently. It is often cultured from conjunctiva in asymptomatic persons. *Staph. aureus* is identified by positive reactions to catalase, coagulase, deoxyribonuclease test, and mannitol fermentation. *Staph. aureus* produces many enzymes, including catalase, which correlates with pathogenicity.  $\beta$ -Lactamases (which play a role in antimicrobial resistance), coagulase, and hyaluronidase are also bacterial products. Toxins produced by *Staph. aureus* include exfoliatins, which produce dramatic epidermal changes in skin infections; toxins associated with toxic shock syndrome; and enterotoxins, which are a major cause of food poisoning.

*Staph. aureus* is the second most commonly isolated organism in clinical cases of postoperative bacterial endophthalmitis and usually produces a virulent, rapidly progressive intraocular infection.

Coagulase-negative staphylococci have at least 11 different subspecies, including *Staph. epidermidis*, *Staph. capitis*, *Staph. haemolyticus*, and *Staph. hominis*. Only *Staph. epidermidis* is consistently pathogenic for humans. *Staph. epidermidis* is a prevalent and persistent species colonizing human skin and mucous membranes.

*Staph. epidermidis* has been increasingly identified as a cause of human infection often associated with foreign bodies, such as implanted catheters, and has become the most common cause of postoperative endophthalmitis.<sup>1-9</sup> Hospitals may not subspeciate coagulase-negative staphylococci, reporting them all as *Staph. epidermidis*.

Production of an exopolysaccharide (or “slime”) may be one factor allowing adherence of *Staph. epidermidis* to plastic surfaces, permitting resistance to phagocytosis and failure of antimicrobial therapy. Virtually all *Staph. epidermidis* infections are hospital-acquired, whereas *Staph. saprophyticus* infections almost always involve the urinary tract and are acquired outside hospital. *Staph. epidermidis* is often resistant to multiple antibiotics, particularly methicillin, and should be considered cross-resistant to all  $\beta$ -lactam antibiotics. Almost all are susceptible, however, to vancomycin and rifampin.

## **Streptococci.**

Streptococci are facultative anaerobic organisms or obligate anaerobes that are spherical or ovoid and found in pairs or chains. They are gram-positive, nonspore-forming, catalase-negative, and nonmotile organisms. The genus *Streptococcus* has more than 20 species, and its classification is complex. The viridans group of *Streptococcus* includes *Strep. mitis*, *Strep. mutans*, and *Strep. pneumoniae* (previously called *Diplococcus pneumoniae*). If the Gram stain is positive, the quellung reaction may be used to identify pneumococcus. The viridans-group streptococci are predominantly respiratory tract pathogens found in short chains. They have been

subtyped by surface antigens into 84 known serotypes. In the laboratory they exhibit fastidious growth, replicating best on complex media and often requiring carbon dioxide. They are thought to produce toxins that increase their pathogenicity. The drug of choice for these organisms is penicillin, but they are also sensitive to vancomycin.

Group D streptococci are separated into enterococcal species, including *Strep. faecalis*, *Strep. faecium*, and *Strep. durans*, and nonenterococcal species (*Strep. bovis* and *Strep. equinus*). *Strep. faecalis* and *Strep. faecium* are found in the gastrointestinal tract in humans and in human feces. Group A streptococci (*Strep. pyogenes*) make up some of the most important human pathogens, accounting for both acute rheumatic fever and poststreptococcal acute glomerulonephritis. In the laboratory, they produce  $\beta$ -hemolysis on blood agar plates, with discoloration around the colonies. These organisms grow in pairs or chains and are gram-positive, nonmotile, nonspore-forming, and catalase-negative. They are facultatively anaerobic, nutritionally fastidious, and usually grow on complex media when supplemented with blood or serum. They may produce extracellular products, including hemolysins, pyrogenic exotoxin, streptokinase, and hyaluronidase.

Group B streptococci (*Strep. agalactiae*) are facultative gram-positive diplococci that are usually easily grown. They have a narrow zone of  $\beta$ -hemolysis on blood agar plates. They are usually isolated from the lower gastrointestinal tract or genital tract of pregnant women and can produce infection in both neonates and adults. These organisms are universally susceptible to penicillin and also ampicillin, vancomycin, and first-, third-, and fourth-generation cephalosporins and ciprofloxacin.

A study of 48 cases of streptococcal endophthalmitis showed that all were sensitive to vancomycin, while nine (19%) were resistant to cefazolin or cephalexin, and 16 (33%) were resistant to gentamicin.<sup>10</sup>

## Gram-Positive Bacilli

### Bacillus.

The genus *Bacillus* has more than 13 members, the most widely

known of which is *B. anthrax*. The most common intraocular pathogen is *B. cereus*, with *B. subtilis* also identified as a cause of endophthalmitis.<sup>11</sup> *Bacillus* is an aerobic spore-forming rod that is gram-positive or gram-variable in stain. The size varies from  $3 \times 0.4 \mu\text{m}$  to  $9 \times 2 \mu\text{m}$ . These organisms grow singly, in chains, or in diplobacillary form. In nature they are usually found in decaying organic matter, dust, soil, vegetables, water, and human flora. *B. cereus* is an important cause of food poisoning and may cause bacteremia as a result of wound or burn infections. It produces multiple extracellular products, including antimicrobial substances, enzymes, and toxins. The enterotoxins are diarrheal and emetic in action, and there are two additional toxins that may be correlated with virulence. Some toxins have produced severe inflammation when injected into the eye.<sup>12</sup> Identification by the laboratory is usually as a cultural contaminant.

Risk factors for *Bacillus* infection include intravenous (IV) drug use, sickle-cell disease, foreign bodies, including IV catheters, immunosuppression from malignancy, neutropenia, corticosteroid use, and acquired immunodeficiency syndrome (AIDS). *Bacillus* is now the most commonly identified organism in traumatic endophthalmitis.<sup>13-17</sup> The infection is particularly virulent and may destroy the eye in 12–24 hours. It is unique in inducing fever and leukocytosis in endophthalmitis.

Vancomycin is the drug of choice against *Bacillus* spp. because  $\beta$ -lactam antibiotics are rarely effective in vitro against *B. cereus*. Strains other than *B. cereus* are susceptible to penicillin, cephalosporins, ciprofloxacin, and gentamicin.

### **Corynebacterium diphtheriae.**

*Corynebacterium diphtheriae* is a gram-positive bacillus that is nonsporulating, noncapsulated, nonmotile, and pleomorphic. Humans are the only known reservoir for *C. diphtheriae* and spread is by airborne respiratory droplets or by direct contact. Occasionally *C. diphtheriae* resides on skin. The main cause of virulence is a potent exotoxin producing diphtheria and skin infection. The choice for primary treatment of this organism is penicillin or erythromycin.

## **Listeria monocytogenes.**

There are seven species of *Listeria* that have been identified, but only *L. monocytogenes* is pathogenic for humans. *Listeria* organisms are gram-positive, nonspore-forming aerobic rods that are motile at room temperature and hemolytic on colony growth. They appear coccoid-shaped in smears. In nature these organisms are found in soil, dust, animal feed, water, sewage, and colonizing animals and humans. *L. monocytogenes* causes a wide variety of infections, including dermatitis and conjunctivitis, but it is a fairly rare infection and the prevalence of symptomatic disease is therefore difficult to estimate. Because of its rarity, there are no good control studies defining the most efficacious drugs, but ampicillin or penicillin are most likely the drugs of choice.

## **Clostridium Species.**

The genus *Clostridium* includes all anaerobic gram-positive spore-forming bacilli. There are 60 recognized species, 30 of which cause clinical disease. These organisms are ubiquitous, found in soil, decaying vegetation, marine sediment, and the gastrointestinal tract of humans, vertebrates, and insects. They are often isolated as part of polymicrobial isolates from infected sites. *C. perfringens* is well known for its ability to cause gas gangrene, a rare infection. It may also produce exotoxin and food poisoning. Penicillin G is the drug of choice, although vancomycin is an appropriate choice for *C. difficile*.

## **Propionibacterium.**

*Propionibacterium* organisms are gram-positive or gram-variable rods that are often pleomorphic, anaerobic, and nonsporulating. Propionibacteria are a predominant component of skin flora and are also found on mucosal surfaces of the mouth, intestines, urethra, and vagina. They are the most common clinical isolate of gram-positive, nonsporulating bacteria. They are found in acne, prosthetic joints, cerebrospinal fluid shunts, endocarditis, and osteomyelitis. They have been identified as a cause of postoperative endophthalmitis of a chronic granulomatous nature, almost exclusively found in patients with intraocular lenses (IOLs).<sup>18-23</sup> *P. acnes* is almost always the clinical isolate.

## Gram-Negative Cocci

### Neisseria.

*Neisseria* organisms are gram-negative diplococci. *N. meningitidis* has fastidious growth requirements, growing best in a moist environment at 35–37°C under carbon dioxide. It has been serotyped on the basis of capsulopolysaccharides into at least 13 serogroups. The carrier state for *N. meningitidis* is the human nasopharynx. Paradoxically, however, despite the fact that it is frequently found in asymptomatic patients, the primary disease manifestations are meningococcal meningitis and sepsis, which tend to occur in epidemics. Both *N. meningitidis* and *N. gonorrhoeae* have been demonstrated to cause endophthalmitis on rare occasions. The disease is almost always endogenous in origin.

### Moraxella.

*Moraxella* organisms are gram-negative cocci in the family Neisseriaceae. They were previously known as diplococcus of Morax-Axenfeld. Moraxellae are normal inhabitants of the upper respiratory tract and are also found on the skin and in the urogenital tract. They are strictly anaerobic, nonsaccharolytic, nonmotile, and grow on routine media. They are best known clinically as a cause of external eye disease and rarely cause systemic disease. The classic infection of *M. lacunata* is chronic angular blepharoconjunctivitis, which occurs in rare epidemics. *M. liquefaciens* is a variant of *M. lacunata* and is occasionally a cause of serious systemic disease. Moraxellae are almost universally sensitive to penicillin, but  $\beta$ -lactamase-producing strains are now found.

## Gram-Negative Bacilli

### Actinobacter.

A member of the family Neisseriaceae, *Actinobacter* is a ubiquitous saprophyte. It has low virulence and is usually the source of nosocomial infections sometimes found in immunosuppressed hosts.

## Haemophilus influenzae.

*Haemophilus influenzae* is a small, nonspore-forming bacterium that is a strict parasite of humans. It is found principally in the upper respiratory tract but is also found in the conjunctiva and in the genital tract. It requires growth factors for isolation and takes up dye inconsistently on staining. Noncapsulated strains are normal inhabitants of the nasopharynx, but invasive diseases such as meningitis, septic arthritis, epiglottitis, and bacteremia tend to be caused by encapsulated strains. Contiguous spread to areas adjacent to the nasopharynx, including otitis media and conjunctivitis, is more often caused by noncapsulated strains. Other *Haemophilus* spp., such as *H. ducreyi* and *H. hemolyticus*, have similar distribution and growth characteristics but a significantly lower pathogenicity. In treatment of meningitis, the drug of choice is a combination of chloramphenicol and ampicillin.

## Pseudomonas.

The genus *Pseudomonas* comprises a group of nonmotile, gram-negative, strictly aerobic organisms found in soil, water, and marine environments. They are straight or slightly curved bacilli that are motile, catalase-positive, and grow well over a wide range of temperatures. The nonfastidious growth requirements of *Pseudomonas* allow a wide distribution in nature. They may be part of normal human flora but are predominantly isolated as a result of nosocomial opportunistic infection. There are five major groups based on ribosomal RNA and DNA homology. The pathogenesis of disease created by *Pseudomonas* is complex and includes the production of extracellular proteases and other toxic proteins, as well as hemolysin, endotoxin, and exotoxin A.

*Pseudomonas* produces a wide variety of clinical syndromes, including endocarditis on prosthetic valves and in IV drug users, lower respiratory infections in persons with compromised defense mechanisms, bacteremia in immunocompromised patients, meningitis and brain abscesses, corneal ulcers, keratitis, ophthalmia neonatorum, scleral abscess, and conjunctivitis. *Pseudomonas* is the most common cause of gram-negative endophthalmitis. Most cases of endophthalmitis are produced by *P. aeruginosa*, but other species have also been isolated in clinical cases.<sup>13,24</sup> Sensitivities include

aminoglycosides and ceftazidime.<sup>24,25</sup>

### **Enterobacteriaceae.**

The family Enterobacteriaceae comprises a large heterogeneous group of gram-negative, nonspore-forming facultative anaerobes; they are among the most important human pathogens. They are widely distributed in soil and plants and are colonizers of the gastrointestinal tract of humans and animals. Although they are uncommonly found outside the gastrointestinal tract, they are a leading cause of nosocomial disease. *Escherichia coli* is the best-studied free-living organism. It is a cause of urinary tract infection and traveler's diarrhea and is the most common cause of nosocomial bacteremia.

The tribe Klebsiellae consists of four genera: *Klebsiella*, *Enterobacter*, *Serratia*, and *Hafnia*. They are all colonizers of the human gastrointestinal tract and are rarely associated with disease in normal hosts; however, they are major causes of nosocomial and opportunistic infections, inducing a wide variety of clinical syndromes.

### **Klebsiella.**

The genus *Klebsiella* contains a group of three species of bacteria, including *K. pneumoniae*. They are a relatively common isolate in gram-negative endophthalmitis<sup>26</sup> and are characteristically resistant to multiple antibiotics. Enterobacter organisms are opportunistic pathogens that rarely produce human disease. When they function as opportunistic pathogens, however, they may be resistant to first-generation cephalosporins. *Serratia* spp. are opportunistic pathogens that have only been recognized as capable of producing human disease since the 1960s. They are more likely to colonize the respiratory and urinary tracts of hospitalized patients than other Enterobacteriaceae. Most hospital infections are caused by catheterization and instrumentation of the urinary and respiratory tracts. These organisms have multiple drug resistances but are most often sensitive to amikacin.

### **Higher Bacteria**

The order Actinomycetales has three major families of pathogens:

the Mycobacteriaceae, Actinomycetaceae, and Nocardiaceae. Actinomycetales comprises a heterogeneous group only partially defined as a collection of microorganisms. They are facultatively anaerobic and are prokaryotic filamentous bacteria. These organisms are slow-growing and gram-positive. They exhibit true branching and form mycelia-type colonies with branching filaments that grow from an ill-defined center. Reproduction, however, is by bacterial fission, and their growth is inhibited by antibiotics.

### **Actinomyces.**

The genus *Actinomyces* includes *A. israelii*, the primary cause of human actinomycosis. *A. israelii* grows best anaerobically and may be isolated in 30–50% of all cultures taken from the mouth. It is not highly virulent but is an endogenous oral pathogen. Actinomycosis presents as a slow-growing cutaneous or soft-tissue swelling of the head, face, or neck. *A. israelii* is susceptible to penicillin, cefazolin, ampicillin, and erythromycin, in addition to other antibiotics.

### **Nocardia.**

*Nocardia* spp. are aerobic actinomycetes that reproduce by fragmenting into bacillary and coccoid elements, distinguished by filamentous growth with true branching. *N. asteroides* is a predominant human pathogen. These organisms grow in a wide range of temperatures on simple media but may grow slowly in mixed cultures. They are weakly gram-positive or stain irregularly. They are also acid-fast. *Nocardia* spp. have a wide distribution in nature. They may be a respiratory saprophyte in humans, as well as being isolated from the skin. Most human infections begin in the respiratory tract. They are found most often in humans in debilitated states or in immunosuppressed patients, and the infections evade the bactericidal mechanisms of the host. In humans they produce a suppurative necrosis and abscess formation typical of pyogenic infection. They usually enter the eye as a result of a traumatic injury or from hematogenous spread. They respond to sulfanilamides, trimethoprim–sulfamethoxazole, and minocycline.

## **Fungi**

Fungi are typically divided into yeasts and molds, although some, such as *Candida*, may grow in both forms. Yeasts are typically round or oval and reproduce by budding. Characteristic yeasts include *Candida*, *Cryptococcus neoformans*, *Blastomyces dermatitidis*, and *Coccidioides immitis*. Molds are composed of tubular structures called hyphae. They grow by branching in a longitudinal extension. Classic molds include *Aspergillus* and the agents of mucormycosis. Organisms that grow in the host as yeast-like forms, but at room temperature in vitro as molds, are called dimorphic fungi and include *Histoplasma capsulatum*, *Blastomyces*, and *C. immitis*. Most fungi reproduce asexually by forming spores through mitosis, although sexual reproduction can occur. Fungi that are pathogenic for humans are typically nonmotile and have rigid cell walls that can be stained with Gomori methenamine-silver and, when the organisms are viable, by periodic acid–Schiff. Only *Candida* can be seen well on Gram stain. Inside the fungal cell wall are sterol-containing cytoplasmic membranes, which are the site of action of polyene macrolide antibiotics, including amphotericin B and nystatin.

## **Candida**

*Candida* is predominantly a unicellular organism that is small, thin-walled, ovoid, and reproduces by budding. Yeast forms, hyphae, and pseudohyphae may all be identified in clinical specimens; their identification is facilitated by staining with KCl 10%. On culture, it grows as a smooth, creamy-white colony that usually must be identified by physiologic rather than morphologic means. *Candida* is widespread in soil, hospital environments, inanimate objects, food, and as a commensal of humans, being isolated from diseased skin, the gastrointestinal tract, female genitalia, and the urine of patients with Foley catheters. The incidence of *Candida* infections has increased with the use of immunosuppression, indwelling catheters, and with increased IV drug use.<sup>27,28</sup> *Candida* typically causes endophthalmitis as a complication of candidemia<sup>29</sup> or as a result of epidemics of contaminated irrigating solutions used in intraocular surgery.<sup>30</sup> It typically responds to amphotericin, triazoles,<sup>31</sup> and 5-fluorocytosine.

## **Aspergillus spp.**

*Aspergillus* spp. have been increasingly identified in endophthalmitis. *Aspergillus* is a ubiquitous mold with many species, the most common of which are *A. fumigatus* and *A. flavus*. *Aspergillus* grows well in soil, decaying vegetation, hay, dung, compost piles, hospital air-conditioner filters, and potted plants, and may be isolated from the air. Intravenous drug users are not uncommonly found to have *Aspergillus* fungemia, thought to be caused by contamination of the injected material during its preparation. Exposure to *Aspergillus* is nearly universal, but disease from *Aspergillus* is uncommon, suggesting that host factors are important.

*Aspergillus* creates corneal ulcers after trauma, and endophthalmitis is seen after hematogenous spread, especially in immunosuppressed patients or those abusing IV drugs. Amphotericin is the drug of choice, at times combined with 5-fluorocytosine. Invasive *Aspergillus* in the soft tissues may require surgical treatment for successful eradication.

## **Histoplasma capsulatum**

*Histoplasma capsulatum* is a dimorphic fungus found in soil, particularly in areas where avian and bat excrement collect, including blackbird and pigeon roosts and chicken houses. Old buildings where bats and pigeons have roosted are frequent sources of *H. capsulatum*. The mycelial form consists of septate-branching, hyphae-bearing spores, while the yeast form is oval. Reproduction occurs through budding. Within the viable tissues, *H. capsulatum* is found almost entirely within macrophages. It is best stained with methenamine-silver but may also be identified with hematoxylin and eosin. Infection begins in *H. capsulatum* with inhalation of spores. Immunity is based on cellular immune mechanisms, and *H. capsulatum* is killed by activated macrophages after living as an intracellular parasite.

Histoplasmosis is the most common human fungus infection in the United States. Virtually all persons in the Ohio river valley and along the lower Mississippi river have been infected. Two eye syndromes are produced by *H. capsulatum*. The presumed ocular histoplasmosis syndrome consists of a morphologic triad of fundus

scarring consisting of peripheral punched-out spots, macular disciform scars, and peripapillary scarring. This is thought to be a late effect of *H. capsulatum* after hematogenous spread has created earlier choroidal infections. Organisms have not been identified in this form of the disease. Endophthalmitis associated with disseminated histoplasmosis has been described in an immunocompromised host.<sup>32</sup> Amphotericin is the drug of choice in active disease but is not indicated in presumed ocular histoplasmosis syndrome.

### **Blastomyces dermatitidis**

*Blastomyces dermatitidis* is a dimorphic fungus that grows in a mycelial form at room temperature, and as a yeast at 37°C. These organisms have not been well studied but probably exist in nature in warm, moist soil of wooded areas rich in organic debris. *B. dermatitidis* is commonly found in outdoorsmen and hunters. It is thought to enter the lung, subsequently producing a widespread pyogranulomatous infection through hematogenous spread involving the lungs, skin, bone, and genitourinary tract. It is a relatively uncommon cause of endophthalmitis. Amphotericin is the treatment of choice.

## **Helminths, Protozoa, and Ectoparasites**

Protozoa (as represented by *Toxoplasma gondii*), helminths (including *Onchocerca volvulus*, *Taenia solium*, and *Toxocara canis*), and ectoparasites all produce infestations that may cause a chronic intraocular infection.

### **Helminths**

Helminths are worms of sufficient size to be visible to the naked eye. Helminths may be the most prevalent infective causative agents in human disease. They are divided into three groups: (1) nematodes, or roundworms; (2) trematodes, or flukes; and (3) cestodes, or tapeworms. Onchocerciasis is produced by *O. volvulus* and is the leading cause of blindness in the world, with over 30 million humans affected. *Onchocerca* is transmitted to humans by bites of blackflies. The larvae then make their way through the skin

and lodge in connective tissue, where adult worms tend to collect in nodules of tissue. Within the eye they produce chronic infestation. The microfilariae, swimming in the anterior chamber, may be identified by slit-lamp examination. A single dose of ivermectin is capable of killing the microfilariae but not the adult worms.

*Taenia solium*, a trematode, is the pork tapeworm for which humans are the only definitive host. Ingestion of the organism allows the development of the intermediate-stage *Cysticercus cellulosae*. This organism may invade almost any area of the body, including the vitreous cavity. Other helminths of ocular importance are *Toxocara canis* and *T. cati*. The predominant hosts for these organisms are dogs and cats, respectively. There are a large number of viable eggs, particularly from *T. canis*, in the environment. Eggs are spread by direct ingestion or, in the case of dogs, by eating infected meat. *T. canis* in children produces a chronic inflammatory granulomatous disease involving the vitreous and retina.<sup>33</sup>

## Protozoa

Toxoplasmosis is the most common protozoon causing eye disease.<sup>34</sup> *Toxoplasma gondii* is an obligate intracellular protozoon that is ubiquitous in nature, infecting all herbivorous, carnivorous, and omnivorous animals. The definitive host is the cat. The ingestion of raw or uncooked meat allows tissue cysts to enter the gastrointestinal tract where they are broken down. They then invade the walls of the gastrointestinal tract and spread throughout the body to many tissues. The organisms remain viable for the life of the host. Although most humans are asymptomatic for the infection, a recurrent panuveitis may be an ocular manifestation of infestation.

## Ectoparasites

Ectoparasites are organisms that live on the skin of a host, from which they derive their sustenance. The phylum Arthropoda includes the two-winged, or dipterous, flies. The larvae or maggots of these flies may invade living or necrotic tissue of animals and humans, producing myiasis. Multiple dipterous flies are thought to be capable of producing ocular myiasis. It is thought that the larvae

are imbedded in the eye, that they burrow directly through the sclera and then under the retina. Typically, they leave asymptomatic tracks throughout the fundus, but a number of cases of destructive endophthalmitis have been reported, particularly from Scandinavia.

## Experimental Endophthalmitis

Experimental models of endophthalmitis have been produced with gram-positive and gram-negative organisms and with fungi; most models have been used to evaluate various forms of treatment.

Meyers-Elliott and Dethlefs<sup>35</sup> injected *Klebsiella oxytoca* organisms into the vitreous cavity of the phakic rabbit. Pathologic evaluation demonstrated widespread polymorphonuclear leukocyte invasion throughout ocular tissues within 24 hours and significant photoreceptor degeneration within 48 hours. Peak numbers of organisms could be cultured from the eye at 24 hours, but they declined spontaneously, with no organisms being recovered after 72 hours. Pathologic signs continued to increase once the cavity was sterile, however, implicating endotoxins as important to ongoing tissue damage. Davey and colleagues<sup>36</sup> injected *K. pneumoniae* and *P. aeruginosa* into the vitreous of the phakic rabbit and noted that bacterial growth peaked at 48 hours, with the number of organisms falling spontaneously after this. Measurable changes in biochemical parameters of the vitreous did not seem to account for this phenomenon; the authors postulated that it might be a characteristic of gram-negative infections. Meredith and coworkers<sup>37</sup> created an experimental model of *Staph. epidermidis* endophthalmitis by injecting various numbers of organisms into the vitreous cavity of the aphakic rabbit. Low numbers of organisms produced mild disease with slow progression; some infections appeared to be self-limited. Larger numbers of organisms produced infections of greater intensity, which were almost uniformly steadily progressive. Organisms could not be recovered from the vitreous cavity after 96 hours, however, regardless of the size of the initial inoculum. This fact suggests that progressive inflammatory signs were related to factors other than continuing active infection. Other models of *Staph. epidermidis* have yielded organisms from the

phakic eye as long as 7 days after their injection into the vitreous. Peyman<sup>38</sup> produced endophthalmitis with *Staph. aureus* in phakic rabbits to compare various treatment regimens, reporting uniformly poor results with loss of the eye in untreated animals.

Beyer et al.<sup>39</sup> studied the role of the posterior capsule in the development of *Staph. aureus* endophthalmitis in the primate. Nine monkeys had bilateral lens extraction; in one eye a large capsulotomy was performed, while in the other the capsule was intact. Inoculation of  $10^5$  *Staph. epidermidis* organisms was made into the anterior chamber, and the vitreous was cultured after 72 hours. Only one culture was positive with the capsule intact, but all nine cultures were positive when the capsule was opened. The experiment was repeated with a posterior-chamber lens implanted. None of ten eyes with an intact capsule and IOL was culture-positive, whereas 40% of the eyes with the capsule open and a lens in place were culture-positive and an additional 20% showed histopathologic signs of vitreous inflammation. An intact posterior capsule thus appeared to inhibit the spread of infection from the anterior chamber into the vitreous cavity, an effect that was not compromised by the addition of a posterior-chamber IOL.

Anaerobic organisms have also been used to produce clinical disease in the rabbit. The injection of 1000 organisms of *Fusobacterium necrophorum* into the vitreous cavity of the phakic rabbit produced clinical infection in 100% of eyes. *P. acnes* was studied in the aphakic rabbit with and without a posterior-chamber IOL. Injection of  $10^8$  organisms into the anterior chamber produced a severe infection, while inoculation of  $2.5 \times 10^6$  produced clinical inflammation that peaked at 3 days but persisted for up to 24 days. The presence of an IOL appeared to favor the development of chronic, low-grade inflammation.

## Clinical Findings

### Postoperative Infection

Postoperative infection is the cause of roughly two-thirds of all cases of endophthalmitis in most clinical series. Although infectious endophthalmitis may follow any operative procedure performed on

the eye, most cases follow cataract extraction, and almost all are bacterial in origin. Studies from a single institution suggest that the incidence of endophthalmitis over the past several decades has been declining. At the Bascom Palmer Eye Institute, the incidence from 1984 to 1994 was 0.09%, dropping to 0.04% from 2000 to 2004.<sup>40</sup> Studies indicate that causative organisms in infection after cataract surgery are usually genetically identical to the patient's own flora.<sup>41,42</sup> In 75–95% of the reported cases, the causative organisms are gram-positive. A significant percentage of cases of apparent infectious endophthalmitis proved to be culture-negative.<sup>2,3,43</sup>

## Cataract Extraction

Allen<sup>44</sup> reviewed 30,000 intracapsular cataract procedures performed at the Massachusetts Eye and Ear Infirmary from 1964 to 1977 and found an incidence of endophthalmitis of 0.057%. A review of 23,625 cases of extracapsular cataract extraction from Bascom Palmer Eye Institute revealed an incidence of 0.072%.<sup>5</sup> More recent figures from two studies in the phacoemulsification era suggest an incidence of 0.03%<sup>45</sup> to 0.04%.<sup>38,46,47</sup> National registries in Sweden<sup>48</sup> and Norway<sup>49</sup> identified rates of 0.04% and 0.11–0.16%, respectively. A large study from Saudi Arabia revealed an incidence of 0.08%.<sup>50</sup>

Symptomatically, typically the patient notes a sudden increase in pain 1–7 days after surgery. Examination demonstrates conjunctival chemosis and increased injection, often with a significant amount of yellowish exudate in the conjunctival cul-de-sac. The upper lid becomes edematous and may be difficult to open to complete a thorough examination. The cornea demonstrates variable degrees of edema, and pigmented cells may accumulate on its posterior surface. The surgical wound may show signs of dehiscence, and in advanced cases exudate can stream from the wound. The anterior chamber shows heavy flare and cells, and hypopyon is often present in the inferior angle, sometimes mixed with a tinge of red blood. In more extreme cases, the anterior chamber is filled with exudate and the cornea is white. When an IOL is in place, a fibrin membrane is usually present over both surfaces.

Heavy cellular debris is present in the vitreous, and there may be focal accumulations of whitish material or sheets of opacification within the vitreous. The intraocular pressure may be low, normal, or high. The pupil often dilates poorly, making examination with an indirect ophthalmoscope difficult. Retinal periphlebitis<sup>51</sup> has been reported as an early sign, but in most cases the retinal vessels are seen poorly, if at all. With more severe disease, large areas of opacity are seen within the vitreous; there may be a red reflex, or only a dark appearance to the posterior cavity.

Infection caused by *Staph. epidermidis* and other species of coagulase-negative staphylococci may have the clinical onset delayed by 5 days or more after surgery. Even then, the clinical signs and symptoms may be mild and may be difficult to distinguish from a noninfectious inflammatory process.<sup>1,4,52,53</sup> There was no hypopyon or pain in 25% of confirmed cases in the Endophthalmitis Vitrectomy Study (EVS).<sup>54</sup> In this study a number of clinical features at initial presentation were associated with microbiologic factors. More severe initial findings suggest infection with gram-negative bacteria, *Streptococcus* or *Staph. aureus*. Factors noted at initial diagnosis correlating with gram-negative and gram-positive organisms other than gram-positive coagulase micrococci included corneal infiltrate, cataract wound abnormalities, afferent pupillary defect, loss of red reflex, initial light perception only vision, and symptom onset within 2 days of surgery. Gram-negative organisms were not identified in those eyes in which retinal vessels were visualized preoperatively; 61.9% of those eyes had equivocal or no growth. Diabetes mellitus was associated with a higher yield of gram-positive, coagulase-negative micrococci, while there was a shift toward other gram-positive organisms in eyes undergoing secondary IOL implantation compared with those that had initial cataract surgery.<sup>55,56</sup>

Late-onset disease may occur with predisposing anatomic problems such as a persistent conjunctival filtering bleb or the presence of a vitreous wick.<sup>57</sup> Chronic, low-grade inflammation that ultimately proves to be of an infectious origin may occur in rare instances and has been termed chronic postoperative endophthalmitis or delayed-onset endophthalmitis.<sup>19,58</sup> This may occur secondary to coagulase-negative gram-positive organisms

(such as *Staph. epidermidis*)<sup>19,58</sup> and also results from infections with the anaerobic species *P. acnes*.<sup>18–23</sup> In reviews of cases of endophthalmitis after cataract extraction, a significant incidence of intraoperative complications has been found.<sup>19–21,59–61</sup> Postoperative filtering blebs, wound leaks,<sup>59</sup> and vitreous wick are also found more frequently in infected eyes.<sup>2</sup> Infection can also result after the cutting of sutures holding the cataract wound or after an invasive procedure to incise the posterior capsule.<sup>2,62</sup>

The type of cataract incision has recently attracted attention as a possible contributor to the incidence of postoperative infection. A case–control study demonstrated a threefold greater risk of endophthalmitis with clear corneal incisions than with scleral tunnel incision.<sup>63</sup> However, this has not been confirmed by newer studies.<sup>64,65</sup> Temporal incisions were noted to have a higher incidence of infection than superior incisions in another study.<sup>66</sup> A case–control study of secondary IOL implantation showed endophthalmitis to be associated with diabetes mellitus, transscleral suture fixation of posterior-chamber IOLs, polypropylene haptics, preoperative eyelid abnormalities, reentry of the eye through a previous wound, and postoperative wound defects.<sup>67</sup>

Gram-positive organisms are found in 75–90% of culture-positive cases.<sup>3,55</sup> Most common is *Staph. epidermidis*, followed by *Staph. aureus* and *Streptococcus* spp. Gram-negative organisms accounted for only 6% of the culture-positive cases in the EVS.<sup>3,55</sup> Fungi are rare, with the exception of epidemics such as those of *Candida parapsilosis*<sup>68</sup> and *Paecilomyces lilacinus*,<sup>69</sup> which were traced to infected irrigating solutions. Bacterial epidemics have also been traced to an infected phacoemulsifier (*Pseudomonas*)<sup>70</sup> and to infected viscoelastic material (*Bacillus* spp.).<sup>71</sup> Culture-negative cases account for 25–35% of cases of pseudophakic endophthalmitis.<sup>2,3,55,72</sup>

To this day there is no standardized approach to the perioperative use of antibiotics during cataract surgery. A recent review paper reported a preventative effect of intracameral antibiotics while topical antibiotics did not appear to be effective in reducing the rate of postoperative endophthalmitis.<sup>73</sup>

## Corneal Transplantation

Since endophthalmitis after corneal transplantation is rarely seen, its characteristics are less well defined. In three large series of corneal transplants, an incidence of 0.65%, 0.11%, and 0.08% of postoperative endophthalmitis was reported.<sup>46,74,75</sup> In a review of over 90,000 cases between 1972 and 2002, the incidence after PKP was 0.38%.<sup>76</sup> Guss et al.<sup>74</sup> studied 445 corneal transplant cases and demonstrated that, in addition to three acute cases, there were eight other cases, six of which occurred after an ulcerative process in the graft. Endophthalmitis of delayed or late onset can also result from suture abscess formation or from bacterial access to the anterior chamber associated with a loose suture.<sup>77</sup> In an ulcerative process, entry may occur because of disruption of continuity of the graft, or the bacteria may invade through an intact but thinned cornea. Endophthalmitis following corneal transplantation has also been associated with a vitreous wick. Unlike endophthalmitis following cataract surgery, the onset of the disease may be relatively pain-free and is heralded by an increased anterior-chamber reaction, hypopyon, and loss of red reflex. The bacteria usually involved in these cases are gram-positive, with *Staphylococcus* spp. and *Streptococcus* spp. being equally represented; fungal and gram-negative cases are least common. In the series of Leveille et al.,<sup>78</sup> three of four acute cases were associated with a contaminated donor rim; this was not noted in any of the cases reported by Guss et al.<sup>74</sup> The prognosis in postcorneal transplantation cases is poor; 9 of the 11 cases reported by Guss et al.<sup>74</sup> had final vision of light perception or no light perception.

## Glaucoma Filtration Surgery

The risk of developing endophthalmitis after filtering surgery is similar to the risk following cataract extraction,<sup>5,46,79-82</sup> but most of these cases occur months to years after the original procedure. A prodrome of browache, headache, or eye pain is not uncommon.<sup>83</sup> There may be an antecedent conjunctivitis, but often the abrupt onset of pain and redness constitutes the presenting signs and symptoms. An inferior location to the bleb and use of antifibrotic agents increase the likelihood of subsequent infection.<sup>84-86</sup> The blebs may appear intact in these cases, although some may be Seidel-

positive.<sup>57,86</sup> Thin, avascular, and leaking blebs appear to be at increased risk of infection.<sup>83</sup> The material within the bleb is white or yellow, giving a “white-on-red” appearance against the conjunctival erythema. Eyes with glaucoma drainage devices are also at risk for infection.<sup>81</sup> The spectrum of bacteria isolated from culture-positive bleb infection is quite different from that of endophthalmitis following cataract surgery, with 31–57% demonstrating *Streptococcus* spp. as the causative organism.<sup>57,83,85,87–89</sup> More recent series have found more cases caused by *Staphylococcus* spp. and *Enterococcus* spp. than older reports. Gram-negative species are also more common than after acute postcataract infections.<sup>89</sup> Visual outcomes remain generally poor in these cases, even with modern therapy. In two large series, 50% of eyes had final visual acuity of 20/400 or better,<sup>88,89</sup> in part because of the influence of *Streptococcus* spp. infections on the outcome.

## **Pars Plana Vitrectomy**

The incidence of endophthalmitis after pars plana vitrectomy appears to be about the same as that after other intraocular procedures.<sup>46,90</sup> The diagnosis is most difficult to make because the normal postoperative pain and intraocular inflammation after vitrectomy may mask the symptoms. The diagnosis rests on findings that are more severe than usual; appearance of hypopyon is often rapid and should cause particular concern.<sup>90,91</sup> In one case with intraocular silicone, findings were limited to a whitish material collecting between the silicone and the retina.<sup>92</sup> The spectrum of bacteria in these cases is similar to other acute postoperative infections. In spite of this, the prognosis is uniformly poor, and retention of vision is rare.

The first large, multicenter studies in the era of small-gauge vitrectomy suggested a significant higher rate of endophthalmitis with 25-gauge sutureless vitrectomy (0.23% and 0.84%).<sup>93,94</sup> Since then, several large series have not confirmed these findings.<sup>95–98</sup> Optimized wound construction, modifications in case selection, and a lower threshold for suturing appear to reduce the incidence of endophthalmitis in small-gauge cases to the level of standard 20-gauge cases.

## Intraocular Injection

Introduction of organisms into the eye may occur during a pars plana injection of intraocular gas for pneumatic retinopexy.<sup>99</sup> In recent years intraocular injection of medications to treat age-related macular degeneration, diabetic macular edema, retinal vein occlusions, cytomegalovirus retinitis, and uveitis have increased in frequency dramatically, resulting in increased numbers of cases of endophthalmitis. The reported incidence of endophthalmitis following intravitreal injections varies significantly. A recent review paper described a rate of endophthalmitis from 0.014% up to 0.87% per injection. The overall incidence was 0.051% (50/98 962).<sup>100</sup> A similar incidence of 0.06% (11 of 11,509) was recently reported by investigators of the “Comparison of Age-related macular degeneration Treatments Trials (CATT).<sup>101</sup> A large French multicenter study found an incidence of 0.021% (65 of 316,576).<sup>102</sup> Injection technique used varied from study to study. To this day there is no clear consensus on a “standard” injection protocol as for the use of a sterile drape, gloves, surgical mask, or topical antibiotics. So far, only the use of povidone iodine and a lid speculum is routinely recommended.<sup>103</sup> Cultures most frequently showed coagulase-negative staphylococci as causative organism, with atypical organisms being more common after the use of triamcinolone.<sup>100</sup> With triamcinolone, the typical clinical signs of endophthalmitis may be masked by antiinflammatory effects and the presentation may be difficult to differentiate from a pseudohypopyon without infection, which can occur after triamcinolone injection caused by deposition of the injected material in the anterior chamber.<sup>104</sup>

## Scleral Buckling Procedure

Most infections after retinal detachment repair by scleral buckling are confined to the extrascleral implant. In past years these have resulted in endophthalmitis, but this is now an exceedingly rare occurrence because scleral flaps, diathermy, and polyethylene implants are only rarely used. Organisms may be introduced into the eye during an inadvertent perforation of the sclera by a suture or during the drainage procedure. Since these maneuvers introduce

organisms present in the tear film or adjacent skin and lashes, staphylococcal species are most commonly reported. It has been suggested that the diagnosis, like that after pars plana vitrectomy, rests on findings of pain and inflammation in the early postoperative course that are more severe than expected.

## Strabismus Surgery

Endophthalmitis is a rare but devastating complication of strabismus surgery. True endophthalmitis probably always occurs after an inadvertent suture perforation, although a scleral abscess at the site of a suture could possibly lead to an intraocular infection. Lethargy, asymmetric eye redness, eyelid swelling, and fever have been reported as presenting signs, but diagnosis may be delayed.<sup>105</sup> Prognosis is poor in these eyes, possibly because delays in diagnosis are common.<sup>105,106</sup>

## Other

Endophthalmitis has also been reported after paracentesis,<sup>107,108</sup> keratoprosthesis surgery,<sup>109</sup> especially in patients with Stevens–Johnson syndrome, and ocular cicatricial pemphigoid,<sup>110,111</sup> and radial keratotomy.<sup>112</sup>

## Posttraumatic Endophthalmitis

After postoperative cases, posttraumatic endophthalmitis is the second largest category, accounting for 20–30% of the cases in large mixed series.<sup>43,113–116</sup> The incidence of endophthalmitis after penetrating trauma ranges from as low as 2% to as high as 17%.<sup>13,117</sup> In rural injuries, infections have been reported in 30% of the eyes.<sup>13</sup> Eyes with intraocular foreign bodies have a risk of infection about twice as high as those without a foreign body.<sup>118,119</sup> Other independent risk factors of traumatic endophthalmitis include dirty wound, lens capsule rupture, age greater than 50 years, and delayed presentation of more than 24 hours after the injury.<sup>120</sup>

Of those eyes with open-globe injury which are culture-positive at primary trauma repair, not all develop endophthalmitis.<sup>119,121</sup> Eyes with more virulent organisms were at greater risk of developing clinical infection in one study.<sup>121</sup> The onset of infection

after injury varies with the virulence of the organism and is usually accompanied by increasing pain, intraocular inflammation, hypopyon, and vitreous opacities. As with postoperative endophthalmitis, about two-thirds to three-quarters of the cases are due to gram-positive organisms, with about 10–15% being caused by gram-negative organisms. An important difference, however, is that in recent series, approximately one-quarter of the infections were due to *Bacillus* spp., making this the second most common pathogen in most series of posttraumatic endophthalmitis. Most *Bacillus* infections are associated with intraocular foreign bodies.<sup>13–16,43,118,122,123</sup> Unfortunately, infection caused by *Bacillus* has a particularly poor prognosis, and only two of 25 eyes reported in the literature had a final vision better than being able to count fingers. Fungal infections are also important in series of traumatic endophthalmitis, accounting for 10–15% of the cases; they should be particularly suspected in soil-contaminated injuries. Overall, the reported results of therapy for traumatic endophthalmitis are not as satisfactory as for postoperative endophthalmitis.<sup>124</sup> This is most likely due to a higher proportion of cases caused by virulent organisms, the influence of the initial injury on the final visual outcome, as well as potential delay in diagnosis due to posttraumatic inflammation. Although recent series report vision of 20/400 or better for 42–73% of cases of postoperative endophthalmitis, comparable vision following traumatic endophthalmitis is achieved in only 9–50% of cases.<sup>43,113,115,118,124,125</sup>

## Endogenous Endophthalmitis

Endogenous endophthalmitis accounts for 5–7% of cases in large mixed series of endophthalmitis. Although cases occur in otherwise healthy patients, most occur in patients with systemic disease, including chronic immune-compromising illness such as diabetes mellitus or renal therapy, immunosuppressive disease and therapy, IV drug use, or systemic septicemia.<sup>126–129</sup> Patients may present with mild symptoms of decreased vision, redness, pain, and photophobia. The initial diagnosis is not made at the first presentation in 50% of patients.<sup>126,128</sup> Bilaterality is common. A search for a systemic focus of infection is indicated when

endogenous endophthalmitis is suspected; blood cultures are frequently positive. Assistance of an internist or infectious disease specialist is often sought due to the systemic implications of the condition. Fungal causes are found in 50–62% of cases,<sup>126,129</sup> with *Candida* spp. being the most common isolate in some series and *Aspergillus* in others.<sup>25</sup> In cases of bacterial cause, both gram-positive and gram-negative organisms are identified, with the proportions depending on the location of the series.<sup>130</sup> Visual outcomes are often poor.<sup>128–130</sup> More alarming is the mortality rate, which has been reported to vary from 5%<sup>116</sup> to 29%.<sup>129</sup>

## Therapy

In the past, antibiotics administered topically, subconjunctivally, by IV infusion, and by intramuscular injection were the mainstays of therapy for endophthalmitis. It was not until the 1980s that intravitreal antibiotics were accepted and recommended in bacterial disease.<sup>131</sup>

When pars plana vitrectomy became available, a number of potential advantages were recognized.<sup>132,133</sup> A significant amount of material may be obtained for culture purposes. Removal of infected vitreous allows the classic principles of incision and drainage to be applied to the eye for the first time. Removing infected material reduces not only the number of living bacteria but also the toxins. Media opacities are cleared more rapidly in those eyes that survive the infection, allowing more rapid restoration of visual function. Maylath and Leopold<sup>134</sup> have previously shown that organisms are more effectively cleared from the anterior chamber than from the posterior chamber, and removal of the vitreous allows the vitreous chamber and anterior chamber to become joined in the aphakic eye. Furthermore, it has been suggested that vitreous removal may have a beneficial effect on antibiotic distribution within the eye.<sup>132</sup>

## Antimicrobial Therapy

Although detailed consideration of antimicrobial therapy is beyond the scope of this chapter, several principles deserve emphasis. The target area for microbial therapy in endophthalmitis is the vitreous

cavity. Intravitreal therapy is the cornerstone of antimicrobial administration, whereas the role of subconjunctival and systemic antibiotics is more controversial.

## Choice of Antimicrobial Agent

Because most cases of endophthalmitis manifest as acute fulminant infections, the initial antibiotic administration is usually made without culture results to identify the organism definitively. The choice of agent administered initially is therefore empiric. Broad-spectrum coverage is important, and the choice depends in part on the microbes expected in a given clinical setting. Gram-positive bacteria predominate in all types of acute endophthalmitis, but specific organisms and their frequency vary.

Microbes causing acute postoperative endophthalmitis are most often the patient's own bacterial flora. Staphylococcal species account for more than two-thirds of all cases, but gram-negative organisms are also encountered.<sup>3,55</sup> In acute traumatic endophthalmitis, gram-positive organisms are the most commonly identified, but this includes a high incidence of *Bacillus* species. In traumatic endophthalmitis, the microbes reflect not only the patient's flora but also contaminants from the scene of the trauma. Gram-negative infections and mixed infections are encountered more often than in acute postoperative cases.<sup>11,13,16,118,106</sup> In delayed postoperative endophthalmitis, *P. acnes*,<sup>19-23,135</sup> nonvirulent staphylococci,<sup>19,58</sup> and fungi<sup>19,61</sup> are most often the causative agents. When the infection is associated with a filtering bleb, *Streptococcus* species are identified in a high percentage of cases.<sup>57,136</sup>

Characteristics for ideal drugs for the treatment of bacterial endophthalmitis include the following:

1. Bactericidal properties. Because the eye is an immune-privileged site, like the central nervous system, a bactericidal drug rather than bacteriostatic agent is preferred.
2. Broad spectrum of coverage. Coverage must include gram-positive organisms, especially methicillin-resistant staphylococci and *Bacillus* species in trauma cases, and gram-negative organisms.

3. Excellent therapeutic ratio (activity/toxicity) after intravitreal injection. Toxicity has not been well studied for most antibiotics after intravitreal injections. Toxicity is often defined by histologic studies, electron microscopic studies, and electroretinography (ERG) testing. Most antibiotics are tested in rabbits, which are a limited model because of the relative avascularity of rabbit retinas. This relative avascularity may have contributed to the delayed recognition of the vascular occlusive potential of intravitreal aminoglycosides<sup>137,138</sup> because of the lack of toxicity studies in primates. Toxicity may be increased by repeat injections of certain antibiotics.

4. Good therapeutic ratio after intravenous injections. Most antimicrobials penetrate the vitreous cavity poorly after IV injection because of the blood–eye barrier. Intravitreal antimicrobial levels are only rarely reported to reach levels above the minimum inhibitory concentration (MIC) for organisms usually seen in endophthalmitis after IV or oral administration.<sup>139–146</sup> Hydrophilic antibiotics (including aminoglycosides and  $\beta$ -lactam antibiotics) have less potential for penetration into the eye than lipid-soluble compounds. On the other hand, there is significant systemic toxicity to the antimicrobials commonly used in treating endophthalmitis, particularly the aminoglycosides and amphotericin.<sup>147</sup> Furthermore, some combinations of antibiotics have a favorable spectrum of coverage (e.g., vancomycin and aminoglycosides), but their toxicities are additive when used simultaneously.

5. Favorable pharmacokinetic properties. Intraocular inflammation enhances penetration of certain antibiotics.<sup>139,148–150</sup> Vitrectomy has been shown to enhance the penetration of cefazolin,<sup>144</sup> vancomycin,<sup>150</sup> and ceftazidime<sup>148</sup> into the eye. Repeated IV dosing may contribute to increased penetration into the vitreous cavity after IV administration, particularly in inflamed and previously operated eyes.<sup>148–150</sup> After intravitreal administration, antibiotics are eliminated through either an anterior or posterior route.<sup>151,152</sup> Aminoglycosides are eliminated anteriorly, and the  $\beta$ -lactam antibiotics are removed posteriorly. Vitreous removal shortens the half-life of all antimicrobial agents studied in animal models.<sup>151–153</sup> Lens removal decreases the half-life of antibiotics eliminated

anteriorly.<sup>152</sup> Inflammation may increase the half-life of antimicrobials excreted posteriorly, such as cefazolin;<sup>153</sup> blocking agents such as probenecid may also increase the half-life of these drugs. The half-life for anteriorly excreted drugs such as gentamicin and amikacin is decreased by inflammation.<sup>154,155</sup> A higher initial dose is preferred whenever possible to allow the drug to remain at levels greater than the MICs of common pathogens for a longer period. Known activity of the drug is also an important consideration in the choice of the antibiotics. If drugs are given in equivalent concentrations, the one with higher activity against suspected organisms should be chosen.

## Route of Administration

Intraocular administration of antibiotics is widely accepted as standard care in endophthalmitis (Box 125.2). The major limitation of intraocular antimicrobials is the short duration of action. Most antibiotics studied have a drug level greater than the MICs for the common organisms, producing endophthalmitis for only 36–48 hours. Toxicity is also a significant problem. Injected antibiotics may create vascular shutdown (aminoglycosides),<sup>138,156,157</sup> retinal damage, and retinal necrosis.<sup>158,159</sup> Repeated injections of antibiotics are occasionally administered but may increase the potential for toxicity, as demonstrated by the combination of vancomycin and

### **Box 125.2**<sup>158,159</sup>

## Dosing of Intravitreal Antibiotics in Endophthalmitis

1. Vancomycin 1 mg/0.1 mL
2. Cefazolin 2.25 mg/0.1 mL
3. Amikacin 0.2–0.4 mg/0.1 mL
4. Ceftazidime 2 mg/0.1 mL

In select cases with severe vitreous inflammation consider:

- Dexamethasone 4 mg/0.1 mL

In traumatic endophthalmitis with vegetable matter consider:

- Amphotericin B 5  $\mu$ L/0.1 mL

Systemic antibiotics are recognized to be largely ineffective when used as the only route of administration with the exception of some cases of endogenous endophthalmitis. There is controversy over whether systemic antibiotics should be used, because of their poor penetration into the eye. One study demonstrated cures of endophthalmitis caused by *Staphylococcus* species and other more virulent organisms with use of IV antibiotics only.<sup>160</sup> In the EVS, patients given IV antibiotics in conjunction with intraocular antibiotics did not have a better visual outcome than patients given intravitreal antimicrobials alone.<sup>3</sup> Another recent study demonstrated that in an animal model of *Staph. aureus* endophthalmitis intravitreal vancomycin and amikacin were superior to intravenous imipenem alone, and combination treatment provided no additional benefit to intravitreal administration.<sup>161</sup> The IV antibiotic given for gram-positive coverage was amikacin, which has very poor penetration into the vitreous cavity after IV injection.<sup>162</sup> Other antimicrobial drugs, such as vancomycin and cefazolin, gatifloxacin, or moxifloxacin, which demonstrate better penetration, may be beneficial in some circumstances.<sup>144,146,148,163</sup>

Subconjunctival antibiotics, formerly recommended in endophthalmitis treatment,<sup>164</sup> are currently used as postsurgical prophylaxis. The levels achieved in the vitreous after subconjunctival injection, however, are insignificant in comparison to intravitreal injection and rarely reach therapeutic levels when given alone.<sup>140,165</sup>

Antibiotic administration as part of the infusion fluid has been recommended as part of vitrectomy procedure. This has the advantage of initiating antibiotic exposure to the organisms somewhat earlier than injection into the vitreous cavity at the close of the surgical procedure. Despite some concerns of retinal toxicity, one recommendation is to place gentamicin (8 mg/mL) into the infusion.<sup>166</sup> Because this is approximately one-third of the concentration achieved by injecting 100 mg into a 4-mL eye (25

mg/mL), the peak dosage and effective duration of action are significantly reduced.

## Antimicrobial Agents

Four groups of antimicrobials are commonly prescribed in endophthalmitis: (1) cephalosporins; (2) aminoglycosides; (3) fluoroquinolones; and (4) antifungal agents.

### Cephalosporins.

The cephalosporins are synthetic penicillins active against the bacterial cell wall. They are well tolerated systemically, and cefazolin has been established to be a relatively safe drug when 2.25 mg is injected intravitreally. All the cephalosporins have good broad-spectrum coverage for gram-positive and some gram-negative organisms, but the first-generation drugs are weak against enterococcus and methicillin-resistant staphylococcal organisms. Injection of cefazolin (2.25 mg) into the aphakic eye produces levels greater than the MICs for approximately 48 hours.<sup>153</sup> Penetration in inflamed vitrectomized eyes can be achieved after repeated IV dosages, and cefazolin reaches levels well above the MICs for sensitive organisms.<sup>144</sup> Ceftazidime is a promising antibiotic for gram-negative coverage in endophthalmitis therapy because it has good cerebrospinal fluid penetration and excellent *Pseudomonas* coverage. In a study of 37 gram-negative isolates from cases of endophthalmitis, 80% were susceptible to ceftazidime.<sup>25</sup> Initial reports indicate an excellent therapeutic ratio after intraocular injection.<sup>167,168</sup>

### Vancomycin.

Vancomycin has been recommended as the antibiotic of choice for gram-positive coverage.<sup>169-171</sup> In a study of 246 gram-positive isolates from cases of human endophthalmitis, 100% were susceptible to vancomycin.<sup>25</sup> Its coverage is purely gram-positive, but its spectrum includes all of the staphylococcal species, *Bacillus*, and *P. acnes*. The mechanism of vancomycin is inhibition of cell wall assembly, in addition to damaging protoplasts and inhibiting RNA synthesis. The intraocular therapeutic ratio for vancomycin is good, although the half-life suggests that therapeutic concentrations will

be maintained for only about 48 hours after intravitreal injections.<sup>172,173</sup> Vitreous sampling after intraocular injection in human infection has suggested that potentially therapeutic levels may persist for 3–4 days after initial injection depending on the initial dose.<sup>80,174</sup> Systemic toxicity is seen after high IV dosages and is unfortunately additive with IV aminoglycosides. Penetration into the vitreous cavity of inflamed eyes after IV injection is sufficient to be above the MIC for most pertinent pathogens after repeated dosing in animal models,<sup>150</sup> but produces variable concentrations in humans after a single dose.<sup>175</sup>

### **Aminoglycosides.**

Aminoglycosides have a spectrum that includes both gram-positive and gram-negative organisms. They are chosen particularly for their gram-negative coverage in endophthalmitis. The mechanism of action for aminoglycosides is to inhibit protein synthesis. Unfortunately, the intraocular therapeutic ratio after intraocular injection is a source of problems.<sup>135,138,156,157</sup> Retinal vascular infarction has been frequently reported after gentamicin,<sup>33</sup> and it has also been noted after amikacin administration.<sup>137</sup> Tolerated dosages may be higher for amikacin than for gentamicin, but all of the aminoglycosides cause retinal changes after higher intravitreal dosages.<sup>176–178</sup> The half-life of amikacin is approximately 8 hours in inflamed, vitrectomized eyes.<sup>155</sup> Because of the limitations in the amount given for the initial dosage, the concentration of these antibiotics remains above the MIC for only 24–36 hours after administration. The therapeutic ratio for treatment of ocular disease after IV administration is also unfavorable because of systemic toxicity. Penetration of gentamicin into the eye after IV administration has been studied in both rabbits<sup>179</sup> and humans.<sup>180</sup> It does not reach therapeutic levels in traumatized rabbit eyes,<sup>162</sup> normal rabbit eyes, or human eyes with various ocular diseases after single doses.<sup>180</sup>

### **Fluoroquinolones.**

The quinolones are broad-spectrum antibiotics with both gram-positive and gram-negative coverage. Their mechanism of action is thought to be inhibition of DNA synthesis. The second-generation

drugs are ciprofloxacin and ofloxacin, while levofloxacin is a third-generation agent. The fourth-generation drugs, gatifloxacin and moxifloxacin, have significant potential in the prophylaxis and treatment of endophthalmitis. Initial reports of the therapeutic ratio of ciprofloxacin after intraocular injection suggest that intraocular toxicity occurs at low dosage levels.<sup>181,182</sup> Fluoroquinolones penetrate the blood–ocular barrier more readily than do several of the other classes of antimicrobials. Ciprofloxacin has reasonable penetration after oral administration, but many ocular pathogens have developed resistance to it.<sup>25</sup> After two doses of oral administration, levofloxacin achieves concentrations in the aqueous and vitreous above the MIC (90) for many gram-positive and gram-negative pathogens but not for *Pseudomonas aeruginosa*.<sup>181</sup> Studies of penetration of gatifloxacin and moxifloxacin into noninflamed eyes undergoing vitreous surgery after oral administration of two doses demonstrated that the percentages of serum concentrations achieved in the vitreous and aqueous were 26.17% and 21.01%, respectively. These levels are above the MIC (90) for most of the pathogens producing human disease. These include *Staph. epidermidis*, *Staph. aureus*, *Strep. pneumoniae*, *Strep. pyogenes*, *Enterococcus faecalis*, *Proteus mirabilis*, *E. coli*, and *P. acnes*, among others. Notably, however, neither agent achieved vitreous MIC (90) for *P. aeruginosa* and moxifloxacin did not reach the MIC (90) for *Bacteroides fragilis*.<sup>120,142,146</sup> Because two genetic alterations in the target bacteria must occur for resistance to emerge to the fourth-generation drugs, the rapid development of resistance noted for ciprofloxacin may be avoided.

## Antifungal Agents

Amphotericin has been considered the gold standard in antifungal therapy. Its mechanism of action is the alteration of membrane permeability by combination with sterols and fungal cytoplasmic membranes. The intraocular therapeutic ratio has not been well studied, but the usual recommended dosage is 5 µg/mL.<sup>183</sup> After IV administration, there are significant systemic complications, including renal toxicity. Penetration into the eye is also relatively poor. After intraocular injection, the half-life has been reported to

be 9.1 days. The half-life is further decreased by inflammation and vitreous removal.<sup>183</sup> Vitrectomy and oral fluconazole have been reported to treat *Candida* endophthalmitis successfully, with fewer side-effects.<sup>31</sup> Fluconazole has significant penetration into the noninflamed eye after oral administration.<sup>184</sup> Voriconazole is a triazole antifungal agent that is a second-generation synthetic derivative of fluconazole. It demonstrates a broad spectrum of action, including *Aspergillus* species, *Candida* species, and *Paecilomyces*, and has a low MIC (90) for many organisms. After oral administration, potentially therapeutic levels are achieved in aqueous and vitreous in noninflamed eyes.<sup>143</sup> Uses of intravitreal voriconazole for fungal endophthalmitis have been reported.<sup>185,186</sup>

## Pars Plana Vitrectomy

Pars plana vitrectomy plays a role in many phases of endophthalmitis therapy. As initial therapy it is validated by the EVS results only for acute postcataract extraction infections in eyes presenting with vision of hand motions or less. This recommendation should not be generalized to infection associated with filtering blebs, endogenous endophthalmitis, posttraumatic endophthalmitis, or even chronic or delayed-onset endophthalmitis in which the clinical circumstances, and, most importantly, the causative organisms, are likely to be different.<sup>187</sup> In addition to use as initial therapy in many of these clinical settings, pars plana vitrectomy should also be considered for eyes not responding to an original tap-and-inject strategy, and may be necessary to clear vitreous opacities in eyes cured of infection when spontaneous clearing does not occur.

## Acute Postoperative Endophthalmitis After Cataract Surgery

Early in the development of pars plana vitrectomy, treatment of acute postoperative endophthalmitis was identified as a potential application. Although there was general agreement that the most severe cases might benefit from vitreous surgery, there was no clear indication about when surgery should be undertaken in acute cases of infection.

The EVS was designed to address the issue of the relative efficacy of vitrectomy and intraocular antibiotic injection in the treatment of acute endophthalmitis after cataract surgery compared with initial diagnostic tap and injection of antibiotics alone.<sup>3,188</sup> In this study, patients with acute postoperative endophthalmitis were randomized to one of the two strategies for initial management. Patients with a progressive downhill course after tap and injection were allowed to have a vitrectomy procedure. As a second randomization, patients in each group were assigned to either IV antibiotic therapy or no IV antibiotic therapy. A total of 420 patients with clinical evidence of endophthalmitis within 6 weeks of cataract surgery or secondary IOL implantation were included. Visual acuity was evaluated 9 months after the initial intervention.<sup>3</sup>

In this study, 30.7% of the eyes were culture-negative. Of the 291 culture-positive cases, the isolates identified were as follows: gram-positive, coagulase-negative micrococci 70%; *Staph. aureus* 9%; *Streptococcus* species 9%; *Enterococcus* species 2.2%; gram-negative species 5.9%.<sup>47,48</sup> The initial vision was an important determinant of outcome. In eyes presenting with vision of hand motions or better there was no difference in visual outcome regardless of whether an immediate vitrectomy was performed. In patients with initial vision of light perception, eyes treated by immediate vitrectomy had a threefold increase in the frequency of achieving 20/40 or better acuity (33% vs. 11%), approximately a twofold chance of achieving 20/100 or better (56% vs. 30%), and a 50% decrease in the frequency of severe visual loss (20% vs. 47%) compared with an initial tap-and-inject strategy. Eyes treated with systemic antibiotics did not show improved outcomes compared with those not receiving them. Thus the study recommended that vitrectomy be reserved as an initial treatment strategy for those eyes presenting with light perception vision.<sup>3</sup> Subsequent evaluation of the data suggested that patients with diabetes mellitus had a better outcome with an initial strategy of vitrectomy and antibiotic injection regardless of presenting vision. The conclusions of this retrospective analysis did not reach a level of statistical significance to allow the authors to make a firm recommendation that surgery should be the initial intervention in all diabetic patients.<sup>189</sup> Since small-gauge vitrectomy has become the standard for most retina surgeons, vitrectomy

usage is higher than that recommended from the EVS; however, there has not been evidence of increased benefit.<sup>190</sup>

## Traumatic Endophthalmitis

Traumatic endophthalmitis accounts for approximately 25% of all cases of intraocular infection. These cases create difficult therapeutic problems because of the effects of the injury and the wider, more virulent spectrum of bacteria that are involved in more traumatic infections than in postoperative endophthalmitis.<sup>11,13-16,118,124</sup>

*Bacillus* species are commonly identified after injuries involving farm materials and may be the causative organism in approximately 25% of cases, depending on the environment of the injury.<sup>13</sup> Rates of infection after trauma vary from 2–3% after penetrating injuries to 11–17% with industrial foreign bodies<sup>118,119</sup> to 30% in injuries occurring in rural environments.<sup>13</sup> Vitrectomy has been recommended because of the severity of the injuries, severity of infection, and the more adverse outcome reported in these cases.<sup>124</sup> Vitrectomy allows treatment of the residual intraocular effects of the trauma, such as retained lens cortex, vitreous hemorrhage, and retinal breaks, as well as allowing removal of infected vitreous, bacteria, and toxins.

## Chronic Postoperative Endophthalmitis

The syndrome of chronic or delayed-onset postoperative endophthalmitis has been increasingly recognized. Causative organisms of these cases include *P. acnes*,<sup>18,20-23,135</sup> fungal cases (particularly *Candida parapsilosis*),<sup>19,69</sup> and nonvirulent forms of *Staph. epidermidis*.<sup>19,58</sup> The onset is usually days to weeks after surgery, and the clinical manifestation is one of chronic, indolent inflammation, often initially responding to suppression by topical corticosteroid therapy. *P. acnes* often produces a granulomatous inflammation, usually beginning 4–8 weeks after surgery. It characteristically manifests as a white plaque on the lens capsule. Fungal cases have less specific findings, and the diagnosis is often made by Gram stain, Giemsa stain, and culture. Cooperation with the microbiology department is important in these cases so that appropriate measures can be taken for the proper identification of

the organisms. Cultures should be kept for at least 2 weeks, particularly for *P. acnes* because these organisms may grow slowly. Surgery is recommended in these cases because the slow growth of the organisms makes sterilization more likely after their surgical removal than intraocular antibiotic injection alone.

It is thought to be necessary to remove the white plaque on the lens capsule in cases of *P. acnes*, and in some cases the capsule itself along with the IOL.<sup>18,19,22</sup> High rates of recurrence are noted when only intraocular antibiotics are injected, and persistent disease occurs in a significant percentage of patients even when the capsule is removed. Complete capsulectomy and IOL exchange is almost always successful in eradicating infection either as the initial intervention or as a secondary procedure.<sup>18,19,22</sup> Recurrent inflammation and persistent infection are not uncommon, and secondary procedures are often necessary in both *P. acnes* and fungal infection some weeks after the initial surgery. Recommended antimicrobial therapy includes vancomycin for *P. acnes* and intraocular amphotericin for fungi; imidazoles, including ketoconazole, fluconazole, or voriconazole may be of benefit.<sup>18,19,143</sup>

## **Bleb-Associated Endophthalmitis**

Bleb-associated endophthalmitis may be seen after cataract extraction or after filtering procedures.<sup>18,57,83,89,136</sup> It typically occurs long after the initial surgery and is preceded by a period of irritation and redness of the eye. The classic initial finding is “white on red” because the white bleb filled with inflammatory material is highlighted against the redness of the conjunctiva. *Streptococcus* is the infecting organism in as many as 60% of these cases. In general, bleb-associated endophthalmitis has a poor visual outcome, leading to a recommendation for initial vitrectomy in these cases.<sup>57,136</sup> However, in some cases, particularly in phakic eyes, the initial infection may be confined to the anterior segment (“blebitis”), so systemic and intensive topical antibiotics may achieve good therapeutic levels in the anterior chamber and aqueous, thus curing the condition without vitrectomy surgery or intravitreal antimicrobial injection.<sup>191,192</sup>

## **Endogenous Endophthalmitis**

Endogenous endophthalmitis is often associated with significant systemic illness or IV drug use. In these cases it is important to search for the cause of the endophthalmitis because it is secondary to infection elsewhere and may be associated with a life-threatening condition. Repeated blood cultures and a multidisciplinary approach are often helpful for locating the source of infection.<sup>126,128-130,193</sup> Systemic therapy may be sufficient in some cases if the vitreous cavity is not heavily involved. Vitrectomy has the advantage of both obtaining a reasonable amount of material for cytologic and microbiologic studies to make the diagnosis and allowing removal of the offending organisms. IV medication may penetrate at the site of invasion through the eye wall, but when organisms proliferate within the vitreous cavity, vitrectomy is more often needed. A literature review by Jackson et al. reported a three times better chance of retaining useful vision and avoiding evisceration or enucleation if vitrectomy is performed.<sup>194</sup>

If fungal disease is strongly suspected, most authors<sup>43,132,195</sup> concur that therapeutic vitrectomy is the treatment of choice if the vitreous is significantly involved, although systemic therapy may be sufficient in early endogenous disease. Vitrectomy has also been employed in chronic progressive inflammatory disorders that ultimately prove to be caused by fungus, such as *Cryptococcus*.<sup>196</sup> In these instances the indications are diagnostic, as well as therapeutic.

Parasitic diseases may produce a chronic endophthalmitis with both acute components and secondary complications, such as retinal detachment, vitreous opacity, and cataract. In these instances the acute or active stages of the infection have been the indications for surgical intervention for some authors,<sup>197</sup> although the chronic sequelae are more common indications for surgery in *T. canis* and toxoplasmosis-related endophthalmitis.

## **Preoperative Evaluation**

A careful and extensive history should be taken. Clinical details such as systemic infectious disease, type of eye injury, or previous surgery may hold important clues to the identity of the infecting organism. Particular attention should be paid to the length of time from the surgical insult or trauma to the onset of symptoms and to the time that has passed since symptoms began. Previous antibiotic

or corticosteroid therapy should be noted. A thorough ocular examination should include a careful search for any possible route of entry for the infecting organism. The effects of the inflammation should also be noted: corneal clarity and thickness, condition of any surgical wound, degree of anterior-chamber reaction, hypopyon, clarity of the vitreous, visibility of the retina, and presence or absence of a red reflex. Standardized ultrasonography can define the degree of condensation of the vitreous, determine whether the retina is attached, and identify choroidal swelling.<sup>198</sup> Preoperative ERG findings may have a predictive value for postoperative visual result, but this has not yet been well defined.<sup>116,198</sup>

## **Surgical Techniques**

If an extensive procedure is contemplated, general anesthesia is preferred because of the difficulty of obtaining adequate local anesthesia for an inflamed, painful eye. Local anesthesia may be adequate for shorter procedures or if the patient's medical condition warrants this approach.

Since the introduction of small-gauge vitrectomy, the use of 23G, 25G, and 27G transconjunctival instruments has become more popular in the treatment of infectious endophthalmitis.

The first technical problem that confronts the surgeon is placement of the infusion cannula. Because the media is almost always too cloudy for the surgeon to be able to visualize a pars plana port, this infusion cannot be used for the initial stages of the operation. Because the incision and placement of the infusion port are easier in a firm eye, it is often worthwhile placing an inferotemporal port, reserving its use for later in the procedure, once the location of the tip in the vitreous cavity can be verified.

The clarity of the cornea and anterior chamber and the presence of the crystalline lens or a pseudophakos will determine the incisions into the eye after infusion cannula placement. If the anterior vitreous can be easily seen, two trochars are placed 3.5 mm from the limbus. The anterior chamber often contains significant amounts of fibrin and hypopyon. Because the cornea invariably has some combination of epithelial edema, folds, and cells deposited on the posterior surface, the iris and central anterior vitreous are often impossible to visualize adequately. Initial incisions may be made in

the limbus at approximately the 9.30 and 2.30 clock positions, modifying the location as necessary depending on the condition of the previous surgical wound and on the presence of a filtering bleb. Fluid is infused into the anterior chamber through a secondary infusion on a blunt needle as inflammatory debris is removed with the vitrector handpiece (Fig. 125.1).

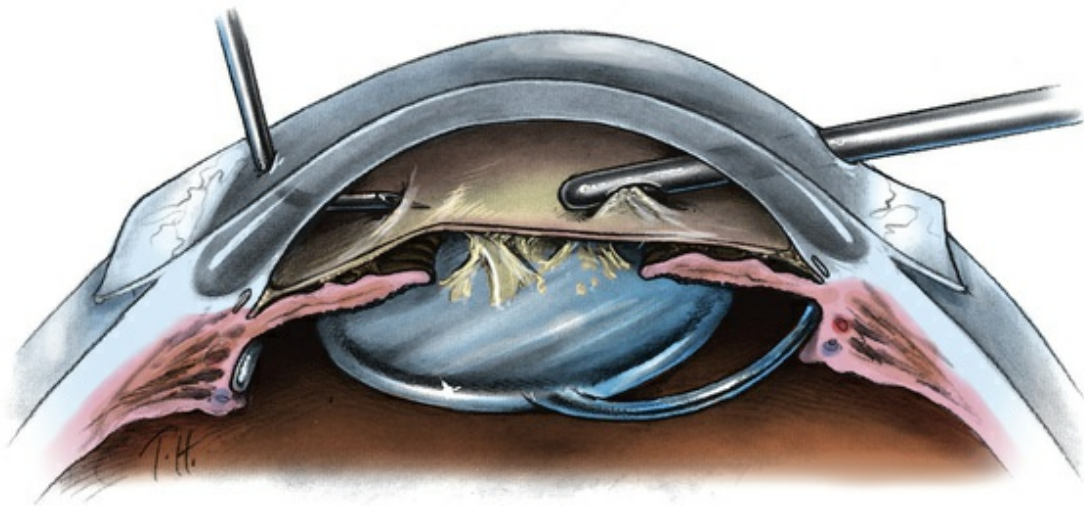

**FIG. 125.1** Opaque material being removed from the anterior chamber; active infusion into the anterior chamber.

An inflammatory membrane usually extends continuously over the lens or pseudophakos and on to the surface of the iris. When a pseudophakos is present, the lens need not be removed; attempting to do so may increase the risk of bleeding. The inflammatory membrane, however, should be removed from its surface for better visualization of the posterior segment. It may be initially incised with a myringotomy blade or other sharp needle and then elevated for removal with a cutting instrument or intraocular forceps (Fig.

125.2). Removal of an inflammatory membrane from the crystalline lens should begin over the iris, close to the pupillary border, if it is believed that the lens can be spared. Often, because of poor dilation of the pupil and poor visualization of the internal structures, the lens in phakic eyes must be removed. The fastest way to accomplish this is with fragmentation through pars plana incisions, although young, soft lenses can often be removed with cutting instruments.

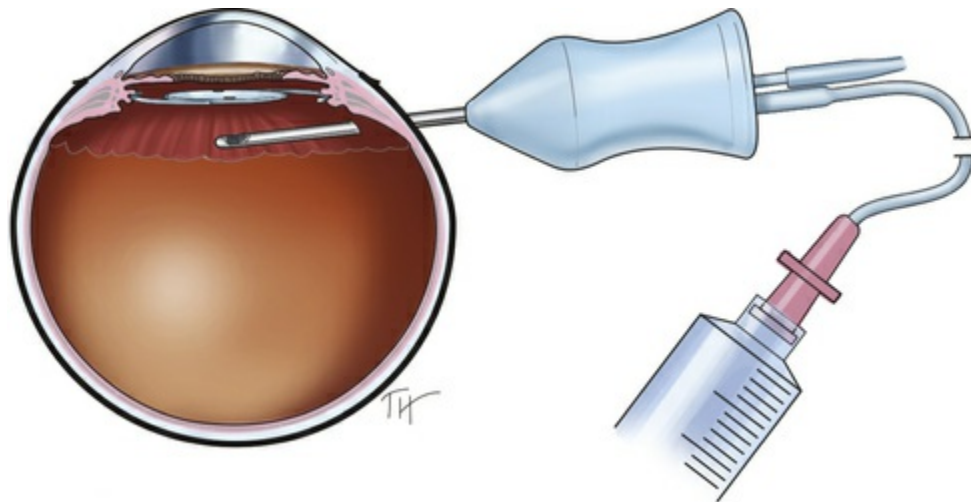

**FIG. 125.2** Elevation of fibrin membrane from lens and iris to mobilize for cutting.

In severe cases the cornea and anterior chamber may be totally opaque. In these eyes, a temporary keratoprosthesis can be used, followed by a penetrating keratoplasty. Alternatively, the initial approach may be to remove a central corneal button and to then proceed with an open-sky vitrectomy, removing as much as possible of the vitreous and then suturing a donor button into position.

Material for culture and stain should be removed from the eye early in the case. Because anterior-chamber samples frequently do not render positive culture results, attention should be directed to obtaining an adequate vitreous sample. In most surgical setups, the tubing that comes from the suction-cutting portion of the instrument can be opened. Alternatively, a very short piece of tubing is attached to the egress port of the vitrectomy probe (Fig. 125.3). A sterile syringe is connected, and the vitreous is withdrawn with manual suction. Approximately 0.2 mL is removed before

starting infusion into the eye to obtain an undiluted sample. The material is then immediately sent to the laboratory for Gram and Giemsa stain, as well as cultures on blood agar, chocolate agar, brain–heart infusion, and Sabouraud's media or broth and in thioglycolate broth. It is important to obtain the specimens for culture before any antibiotics are injected into the eye.

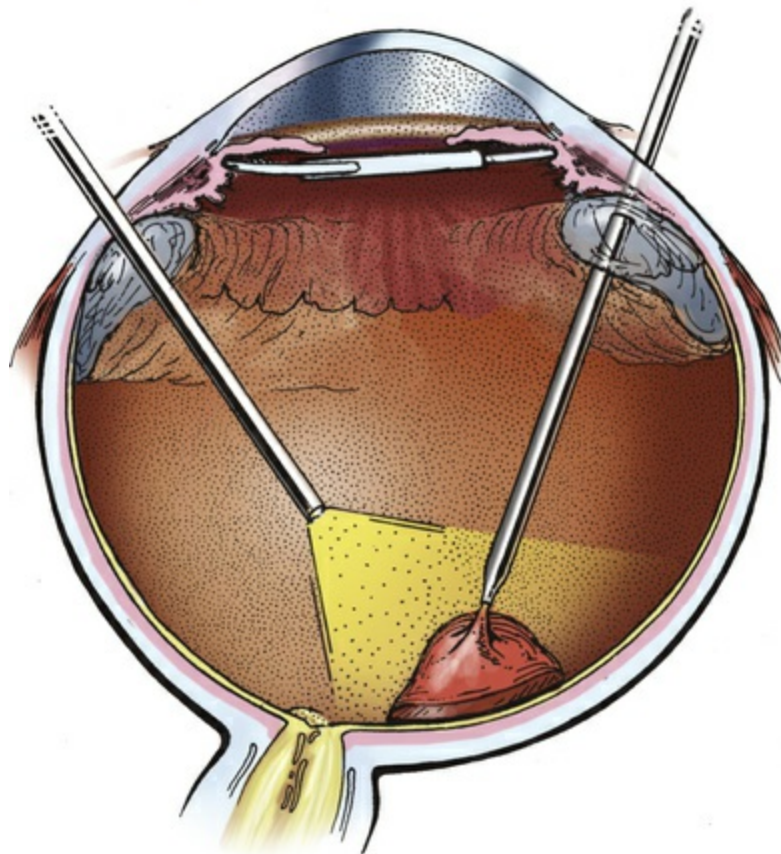

**FIG. 125.3** A short piece of tubing connects a syringe to the vitrectomy probe to obtain an undiluted vitreous sample.

The vitrectomy is now progressively carried posteriorly. The vitreous removal is performed initially in the center of the vitreous cavity. Pockets of more heavily infiltrated vitreous are sometimes located near the vitreous base; in the aphakic eye, peripheral depression may be used to bring these into view. Aggressive removal of all infiltrated vitreous in the basal area should not be attempted because this often results in retinal tears. The presence of a posterior vitreous detachment, on the other hand, allows more complete vitreous removal. If the vitreous is still attached, a judgment must be made about the amount of vitreous to be removed. The cutting of vitreous adjacent to inflamed or necrotic retina will often cause retinal breaks; these are difficult to seal and may result in failure of the case. In eyes with posterior vitreous detachment, a white mound of inflammatory debris may be visible over the posterior pole. This should be approached with care and may be gently aspirated into the cutting port. If the mound proves

to be solid and adherent, small amounts can usually be removed, but in most cases it is unwise to attempt to remove large portions. In some instances the material is flocculent and equivalent to an unorganized hypopyon; this can be gently sucked up with vacuum techniques (Fig. 125.4).

**FIG. 125.4** Vacuuming removal of “hypopyon” from macular area.

If visibility is so poor that the vitreous posterior to the central area cannot be adequately defined, repeated attempts should be made to clear the anterior chamber. Membranes can also be present on the posterior surface of the lens, and these should be removed. If good visibility cannot be obtained, it is better to discontinue the procedure than to risk retinal damage by cutting posteriorly with inadequate visualization.

The procedure is completed by closing all incisions in a watertight manner and injecting intraocular antibiotics. After closure of the conjunctival incisions, subconjunctival antibiotics are

often injected.

The major intraoperative complications to be feared are hemorrhage and retinal detachment. Anterior hemorrhages can occur from the surgical wound site, the iris root, or the iris surface. These may be controlled initially by raising the intraocular pressure, usually by raising the height of the infusion bottle. Visible hemorrhage from a point source can also be controlled with intraocular diathermy. Retinal breaks are a major problem. If vitreous is not attached to the breaks, they can be treated with intraocular argon laser or cryotherapy. Posterior breaks can then be managed with gas tamponade alone, but this makes intraocular antibiotic injection problematic. Consideration should be given to a scleral buckle if anterior breaks are present. If vitreous remains attached to the break, attempts to remove it can be made, but such manipulation may result in further tearing. If this occurs, external buckling must then be provided. A choroidal hemorrhage may be devastating and can destroy the eye. The best way to avoid this complication is to keep intraocular pressure at a constant level during the entire procedure, thereby preventing hypotony. If choroidal hemorrhage does develop, intraocular pressure should be immediately raised to high levels in an attempt to close the bleeding vessel.

Breakdown of the original surgical wound is also occasionally encountered. Resuturing the wound with broader bites may be necessary. Despite the use of transconjunctival vitrectomy techniques, many surgeons still choose to routinely suture all sclerotomies at the end of endophthalmitis cases.

## **Postoperative Management**

If treatment is proceeding well, patients usually have a dramatic improvement in ocular pain by the first postoperative day. Nonetheless, some form of analgesic, including narcotics, is often required. Resolution of the disease can be monitored in part by the progressive reduction in pain.

Antibiotics given intravitreally at the time of surgery maintain high therapeutic levels for 24–48 hours. In bacterial disease, the necessity for repeat intravitreal injection is not known with certainty; levels exceeding minimal bactericidal levels are present

for at least 24–36 hours after most intravitreal injections. Drops may also be prepared by the hospital pharmacy in highly concentrated doses; administered between 4 times a day to hourly, they may have a booster effect but probably do not significantly increase intraocular concentrations. Not all infections are cured by a single dose of injected antimicrobial.<sup>3,199–205</sup> If the inflammation appears to worsen or does not respond as well as expected, particularly if it is associated with persistent pain, the physician should suspect that the infectious process remains active. The index of suspicion should be highest for streptococcal species and gram-negative organisms; gram-positive coagulase-negative micrococci usually respond to initial therapy. A repeat tap and injection of antibiotics, chosen on the basis of the culture results, should be considered; if the media appears significantly opaque, or if the initial therapy was only injection of antibiotics, a vitrectomy may be considered, particularly if most of the vitreous was not removed during the initial procedure. If the initial culture sensitivities show that the organism is resistant to the antibiotic originally injected, injection of an appropriate antibiotic is strongly recommended. In the EVS 8% of eyes were subjected to early secondary intervention.<sup>3</sup>

IV aminoglycosides have not been demonstrated to be effective in improving outcome, but other antimicrobials with better penetration into the vitreous cavity after IV administration may be considered in some cases. Vancomycin,<sup>150</sup> ceftazidime,<sup>146,148</sup> cefazolin,<sup>143,148</sup> or a fluoroquinolone<sup>142,146,150</sup> may be useful when a longer duration of antimicrobial effect is desired than the 24–48 hours provided by intravitreal injection.

Second operations are frequent in patients with endophthalmitis. In the EVS, 35% of all eyes needed some secondary procedure.<sup>3,148</sup> Opacities in the vitreous cavity may continue to interfere with vision, even if the eye responds well in terms of inflammatory signs. The retina should be monitored at regular intervals with ultrasound if the surgeon cannot be sure by indirect ophthalmoscopy that it remains attached. Removal of these opacities may be undertaken with a repeat vitrectomy as an elective procedure once the eye becomes quiet.

## **Control of Inflammation**

In addition to eradication of viable organisms from the eye and sterilization of the vitreous cavity, control of intraocular inflammation is an important therapeutic goal. Inflammation can increase even when microbes are no longer viable. Corticosteroid administration has long been recognized as important to this goal. Subconjunctival administration at the close of the surgical procedure can achieve intraocular levels of medication within the first hours after surgery but has not been rigorously tested in clinical or animal trials. Topical corticosteroids are usually given in frequent dosages after either surgery or vitreous tap and antibiotic injection.

Corticosteroid administration by other routes is often chosen as part of the therapeutic plan. All patients in the EVS received systemic prednisone 30 mg twice daily for 5–10 days.<sup>3</sup> Systemically administered corticosteroids have been demonstrated to reduce inflammation independently of the effects of surgery in animal models of treatment of *Staph. epidermidis* endophthalmitis.<sup>206,207</sup> Intraocular corticosteroid administration was first advocated by Peyman and others<sup>208–210</sup> in treatment of animal models of endophthalmitis. In treatment of a rabbit model of *Staph. epidermidis* endophthalmitis, Meredith et al.<sup>207</sup> demonstrated a beneficial effect of intraocular corticosteroid administration that was equivalent but not superior to systemic administration. Histopathologic studies of treatment of a similar model by Maxwell et al.<sup>211</sup> also demonstrated a beneficial effect of intraocular corticosteroid administration. When intraocular corticosteroids were administered after vitrectomy and intraocular antibiotic injection in a model of *Staph. aureus* endophthalmitis, however, there was an increase in inflammatory scores, corneal opacity, and the number of eyes developing retinal necrosis.<sup>200</sup> These results suggest caution in intraocular corticosteroid use because a beneficial effect may not result in all cases of endophthalmitis. There are a number of prospective, randomized<sup>212–214</sup> and retrospective<sup>215,216</sup> human series that demonstrate earlier reduction of intraocular inflammation after injection of intravitreal dexamethasone but there appears to be no lasting benefit on visual outcome compared to controls. However, one retrospective series found a significantly reduced likelihood of achieving a three-line improvement in visual acuity among patients

receiving intravitreal corticosteroids.<sup>215</sup>

## Complications

The cornea is often edematous in the early postoperative period. Epithelial edema usually clears within the first week if the endothelium has not undergone major damage; stromal edema will also slowly clear. Persistent epithelial defects may occasionally be seen, and their healing can be compromised by the frequent use of topical medications. Pigmented cells may remain on the posterior surface of the cornea for months. If epithelial edema does not clear and the eye seems otherwise salvageable, a corneal graft may be considered.

The intraocular pressure may be elevated or decreased in the postoperative period. Elevated pressure usually responds to medical management and improves as the inflammatory process resolves. Persistent hypotony, which not only contributes to poor corneal clearing but is also usually associated with persistent inflammation and a progressive downhill course, even in the presence of a sterile vitreous cavity, should raise the suspicion of a leaking wound site. Ultrasonography may reveal choroidal detachment; the only management currently available is a vigorous attempt to control the inflammatory process medically.

Inflammatory signs (usually more flare than cells) can persist for many weeks after surgery, especially if the initial disease was severe. Bacterial products such as endotoxins in gram-negative infections and exotoxins in gram-positive infections may persist, even after successful vitrectomy, resulting in a recurrence of vitreous cavity fibrin and cells 24 hours after an adequate vitrectomy. If there is no sign of slow but steady improvement, the ultimate outcome is almost uniformly poor, and phthisis is the usual result.

Cataract may also develop in the postoperative period if the crystalline lens has been left in place. Cataract removal can also be performed electively when the eye becomes quiet. If the ultrasound or clinical examination indicates the presence of significant vitreous opacities associated with the lens change, a pars plana approach may be used for fragmentation of the lens and removal of the vitreous opacities during the same procedure.

Retinal detachment is a feared complication of vitrectomy for endophthalmitis. Retinal detachment occurred in 8.3% of eyes in the EVS.<sup>217</sup> Tears that occur at the time of surgery are managed as outlined earlier. Unrecognized intraoperative tears, such as entry-site tears, can result in a detachment soon after surgery. Necrotic retina may also break down, creating an atrophic retinal break. Standard buckling procedures may help in many cases, but these may be difficult to perform because of the inability to see the fundus clearly on account of corneal opacity, poor dilation of the pupil, persistent opacity of the media, haze on the surface of an IOL, or opacification of the vitreous base. These retinal detachments can sometimes be repaired successfully, but they are reportedly the major cause of failure in most series.<sup>218</sup> Anatomic success was achieved in 78% of the cases in the EVS, but the occurrence of detachment was correlated with a poor visual outcome.<sup>217</sup> Proliferative vitreoretinopathy is a major risk in eyes with detachment; sympathetic ophthalmia has also been reported.<sup>32</sup>

Despite anatomic success, some eyes see poorly. A rough correlation exists between poor visual results and an abnormal ERG, suggesting that these eyes have sustained extensive damage to the retina.<sup>116</sup>

Postoperatively a small percentage of eyes injected with aminoglycosides at surgery develop whitening of the macular area with intraretinal hemorrhages in the posterior pole. Fluorescein angiography demonstrates shutdown of the capillaries and arterioles supplying the macula and vision is frequently poor.<sup>138,156</sup> Histologic examination of similar-appearing lesions produced experimentally in primates by injection of gentamicin shows extensive destruction of the nerve fiber layer.<sup>176</sup>

## Results

The outcome of treatment for postoperative endophthalmitis began to improve dramatically during the 1980s. Factors in this improved outcome include (1) higher incidence of endophthalmitis produced by less virulent organisms;<sup>3,5,219</sup> (2) earlier diagnosis and treatment; (3) widespread acceptance of intravitreal antibiotic therapy; (4) employment of vitrectomy surgery; and (5) control of the

inflammation with corticosteroids.

At this time, the visual outcome after treatment of postoperative endophthalmitis is better than in other forms of the disease. Nine months after therapeutic intervention in the EVS, 53% of the patients achieved visual acuity of 20/40 or better and 74% achieved 20/100 or better; 15% of eyes were equal to or worse than 5/200 and 5% had no light perception. A significantly greater percentage of patients in the vitrectomy group had clear media by the 3-month follow-up visit (86% vs. 75%).<sup>3,5</sup> There was a significant difference in outcome depending on the infecting organism. The rates of achieving final visual acuity of 20/100 or better were as follows: gram-positive, coagulase-negative micrococci, 84%; gram-negative organisms, 14%; *Staph. aureus*, 50%; *Streptococci*, 30%; and *Enterococci*, 14%. Both a positive Gram stain and infection with species other than gram-positive coagulase-negative micrococci were associated with a significantly worse outcome.<sup>3,55</sup>

The specific factors in the outcome of endophthalmitis treatment are difficult to analyze in other series because a number of variables are always involved. Most series report a mixture of case etiologies, including postoperative, traumatic, and endogenous. Traumatic endophthalmitis, bleb-related infections, and many endogenous cases do not in general have outcomes as favorable as postoperative cases. The indications for surgery, timing of surgery, antibiotics administered, dosage and route of antibiotic administration, and corticosteroid therapy are not uniform from one case to the next. Standards for defining success vary from one report to another. However, it appears that the achievement of 20/200 posttreatment vision is becoming a common standard.

A number of prognostic factors have been proposed, the most important of which is probably the virulence of the infecting organism, as demonstrated in the EVS. The percentage of eyes achieving at least 20/400 vision is relatively high in cases in which the culture obtained is negative (53–94%),<sup>1-4,7,55,72,125,220</sup> when *Staph. epidermidis* is the infecting organism (65–91%),<sup>2,10,26,116,136</sup> or if *P. acnes* or a fungus is the infecting organism. In endophthalmitis caused by gram-negative organisms and streptococci, vision of 20/400 or better is reported in 40–50% of cases. When *P. aeruginosa* or *Bacillus* organisms are the infecting microbes, salvage of useful vision is

almost never reported.<sup>14,15,24,113</sup> Delay of therapy for more than 36 hours after onset of symptoms has been reported to be associated with poor visual outcome in one series, whereas delay of more than 24 hours after onset of symptoms in eyes in which vitrectomy was performed was associated with a worse outcome in others.<sup>123,221</sup> In animal experiments administration of antibiotics in a model of *Pseudomonas* endophthalmitis 24 hours after bacterial injection produced sterilization of the vitreous cavity, whereas later injection did not.<sup>201</sup>

Visual acuity at initial manifestation has also been correlated with outcome. In one series, initial vision of light perception infrequently improved to acuity of 20/400 or better (21% of cases), whereas 87% of cases with initial acuity of 20/400 or better had this level of vision after therapy. In the EVS, 33% of eyes with initial vision of light perception achieved 20/40 when treated with immediate vitrectomy.<sup>3</sup> Cases associated with other ocular diseases such as damage from trauma and proliferative vitreoretinopathy tend to have less frequent achievement of 20/400 vision postoperatively.<sup>113</sup>

## Future Directions

In the future, improved antibiotic therapy will undoubtedly play a role in improved results. Defining better drugs for broad-spectrum coverage and identifying antimicrobials with improved penetration into the inflamed postsurgical eye after systemic administration are important goals. Further studies of ocular toxicity of new antibiotics will also allow selection of drugs with better therapeutic ratios for intraocular injection. Drug delivery to the vitreous cavity should be further improved by devising systems for either continuous delivery or better noninvasive delivery. The necessity for reinjection, potential toxicity of reinjection of various antibiotics, and proper timing of reinjection also need further study.

Advances in vitrectomy, as the recently described addition of 0.025% povidone iodine to the saline solution, may help to further reduce the bacterial load during surgery.<sup>222</sup>

Further, the invention of new molecular diagnostic methods may enhance the results of standard microbial culture and allow for

quicker adjustment of antimicrobial therapy.<sup>223</sup>

Improved control of inflammation initiated by the infection will be critical to improve the visual outcome. This will include expanded understanding of the role of corticosteroids in endophthalmitis treatment and a definition of the best route of administration. Other means of reducing intraocular inflammation, particularly in *Bacillus* and *Pseudomonas* infections, must be devised and may include repeat surgery or lavage. Blockage of toxins that mediate intraocular damage may be developed clinically.<sup>203</sup> Finally, rapid diagnostic systems that allow immediate identification of bacteria and more specifically targeted antimicrobial therapy should further increase the efficacy of treatment.

## Conclusion

Endophthalmitis remains a devastating complication of intraocular surgery and penetrating ocular trauma despite recent advances in diagnosis and treatment. Two-thirds of cases are postoperative, and 20–25% occur after penetrating trauma. Gram-positive organisms predominate in incidence and usually fare better than gram-negative infections, with *Staph. epidermidis* having a better prognosis than *Staph. aureus*. Fungal endophthalmitis accounts for 5–10% of all cases.

Intraocular antibiotics are well established as the mainstay of treatment for endophthalmitis because of the poor penetration of antibiotics into the vitreous cavity when administered by other routes because of the blood–retina barrier. Antibiotics are sometimes injected into the vitreous cavity as the only intravitreal therapy, whereas on other occasions they are combined with pars plana vitrectomy.

Pars plana vitrectomy has the advantage of removing bacteria and their toxins and clearing the ocular media, allowing a more rapid visual recovery. The eye is sterilized more quickly and reliably. Most authors recommend vitrectomy as the initial therapy for fungal infections and for the secondary structural changes, such as vitreous opacification, occurring after chronic infections such as *T. canis*. Most authors recommend vitrectomy for *P. acnes* infections and for traumatic endophthalmitis. In bacterial infections,

immediate vitrectomy is recommended for the most severe infections, including clinical settings such as filtering blebs, which are known to have a high incidence of virulent organisms. Vitrectomy is then followed by intraocular antibiotic injection. Although severity of infection is difficult to define precisely, mild to moderate infections are managed with immediate vitrectomy by some authors, but others recommend initial intraocular antibiotic injection, followed by vitrectomy only if the disease worsens. The EVS demonstrated that vision with only light perception was an indication for immediate vitrectomy based on improved results in these eyes compared with a strategy of vitreous tap and injection of antibiotics.

Results of therapy for endophthalmitis have improved in the last decade. Reasonable return of vision is often achieved in cases with negative culture results and infections with *Staph. epidermidis* and some fungi. Smaller percentages of eyes infected with *Staph. aureus* and even fewer with gram-negative organisms survive with recovery of ambulatory vision. Infections after trauma have a poorer prognosis than postoperative cases after cataract extraction; postoperative pars plana vitrectomy eyes and eyes with filtering blebs do poorly. The length of time from onset of infection to initiation of therapy and differences in virulence from one strain of bacteria to another are other important factors in outcome.

### **Conclusion**

## **Introduction**

Uveitis is a type of intraocular inflammation that can affect vision and may lead to legal blindness. Uveitis is classified into autoimmune, infectious, and malignant forms based on the underlying pathogenic mechanism. The diagnosis of different forms of uveitis is primarily based on a combination of the patient history and clinical manifestation rather than laboratory findings.<sup>1</sup> A patient's medical history, the course of uveitis, the typical appearance of the ocular involvement, and therapeutic response are also important in making a diagnosis. Regardless of cause, accurate diagnosis and appropriate pharmacotherapy are critical for positive visual outcomes. Diagnostic vitrectomy can be helpful in discriminating between different causes of uveitis. For example, few oncologists would agree to treat a patient with presumed intraocular lymphoma without an adequate biopsy result. However, histopathologic diagnosis of biopsy specimens is not common due to the difficulty of obtaining and manipulating ocular specimens.

The vitreous, which constitutes most of the ocular volume, can be a valuable tool for an accurate diagnosis, and considering specimen volume requirements, evaluating vitreous samples is of greater value than using aqueous humor samples.<sup>2</sup> In addition, vitrectomy can be beneficial for managing vitreoretinal complications in uveitis patients. This chapter, which is divided into diagnostic and therapeutic vitrectomy sections, covers the surgical indications, principles, and techniques for management of uveitis. Novel advances in laboratory techniques are also discussed.

## Diagnostic Vitrectomy

### Indications

The efficacy of evaluating vitreous cytology has been well documented. However, diagnostic vitrectomy is usually performed as a final diagnostic option due to the increasing risk of vitrectomy-related ocular complications. Recently, advances in surgical techniques such as small-gauge vitrectomy and wide-viewing systems have expanded the use of diagnostic vitrectomy. Diagnostic vitrectomy is indicated in an inflamed eye when the course or appearance of uveitis is not typical for an autoimmune disease and the presence of an infectious agent or malignant process is suspected. Diagnostic vitrectomy is usually indicated in rapidly progressive disease with inconclusive noninvasive workup. If the disease fails to respond to therapy in an expected manner, the physician should reconsider the original diagnosis; in such cases, other diagnoses need to be considered. Indications for diagnostic vitrectomy are shown in [Box 126.1](#). Since many etiologies should be considered, multiple tests such as culture, cytology, and polymerase chain reaction (PCR) are generally recommended;

**Box 126.1** Clinicians should get as much vitreous sample as they can.

### Indications of Diagnostic Vitrectomy

#### Infectious Uveitis

Endophthalmitis:<sup>3</sup> bacterial, fungal, parasitic, or viral

Traumatic endophthalmitis including intraocular foreign body

Postsurgical endophthalmitis

Endogenous endophthalmitis

Sterile endophthalmitis

Vitritis

Retinitis

Choroiditis

Retinal vasculitis

## **Noninfectious Uveitis**

Autoimmune uveitis<sup>4</sup>

Primary intraocular lymphoma<sup>5</sup>

Carcinoma metastasis<sup>6</sup> including leukemia infiltration

Choroidal melanoma<sup>7</sup>

## **Surgical Principles and Techniques**

### **Preoperative Preparation**

Patients should be evaluated for concurrent diseases, including systemic infection, primary CNS lymphoma, or systemic lymphoma/leukemia. Because extraocular lymphoma is sometimes diagnosed late, patients should be evaluated systemically with caution. Sequential extraocular lymphoma is considered to have the highest specificity in confirming the diagnosis of an intraocular lymphoma.

Informed consent for diagnostic vitrectomy should be obtained

after discussing with the patient the necessity of performing the surgery and its potential for vision-threatening complications such as retinal tear or detachment, cataract formation, proliferative vitreoretinopathy, or postoperative endophthalmitis. Advances in surgical and laboratory techniques have expanded the indications for diagnostic vitrectomies. Laboratory tests of intraocular fluid or vitreous samples should be tailored according to the preliminary preoperative diagnosis. In addition, proper transportation of vitreous samples, judicious selection of ancillary tests, interpretation by experienced pathologists, and preoperative communication between the clinician and the pathologist are crucial for high diagnostic yields.

From a technical viewpoint, cutting with a vitrector does not appear to cause more cellular degeneration compared to simple aspiration. Vitreous tap can be performed in the outpatient department under local anesthesia, but three-port vitrectomy is typically considered to be the standard procedure. Further studies have yet to determine if the use of 23-, 25-, or 27-gauge (G) sutureless vitrectomy affects diagnostic yield compared with conventional 20G vitrectomy. In general, small-gauge vitrectomy is considered not to affect cellular integrity. 20G, 23G, or 25G vitrectomy are known to produce sufficient amounts of vitreous samples with good preservation of cellular integrity necessary for a cytologic evaluation.<sup>5,8-11</sup> More recently, 27G cutters have been introduced and will likely provide another option for diagnostic vitrectomy though the technique requires further clinical studies. Some authors advocate a lower cutting rate and higher duty cycle because larger and more intact pieces of the aspirated vitreous may have a better yield.<sup>12</sup> Cell viability was found to begin to decrease at 600 cpm and was lowest at a high cutting rate.<sup>13</sup> However, these settings have not yet proven to be more advantageous compared to traditional sampling techniques.<sup>14</sup> Because of the limited volume of vitreous samples, clinicians should be aware of the minimum sample requirement for microbiologic and malignancy workup and ensure that an adequate amount of vitreous is sampled accordingly.

## **Vitreous Sampling**

Adequate sampling of the vitreous is still challenging despite

advances in vitrectomy system technology. Vitreous biopsy can be a vitreous tap or diagnostic vitrectomy. Vitreous tap is performed in the outpatient department under local anesthesia. Subconjunctival injection of 0.1 mL of 2% lidocaine can be given at the site of entry into vitreous cavity. The 23- to 25G needle is inserted in the vitreous cavity under visualization with a surgical microscope. The empty syringe withdraws the vitreous in the eye. After withdrawal, a similar quantity of antibiotics or balanced salt solution (BSS) is usually injected into the vitreous cavity. Obtaining vitreous samples by tap is easier, but the quantity of obtained samples is small and is associated with a high rate of false-negative results.<sup>15,16</sup>

In contrast, three-port vitrectomy enables the operators to obtain the vitreous samples in the area with active disease such as the vitreous opacity or fungus ball under direct visualization. This can be also performed using the single-port technique,<sup>17</sup> but as single-port vitrectomy has no direct visualization, its use can have a lower diagnostic yield. Obtaining vitreous samples by three-port vitrectomy is more difficult and should be done in an operating room, but the amount of recovered material is usually sufficient and can have higher diagnostic yields compared to a vitreous tap. But as the purpose of diagnostic vitrectomy is to obtain maximal tolerable amounts of undiluted tissue from which a diagnosis can be made, small amounts of collected samples with few inflammatory cells and without adequate preparation of samples can reduce the diagnostic yield.

The standard technique for performing three-port pars plana vitrectomy (PPV) involves keeping the cutter tip within the vitreous. The undiluted vitreous humor is collected through the suction line with a 3- or 5-mL syringe directly connected to the vitreous cutter. This syringe is manually aspirated by an assistant while the operator visualizes the diseased area in the vitreous cavity. The operator can compress the eyeball with his/her fingers or a cotton swab to prevent eyeball collapse (Fig. 126.1). When the eye visibly softens, the infusion is turned on.<sup>18</sup> In our experience, up to 1.5 mL of undiluted vitreous can be safely obtained using this technique. Other techniques, such as using continuous air or perfluorocarbon liquid (PFCL) infusion, can yield large volumes of undiluted vitreous without compressing the eyeball. Air substitutes

the vitreous removed from the eyeball, and this can yield vitreous samples ranging in volume from 0.6 to 1.5 mL.<sup>12</sup> Perfluorocarbon-perfused vitrectomy, in which BSS is replaced with PFCL during vitreous aspiration, can be a good option for preventing complications of hypotony such as suprachoroidal hemorrhage.<sup>19</sup> Using this technique, an average of 2.24 mL of undiluted vitreous could be obtained. However, a major disadvantage, in addition to the high cost of perfluorocarbon, is that samples obtained using this technique need to be frozen to completely remove the perfluorocarbon.

**FIG. 126.1** Undiluted vitreous specimen is obtained using the vitreous cutter directly connected to a 3- or 5-mL syringe. In the case of a standard three-port vitrectomy, an assistant manually acquires the vitreous aspirate with a syringe while the operator compresses the eyeball with cotton swabs. The infusion is turned off until the eye visibly softens.

The undiluted vitreous sample is then typically referred to for cytologic analysis with either Papanicolaou (Pap) or hematoxylin-eosin staining, viral culture, or immunohistochemical staining. The supernatant of the undiluted sample is sent for cytokine analysis and determination of antibody levels. The diluted vitreous wash is typically used for Gram staining, DNA gene rearrangement studies,

flow cytometry, PCR testing, and filtered for bacterial and fungal cultures. Cytologic analysis may also be performed with the diluted specimen after centrifugation in a pathology laboratory. Vitreous cells and bacterial or fungal cultures are transported at room temperature.

## Handling and Preparation of Vitreous Samples

Careful handling of ocular specimens obtained for diagnostic purposes is essential. Advanced planning and notification of the pending procedure to laboratories are useful in ensuring that the specimen will be processed correctly. In addition, it is essential to coordinate the diagnostic vitrectomy with the microbiology laboratory so that the samples can be placed in appropriate culture media; handling errors may result in false negatives. Attention should be paid to adequate preparation of microbiologic culture media, accurate cell culture procedures, and molecular analysis. Some authors recommend that the vitreous sample be collected in a tube containing RPMI-1640 medium to improve the cytologic diagnosis of intraocular lymphoma from vitreous fluid.<sup>20</sup>

When an infectious cause is suspected, immediate sampling and transfer of the vitreous specimen to a sterile, airtight test tube with a screw cap is strongly recommended for cultivating pathogens. To maximize the chance of pathogen detection, it is recommended that the aqueous humor be also obtained. Considering that the specimen volume is usually insufficient for culture in all types of culture media, appropriate culture media should be selected according to the initial diagnosis.

Overall range for diagnostic yields from vitrectomy is wide according to various reports. Generally, the number of tests that can be carried out on a vitreous specimen depends on the amount of material retrieved. In addition, patient selection, surgical technique, and vitreous specimen analysis are factors that may contribute to this variation. Ideally, cytologic analysis and microbiologic cultures should be performed with undiluted vitreous specimen as soon as it is collected from the eye. Cytokine, chemokine, and flow cytometry analysis can also be performed using the aqueous humor that is

obtained. It is nevertheless important to realize that a negative cytologic diagnosis or microbiologic culture does not prove the absence of malignancy or infection. PCR analysis is recommended in cases where viral infection is suspected because the quantity of organisms shed into the vitreous cavity is minute and viral culture more often than not is likely to fail; as an example, a positive detection of human herpesviruses with PCR from the vitreous of patients with uveitis has been identified.<sup>21,22</sup>

## Retinal or Choroidal Biopsy

If a vitreous biopsy does not yield a diagnosis, chorioretinal biopsy of the involved eye can be considered, depending on the location of lesions and response to therapy. Chorioretinal biopsy increases the probability of achieving a correct diagnosis. Retinal or choroidal biopsy is considered when the inflammatory process is localized primarily in the sensory retina or the retinal pigment epithelium (see [Chapter 127](#), Vitreous, retinal, and choroidal biopsy). In such cases, if the disease only involves the retina or choroid, pathogens may not spill into the vitreous. For example, cytomegalovirus, which is difficult to culture from the vitreous fluid, can be cultured from the retina or seen on the electron microscopic examination of the retina.

An endoretinal biopsy can be helpful in diagnosing tuberculosis, sarcoidosis, and lymphoma.<sup>23</sup> Accurate biopsy results will lead to a specific treatment for uveitis of suspected infectious or malignant origin. Histologic examination of chorioretinal biopsies provides some advantages over cytologic examination of vitreous specimens. In the biopsy, more material is available for immunohistochemistry; this allows for more precise classification and differentiation of the pathology of the lesion. Despite these advantages, choroidal and retinal biopsies are used as a last resort considering the severe complications that may accompany the procedure.

Retinal or choroidal biopsy can be performed under retrobulbar block or topical anesthesia. Standard three-port vitrectomy is the preferred technique. The surgical technique for performing a chorioretinal biopsy can either be transscleral or transvitreal depending on the location of the lesion. In patients with panuveitis,

a choroidal mass, and a detached retina, it is recommended that transvitreal endoretinal biopsy be performed at the junction of the attached and detached retina. Upon completion of the vitrectomy, the area with active disease can be identified more accurately; this area can then be biopsied. However, a biopsy specimen obtained from a retinal area in which the disease is quiescent will rarely provide diagnostic information.

Retinochoroidal tissue is taken after dissecting using intraocular scissors and forceps. The preferred location for this surgical procedure is the superior and nasal retina. Intense endolaser or heavy endodiathermy at the margin of the biopsy is performed prior to long-acting gas or silicone oil tamponade.<sup>24</sup> In cases in which the retina is still attached, a cannula is used to inject saline under the sensory retina to create a small bleb. The advancing edge of the lesion should be included if retinitis is suspected, since actively replicating microorganisms are most likely to be found in this location.

The retinal or chorioretinal biopsy specimen should be divided in order to permit culture, histologic examination, and monoclonal antibody studies. PCR can be performed on the retinal tissue as well. However, it has been reported that retinochoroidal biopsies may be associated with the risk of retinal detachment and that false-negative results often occur in these specimens.<sup>25</sup> In addition, proper positioning is essential to maintain retinal tamponade after endoretinal biopsy.

Potential complications include vitreous hemorrhage, retinal detachment, and the potential for intraocular or extraocular dissemination. However, diagnostic vitrectomy using the vitrector to obtain tumor cells has resulted in no intraocular dissemination or increased metastasis to date.

## Diagnostic Techniques for Vitrectomy Specimens

Ancillary tests have been invaluable in addressing the diagnostic limitations of traditional histopathologic and microbiologic analyses. Flow cytometry, gene rearrangement studies, and cytokine measurements are useful adjuncts to cytologic analysis for

diagnosis of malignancy, in particular, primary intraocular lymphoma (PIOL). Selecting one or more of these tests depends on the preoperative diagnosis. Due to the limited volume of samples obtained, the number of diagnostic tests that can be performed is limiting. Differences in reported yields have been attributed to patient selection with higher diagnostic yields for clinical suspicion of infection or lymphoma. Clinicians should be aware of the sensitivity, specificity, and overall positive and negative predictive values of the diagnostic test to avoid misinterpreting the results.

## **Cytologic Evaluation**

Cytologic evaluation helps to differentiate infectious, noninfectious, and malignant etiologies. Cytologic examination reveals the phenotypes of infiltrating cells into the vitreous in malignancy and microbe or fungal hyphae in infectious etiology. Noninfectious etiologic diagnosis is based on presence of nonspecific inflammatory cells. Vitreous humor fluid obtained by PPV is centrifuged, and the cells are smeared onto glass slides and then either immersed in 95% ethanol for Papanicolaou staining or left to dry for subsequent Giemsa staining. The diagnosis of a PIOL depends primarily on cytologic examination of the vitreous sample. It might be difficult to differentiate retinal cells from malignant lymphoma cells by the Pap stain because they appear as mostly round cells by the Pap stain. However, cellular processes can be clearly differentiated using the Giemsa stain. Therefore, Giemsa stain is recommended when performing intraocular cytology. The characteristic feature, from either Giemsa or Diff Quick staining, is the presence of large B-cell lymphoblasts and atypical lymphocytes with high nuclear/cytoplasm ratios amongst small round lymphocytes.<sup>26</sup> However, diagnosis of PIOL is difficult, resulting in a high false-negative rate due to the small sample volumes with low number of malignant cells, inadequate preparation of samples or carrying media, and previous administration of corticosteroids.

In chronic endogenous uveitis, cytology reveals classic degenerative inflammatory cells with poor morphology, although cytologic examination of the vitreous specimen can be difficult because there may be a relative lack of inflammatory cells. Cytologic examination can also be helpful in diagnosing

sarcoidosis. Kinoshita et al. showed multinucleated giant cells in 85.7% of cases and lymphocytes and epithelioid cells in all cases of intraocular sarcoidosis.<sup>4</sup>

## **Histopathologic Evaluation**

It is recommended that the biopsy tissue be immediately processed by an ophthalmic pathologist. The biopsy specimen is generally divided into three portions: one-third is fixed for routine histopathologic evaluation, including light and electron microscopic examinations. The second portion is frozen in optimal cutting temperature embedding compound for immunopathologic and molecular characterization. The third portion is sent for culture of viruses and other microorganisms or for tissue culture. If the biopsy specimen is not sufficient for all three aforementioned procedures, the tissue should be processed for frozen sections, as these can undergo routine histopathology, immunohistochemistry, and molecular analysis. Svozilkova et al. reported that the highest percentage of positive results was achieved by histopathologic evaluation in uveitis.<sup>2</sup>

One interesting indication for histologic evaluation is ocular toxocariasis, which has a variable presentation, from localized peripheral or macular granulomas to chronic endophthalmitis. Histologic analysis reveals peripheral granuloma with fibrous membrane. Histologic evaluation can also be helpful in the diagnosis of ocular tuberculosis. In specimens from patients with ocular tuberculosis, microscopy reveals necrotizing granulomatous inflammation with the presence of a giant cell near the area of necrosis.

## **Microbiologic Culture**

Microbiologic culture plays a crucial role in the diagnosis of infectious diseases. However, microbial culture collections are challenging due to difficulty in obtaining and manipulating the vitreous samples. When an infectious cause is suspected, different types of microbial culture media are recommended for isolation of the causative agent: for bacterial infections, blood agar, MacConkey agar, and *Brucella* agar are used; for infections caused by pathogenic fungi and yeast, Sabouraud dextrose agar is used; for viral

infections, shell vial culture is used, in which the final pathogen is identified on the basis of the cytopathic effects.

To diagnose infection, vitreous samples are routinely sent for Gram staining, culture, and antibiotic sensitivity tests. Currently, microbiologic culture is still the gold standard for diagnosing infectious uveitis (Fig. 126.2). Microbiologic cultures are recommended to be performed with undiluted vitreous specimen as soon as it is collected from the eye. Some authors advocate that the vitreous wash fluid that is collected in the vitrector cassette can be used for additional filtered microbiologic cultures. Diluted samples are passed through a Millipore filter and the filter, which contains the microorganisms and cellular elements on the surface, is then cut and used for culture. It should be kept in mind that a negative microbiologic culture does not prove the absence of infection. If the first trial fails, clinicians are recommended to repeat the microbiologic culture. Vitreous tapping can be performed in the outpatient clinic in vitrectomized eyes.

**FIG. 126.2** Morphology of *Candida albicans* on Sabouraud Dextrose Agar (SDA) agar at incubation time of 24 hours and incubation temperature of 30 °C. Gram stain showing gram-positive, 2–8- $\mu$ m sized, oval, budding yeast cell. Magnification  $\times$ 1000.

Some experts advocate immediate culture inoculation by the

surgeon in the appropriate media in order to maximize organism recovery.<sup>18</sup> However, in viral retinitis it should be noted that viral cultures of the vitreous can reveal false-negative results because of neutralizing antibodies or low viral shedding. In addition, communication with the microbiologists to hold long-term cultures, sometimes for a month, is important to avoid missing slower-growing organisms such as *Propionibacterium acnes* and fungi.<sup>27-29</sup>

## **Molecular Analysis**

The most obvious reason for performing a molecular analysis is to rule out lymphoma as the cause of a masquerade syndrome and to identify the causative agents of infections. For PIOL, molecular analysis of vitreous specimens is primarily used to study the genotypic classification of PIOL with the goal of identifying prognostic factors. As an example, with *bcl-2* gene translocation, it has been reported that patients were significantly younger than those who lacked the translocation, suggesting the need for aggressive treatment based on this molecular signature.<sup>30</sup> PCR is also used to detect monoclonality within the variable region of the third complementary determining region (CD3) in the immunoglobulin heavy chain gene of malignant B-cells. Single-band detection of immunoglobulin heavy chain rearrangement can also be useful in PIOL.<sup>31</sup>

For infections, it is important to detect the DNA of microorganisms in the aqueous or vitreous humor and this is done by PCR, as it amplifies minute quantities of nucleic acid from infectious organisms and viruses into analytic amounts.<sup>32</sup> A PCR diagnosis is very useful since only a small quantity of ocular samples is required for the detection of a causative agent. For example, the addition of PCR to identify bacterial DNA has increased the diagnostic sensitivity from 48% to more than 80%.<sup>33</sup> Recently, some authors attempted to use various approaches for DNA extraction with PCR to enhance PCR sensitivity.<sup>34</sup> Samples were first analyzed by multiplex quantitative real-time PCR for various viral pathogens. Subsequently, samples were examined by broad-range real-time PCR for bacterial and fungal pathogens. Their results indicate that a comprehensive PCR system can be used to diagnose infectious uveitis with high positive results. PCR can

also be used to screen vitrectomy samples for a variety of pathogens, such as *Propionibacterium acnes* or *Mycobacterium tuberculosis*, in unresponsive or atypical uveitis cases.<sup>35</sup> Microbial DNA amplification by PCR and intraocular antibody measurement is particularly helpful in detecting infection by organisms that are difficult to culture. Moreover, prior short-term use of intravitreal antibiotics does not seem to affect the ability of PCR-based DNA amplification.

## **Flow Cytometry**

Flow cytometry allows concurrent analysis of several different cell surface markers. This technique involves centrifuging diluted vitreous and resuspension in cell culture medium. Cells are counted and stained with antibodies to detect cellular surface markers that identify leukocytes. In addition, flow cytometry has been shown to be useful in the diagnosis of intraocular lymphoma.<sup>36</sup> The test relies on the fact that most PIOLs are composed of monoclonal populations of B-cell lineage origin that stain positive for B-cell markers. Combined analysis by cytologic examination and flow cytometry appears to be more confirmatory for lymphoma than using either test alone. Both techniques require a sufficient number of cells and an experienced cytopathologist.

## **Cytokine Measurement**

Cytokine assay measurement can provide polymorphonuclear cellular activity. B-cell malignancies can secrete high levels of interleukin (IL)-10, an immunosuppressive cytokine, while inflammatory conditions are associated with high levels of IL-6, a proinflammatory cytokine. Some authors have shown that PIOLs can produce high IL-10 levels, with IL-10/IL-6 ratios of greater than 1.<sup>37</sup> Cytokine levels and IL-10/IL-6 ratios by themselves are not diagnostic of PIOL, but they can be useful adjunctive tests in corroborating the diagnosis of PIOL and determining whether there is a significant response to treatment. In contrast to a molecular analysis, the measurement of cytokine levels via ELISA (enzyme-linked immunosorbent assay) is much easier. Therefore, measurement of IL-10 and IL-6 levels is recommended for patients with suspected PIOL in hospitals where a cytopathologist is not

present.

The use of the cytokine analysis is now widely accepted in clinical practice to facilitate differentiating the cause of endogenous uveitis. For ocular sarcoidosis, Kojima et al. demonstrated that the CD4/CD8 ratio of vitreous-infiltrating T lymphocytes has high diagnostic value, and this was demonstrated by a combination of PCR, cytology, and flow cytometry.<sup>38</sup> We have also shown that the intraocular cytokine or chemokine environment can vary between patients; therefore, the underlying immunopathogenesis may be different between endogenous uveitis cases.<sup>39,40</sup> Because the vitreous is considered to be a reservoir of proinflammatory mediators that contribute to the development of many inflammatory diseases of the eye, vitreous samples can be a valuable tool for accurate diagnosis of the pathogenic mechanism.

## Future Directions

Diagnostic yields of vitrectomy specimens depend on initial patient selection, number and types of tests used, and the vitrectomy technique employed. Considering that a diagnostic vitrectomy may be performed after treatment with antibiotics or antiinflammatory medications, microbial load and malignant cell counts may be suppressed, thus yielding false-negative results. More sensitive diagnostic techniques are needed to overcome this problem. Commercially available laboratory approaches such as a comprehensive PCR system can be used for ocular infectious diseases in the near future. An additional factor that can affect the diagnostic outcome is the lag time between collecting and processing the specimen. For a prompt identification of causative agents, a rapid and accurate diagnostic system is required. Moreover, future studies will be aimed at exploring the genotypic classification of PIOLs based on the quantitative molecular framework of gene expression profiling with the goal of providing useful adjuncts to the pathologic diagnosis of this complex disease.

## Therapeutic Vitrectomy

In the past, vitrectomy was reluctantly recommended for uveitis

patients due to the high incidence of complications, including uncontrolled inflammation, retinal tears or detachment, proliferative vitreoretinopathy, cataract, and hypotony. Recently, rapid advances in microsurgical techniques have contributed to safer surgical intervention for ocular inflammation. In general, therapeutic vitrectomy aims at improving vision by clearing the visual axis, reducing inflammation in active disease and thereby treating nonresolving cystoid macular edema. Vitrectomy facilitates postoperative control of inflammation by immune-suppressive drugs, perhaps by removing a depot of activated lymphocytes, and cytokines and increasing the effectiveness of drugs or by improving penetration of drugs into the eye.

## Indications

Therapeutic vitrectomy for uveitis is conventionally indicated for (1) media opacity causing significant visual loss;<sup>41</sup> (2) intractable cystoid macular edema (CME);<sup>42</sup> (3) cyclitic membrane removal for the treatment of nonresponding hypotony; and (4) other vitreoretinal complications, including traction retinal detachment, rhegmatogenous retinal detachment, macular pucker, hemophthalmos, hypotony,<sup>43</sup> or macular hole.<sup>44</sup> Recent advances in vitrectomy techniques have expanded the indications for therapeutic vitrectomy. Vitrectomy can be used as an adjunctive procedure with intravitreal applications of antiinfectious, cytostatic drugs, or intravitreal sustained-release drug implants.<sup>45-47</sup>

The risks and benefits of therapeutic vitrectomy for uveitic disease seem to be similar to those described for diagnostic vitrectomy; patients should be informed before surgery so that the patient's expectations can be adjusted accordingly.

## Surgical Principles and Techniques

It is well recognized that chronic inflammation, even a low-grade one, can irreversibly damage the retina and optic nerve. As such, inflammatory control, both pre- and postoperatively, is vital. Preoperative rigorous control of inflammation is critical for a good surgical outcome. With a few exceptions, such as rhegmatogenous retinal detachment and infectious endophthalmitis, surgery should

be performed when inflammation is quiescent. It is certainly advisable to adequately suppress inflammatory activity utilizing topical, regional, and systemic steroids for a minimum of 3 months prior to surgery. Previous studies consistently demonstrate the importance of perioperative control of inflammation. Systemic corticosteroids are still the best drugs for controlling inflammation during the perioperative period. We prefer administering steroids one day before surgical intervention; typically, 1 mg/kg per day of steroid treatment is adequate. However, when diagnostic vitreous biopsy is also planned, ensuring that patients with suspected PIOL are not receiving corticosteroid medication at the time of vitrectomy improves the diagnostic yield for lymphoma, since lymphoma cells degenerate in response to corticosteroid treatment.<sup>48</sup>

A standard 20G, 23G, 25G, or 27G three-port PPV are currently used. Special attention needs to be given to the removal of peripheral vitreous base and posterior cortical vitreous. Since the largest accumulation of vitreous opacities is often found in the vitreous base and remnant posterior cortical vitreous, providing a platform for fibroglial proliferation, near-complete vitreous removal is of high importance. The peripheral retina becomes usually thin and fragile due to the long-standing intraocular inflammation, making it vulnerable to tearing and subsequent detachment. During peripheral vitrectomy, careful shaving of the vitreous base using scleral depression techniques and high cutting rate with low aspiration is essential to avoid iatrogenic tears. Wide-angle viewing systems have allowed for much better visualization of the peripheral retina so that nearly complete removal of the vitreous base is possible. Triamcinolone acetonide has been used during vitrectomy as an aid to visualize residual vitreous cortex and peripheral vitreous.<sup>49</sup> The use of surgical adjuvants is now widely accepted in clinical practice to facilitate peeling of the internal limiting membrane (ILM) during vitrectomy because membranes in uveitic eyes are very fragile and adhere to the retina. Indocyanine green (ICG) can also be used to visualize the ILM during PPV and ILM peeling.<sup>50</sup> The ILM can also be selectively stained by brilliant blue G, which is less toxic to the retina than ICG.

Giant retinal tears that may complicate viral retinitis, such as acute retinal necrosis or cytomegalovirus retinitis, are managed by

vitrectomy with or without scleral buckling. In viral retinitis, the retina becomes necrotic with possible ischemic areas. The use of a high buckle might increase this ischemia, leading to retinal neovascularization, so a broad low buckling is recommended. An alternative option is to perform a PPV and to reattach the retina with gas or silicone oil tamponade, with laser photocoagulation. However, laser photocoagulation should be performed very carefully and at the physician's discretion because it promotes postoperative inflammation.

Cataract extraction is often combined with vitrectomy since cataracts are a common complication of intraocular inflammation as well as a complication of long-term corticosteroid therapy. The operator should take special care to avoid contact with the iris during the procedure. An intraocular lens (IOL) can be implanted in the bag during combined cataract extraction with vitrectomy though it was not recommended in the past. The use of disposable iris retractors will provide the surgeon with an adequate view in patients with posterior synechia and small pupil. The pupillary aperture can also be enlarged with the vitrectomy probe or vitreous scissors. In patients with synechia, in-the-bag implantation of the IOL is important because postoperative recurrence of synechia can cause serious complications.

Intravitreal administration of drugs at the end of therapeutic PPV may alone be sufficient to decrease inflammatory activity. Administration of intravitreal triamcinolone acetonide at the end of vitrectomy can effectively reduce immediate postoperative inflammation, which has been demonstrated in patients with retinal vascular diseases and proliferative vitreoretinopathy.<sup>51,52</sup> Antimicrobial medications can be administered at the end of vitrectomy in patients with viral, bacterial or fungal endophthalmitis. In patients with fungal endophthalmitis, intravitreal application of amphotericin B alone inhibited uveitis activity, and no exacerbation was observed during the postoperative period.<sup>2</sup>

## Outcomes

Vitrectomy can be safe and effective for management of

vitreoretinal complications in patients with persistent panuveitis.<sup>44,53,54</sup> Retinal detachment, vitreous hemorrhage or macular hole can be successfully managed with vitrectomy. Visual improvement has also been reported in most patients who underwent vitrectomy in uveitis cases.<sup>55</sup> It has been suggested by several authors that PPV reduces or eliminates recurrences of inflammation because it reduces the antigen load, inflammatory mediators or toxic elements from the vitreous. Moreover, a clear vitreous cavity facilitates diffusion of intravitreally injected drugs and permits better examination of the eye postoperatively. However, although the removal of the vitreous can decrease accumulation of cells and haze during an episode of inflammation, vision can be affected by new inflammatory episodes.

Some retrospective studies suggested that PPV can reduce the overall inflammatory activity of disease, and improve refractory uveitic CME.<sup>56</sup> Vitrectomy may also modulate the natural history of inflammation in patients with intermediate uveitis. A prospective randomized pilot study also reported the comparison of PPV with immunomodulatory therapy for patients with intermediate uveitis.<sup>57</sup> A higher percentage of patients treated with PPV achieved resolution of uveitis compared to those given immunomodulatory therapy, although there was no statistically significant difference in visual outcome for either group during the 18-month follow-up.

Visual improvement has been reported for vitrectomy treatments for epiretinal membranes associated with pars planitis and sarcoidosis. Epiretinal membrane peeling usually results in significant visual improvement and restoration of normal foveal contour in patients with uveitis,<sup>58</sup> even though the efficacy of ILM peeling seems to be controversial (Fig. 126.3). However, there is a possibility of poor visual outcome associated with CME or recurrence of the membrane with persistent inflammation. Moreover, associated vascularization or scarring of the underlying retina is more common with epiretinal membranes associated with uveitis, which can limit positive visual outcome. Outcomes of PPV with silicone oil tamponade were reported in patients with chronic hypotony due to uveitis.<sup>43</sup> Eyes with posterior inflammation contained a dense anterior hyaloid that may be associated with ciliary body traction. If ciliary atrophy was present, intraocular

pressure was restored only in eyes that received silicone oil tamponade treatment.

**FIG. 126.3** (A) Epiretinal membrane is present in a 57-year-old patient with intermediate uveitis. (B) On spectral domain optical coherence tomography (OCT), epiretinal membrane with macular edema could be visualized. (C) Postoperative photograph revealed smooth macula without epiretinal membrane. (D) Postoperative OCT revealed normal foveal contour.

Postoperative complications such as hypotony, retinal detachment, and vitreous hemorrhage should be kept in mind after vitrectomy in uveitis. Hypotony generally responds to topical, systemic, or periocular/intraocular corticosteroids. Recurrence of uveitis following vitrectomy can also occur. Vitreous cells are sparser and affect vision less because the vitreous gel is absent. There may be a false sense that the inflammation is entirely under control in the absence of vitreous cellular reaction.

Some issues still remain controversial, including whether vitrectomy reduces the activity of disease and the number of recurrences, and whether vitrectomy actually reduces CME. A

large, prospective, randomized clinical trial is needed to draw a firm conclusion on the subject. In addition, clinicians should keep in mind that vitrectomy improves visual acuity and inflammatory control in some patients, but postoperative complications such as retinal detachment, vitreous hemorrhage, and high intraocular pressure can limit the visual outcome.<sup>2</sup>

## Future Directions

The complexity of performing a prospective study for vitrectomy in uveitis is at the present very difficult. No randomized clinical trials or comparative interventional case series have tested the hypothesis that vitrectomy has an antiinflammatory effect independent of its role in correcting uveitic complications or clearing the ocular media. A large, randomized, prospective clinical trial is required to test this hypothesis. In addition, biologic plausibility of vitrectomy in uveitis is still lacking, including topics such as postvitrectomy reduction in intraocular inflammatory mediators and changes in the vitreoretinal interface influencing CME. Further work is needed to verify these hypotheses. Improved applications of antibiotic therapies and control of inflammation should be pursued. In addition, blocking the products of inflammatory reactions is a worthwhile therapeutic goal. A more systematic investigation would support the perceived importance of vitrectomy in the management of uveitis.

## Conclusion

The major indications for performing vitrectomy in uveitis cases are to analyze vitreous fluid for diagnostic purposes and to treat complications. Vitreous biopsies are routinely used to help diagnose patients with posterior uveitis of uncertain etiology. Vitreous biopsy for uveitis can be both diagnostic and therapeutic for patients who have life-threatening but treatable illnesses. It is important that the procedure be safe, yield a large volume of high-quality sample, and, ideally, be cost-efficient. When performed appropriately, diagnostic vitrectomy with carefully selected ancillary testing is a valuable tool for the assessment and diagnosis

of uveitis in a large proportion of patients. Key factors that can improve diagnostic yield include obtaining sufficient volume of cells from the vitreous or subretinal space, choosing appropriate tests for specimen analysis, informing the laboratory of the suspected clinical diagnosis, promptly delivering the samples, and having the diagnostic tests performed by experienced personnel. Moreover, with the advent of modern vitreoretinal microsurgical techniques, the spectrum for surgical intervention in various forms of uveitis has been notably expanded and the visual outcomes have been improved. Removal of optically relevant vitreous opacities, improvement of CME, peeling of epiretinal membranes, and release of traction in the presence of abnormal vitreoretinal adhesions are the most common indications for vitreoretinal procedures in the management of uveitis patients.

## **Introduction**

The diagnosis of posterior segment infectious or inflammatory disease is based primarily on clinical examination. In the majority of cases, the slit-lamp biomicroscopic and ophthalmoscopic appearance of the vitreous, retina, and choroid is diagnostic of a specific disorder, especially when combined with the findings from ancillary tests such as fluorescein angiography, ocular echography, and radiologic and serologic tests.<sup>1</sup>

However, not all patients have the characteristic clinical features or classic appearance of a specific disease, and the etiology of their disorder can be a diagnostic dilemma. The inability to make a specific diagnosis has been reported in up to 33% of patients who present with intraocular inflammation.<sup>2</sup> Moreover, some infectious and malignant processes are manifested first, or only, in the eye, in which case the diagnostic yield from systemic testing is low. This is often the situation in patients with atypical malignancy in the eye; chronic low-grade endophthalmitis after cataract surgery; intraocular inflammation of atypical viral, bacterial, or fungal origin; and some types of progressive retinitis, choroiditis, and pigment epitheliopathies. In these patients, particularly if they are immunocompromised or if one of the possible diagnoses is malignancy, the disease process may threaten not only vision but also life. Intraocular biopsy provides affected ocular tissue for culture, examination, and other tests to help with therapeutic decision-making.<sup>3</sup> In most of these cases, therapeutic intervention will be either antimicrobial, antineoplastic, or antiinflammatory.<sup>4,5</sup>

A number of factors in recent years have brought about an increased demand for tissue diagnosis in posterior segment

inflammatory disease. One of these is the rise in the number of individuals who have been iatrogenically immunosuppressed as a result of systemic disease, malignancy, or organ transplantation. In addition, the frequent use of intravitreal steroids has also led to the report of opportunistic ocular infections in immunocompetent individuals.<sup>6</sup> The clinical presentation of ocular inflammatory disease may be variable and atypical in these immunocompromised patients; the possible etiologic agents are numerous and diverse, and serologic testing is frequently misleading. Another factor increasing the indication for intraocular biopsy is the common practice in modern cataract surgery to place intraocular lenses directly into intact capsular bags. These capsular bags can rarely serve as small reservoirs and sequester low-virulent organisms which multiply, and subsequently clinicians are confronted with a chronic, smoldering, postoperative endophthalmitis that is due to organisms such as *Candida parapsilosis* or *Propionibacterium acnes* (Figs. 127.1–127.5). These cases often cannot be adequately treated until a tissue diagnosis is made.

**FIG. 127.1** After cataract surgery, inflamed eye of a patient with chronic indolent uveitis is caused by *Candida parapsilosis*.

**FIG. 127.2** *Candida parapsilosis* organisms crowd this capsular bag, surrounded by an area of dense neutrophilic incursion.

**FIG. 127.3** Characteristic posterior capsular plaque seen in a patient with chronic postcataract inflammation caused by *Propionibacterium acnes*.

**FIG. 127.4** *Propionibacterium acnes* organisms fill the capsular bag in this patient with smoldering endophthalmitis and retinal detachment more than 1 year after cataract surgery.

**FIG. 127.5** High-power view of the *Propionibacterium acnes* organisms seen in [Fig. 127.4](#).

Ongoing advances in laboratory testing continue to improve the diagnostic yield from biopsied material. For example, polymerase chain reaction (PCR) testing, a biochemical technique, is able to

detect infinitesimally small amounts of specific nucleic acids, which permits identification of genetic components of infectious organisms. In fact, modifications to traditional PCR methods (multiplex, nested PCR) allow for simultaneous testing for numerous pathogens such as herpes simplex virus (HSV), varicella-zoster virus (VZV), and cytomegalovirus (CMV) without significant loss in sensitivity or specificity.<sup>7</sup> This allows for quick and efficient testing for multiple pathogens. Furthermore, quantitative PCR (qPCR) allows for in situ quantification, thus allowing the clinician an idea of the disease burden.<sup>8</sup>

Finally, advances in vitreoretinal surgical instrumentation and increasing use of 25- and 23-gauge (G) transconjunctival pars plana vitrectomy<sup>9</sup> have allowed for possibly safer access and acquisition of ocular tissue for analyses. [Table 127.1](#) lists common indications for ocular biopsy.

---

**TABLE 127.1**  
**Common Indications for Biopsy**

---

Biopsy Site	Diagnostic Dilemma
Vitreous	Endophthalmitis (bacterial or fungal)
	Intraocular lymphoma
	Retinitis with associated vitritis
Retinal	Retinitis (atypical or not responsive to empiric therapy)
Choroidal	Tumor
	Choroiditis (atypical or not responsive to empiric therapy)

The efficacy of ocular biopsy depends partly on the expertise of the surgeon who obtains the specimen and the laboratory personnel who analyze the specimen(s). Before embarking on surgery, harvesting and handling of the specimen should be carefully mapped out in advance. The pathologist should be familiar with ophthalmic disease processes, aware of the diagnoses being considered, and involved at the outset in planning how the specimen will be handled from the moment it is taken – a step that is critical to the success of the procedure.<sup>4,10,11</sup>

The pathologist's available investigative methods include, among others, light microscopy, electron microscopy, immunohistochemistry, and PCR. PCR can be used to identify unique DNA and RNA sequences specifically from infectious agents and, occasionally, from other disease processes, such as

proliferating monoclonal B lymphocytes in ocular malignant lymphoma.<sup>11-15</sup> The laboratories responsible for culture and identification of bacterial, fungal, and viral disease should receive the specimen as soon as possible. It should be plated on a variety of specific media and maintained under the correct (aerobic, anaerobic, temperature) conditions. Plates may need to be specially treated or held for extra time to reveal growth from some of the more fastidious organisms. Despite disadvantages such as inability to detect certain microbes and relatively low yield compared to more modern testing such as PCR, microbial culture remains the gold standard for the diagnosis of most intraocular infections.

## Vitreous Biopsy

With the evolution of modern vitrectomy techniques, including 23G, 25G, and 27G vitrectomy, removal of vitreous from the eye has become a common and relatively safe procedure.<sup>16</sup> A number of different goals are achieved with diagnostic vitrectomy.<sup>5,17</sup> In vitritis with a possible neoplastic, infectious, or inflammatory cause, diagnostic vitrectomy may provide a definitive diagnosis, thereby allowing appropriate therapy to be instituted.<sup>5,10</sup> In some cases of retinitis and choroiditis, a diagnosis can be made from vitreous sampling alone, particularly if marked vitritis is present. The vitrectomy also removes or debulks infectious material within the eye, reduces the intraocular load of inflammatory cells and debris, effectively removes material (e.g., retained lens material and blood) that may be part of the pathogenesis of the ocular disorder, allows clinicopathologic correlation in the active stages of disease for some conditions, and helps to define the pathophysiologic basis of many disorders.<sup>5</sup> Cytopathologic diagnosis has proved valuable in reported series or case reports of patients with endogenous and exogenous bacterial and fungal infections (Fig. 127.6); nematode endophthalmitis; inflammatory pseudotumor of the iris and ciliary body; pars planitis; phacoanaphylaxis; intraocular lymphoma; leukemia; metastatic melanoma; metastatic carcinoma; medulloepithelioma of the ciliary body; secondary glaucoma (including blood-induced, phacolytic, and melanolytic glaucoma); epithelial ingrowth; proliferative vitreoretinopathy; and

miscellaneous conditions with vitreous opacities (including chronic inflammation in patients with suspected lymphoma, acute retinal necrosis, birdshot chorioretinopathy, toxoplasmosis, Whipple disease, amyloidosis, and asteroid hyalosis).<sup>4,5,18,19</sup> Vitrectomy may also help to clear vitreous opacities, remove scaffolding on which postoperative cicatricial proliferation can grow, relieve traction, and allow for improved intraocular penetration of antibiotics.<sup>5,17</sup> [Table 127.2](#) lists a sample of vitreous findings in major disease categories.

**FIG. 127.6** This 61-year-old woman had a history of idiopathic uveitis, quiescent for years, and cataract surgery 10 years previously. She developed a red eye and decreased vision with active anterior segment inflammation, shown here with cellular and fibrinous anterior chamber deposits. A retinal detachment was noted on echography. Examination of smears and culture of the vitrectomy specimen from the time of detachment repair revealed *Cryptococcus* organisms.

**TABLE 127.2**

**Sample of Vitreous Findings in Major Disease Categories**

	Noninfectious Uveitis	Infectious Uveitis	Tumor
Cells	Inflammatory	Microbes	Malignant cells
Immunohistochemistry	CD4 <sup>+</sup> cells	Polymorphonuclear cells	Light chain restriction in lymphoma
Culture	Negative	Positive	Negative
Antibody	Negative	Positive	Negative

Cytokines	IL-1, -2, -6	IL-6	IL-10
Polymerase chain reaction	No gene sequences	Microbial or viral products	CDR3 of IgH gene

## Surgical Technique

To obtain an undiluted specimen, a variety of vitrectomy techniques (with either 20-, 23-, 25-, or 27G instrumentation) may be used. If a large sample (>0.5 mL) of vitreous is needed, a standard three-port vitrectomy system should be utilized. A 10-mL Luer-Lok syringe is spliced via a three-way stopcock into the aspiration line (Fig. 127.7). Manual aspiration and specimen collection are carried out for retrieval of an undiluted specimen from the most intensely involved area (usually posteriorly, inferiorly, or over the area of retinitis or chorioretinitis).

**FIG. 127.7** Technique of specimen collection in diagnostic vitrectomy. A 10-mL syringe is spliced into the vitrectomy aspiration tubing, and a choice undiluted specimen is obtained with manual aspiration.

Alternatively, a vitreous “trap” method may also be performed using two 18G needles, a male adaptor, and a sterile red-topped test tube.<sup>20</sup> In the vitreous trap method, the male adaptor is attached to one of the needles and the needles are attached to the ends of the aspiration tubing. The two needles are then inserted into the test tube. The diagnostic vitrectomy is performed, and the pure vitreous

sample is directed into the test tube.

After a sufficient amount of sample is obtained, the infusion is turned on and either fluid or air is infused before large choroidals form and the eye begins to collapse.<sup>16</sup> The vitrector is withdrawn from the eye, and the vitreous specimen is aspirated into the syringe. Vitrectomy can then be completed. At completion of the surgery, the cassette with the dilute residual vitreous is also sent to the pathology laboratory, where the specimen is concentrated, using a micropore filter, or cytopspin smears are made.<sup>4,21</sup>

If a small sample ( $\leq 0.5$  mL) of vitreous is needed, a 27G vitrectomy with a single incision may be utilized.<sup>22,23</sup> In this technique, the 27G vitrector is inserted perpendicular to the pars plana. Using a cut rate of 800 cuts/minute and an aspiration rate of 600 mmHg, a small amount of undiluted vitreous may be safely removed from the eye without the need of an additional infusion line or endoillumination port. The 27G scleral wound is also self-sealing and does not require sutures.

## Histologic Technique and Preparations

The number of investigations that can be carried out on an individual specimen depends on the amount of harvested material. Ideally the undiluted vitreous specimen is plated for aerobic and anaerobic bacterial, fungal, and (occasionally) viral culture if an infectious etiology is suspected. An aliquot is collected for immediate Gram stain, periodic acid–Schiff stain, and Giemsa stain, and another one is done for PCR analysis. The remainder is kept for light and electron microscopy or immunohistochemistry.

If primary intraocular lymphoma is suspected, obtaining a sufficient vitreous sample for cytologic testing is essential. Consultation with an experienced cytopathologist is recommended because correct identification of lymphoma cells in the biopsy sample is essential for the diagnosis. In addition to characterizing cells from the vitreous biopsy, testing for immunohistochemical markers for leukocytes (e.g., CD45), B cells (e.g., CD 20), and T cells (e.g., CD45RO) can also aid in the diagnosis.<sup>16,24,25</sup> Other diagnostic modalities that can be useful include flow cytometry, PCR to detect V–J immunoglobulin gene rearrangements, and measurements of

interleukin (IL)-6 and IL-10 in aqueous or vitreous samples.<sup>24-26</sup>

Table 127.3 summarizes the key laboratory features of several patients who underwent 25G diagnostic vitrectomy for suspected intraocular lymphoma. Additional information on the diagnosis and management of primary intraocular lymphoma is available in Chapter 159, Leukemias and lymphomas.

**TABLE 127.3**

**Summary of Vitreous Biopsy Results in Series of Patients With Intraocular Lymphoma**

Patient	Cytopathology	Flow Cytometry	Gene Rearrangement	Final Diagnosis
1	Scattered lymphocytes, monocytes	CD45 (bright), CD19 (dim), monoclonal $\kappa$ light chain	IgH gene rearrangement detected	B-cell intraocular lymphoma
3	Atypical lymphoid cells with irregular nuclei, lymphocytes	T-cell leukemia, abnormal CD3 (dim) population	TCR gamma gene rearrangement detected	T-cell intraocular lymphoma
9	Atypical lymphoid cells with irregular nuclei and condensed chromatin	No evidence of lymphoma	IgH gene rearrangement detected	B-cell intraocular lymphoma
12	Atypical lymphoid cells with irregular nuclei	T-cell predominance, no evidence of lymphoma	$\kappa$ light chain gene rearrangement detected	B-cell intraocular lymphoma

## Results

In cases of infectious endophthalmitis, vitreous samples can often reveal the presence of microbes. Unfortunately, these may not be found in all infectious cases, principally because of suboptimal sampling, inadequate culturing, or pretreatment with antimicrobials that render microbes nonculturable on routine media.<sup>12</sup> In the Endophthalmitis Vitrectomy Study, confirmed microbiologic growth was demonstrated in intraocular specimens from 291 of 420 patients (69.3%).<sup>27</sup> More recently, PCR testing has been applied to identify bacterial causes of endophthalmitis. Very little tissue is needed for PCR. Usually 50–100  $\mu$ L samples are sufficient, but even a sample as small as 1  $\mu$ L can be processed for PCR testing.<sup>28</sup> Numerous studies have demonstrated PCR to be

sensitive and specific in diagnosing bacterial and fungal endophthalmitis, even when corresponding cultures were negative.<sup>29-31</sup> Furthermore, PCR has also been shown to be a useful tool in the diagnosis and management of challenging cases of infectious viral chorioretinitis.<sup>32</sup>

Several studies have shown that PCR has sensitivities exceeding 90% for varicella-zoster virus (VZV), herpes simplex virus (HSV), and cytomegalovirus (CMV), with specificities in excess of 95% for these organisms.<sup>28</sup> Sensitivity approaches 95% in detecting untreated CMV retinitis, dropping to 48% in treated eyes.<sup>33-35</sup> Moreover, false-positive rates are low.<sup>36</sup> In addition, PCR can aid in detecting antiviral-resistant strains of CMV, which have mutations in the UL97 polymerase gene.<sup>28</sup> Information on possible antiviral resistance is essential in the management of viral retinitis and may influence the choice of agent for a particular patient. Of note, PCR inhibitor has been detected in normal aqueous and vitreous fluids, but it can be removed by diluting the specimen, by chloroform extraction, or by thermostable DNA polymerases.<sup>37</sup>

The clinical indications for diagnostic vitrectomy and associated results were reported by Palexas and colleagues,<sup>38</sup> who published on 405 consecutive vitreous biopsy cases studied at the Wilmer Eye Pathology laboratory. Vitrectomy had been performed in six categories of eye disease: posttraumatic infections (8.4%); postoperative endophthalmitis (38.5%); endogenous endophthalmitis (6.2%); idiopathic inflammation (25.4%); intraocular neoplasm (14.3%); and miscellaneous (7.2%). Diagnostic vitrectomy was performed in 215 cases (53%) for suspected endophthalmitis. Of these cases, 60 (28.8%) had microbial organisms present, while only 36 (16.7%) were culture-positive. Of note, Gram-positive bacteria were most common in the postoperative endophthalmitis group (74%) while fungal infections were most common in patients with endogenous infections. Neoplasms were diagnosed in 58 (14%) of the 405 vitrectomy specimens, the most common being ocular lymphoma in 42 (72%) (Fig. 127.8). Other malignancies diagnosed cytopathologically included metastatic squamous cell carcinoma and acute lymphoblastic leukemia.

**FIG. 127.8** (A–C) Examples of tumor cells with large, round nuclei with numerous micronucleoli or prominent nucleoli and nuclear membrane infoldings. Millipore filter, modified Papanicolaou stain. (A,  $\times 1500$ ; B,C,  $\times 1900$ .)

Atypical toxoplasmic chorioretinitis that mimics viral retinitis can also be diagnosed by vitreous biopsy.<sup>39</sup> In a series of 22 patients with widespread chorioretinitis, 16 individuals were diagnosed with toxoplasmosis using PCR, culture, antibody detection, histopathologic examination, or a combination of the aforementioned techniques. Bottos and colleagues have also demonstrated the utility of PCR in diagnosing an atypical strain of *Toxoplasma gondii* as the causative agent in an unusual bilateral retinochoroiditis.<sup>40</sup> The correct diagnosis is important in challenging cases since treatment with proper medicines may help avoid vision loss.

In addition to advances in surgical technique and laboratory testing, the development of imaging modalities such as wide-field fluorescein angiography has also provided the clinician with increased information when managing complicated posterior uveitic conditions. For the first time, clinicians are able to obtain high-quality fluorescein images of the peripheral vasculature and

## Case 127 Pathologic changes.<sup>41,42</sup>

A 29-year-old white woman with history of acute myeloid leukemia, status post allogeneic bone marrow transplant 2 months prior, was referred for evaluation of blurred vision OD. She had recently been diagnosed with CMV colitis, but ganciclovir had been discontinued because of thrombocytopenia. Visual acuity was 20/320 OD. A serous retinal detachment of the macula was present with white flocculent material beneath it (Fig. 127.9). A chest radiograph examination at this time revealed a right lower lobe infiltrate interpreted as pulmonary aspergillosis. She was treated with systemic antibiotics, including amphotericin B and flucytosine, but 3 days later the ocular lesion was substantially larger (Fig. 127.10). A diagnostic vitrectomy was performed, and 5  $\mu$ g of intravitreal amphotericin B was given at the end of surgery. The vitreous specimen revealed branching septate hyphae and vitreous culture grew *Aspergillus flavus*.

**FIG. 127.9** Retinitis that developed from *Aspergillus* infection after bone marrow transplantation. (Reproduced with permission from Coskuncan NM, Jabs DA, Dunn JP, et al. The eye in bone marrow transplantation. VI. Retinal complications. Arch Ophthalmol 1994;112:372 – 9. © (1994) American Medical Association. All rights reserved.)

**FIG. 127.10** Same eye as in Fig. 124.9, shown 3 days later, despite intravenous amphotericin B and systemic flucytosine, with progressive fulminant infection. Histopathologic study of the vitreous biopsy disclosed branching, septate hyphae, and culture positivity for *Aspergillus flavus*. (Reproduced with permission from Coskuncan NM, Jabs DA, Dunn JP, et al. The eye in bone marrow transplantation. VI. Retinal complications. Arch Ophthalmol 1994;112:372–9. © (1994) American Medical Association. All rights reserved.)

### **Case 127.2**

A 36-year-old white man was seen with a 2-week history of blurred vision in the left eye. Past history was positive for systemic lymphoma stage IIIA, which was treated with total nodal irradiation and chemotherapy. A relapse was successfully treated with chemotherapy, resulting in remission for 3 years, until a bone marrow biopsy showed Burkitt's lymphoma. He was treated with chemotherapy, including seven intrathecal methotrexate injections for central nervous system relapse, and was referred for bone marrow transplantation. He had undergone bone marrow harvesting and had started cytoreductive therapy before transplantation. Vision was counting fingers. Fundus examination disclosed a retinitis involving the macula and optic nerve head with white vitreous opacities (Fig. 127.11). Diagnostic vitrectomy revealed atypical lymphocytes characteristic of lymphoma. The patient was treated with ocular irradiation, and his vision improved to 20/30 one month later (Fig. 127.12).

**FIG. 127.11** Ocular recurrence of lymphoma that developed after cytoreductive therapy and before bone marrow transplantation in a patient with previous chemotherapy and radiation. Vitreous biopsy revealed atypical lymphocytes consistent with a B-cell lymphoma. (Reproduced with permission from Coskuncan NM, Jabs DA, Dunn JP, et al. The eye in bone marrow transplantation. VI. Retinal complications. Arch Ophthalmol 1994;112:372–9. © (1994) American Medical Association. All rights reserved.)

**FIG. 127.12** Same eye as in Fig. 124.11, shown 1 month later. After ocular irradiation and bone marrow transplantation, the infiltrates have almost entirely resolved, and vision is 20/30.

### **Case 127.3**

A 53-year-old white male was referred for evaluation of bilateral anterior uveitis in the setting of recent branch retinal artery

occlusion (BRAO). The anterior uveitis was noted OU 3 days following the BRAO. Despite topical steroid eyedrops, the inflammation worsened and he was referred for evaluation. Examination revealed panuveitis with occlusive vasculitis in both eyes and possible acute retinal necrosis. Wide-field imaging allowed for accurate assessment of the degree of vascular nonperfusion (Figs. 127.13 and 127.14). He was empirically treated for possible infection with herpetic virus due to a high serum IgG positivity for herpes zoster virus. The patient's condition continued to progress despite empiric treatment, and a diagnostic vitrectomy was performed, which was negative for an infectious etiology by PCR and culture. Because of the negative vitrectomy, an infectious etiology was thought to be less likely and aggressive steroid therapy was initiated with significant clinical improvement.

**FIG. 127.13** Optos ultrawide-field imaging of right eye demonstrating superior/inferior arcade infarctions with peripheral ghost vessels and sheathing.

**FIG. 127.14** Ultrawide-field fluorescein angiography demonstrating disc leakage, large vessel leakage, and nonperfusion of inferior retina.

## Transvitreal Retinal Biopsy

Vitreous biopsy is limited by its dependency on the spillover of cells from the diseased tissue in question into the vitreous cavity to allow a diagnosis. Some ocular pathologic processes are primarily confined to the retina, choroid, or both, and only histologic examination of these areas can yield a diagnosis. The transvitreal approach to retinal biopsy is of particular value in lesions located posterior to the equator, although more peripheral lesions are also accessible, particularly in pseudophakic and aphakic eyes. This approach also allows concomitant vitreous sampling.<sup>43-47</sup>

### Surgical Technique

A three-port vitrectomy with either 20G, 23G, or 25G instrumentation is performed, and the cortical vitreous is removed. A chandelier illumination system can be placed as a fourth port to allow for bimanual vitrectomy and retinal biopsy. An appropriate site is chosen for the retinal biopsy, preferably in the superior and nasal retina, at the junction of infected and uninfected retina, as

peripheral as possible, and in a relatively avascular area.

The specimen should include the advancing edge of the retinitis because this is where actively replicating, viable organisms are most likely to be found. Central areas of the lesion may contain only necrotic tissue. Cautery at the area of the biopsy site is occasionally needed if large vessels are present. The tissue is excised with scissors, leaving a small area of anchoring attachment (Fig. 127.15). The biopsied retina is grasped securely with forceps so that as little as possible of the specimen is crushed and is removed from the eye (Fig. 127.16). Laser is not necessary at the biopsy edges involved by inflammation, but it is placed at the edges of normal retina. An air-fluid exchange is performed, and occasionally a long-acting gas is injected.

**FIG. 127.15** After cortical vitreous is removed, the retina is engaged with automated scissors and a specimen is excised, leaving a tiny tissue bridge to anchor the biopsy to the eye wall.

**FIG. 127.16** Technique of transvitreal retinal biopsy. Forceps are introduced into the eye, and the specimen is grasped securely but carefully so that as little as possible is crushed and removed from the eye. The cut edges of retina are then photocoagulated, and a fluid–gas exchange performed.

## Histologic Technique and Preparation

After the tissue sample is removed from the eye, it is immediately placed in glutaraldehyde/formaldehyde fixative. If orientation is important, the sample may be placed on a piece of filter paper or other material and the correct localization marked on the paper. This is an important point of discussion for the surgeon and the pathologist before the surgical procedure. Depending on the size of the specimen, it is processed for light and electron microscopy and immunohistochemistry.

## Results

Rutzen et al.<sup>48</sup> reported a series of 24 transvitreal retinal biopsies, 19 from eyes with clinical signs suggestive of viral retinitis. The clinical diagnosis was confirmed by electron microscopy, immunohistochemical staining, in situ DNA hybridization, and/or PCR in 10 of the 19 eyes (53%). Virus was identified in seven of 10 cases of suspected CMV retinitis, in one of seven cases of acute

retinal necrosis, and in two of two cases of progressive outer retinal necrosis. The remaining five biopsies disclosed *Candida* organisms in one specimen, subretinal fibrosis in one, and chronic inflammation in three.

Johnston and colleagues<sup>49</sup> performed a retrospective review of retinal and choroidal biopsies undertaken in cases of unclear uveitis of suspected infectious or malignant origin. In this series, 13 patients underwent either a retinal or choroidal biopsy. The pathologic diagnosis differed from the initial clinical diagnosis in five (38%) cases and helped to direct treatment in seven (54%) cases. Retinal biopsies were invaluable in making the proper diagnosis in

#### **Case 127.4**

A 65-year-old white man had metamorphopsia and a gray scotoma. His history was positive for non-Hodgkin lymphoma and two courses of chemotherapy, followed by autologous bone marrow transplantation 7 months previously. Vision was 20/400, and white macular retinitis was seen with minimal vitreous inflammation (Fig. 127.17). A retinal biopsy disclosed intracytoplasmic nucleocapsids measuring 120–140 nm and several intracytoplasmic spherical electron-dense bodies measuring 120–350 nm, consistent with CMV retinitis (Fig. 127.18). The PCR analysis of the vitreous was also positive for CMV. The infection responded well to ganciclovir (Fig. 127.19).

**FIG. 127.17** Macular retinitis after bone marrow transplantation in a 65-year-old man.

**FIG. 127.18** Same eye as in Fig. 127.17. Retinal biopsy disclosed cytomegalovirus cells, with cytoplasmic particles typical of herpes virus. Polymerase chain reaction was positive for cytomegalovirus.

**FIG. 127.19** Same eye as in Fig. 127.17, 1 month after the biopsy. With the patient undergoing ganciclovir treatment, the retinitis is resolving well. Note the healed biopsy site just below the superotemporal arcade.

### **Case 127.5**

A 34-year-old white man developed blurred vision and floaters in his left eye. He had a history of bone marrow transplantation, with graft-versus-host disease requiring persistent immunosuppression. At first the white peripheral retinitis was thought to represent

CMV infection, and he was unsuccessfully treated with ganciclovir (Fig. 127.20). Because of the atypical clinical picture (including no old toxoplasmic scars on earlier ophthalmologic evaluation), a retinal biopsy was performed, disclosing *Toxoplasma* organisms (Fig. 127.21).

**FIG. 127.20** Atypical retinitis featuring active borders with central scarring. Retinal biopsy confirmed *Toxoplasma* infection. specimen.

## Transvitreal and Transscleral Choroidal Biopsy

In certain ocular disease processes, the pathologic evidence is primarily located at the level of the choroid. In such cases, the cells recovered by vitrectomy may be nonspecifically inflammatory in nature and not representative of the actual disorder.<sup>50,51</sup> Therefore the biopsy of the choroid (and retina) may be informative and useful.<sup>8,43,52</sup> Choroidal and chorioretinal biopsies have been performed to investigate nonspecific uveitis, acute retinal necrosis, tuberculous choroiditis, and retinal pigment epitheliopathies and to identify malignant incursion into the choroid.<sup>8,43</sup>

Transscleral chorioretinal biopsy was pioneered by Foulds, Peyman, and others who developed procedures that allow choroidal tissue sampling but minimize associated complications, particularly retinal detachment.<sup>53-59</sup> Cole and colleagues have reported on the success of transvitreal chorioretinal biopsy using 20G instrumentation and vertical-cutting scissors to remove a large specimen (at least 2 × 2 mm) from the biopsy site.<sup>60,61</sup> Among the nine eyes that underwent biopsy, a positive histologic diagnosis was made in five cases (55.6%).

## Surgical Technique

### Transvitreal Biopsy

A standard three-port pars plana vitrectomy is performed and endolaser is applied around the margins of the intended biopsy site, which should measure at least 2 × 2 mm.<sup>60,61</sup> Vertical cutting intraocular scissors are used to isolate the retinal and choroidal biopsy specimen by cutting within the margins of the laser burns. The blade of the scissor should penetrate the choroid until clear white sclera is visible. In order to prevent intraocular hemorrhage, the infusion bottle should be raised to elevate the intraocular pressure. After obtaining the specimen, the sclerostomy site should

be enlarged to allow for removal of the specimen from the eye. The specimen should be immediately sent for processing and analysis. After fluid/gas exchange, 20% SF<sub>6</sub> gas can be injected into the eye to tamponade the retina.

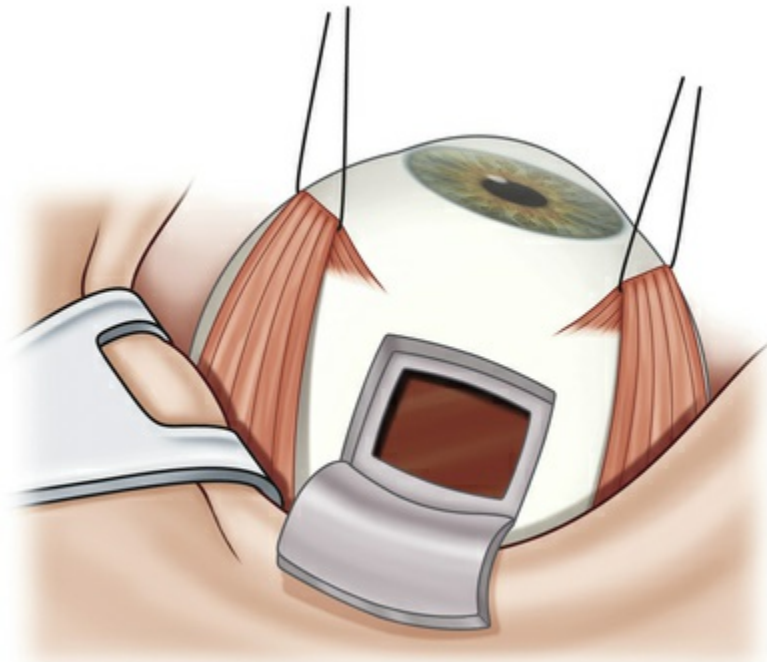

Recently, a surgical technique using a newly developed instrument, the Essen biopsy forceps, was reported to be effective in the diagnosis of choroidal tumors in 20 patients.<sup>62</sup> After performing a standard 23G vitrectomy, Akgul and colleagues used a modified version of a CE-certified intraocular forceps, which was redesigned to capture and hold a sufficient tissue sample, to grasp a biopsy of the tumor. Laser is applied prophylactically to the retinotomy site, but no fluid–gas exchange was performed.

## **Transscleral Biopsy**

The conjunctiva is incised, and the rectus muscles in the involved quadrant are isolated with silk sutures.<sup>63</sup> In biopsies of the choroid and retinal pigment epithelium, the retina tends to bulge into the biopsy site with a risk of retinal tear or incarceration. This risk is reduced by performing a pars plana vitrectomy first.<sup>59</sup> If visualization is adequate, a heavy barrier of photocoagulation, cryotherapy, or diathermy is applied some days preoperatively around the planned biopsy area. Otherwise, endolaser therapy or cryotherapy is applied at the time of vitrectomy. The biopsy site is marked on the sclera, and a 6 × 6 mm scleral flap, nearly full-thickness and hinged (usually posteriorly), is dissected beginning about 5–6 mm posterior to the limbus, depending on the lesion site. The flap is retracted, exposing a near-bare choroid with a few remaining thin fibers of overlying sclera. Diathermy or cautery is done along the outer margin of the inner choroidal bed. A sharp blade is used to make an incision, or two parallel incisions, through the choroid (and retina, if retina is to be removed). One blade of a 0.12 forceps is placed through the incision, and the biopsy specimen is grasped at one edge. The block excision is then completed with Vannas scissors ([Fig. 127.22](#)). During removal of the specimen, particular attention is directed at grasping the tissue only once and ensuring that the entire specimen is delivered in one piece. If the retina is not being removed, it is carefully separated from the choroid and left intact. The biopsy specimen is then placed in

fixative or handled as planned with the pathologist. Any prolapsed vitreous is then removed from the wound, and the scleral flap is sutured with interrupted 9–0 nylon or 7–0 Vicryl. Fluid–gas exchange is performed.

**FIG. 127.22** Technique of transscleral choroidal biopsy. After the area planned for biopsy is delimited by photocoagulation or cryotherapy and a pars plana vitrectomy is performed, the biopsy site is carefully marked on the sclera and a scleral flap (usually hinged posteriorly) is developed. The near full-thickness scleral flap is retracted, and the choroidal tissue and overlying thin scleral lamellae are incised with a sharp blade. Scissors may be used to complete the dissection.

Another technique for obtaining a specimen of sclera, choroid, retinal pigment epithelium, and retina from the eye is to use a corneal trephine and to reconstitute the eye wall with a full-thickness donor scleral graft. In this situation, hemostasis may be improved by systemic hypotensive anesthesia.<sup>53,54,64</sup>

Cyanoacrylate tissue glue can be used to stabilize the choroidal specimen before its removal from the eye.<sup>53,54</sup> A drop of

cyanoacrylate glue is applied to the exposed choroid, forming a dense plaque that can be grasped or glued to an arrowhead sponge.

## Histologic Technique and Preparations

Handling of the choroidal or chorioretinal biopsy specimen depends greatly on the amount of tissue harvested. Consultation with the pathologist is important to prioritize the tests that can be performed. Ideally, the tissue can be divided into three parts in a sterile manner under a dissecting microscope for microbiology, tissue culture, routine light histologic and immunopathologic studies, and electron microscopy.<sup>1</sup>

## Results

Martin et al.<sup>63</sup> reported their results with chorioretinal biopsy performed on seven eyes with progressive chorioretinal lesions of unknown cause. Chorioretinal biopsy provided useful information for determining the diagnosis (multifocal choroiditis with subretinal fibrosis, sarcoidosis, and viral retinitis) and led to change of therapy in five patients. Final visual acuity was unchanged or improved in five eyes.

Foulds and colleagues<sup>10,43,53,54</sup> reported on 34 transscleral biopsies of the choroid and retina for the diagnosis of choroidal melanoma, acute retinal necrosis, chronic uveitis, and progressive retinal pigment epitheliopathy. An adverse event occurred in only one case: a retinal break developed, with associated vitreous hemorrhage and resultant proliferative vitreoretinopathy. Initial **Case 127.6** might have prevented this complication.<sup>10,43,53,54</sup>

A 58-year-old man with a history of prostate cancer, thought to be in remission, had an amelanotic intraocular mass OS at presentation. Echographic study showed a plaque on the surface of the mass similar to a previously reported benign fibrous tumor. Needle aspiration biopsy was nondiagnostic. Because of tumor enlargement, choroidal biopsy was performed and disclosed features diagnostic of metastatic carcinoma of the prostate (Fig. 127.23).

**FIG. 127.23** Biopsy of an amelanotic choroidal mass in this 59-year-old man with prostatic carcinoma without known metastases revealed stratified squamous epithelium that was later determined to be squamous metaplasia of prostate carcinoma under the influence of estrogen therapy. The cells stained positive for prostate-specific antigen phosphatase and prostate-specific antigen, which is diagnostic of prostatic carcinoma, with the mass infiltrating the choroidal tissue.

## Fine-Needle Biopsy

Fine-needle aspiration biopsy techniques have been used extensively in the diagnostic evaluation of many human tumors, including tumors of the orbit and eye.<sup>65</sup> With an ever-increasing knowledge of gene expression profiling, clinicians have the ability to provide prognostication in such entities as choroidal melanoma with these minimally invasive techniques.<sup>66,67</sup> Furthermore, imaging modalities such as spectral domain optical coherence tomography can be utilized to assist in location and wound architecture of the fine-needle biopsy.<sup>68</sup> Although there is a theoretical risk of tumor dissemination along the needle track, no such occurrence has been documented with a needle of 25G or finer; nor has vitreous hemorrhage or retinal detachment been a problem.<sup>69,70</sup>

## Surgical Technique

The technique involves 22G–30G disposable needles for intraocular aspiration.<sup>71,72</sup> The length of the needle selected depends on the intraocular location of the tumor and the planned biopsy route. The biopsy needle is connected to a 10-mL plastic disposable aspirating syringe via a standard plastic tubing. The connector tubing is used so that there will be no induced movement in the needle tip during the biopsy as the assistant exerts suction in the line for aspiration (Fig. 127.24).

**FIG. 127.24** Technique of fine-needle aspiration biopsy. A 25-gauge,  $\frac{1}{2}$ -inch needle is inserted through the pars plana in this eye and into the tumor, which is located posteriorly. Once the needle is within the lesion to be biopsied, an assistant exerts forceful suction on a 10-mL syringe connected to the needle via tubing.

## Results

Transscleral fine-needle aspiration biopsy can be feasible in diagnosing choroidal melanoma. In addition, aspiration biopsy may assist in assessing cytogenetics of these tumors. In a prospective, interventional case series, 30G fine-needle aspiration biopsy diagnosed macular choroidal melanoma in 17 of 24 (71%) eyes.<sup>65</sup> Adverse events such as submacular hemorrhage (nine eyes) and

vitreous hemorrhage (five eyes) resolved spontaneously within 1 month of the biopsy. In addition, four eyes had retinal perforation, but this did not require treatment and did not result in retinal detachment. Examples of cellular specimens obtained by needle aspiration biopsy are seen in [Fig. 127.25](#).

**FIG. 127.25** Examples of tumor cells obtained by needle aspiration biopsy. The large tumor cell in the lower right box has pigment in the cytoplasm and a large round nucleus with prominent nucleolus, characteristic of malignant melanoma.

## Complications of Intraocular Biopsy

The risks of intraocular biopsy are those of vitreoretinal surgery in general. These include increased intraocular pressure, cataract progression, peripheral retinal tears, retinal detachment, choroidal hemorrhage, vitreous hemorrhage, endophthalmitis, exacerbation of the underlying inflammatory disease, and proliferative vitreoretinopathy.<sup>65</sup> The most hazardous of the biopsy procedures is the transscleral choroidal or retinochoroidal resection.

## Conclusion

Vitreous, retinal, and choroidal biopsy have roles in the management of disorders of the posterior segment of the eye. Noninvasive means of establishing a diagnosis are exhausted before surgical procedures are considered. In some patients, however, the clinical appearance and serologic and other laboratory investigations are nondiagnostic, and a biopsy is recommended if there is substantial likelihood that the results will improve patient management. Advancements in surgical instrumentation and diagnostic studies have increased the yield from vitreous, retinal, and choroidal biopsies, and these procedures can be safely performed by retina surgeons who are faced with diagnostic dilemmas.

## **Introduction**

In 1959, Paris Royo and Wilbur Quay reported experiments that were among the earliest steps taken in intraocular retinal cell transplantation.<sup>1</sup> Using a paradigm originally developed by Van Dooremaal,<sup>2</sup> Royo and Quay transplanted rat fetal retina into the

anterior chamber of maternal rat eyes. Prolonged graft survival and a normal rate of graft development and differentiation were noted. Expanding on this work, del Cerro and his colleagues<sup>3</sup> transplanted embryonic rat retina into the anterior chamber of adult eyes from various rat strains with similar results. After Gouras and coworkers<sup>4</sup> successfully transplanted cultured human retinal pigment epithelium (RPE) cells to monkey Bruch's membrane from which the retina had been removed, Li and Turner, in 1988, reported prevention of photoreceptor cell degeneration by RPE transplants in the Royal College of Surgeons (RCS) rat, an animal with an inherited defect causing impaired RPE phagocytosis of outer segments and progressive RPE and photoreceptor death.<sup>5,6</sup> Li and Turner's work, which has been replicated by many investigators, was the first successful treatment of retinal degeneration with cellular transplantation.

In principle, successful transplantation requires graft survival and integration with the host. Graft survival depends on a number of factors, both immunologic and non-immunologic,<sup>7</sup> that will be discussed in this chapter. Regarding graft–host integration, RPE cell transplants integrate readily with host photoreceptors through the extension of apical villous RPE processes around photoreceptor outer segments. In contrast, synapse formation between retinal grafts and host retina is much more complex. Experiments in the central nervous system, however, have established the possibility that synapse formation between donor and host neural tissue can occur. For example, Lund and others<sup>8,9</sup> demonstrated that embryonic retina transplanted into neonatal and adult rat tectum develops the proper layering of the normal retina and extends neuronal projections only to the normal retinorecipient structures, i.e., the superior colliculus, the pretectum, and the dorsal lateral geniculate nucleus. Similarly, intraocular retinal transplants establish with their targets functional connections that elicit light-driven visual response<sup>10</sup> and mediate visual behaviors.<sup>11,12</sup> These and other studies<sup>13,14</sup> have stimulated interest in transplantation as a treatment for retinal disease. The background and rationale for transplantation, results of transplants in experimental animals and humans, immune response to transplanted tissue, nonimmunologic causes of graft failure, and future directions for development of

transplantation for RPE and photoreceptor grafts will be considered in this chapter.

## Background and Rationale for RPE Transplantation in Age-Related Macular Degeneration

Late complications of age-related macular degeneration (AMD) are major causes of irreversible loss of central vision among the elderly.<sup>15,16</sup> Severe visual loss in AMD occurs due to growth of abnormal blood vessels (choroidal new vessels, CNVs) under the RPE and retina with secondary exudative retinal detachment, subretinal hemorrhage and lipid exudation, and outer retinal degeneration.<sup>17</sup> It can also result from atrophy of RPE with consequent atrophy of overlying photoreceptors and underlying choriocapillaris (geographic atrophy, GA). The prevalence of AMD-associated CNV or GA is approximately 1.47%, increasing to 10% in people older than 80 years.<sup>18</sup> There is no fully effective therapy for either CNVs or GA. Blocking the effects of vascular endothelial growth factor (VEGF) by frequent intravitreal injection of antibodies is the best currently available treatment for CNVs, but only 30–40% of the patients experience a moderate visual improvement.<sup>19–21</sup> Cell-based therapy, which involves placing cells in the subretinal space, potentially offers a better option compared to pharmacologic monotherapy with anti-VEGF agents. Advantages of such an approach would include long-term therapy without frequent minor surgical injections with medications; since cells like RPE produce numerous factors that help maintain the normal retinal and choroidal anatomy and physiology,<sup>19,22–26</sup> transplantation of such cells could provide a richer and more effective therapy that is less susceptible to treatment resistance;<sup>27</sup> cell transplantation could potentially restore the subretinal anatomy that is altered by growth (and surgical removal) of CNVs or by atrophy of RPE. Another indication for transplantation of RPE in AMD might be in patients who develop RPE tears<sup>28</sup> while receiving anti-VEGF therapy,<sup>29</sup> which have a poor visual prognosis. RPE transplantation in patients with exudative macular degeneration might require

prior removal of CNVs, which would result in loss of adjacent native RPE and the subjacent RPE basement membrane,<sup>30,31</sup> causing a more complex graft bed than normal. On the other hand, in GA, transplantation of cells would involve resurfacing of the atrophic areas with less surgical manipulation with the goal of restoring the normal structure and function of the photoreceptor–RPE–choriocapillaris complex.

A number of preclinical experiments in animal models have demonstrated that transplantation of cells, e.g., RPE or stem cells or cells secreting growth factors, into the subretinal space can prevent photoreceptor degeneration and preserve function.<sup>32–38</sup> The RCS rat is used commonly for these studies. A recessive mutation in merTK tyrosine kinase receptor in RPE<sup>6</sup> causes a failure of outer segment phagocytosis by the RPE. Consequently, debris accumulates in the subretinal space, and there is eventual loss of photoreceptors causing blindness. Transplantation of RPE into the subretinal space of RCS rats causes a decrease in the amount of subretinal debris,<sup>34</sup> prevents loss of photoreceptors,<sup>5</sup> maintains synaptic connections of rescued photoreceptors,<sup>39</sup> maintains electroretinography responses in areas of rescued retina,<sup>40</sup> and preserves pupillary light reflexes,<sup>41</sup> cortical visual functions,<sup>32,35</sup> and visual acuity.<sup>35,42,43</sup>

Results of macular translocation surgery may mean that establishment of a healthy subfoveal RPE monolayer in AMD eyes can restore macular function. In macular translocation, the retina is moved so that the fovea is relocated to an area away from submacular disease. This maneuver can result in improved visual acuity.<sup>44,45</sup> However, after translocation, the fovea rests on previously extrafoveal RPE, Bruch's membrane, and choriocapillaris. Thus, the procedure is not completely analogous to an RPE transplant per se. In addition, the recurrence of GA in the new location of the fovea following macular translocation<sup>46</sup> suggests that at least some cases of GA may not be treated successfully with RPE transplantation solely.

## Cell Selection for RPE Transplantation

## Stem Cell-Derived RPE

Stem cells are undifferentiated cells that have the capacity for self-renewal (i.e., can divide indefinitely to produce more karyotypically stable stem cells) and pluripotency (i.e., produce cells that are destined to differentiate into more than one type of cell).<sup>47-49</sup> (See [Chapter 37](#), Stem cells and cellular therapy.) During the course of differentiation, stem cells form intermediate populations of increasingly committed progenitor cells that have a decreasing proliferative capacity. Embryonic stem cells (ESCs) are derived from the inner cell mass of the blastocyst and are capable of differentiating into cells of all three germ layers.<sup>50,51</sup> Embryonic and fetal tissues (e.g., retina) contain cells that vary in their differentiation status, ranging from progenitor cells, that can proliferate but have a restricted differentiation potential compared to embryonic stem cells, to committed but still immature rods and cones isolated from fetal retina. In adults, multipotent stem cells exist that can differentiate to replace lost or injured cells. Such cells have been isolated from various organs,<sup>52,53</sup> including the eye.<sup>54-56</sup> Stem cells isolated from a particular tissue can be induced to differentiate into cells of an unrelated tissue. Bone marrow cells, for example, can undergo metaplasia to form skeletal muscle,<sup>57</sup> neural stem cells can develop into muscle<sup>58</sup> ([Table 128.1](#)). It seems that stem cells exhibit plastic behavior depending upon their environment and signals from damaged tissues.<sup>59</sup> The central nervous system contains neural progenitor cells. They exist in both embryonic and adult tissues and can differentiate into glial and neuronal lineages. The capacities for self-renewal and pluripotency render stem cells candidates to replace lost or injured cells. In summary, potential sources for replacement of RPE include non-eye-derived embryonic stem cells from the blastocyst, bone marrow-derived stem cells, neural progenitor cells, and eye-derived progenitor cells.

---

**TABLE 128.1**

### **Potential Sources of Cells for Retinal Cell Replacement**

---

Cell Type	Potential Developmental Capacity
Totipotent stem cell	Can develop into cells derived from all lineages, i.e.,

(mammalian zygote, blastomeres)	ectoderm, mesoderm, and endoderm, as well as supporting tissues like placenta
Pluripotent stem cell (e.g., embryonic stem cell from inner cell mass)	Can develop into cells derived from all three germ layers (ectoderm, mesoderm, endoderm)
Multipotent stem cell (e.g., retinal progenitor cell)	Can develop into different cell types derived from one lineage
Reprogrammed cell (induced pluripotent cell)	Somatic cell reprogrammed by nuclear transfer, limited transfer of transcription factors, or cell fusion to enhance potency
Immature postmitotic rod precursor cell	Rod photoreceptors
Neural retina and retinal pigment epithelium	Rods, cones, Müller cells, or committed retinal neurons

Modified from Jaenisch R, Young R. Stem cells, the molecular circuitry of pluripotency and nuclear reprogramming. *Cell* 2008;132:567–82 and Zarbin MA. Retinal pigment epithelium-retina transplantation for retinal degenerative disease. *Am J Ophthalmol* 2008;146:151–3.

During development, the various retinal cells are derived from a common population of multipotent retinal progenitor cells (RPCs).<sup>60</sup> Embryonic retina can be a potential source of such cells. Such cells exist in adults in lower species like fish and amphibians in the ciliary margin zone (CMZ), located in the retinal periphery, surrounded by a pigmented ciliary margin.<sup>61–63</sup> These cells can regenerate the neural retina throughout the life of the organism.<sup>64</sup> Progenitor cells from chick CMZ can regenerate retina if there is ectopic expression of fibroblastic growth factor and sonic hedgehog.<sup>65</sup> More importantly, retinal progenitor cells have been isolated from mouse eyes and from fetal and adult human eyes.<sup>55,66–69</sup> Efforts to induce RPCs to differentiate into RPE continue,<sup>70,71</sup> and there is evidence that the human eye harbors stem cells that can differentiate into RPE cells.<sup>72</sup>

Due to ethical considerations associated with the use of stem cells from human embryos, methods have been developed to establish stem cell lines without destruction of the embryo.<sup>73,74</sup> It is also possible to generate embryonic stem cells by somatic nuclear transfer, nucleus transfer from an adult, neonatal, or fetal somatic cell into an unfertilized oocyte, whose nucleus has been removed.<sup>75–77</sup> The oocyte would then reprogram the donor nuclear DNA and develop in a normal embryonic pattern and form embryonic stem cells (NT-ESCs). The result of such reprogrammed cells could be the creation of genetically matched cell lines for autologous transplants.<sup>78</sup> However, mitochondrial DNA (mtDNA)

primarily derived from the oocyte can still elicit an immune response. In a humanized mouse study, genetically matched NT-ESCs were rejected based on mtDNA mismatch, but it was possible to induce immunologic tolerance to the allogeneic mitochondrial peptides.<sup>79</sup> However, ethical considerations remain.

Alternatively, adult fibroblasts can be manipulated by transferring into these cells transcription factors like Oct4, Sox2, Klf4, and c-Myc that can reactivate developmentally regulated genes, thus inducing the cells to become an induced pluripotent stem cells (iPSCs).<sup>80,81</sup> Nuclear transfer may be more effective at establishing the ground state of pluripotency than factor-based reprogramming, which can leave an epigenetic memory of the tissue of origin that may influence efforts at directed differentiation for applications in disease modeling or treatment.<sup>82,83</sup> Although iPSCs are pluripotent stem cells, iPSCs and ESCs do differ in some important ways. iPSCs have the theoretical advantage of not being rejected by the patient from whom they are derived (versus ESCs, unless the ESCs were harvested from the patient as an embryo). Abnormal gene expression in some cells differentiated from iPSCs (both via a retroviral and episomal approach), however, can induce a T-cell-dependent immune response in a syngeneic recipient.<sup>84</sup> This response is likely due to the abnormal expression of antigens (e.g., Zg16, Hormad1) not expressed during normal development or differentiation of ESCs, leading to loss of tolerance.<sup>84</sup> Expression of these antigens is a reflection of epigenetic differences (e.g., DNA methylation) between iPSCs and ESCs.<sup>85,86</sup> These differences may not be relevant in terminally differentiated iPSCs, as immunogenicity of autologous differentiated iPSCs may depend on the terminal cell type. In a humanized mouse study, differentiated autologous iPSC-RPE were not immunogenic while differentiated iPSC-smooth muscle cells (iPSC-SMC) were highly immunogenic.<sup>87</sup>

RPE can be derived easily from embryonic stem cells (perhaps because RPE develop early during embryogenesis)<sup>42,70,88-90</sup> as well as from iPSCs.<sup>91-95</sup> Stem cell-derived RPE have been shown to express RPE properties such as ion transport, membrane potential, transepithelial resistance, polarized vascular endothelial growth factor secretion, neurotrophic factor secretion, visual pigment recycling, pigmentation, and gene expression profiles similar to

those of native RPE.<sup>96-103</sup> Rodent models of retinal degeneration have demonstrated the ability of iPSC-RPE and ESC-RPE to perform some RPE functions in vivo (e.g., trophic factor secretion, photoreceptor rescue, preservation of visual function, visual pigment recycling).<sup>24,38,42,97,99,104</sup>

With stem cells, there is a risk of dedifferentiation in the subretinal space and potentially developing into a teratoma. Indeed, in one study, when embryonic stem cell-derived neural cell precursors were injected into mouse subretinal space, 50% of the eyes developed teratomata within 8 weeks.<sup>105</sup> However, in another study, a more stringent selection of 18 different human embryonic stem cell lines did not result in teratoma formation.<sup>42</sup> In yet another study, 7 iPSC and 5 ESC mouse lines were compared to assess teratoma rates in C57BL/6 wild-type mice. Both stem cells showed a high incidence of teratoma formation with no statistically significant differences between ESC and iPSC lines.<sup>106</sup> Tumorigenicity of ESC and iPSC lines may thus be cell line-dependent. Regardless, iPSCs are more prone to genetic instability than ESCs. With iPSCs, there is a risk of insertional mutagenesis due to the use of viral vectors, and risk of teratoma formation due to the use of oncogenic factors such as c-Myc, during cell production. Newer techniques of iPSC production using nonintegrating reprogramming methods<sup>107-109</sup> lessen such concerns. In a study comparing integrating (lentiviral) and nonintegrating (episomal or Sendai virus vectors) reprogramming for iPSC generation, nonintegrating reprogramming was found to yield a more stable genome, using the parental cell line genotype for comparison.<sup>109</sup> Genomic stability is critical to prevent genetic aberrations associated with cancer. The inherent tumorigenicity risk of undifferentiated stem cells, particularly iPSCs, emphasizes the importance of monitoring genomic stability and assessing the purity of iPSC-RPE cultures for patient use. With ESC-RPE, the risk may not be as great; an ESC-RPE preparation currently in use in clinical trials showed no tumor formation in mice undergoing subretinal injections of ESC-RPE containing up to 1% undifferentiated ESCs. ESCs alone formed teratomata by 2 months post-subretinal injection.<sup>110</sup> These studies suggest that a critical number of undifferentiated stem cells must be present for tumor

formation. iPSC-RPE preparations, using the method generated for a clinical study, showed no tumor formation after subretinal injection in albino nude rats, RCS rats, and nonhuman primates.<sup>99,111</sup> In these studies of iPSC-RPE, a highly sensitive qRT-PCR method was used to detect residual iPSCs to establish purity of iPSC-RPE cultures.<sup>112</sup>

Recently, *in situ* RPE (native) were found to contain a small population of multipotent cells (RPESC) that can be expanded in culture and redifferentiated into RPE.<sup>56</sup> In addition to offering the possibility of a more efficient way to generate RPE, RPESCs have limited differentiation potential and therefore may be safer than iPSC-RPE for patient transplantation.<sup>113-115</sup> One potential disadvantage of RPESCs is their limited expansion capability.

Autologous bone marrow-derived stem cells (BMSCs) are another potential source of stem cells. BMSCs can be enriched by selecting for cells with RPE differentiation potential by cell sorting based on surface markers (C35<sup>+</sup>C38<sup>-</sup>); these cells can then be induced to differentiate into RPE by co-culturing with mitomycin C-inactivated RPE cells.<sup>116,117</sup> Although BMSC-RPE tested positive for some RPE markers and were shown to phagocytose outer segments, it is not clear that fully functional RPE cells can be generated with this approach. Thus far, studies have described the differentiated cells at early time points only, and full characterization has not been reported.<sup>117</sup> RPE derived from mouse BMSCs that have been transplanted into subretinal space of RCS rats rescue photoreceptors.<sup>118</sup> Additional experiments are needed to determine whether one source is preferable or whether several different sources might be equivalent in their potential to provide RPE cells for clinical use. To be useful for cell-based replacement therapy, stem cells must have the following properties:

1. Proliferate extensively to generate sufficient quantities of material to serve as a “universal donor” and maintain genetic stability after expansion.
2. Differentiate into the desired cell type(s). ESC-derived RPE can spontaneously dedifferentiate to non-RPE-like cells and spontaneously redifferentiate into RPE-like cells, indicating phenotypic instability.<sup>119</sup> The cultures may not retain a stable

phenotype after 5–8 passages. ESCs and iPSCs vary in their tendency to differentiate into cells of a given lineage.<sup>82,119</sup> As mentioned above, a number of different criteria should be applied to define a “differentiated” RPE<sup>48</sup> and photoreceptor cell.<sup>120</sup> The retinal and subretinal microenvironment can influence the differentiation and functionality of transplanted cells, including expression of developmental markers and markers of proliferation.<sup>121,122</sup>

3. Survive in the recipient after transplantation.
4. Integrate into the surrounding tissue after transplantation.
5. Function appropriately for the duration of the recipient's life.

RPE cell transplants are an attractive starting-point for cell-based combination replacement and rescue therapy in the eye because: (1) ESCs and iPSCs can be induced to differentiate into RPE relatively easily, and, at least in the case of ESC–RPE, one can generate large quantities of cells with stable genotype and appropriate phenotype; (2) RPE cells integrate easily with host photoreceptors; (3) RPE cells elaborate trophic substances that support photoreceptors;<sup>24,35,103</sup> (4) there is abundant evidence for transplant efficacy in pre-clinical models; (5) diseases in which RPE cells appear to be targeted primarily include Best disease<sup>123,124</sup> and some forms of retinitis pigmentosa,<sup>125–127</sup> and secondarily include Stargardt macular dystrophy<sup>128,129</sup> and AMD.<sup>130,131</sup> However, abnormalities in Bruch's membrane may prevent transplanted stem cell-derived RPE from surviving and differentiating long-term in AMD eyes.<sup>24</sup> Since Bruch's membrane is derived from mesoderm, there is no expectation that ESC- or iPSC-derived RPE will manufacture Bruch's membrane.

## Non-RPE Subretinal Cell Transplants

Non-RPE cell-based therapy for AMD involves subretinal transplantation of cells that can perform some, if not all, RPE functions and may offer an advantage over transplantation of stem cell-derived RPE. At a minimum, non-RPE cells must be able to

survive in the subretinal space following transplantation without tumor formation and support the photoreceptors and/or RPE. Neural progenitor cells (NPCs) derived from iPSCs (iPSC-NPCs)<sup>132</sup> or ESCs (ESC-NPCs)<sup>133</sup> and human central nervous system stem cells (HuCNS-SCs)<sup>134,135</sup> rescue photoreceptors in the RCS rat. After subretinal injection, iPSC-NPCs, ESC-NPCs, and HuCNS-SCs migrated out from the injection site, survived long-term in the subretinal space, preserved native RPE and photoreceptors, preserved visual function, and showed no tumor formation. Importantly, iPSC-NPCs and HuCNS-SCs ingested and degraded photoreceptor outer segments.<sup>132,135</sup> NPCs have the capacity to migrate to damaged sites, secrete a host of factors, including immune mediators and trophic factors, and remain undifferentiated after transplantation.<sup>136,137</sup> Because of the migration potential of NPCs and HuCNS-SCs, cells can be transplanted outside areas of diseased/atrophic RPE. By 40 days after transplantation, HuCNS-SCs cover a 7-mm<sup>2</sup> area.<sup>134</sup> The fovea occupies a 1.8-mm<sup>2</sup> area. Thus, one may be able to transplant these cells in an extrafoveal location with the expectation that they will migrate under the fovea and rescue cones, thus preserving high-acuity vision. Normally, delivery of cells to a subfoveal location requires foveal detachment, which may compromise the patient's vision, particularly in the setting of retinal degenerative disease.<sup>138</sup> Safety of NPCs has been demonstrated in clinical trials for ALS,<sup>139</sup> cerebral palsy,<sup>140</sup> and spinal cord injury.<sup>141</sup> The safety of subretinal HuCNS-SCs transplants has been demonstrated in phase I/II clinical trials to treat AMD patients (<http://www.stemcellsinc.com/Clinical-Programs/AMD>).

Additional cell preparations under consideration for subretinal transplantation are bone marrow mesenchymal stem cells (BMSCs) and umbilical cord mesenchymal stem cells (UCMSCs). Both cell preparations offer the possibility of autologous cell transplantation and have been shown to rescue photoreceptors in RCS rats.<sup>142-144</sup> Intravenously injected BMSCs can home into areas of chemically induced RPE loss in mice.<sup>145</sup>

## Cell Delivery Strategies

## Cell Suspension vs. Polarized Sheet

Delivery of a cell suspension to the subretinal space has the advantage of simplicity, i.e., injection through a small retinotomy after a relatively small retinal detachment is created. However, there is a greater chance of cell efflux into the vitreous cavity following bolus injection relative to cell sheet placement. Injection of a polarized cell sheet, with or without a support, will require a larger retinal detachment, larger retinotomy, and specialized instruments to assure placement of the polarized RPE in the correct orientation and location. Theoretically, cell suspension delivery could cover a larger area while sheet delivery is limited to the size of a sheet that can be manipulated for successful placement. Potential advantages to transplanting sheets of cells on a scaffold are threefold. First, one can transplant cells that are differentiated and organized anatomically, resembling the in situ configuration. Highly differentiated transplanted cells may be better suited for subfoveal RPE transplantation, for example, than RPE suspensions. Once the foveal photoreceptors are detached, they begin to degenerate. Clinically, this process is stopped by reapposition of the retina against functional RPE cells. When RPE cells are delivered as a suspension, time is required for them to attach to Bruch's membrane and to reacquire features of differentiation. In principle, this time interval (up to 1–2 weeks) can be eliminated by use of a scaffold delivering differentiated RPE cells. A second potential advantage is that scaffold delivery may be associated with a lower antigen load. Fewer cells are delivered with scaffolds than with cell suspensions. There may be an advantage to reducing the antigen load with regard to stimulating immune surveillance of the transplanted cells. Third, it may be possible to integrate growth factors, immunomodulatory molecules, or other useful moieties into the scaffold, thus prolonging RPE graft survival as well as photoreceptor survival. In cell culture studies, polarized sheets were found to be less prone to oxidative stress-induced cell death than nonpolarized and subconfluent ESC-RPE.<sup>146</sup> In preclinical animal studies, Schwartz et al.<sup>110</sup> found ESC-RPE integrated into the host RPE layer following bolus injection into the subretinal space of NIH III mice. In a preclinical nonhuman primate study, Kamao et al.<sup>99</sup> found injected iPSC-RPE tended to accumulate in the lower

bleb margin 7 days after cell suspension delivery while iPSC-RPE sheets maintained their position. In the same study, Kamao et al. compared bolus vs. sheet iPSC-RPE transplantation in the RCS rat and found similar extent of photoreceptor preservation and ERG responses. Using a mouse model, Carido et al.<sup>147</sup> found ESC-RPE primarily formed clusters on top of the existing RPE monolayer while in eyes devoid of RPE (killed by iodoacetate); transplanted ESC-RPE formed a monolayer. iPSC-NPCs were primarily layered between the native RPE and photoreceptors after bolus injection into the subretinal space of RCS rats.<sup>132</sup> HuCNS-SC behaved similarly with some integration into the host inner retina in long-term survival animals.<sup>134</sup> Overall, it is difficult to predict how cell suspensions will behave in the human subretinal space, particularly when examining results of rodent studies, since the number of cells injected are relatively high in the small rodent eye. In AMD patients, it is likely that cell survival will be impaired in areas devoid of RPE (i.e., areas of GA), exposing diseased Bruch's membrane (unlike the iodoacetate model used in preclinical studies, where Bruch's membrane is not diseased).<sup>148</sup>

## RPE on Scaffold Supports

Transplantation of a monolayer of differentiated, functional RPE on a scaffold support would allow placement of an RPE graft in the right orientation and might even prevent the age-related changes in Bruch's membrane from damaging the transplanted RPE cells.<sup>91,92</sup> In addition to supporting a polarized monolayer of functional RPE, an ideal scaffold would be biocompatible or biodegradable, would have transport and diffusion properties resembling normal Bruch's membrane, would not migrate in subretinal space after surgical delivery, and must have handling properties that would enable tissue delivery without damaging the cells. In addition to natural materials such as gelatin, collagen, and silk, various polymers including parylene, polyester, poly (L-lactide-co-caprolactone), and others have been used with RPE, stem cell-derived RPE, and Schwann cells (reviewed in reference<sup>149</sup>). Advances in biomedical engineering have allowed the manufacture of scaffolds with specific physical properties, thereby enabling the creation of an artificial

Bruch's membrane. As noted above, in addition to the advantage of delivery of a functional RPE monolayer to the subretinal space, scaffold delivery may permit the incorporation of drugs that might retard graft rejection and foster graft integration and/or retinal preservation. A study comparing survival of ESC-RPE cell suspensions with ESC-RPE monolayers on parylene scaffolds following transplantation in immunocompromised nude rats reported that cells on the scaffold survived longer than cell suspensions.<sup>150</sup> To date three substrates have been approved for clinical trials (Table 128.2). In one clinical study, ESC-RPE on a polyester membrane will be introduced into the subretinal space of patients with wet AMD ([www.clinicaltrials.gov](http://www.clinicaltrials.gov)). Polyester membranes are a component of transwell culture plates and are used routinely in RPE culture.<sup>151</sup> Aside from the challenges of creating scaffolds with the previously mentioned properties, an instrument must be designed and manufactured to allow precise insertion and placement in the subretinal space without damage to cells and undue damage to the overlying retina.<sup>152</sup>

# Results of RPE Transplants in Humans

## RPE Transplants

The first human RPE transplant in AMD was reported by Peyman and coworkers in 1991.<sup>153</sup> Since then, numerous reports have described the results of allogeneic and autologous RPE transplantation.<sup>154–167</sup> These surgeries have involved removal of CNV and placement of suspended allogeneic RPE cells,<sup>153</sup> autologous RPE cells,<sup>157,163</sup> patches of RPE,<sup>155,164</sup> or autografts of RPE-choroid.<sup>157,160,161,163,165,166</sup> Thus far, RPE transplantation has not been successful in the majority of patients undergoing surgery, although a few patients show improvement of two or more lines of visual acuity following autografts.<sup>157,159,160,162,163,165</sup> Allogeneic RPE transplants in AMD patients that have undergone CNV excision have failed with poor visual outcome and, in patients who are not immune-suppressed, subretinal fibrosis and chronic fluid leakage in the dissection bed.<sup>154,155,167</sup> In autologous transplants, graft failure has resulted from intra- and postoperative subretinal hemorrhage, failure of graft revascularization, fibrous encapsulation of the graft, and development of epiretinal membrane, proliferative vitreoretinopathy, and retinal detachment.<sup>159,160,162</sup> Optical coherence tomography (OCT) studies indicate the presence of outer retinal atrophy in the majority of patients undergoing autologous RPE transplants, whether as cell suspensions or as sheets of RPE–Bruch's membrane–choroid.<sup>163,168</sup> Immune rejection and graft failure may underlie these results. The allogeneic RPE transplants may not have survived in the subretinal space independent of immune rejection. Tezel and coworkers showed that if RPE cells cannot adhere to their basement membrane (or comparable surface) within 24 hours, they undergo apoptosis.<sup>169</sup> All previous demonstrations of successful RPE transplants in laboratory animals have involved transplantation onto normal Bruch's membrane (Fig. 128.1) or onto native RPE.<sup>4,5,33,34,170–173</sup> In AMD, Bruch's membrane is itself abnormal.<sup>130,174–176</sup> Uncultured RPE isolated from adult human donor eyes show very limited adherence to aged submacular human Bruch's membrane in vitro.<sup>177</sup> In organ culture experiments,

even cultured fetal RPE, which exhibit robust attachment to Bruch's membrane, cannot survive for more than 1–2 weeks on aged or AMD submacular human Bruch's membrane,<sup>24,148,178–180</sup> presumably due to age- and AMD-related changes in this substrate.

Histopathology of an immune-suppressed patient who underwent CNV excision plus uncultured adult RPE transplantation indicates that the cells were not organized as a monolayer, and there was photoreceptor atrophy over the transplant (Fig. 128.2).<sup>164</sup> These results are consistent with the observations of RPE behavior on human submacular Bruch's membrane in organ culture.

**FIG. 128.1** Rescue of photoreceptors by subretinal retinal pigment epithelium (RPE) transplants in dystrophic retina. Toluidine blue-stained semi-thin sections of nondystrophic (A), and dystrophic (B,C) Royal College of Surgeons rat retina. (A) Six-month-old nondystrophic rat retina shows intact outer nuclear layer, 8–10 cells thick. (B) Retina of a 6-month-old dystrophic rat that received a well-characterized, nontumorigenic, SV40 T-transformed human RPE cell line (h1RPE7) 5 months prior to sacrifice. This section is about 1400  $\mu\text{m}$  from the site of injection and shows 2–3-cell-thick outer nuclear layer (ONL). Areas closer to the injection site had up to 6-cell-thick ONL. (C) A 6-month-old dystrophic rat that underwent sham-surgery 5 months prior to sacrifice received only the carrier medium without any cells. No photoreceptor nuclei are seen. *DZ*, debris zone; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *IS*, photoreceptor inner segments; *ONL*, outer nuclear layer; *OPL*, outer plexiform layer; *OS*, photoreceptor outer segments.

**FIG. 128.2** Histopathology of retinal pigment epithelium transplant under the fovea. (A) Transplant site (*arrow*) contains multiple layers of pigment-laden cells. Residual neovascular scar (NV) is present between transplant and Bruch's membrane (BM). Large cysts (C) are present in the outer retina. (B) There is photoreceptor degeneration over an area containing a thin layer (*arrow*) of pigmented cells. Pigmented cells that are not attached to Bruch's membrane are in the subretinal space (*arrowhead*). Residual disciform scar with neovascularization (NV) is present internal to Bruch's membrane (BM). (C) The outer nuclear layer (ONL) is disrupted over a mound of pigmented cells (*arrow*) present in center of transplant site. A bilayer of pigmented cells (*arrowhead*) is visible. Choriocapillaris (CC) and choroidal (Ch) vessels are patent external to Bruch's membrane (BM). Basal laminar deposit (BLD) is present internal to residual neovascularization (NV). (D) Occasional lymphocytes (*arrows and inset*) are present in the choroid away from the transplant bed.

Scale bars: 200  $\mu\text{m}$  (top left), 100  $\mu\text{m}$  (bottom left, top right), 50  $\mu\text{m}$  (bottom right). (With permission from Del Priore LV, Kaplan HJ, Tezel TH, et al. Retinal pigment epithelial cell transplantation after subfoveal membranectomy in age-related macular degeneration: clinicopathologic correlation. *Am J Ophthalmol* 2001;131:472-480.)

## ESC-RPE and iPSC-RPE Transplants

The first clinical trials of stem cell-derived RPE utilized ESC-RPE to treat patients with Stargardt macular dystrophy (SMD) and atrophic AMD.<sup>110,181</sup> ESC-RPE (50,000–150,000 cells/eye) were transplanted as a bolus injection with the goal of delivering cells in the area of transition between atrophic and clinically intact-appearing RPE. (In the areas where RPE appeared intact clinically, they likely were diseased.) Placing the donor cells in this junctional locus might be similar to transplanting cells in eyes with earlier stages of AMD, where this therapy might be most useful. Patients were immunosuppressed with low-dose tacrolimus and mycophenolate mofetil 1 week prior to surgery, which was to be continued for several months postoperatively. ESC-RPE showed no signs of tumor formation, and the transplants appeared to be well tolerated up to 37 months after surgery (longest patient follow-up in this report). Pigmented cells, presumably ESC-RPE, appeared to expand outward or migrate away from the injection site and accumulated along the edge of areas of RPE atrophy in both SMD and AMD patients (Fig. 128.3). Identification of the pigmented cells seen in fundus photos as transplanted ESC-RPE is not certain, as noted by the investigators of this study. It is possible that other cells such as macrophages that have engulfed released pigment could account for pigmented cells observed in the subretinal space. Some visual improvement in most patients was reported at 1 year,<sup>181</sup> but some concern has been expressed regarding the interpretation of the visual results.<sup>182</sup> Another study, using the same ESC-RPE preparation and similar immunosuppressive regime, reported similar findings at 1-year follow-up of four Asian patients, two with atrophic AMD and two with SMD.<sup>183</sup>

**FIG. 128.3** Fundus images of eyes with pigmentation after transplantation with human embryonic stem cells-retinal pigment epithelium (hESC-RPE) (A–C). Colour fundus photographs and spectral domain optical coherence tomography (SD-OCT) images at baseline of an eye from a patient with age-related macular degeneration (dotted circle shows an outline of the transplanted area), 3 months, and 6 months. Note the presence of a pigmented patch of transplanted cells (B,C, *arrows*) that becomes larger and more

pigmented by 6 months. OCTs (inset) show the presence of cells on the inner aspects of Bruch's membrane at 6 months compared with baseline. (D–F) Colour fundus photographs and SD-OCT images at baseline of an eye from a patient with Stargardt macular dystrophy (dotted circle shows an outline of the transplanted area), 6 months, and 1 year. Note the absence of pigment in the preoperative photograph (D). Patches of pigmented cells are evident around the border of baseline atrophy in retinal pigment epithelium (E) that become more prominent at 1 year (F, *arrows*). SD-OCT images at baseline (D) and 6 months (E) show increasing pigmentation is at the level of the retinal pigment epithelium, normal monolayer retinal pigment epithelium engraftment, and survival at 6 months (E, *arrows*) adjacent to a region of bare Bruch's membrane devoid of native retinal pigment epithelium. (G–I) Colour fundus photographs of a patient with Stargardt macular dystrophy (dotted circle shows an outline of the transplanted area). A large central area of atrophy is visible on the preoperative photograph (G). An area of transplanted retinal pigment epithelium cells is visible at the superior half of the atrophic lesion at 6 months (H) that becomes larger and more pigmented at 15 months (I). (With permission from Schwartz SD, Regillo CD, Lam BL, et al. Human embryonic stem cell-derived retinal pigment epithelium in patients with age-related macular degeneration and Stargardt's macular dystrophy: follow-up of two open-label phase 1/2 studies. *Lancet* 2015; 385:509–516.)

The first autologous iPSC-RPE transplant was done in a patient with exudative AMD in a clinical study performed in Japan in 2014. The iPSC-RPE were introduced as a sheet containing mature, functional RPE with no scaffold support. The sheets were harvested from a porcine collagen I gel substrate using collagenase I to release the sheet from the substrate. (Immunocytochemistry evidence indicates there is no collagen I remaining on the basal surface of the cell sheet.<sup>99</sup>) The first patient was reported to be “faring well”, one year after transplantation.<sup>184</sup> Transplantation surgery for the second patient was halted in 2015 after the discovery of six gene mutations that were not present in the patient's fibroblasts from which the iPSCs were derived. Three mutations were gene deletions; three

were nucleotide changes (single nucleotide polymorphism, SNP). One SNP was in a low-risk oncogene.<sup>185</sup> The mutations are thought to have been the result of the reprogramming method.

## Immune Response to RPE Transplants

### Immune Privileged Sites and Immune Privileged Tissue

An immune privileged site (e.g., the ocular anterior chamber) accepts allografts for prolonged periods compared to a nonimmune privileged site (e.g., the subconjunctival space). Immune privileged tissue can survive for prolonged periods in a nonimmune privileged site compared to nonimmune privileged tissue. Thus, resistance of an allograft to immune rejection can be due to properties of both the transplantation site and the transplanted tissue.

Immune privilege in the eye is the result of multiple anatomic and physiologic factors acting on both the innate and adaptive immune systems.<sup>186,187</sup> Streilein et al.<sup>187</sup> noted that among the factors and mechanisms responsible for ocular immune privilege are (1) the blood–ocular barrier, which minimizes contact of allografts with the cells and molecules of the systemic immune system, thus blunting the immune response to alloantigens; (2) deficient lymphatic drainage of the eye, which leads to initial alloantigen presentation in the spleen (versus regional lymph nodes) and, therefore, relatively less inflammatory immune responses; (3) an unusual distribution and functional properties of bone marrow-derived antigen-presenting cells; and (4) an ocular microenvironment rich in soluble or cell membrane-associated immunomodulatory factors. Examples of such factors include transforming growth factor (TGF)- $\beta$ 2,  $\alpha$ -melanocyte-stimulating hormone, vasoactive intestinal peptide, calcitonin gene-related peptide, macrophage migration inhibitory factor, interleukin (IL)-1 receptor antagonist, Fas ligand, CD46, CD59, and free cortisol.<sup>188-195</sup> These molecules help to create an immune-suppressive

microenvironment by affecting the function of immune cells that come in contact with transplanted tissue or inhibiting complement activation. Ocular sympathetic innervation is necessary for maintenance of high ocular levels of TGF- $\beta$ , and denervation leads to loss of immune privilege.<sup>196</sup>

Ocular immune privilege is a dynamic state of immune regulation that results in the induction of an antigen-specific “deviant” systemic immune response characterized by (1) active downregulation of donor-specific delayed hypersensitivity reactions; (2) activation of regulatory cytotoxic CD8<sup>+</sup> T cells that suppress delayed hypersensitivity as well as suppress B-cells producing complement-fixing antibodies; (3) activation of regulatory CD4<sup>+</sup> cells that block terminal differentiation of delayed hypersensitivity effector cells; and (4) enhancement of B-cells that produce noncomplement-fixing antibodies. Initial descriptions of this response were based on experiments in which alloantigens were placed in the ocular anterior chamber, which led to the acronym ACAID, anterior chamber-associated immune deviation.<sup>188,189,197,198</sup>

Immune privilege exists in the subretinal space, but it is not absolute. Subretinal allografts resist immune rejection and induce the development of systemic tolerance in the form of a suppressed antigen-specific delayed hypersensitivity reaction.<sup>198,199</sup> RPE cells may create a local immune suppressive microenvironment through the production of immunomodulatory factors such as TGF- $\beta$ <sup>200–202</sup> and through suppression of T-cell activation<sup>203,204</sup> and the induction of activated-T-cell apoptosis.<sup>205,206</sup> In addition, RPE expresses ligands for T-cell inhibitory receptor programmed cell death-1 (PD-1) receptors on T cells. These ligands (PDL1 and PDL2), whose expression is upregulated by interferon- $\gamma$ , bind to PD-1 and suppress T cells.<sup>207,208</sup> RPE also expresses a novel immunosuppressive factor, cathepsin L inhibitor, CTLA-2 $\alpha$ , that converts exposed T cells to regulatory T cells.<sup>209</sup>

The RPE can behave as immune privileged tissue. Neonatal RPE sheets resist immune rejection at heterotopic sites (i.e., anatomic locations in which the transplanted tissue is not found normally) when compared to nonprivileged tissue.<sup>210</sup> It is not known whether adult RPE, as a sheet or single cell suspension, is immune

privileged. Constitutive expression of Fas ligand on the RPE may contribute to its status as immune privileged tissue.<sup>210,211</sup> This status does not mean, however, that the RPE is incapable of sensitizing its host. Allogeneic neonatal RPE grafts can sensitize recipient mice if the grafts are placed at a nonimmune privileged site.<sup>210</sup>

RPE cells express transplantation antigens. Low levels of major histocompatibility (MHC) class I antigens are present on the surface of fetal RPE cells.<sup>212</sup> Also, RPE cells may express minor histocompatibility antigens. They do not seem to express MHC class II antigens normally although they can do so if exposed to interferon (IFN)- $\gamma$ .<sup>213</sup> Culturing RPE cells also can induce MHC antigen expression.<sup>214</sup> In addition, RPE cells can process antigen prior to antigen presentation.<sup>215</sup> Higher levels of IFN- $\gamma$ -induced MHC class II antigen expression on RPE cells leads to increased activation of antigen-specific T cells as manifested by the production of proinflammatory tumor necrosis factor- $\alpha$ .<sup>216</sup> This activation does not include T-cell proliferation or production of IL-2, however, as is the norm for T-cell activation.

Implantation of neonatal allogeneic RPE cells into ocular immune privileged sites (e.g., the subretinal space) suppresses typical delayed hypersensitivity in the recipients, and the capacity to do so appears to be related to the immune privileged status of the graft site rather than to the immune privileged status of the graft.<sup>210</sup> Thus, it may be that if RPE transplantation is done in a setting in which the immune privilege of the recipient site is compromised (e.g., breakdown of the blood–ocular barrier due to removal of native RPE), then allogeneic RPE grafts will be rejected despite their immune privileged status. If native RPE cells are compromised with sodium iodate, for example, tumor cells or ovalbumin injected into the subretinal space do not induce immune deviation.<sup>198</sup> Immune deviation appears to be impaired persistently (i.e., after restoration of the blood–retinal barrier is complete) following iodate treatment and may be due to entry of plasma proteins into the subretinal space.<sup>198</sup>

In patients receiving RPE transplants after CNV excision, the outer blood–retinal barrier will be compromised both by the presence of CNVs preoperatively and by the iatrogenic RPE defect in the transplant bed postoperatively. Experimental studies indicate

that the outer blood–retinal barrier is disrupted for approximately 1 week after hydraulic debridement of the native RPE.<sup>217,218</sup> Experiments in mice indicate that breakdown of the outer blood–retinal barrier for approximately 14 days (beginning a few days before antigen inoculation) abolished immune privilege and abrogated immune deviation to cell-associated and soluble antigens in the subretinal space.<sup>198</sup> It should be noted that placement of alloantigen in the eye in ocular immune privilege experiments involves disruption of the blood–ocular barrier. That immune privilege is extended despite this disruption indicates the importance of the factors in the microenvironment. Persistent loss of the blood–retinal barrier (e.g., due to CNVs) may result in dilution or absence of immunomodulatory factors in the microenvironment in addition to increased access to subretinal space by systemic immune cells. Also, the role of age-related changes in the RPE *vis-à-vis* subretinal immune privilege is unexplored. Finally, the extent to which immunologic abnormalities associated with AMD,<sup>131</sup> even in the absence of CNVs, compromise the normal immune suppressive environment of the subretinal space is unknown.

In summary, immune privilege may promote allograft survival in the subretinal space, but the changes due to disease and surgical intervention may significantly affect the degree of privilege.

## Are RPE Transplants Rejected?

It is not clear that orthotopic (i.e., transplants placed in an anatomic location in which they are found normally) allogeneic RPE transplants are rejected. Some clinical and experimental evidence indicates that they are rejected.<sup>154,155,167,173,219–224</sup> In contrast, other studies indicate that RPE transplants, including iPSC-RPE, may not be rejected.<sup>87,99,170,225</sup> In still other studies, it is not clear whether rejection occurred or not.<sup>226</sup> Interpretation of many early studies, however, is complicated by the fact that it was difficult to identify unambiguously the transplanted RPE cells due to lack of a unique histologic or clinical marker. Another confounding factor in comparing the animal studies involving transplant rejection (reviewed in reference<sup>227</sup>) is that the transplantation surgery in some

studies resulted in damage to the blood retinal barrier, which may have promoted transplant rejection. In a rodent study by Lu et al.,<sup>228</sup> after excluding animals in which the blood–retina barrier was compromised following bone marrow-derived somatic cell subretinal transplantation, it was noted that immunosuppression was not necessary since there was no statistical difference in rejection rates and outcome in immunosuppressed vs. nonimmunosuppressed animals. For stem cell-derived RPE, undifferentiated cells present as a contaminant in the cell preparation could lead to rejection. As discussed previously, nondifferentiated iPSCs are likely to be immunogenic; even with nonintegrating methods, some degree of immunogenicity is induced.<sup>229</sup> Terminally differentiated cells are less likely to be immunogenic.<sup>87</sup>

In a pilot study, transplanted allogeneic uncultured adult human RPE did not appear to be rejected in AMD patients who had undergone CNV excision and were treated with systemic azathioprine, prednisone, and cyclosporine, which suggests that immune suppression might prevent RPE transplant rejection in this setting.<sup>164</sup> However, these elderly patients were not able to tolerate systemic triple immune suppressive therapy for an extended time. Local immune suppression is somewhat effective in laboratory experiments involving intravitreal injection of cyclosporine,<sup>230</sup> but it has not been reported in human RPE transplants. In clinical trials using subretinally transplanted ESC-RPE to treat patients with SMD and atrophic AMD, patients were treated with oral systemic immunosuppression (low-dose tacrolimus and mycophenolate mofetil (MMF)) 1 week prior to surgery and for 6 weeks after surgery. At week 6, the protocol required discontinuation of tacrolimus and continuation of MMF for an additional 6 weeks or longer. However, three of the patients did not tolerate the full immunosuppressive regimen, and the regimen was modified for an additional seven patients who continued the MMF for up to >66 weeks. No signs of acute graft rejection were noted in the 18 patients of this study, indicating that immune suppression following allogeneic cell transplantation is possible.<sup>231</sup> Autologous RPE transplants (e.g., transplants of uncultured peripheral RPE cells to the submacular space of the same eye) should not undergo

graft rejection. Methods for harvesting RPE cells for autologous transplants exist,<sup>159,232</sup> but in vitro data indicate that harvested aged human RPE do not adhere well to aged submacular Bruch's membrane, even in the presence of native RPE basement membrane.<sup>177</sup> This result may explain why patients undergoing autologous RPE transplants after CNV excision have generally shown very limited visual improvement.<sup>159,163</sup> Also, aged autologous adult RPE may exhibit aging and AMD changes that render them unsuitable for transplantation.<sup>233,234</sup>

## RPE Graft Failure

As noted above, RPE transplants in humans may have failed independently of immune rejection of the graft. Attachment of RPE to Bruch's membrane after transplantation is crucial as RPE undergo apoptosis otherwise.<sup>235</sup> In vitro studies indicate that trypsin-harvested, cultured fetal human RPE can adhere to adult submacular Bruch's membrane even on surfaces lacking native RPE basement membrane.<sup>24,178,179,236</sup> In contrast, uncultured collagenase IV-harvested adult RPE adhere poorly to aged human submacular Bruch's membrane even in the presence of native RPE basement membrane.<sup>177</sup> Del Priore and coworkers have shown higher attachment rates with cultured RPE from older donors when seeded onto peripheral Bruch's membrane of older persons.<sup>237-240</sup> This higher attachment rate might reflect a difference in integrin expression of primary isolated RPE cells versus cultured cells.<sup>178,241</sup> It also might reflect differences in extracellular matrix composition of peripheral versus submacular Bruch's membrane.<sup>174,242</sup> Histology of excised CNVs,<sup>30,31,243</sup> histopathology of eyes following CNV excision,<sup>244,245</sup> and postoperative clinical findings<sup>30,246</sup> all suggest that CNV dissection exposes both the superficial and deeper layers of the inner collagenous layer of Bruch's membrane, which will constitute much of the surface to which transplanted RPE must adhere and on which they must survive if transplants are done after CNV excision. Cultured fetal human RPE can adhere to the superficial and deep inner collagenous layers of aged human submacular Bruch's membrane, but long-term survival is impaired.<sup>24,179,241</sup> An additional age-related change in Bruch's

membrane that could contribute to poor graft survival and function is the increased deposition of cholesterol.<sup>247</sup> It is not known if the lipid deposits, which may contribute to the decreased hydraulic conductivity of aged Bruch's membrane,<sup>242</sup> might affect RPE transplant function or survival by masking extracellular matrix ligands. In vitro studies show that fetal RPE can attach to a high degree on the surface of the inner collagenous layer and that the majority of cell death occurs after 7 days in culture, indicating that poor cell survival is a post-attachment event.<sup>24</sup> The poor visual results associated with autologous iris pigment epithelium (IPE) transplants might be due to graft failure and, perhaps less likely, from limitations in the ability of IPE to replace RPE.<sup>248-250</sup>

In a SMD patient receiving an ESC-RPE transplant, pigmented autofluorescent cells were observed in the atrophic lesion following transplantation into this area. With time, the pigmented cells and autofluorescent signal disappeared, indicating either graft failure or loss of cell pigmentation (Fig.128.4). An in vitro study examining similarly prepared ESC-RPE on aged and AMD Bruch's membrane predicted graft failure with time in culture as the majority of transplanted ESC-RPE were dead or dying after 21-day culture.<sup>24</sup> These studies point out the need for a method to improve graft survival on AMD Bruch's membrane, since Bruch's membrane in atrophic lesions has not supported transplanted cell survival.

**FIG. 128.4** Autofluorescence images of a patient with increasing pigmentation consistent with transplanted human embryonic stem cells-retinal pigment epithelium (hESC-RPE). Autofluorescence images (A–D) of a Stargardt macular dystrophy patient, which correspond to the color fundus photographs in Figs. 128.3G–I.

Preoperative autofluorescence imaging shows hypoautofluorescence centrally with small satellite lesions of hypo-autofluorescence, and a surrounding

rim of hyperautofluorescence (A). Two weeks (B) and 3 months (C) after surgery. There is speckled hyperautofluorescence in the upper half of the central atrophic lesion (B,C, *arrows*) that diminishes by 1 year (D). (From Schwartz SD, Regillo CD, Lam BL, et al. Human embryonic stem cell-derived retinal pigment epithelium in patients with age-related macular degeneration and Stargardt's macular dystrophy: follow-up of two open-label phase 1/2 studies. *Lancet* 2015;385:509-516.)

## RPE Replacement: Future Directions

The seminal work by Advanced Cell Technology, Inc., now Astellas Institute for Regenerative Medicine (AIRM), paved the way for RPE transplantation clinical trials by demonstrating the safety of ESC-RPE transplants in AMD and SMD patients. Halting of the autologous iPSC-RPE transplantation study to treat patients with exudative AMD in Japan emphasizes the necessity of careful assessment of donor tissue to assure safety of the transplants. As yet undetermined from these early clinical trials is whether significant long-term visual improvement can be achieved through stem cell-derived RPE transplants. The results of current and future clinical trials ([Table 128.2](#)) will drive the future of cell transplantation therapy for patients with AMD and SMD. It is likely that cell selection, preparation, and delivery strategy will vary, depending upon the target disease and the stage of disease progression.

## Histocompatibility Leukocyte Antigen (HLA) Matching

Autologous iPSC-RPE transplantation theoretically should circumvent the need for immunosuppressive therapy. Aside from the possibility of the stem cell-derived RPE containing the same genetic defects that led to RPE atrophy in the patient, autologous iPSC-RPE transplantation may not be practical as a large-scale therapeutic for other reasons. Currently, most methods to generate RPE from stem cells are labor-intensive and time-consuming. New protocols have been developed to increase the efficiency, reduce the

need for laborious hand picking of pigmented colonies, and/or reduce the time to differentiate into RPE,<sup>102,251–254</sup> but the high costs of creating clinical grade cells remain. Regardless of the method of differentiation, rigorous testing at all stages of clinical grade cell production must take place beginning with the procurement of the starting cells through the final product to assure purity, safety, stability, and functionality of transplanted cells. These requirements increase the costs of cell production.

An alternative to autologous transplantation is the creation of iPSC lines with a range of HLA types to allow for HLA matching to minimize the need for immunosuppressive therapy. As formidable as this approach seems, it is possible to generate an iPSC haplobank for a given population within a geographic region as HLA alleles and haplotypes are conserved within populations.<sup>255</sup> For example, one estimate is that an iPSC bank from 150 homozygous HLA-typed individuals could match 93% of the United Kingdom population and, due to limited diversity of the Japanese population, as few as 50 such lines could potentially match 90% of the population.<sup>229</sup>

## Immune Rejection

Many different strategies can be pursued to prevent graft rejection, including systemic or local drug therapy with established (e.g., prednisone, azathioprine, cyclosporine) or new (e.g., recombinant cytokines) compounds or via other techniques, e.g., diminishing MHC class-II-positive cells in the transplant.<sup>256</sup> Cyclosporine does not appear to interfere with the ability of allogeneic neonatal retinal grafts to induce ACAID, nor does prolonged treatment with systemic cyclosporine interfere with persistence of allospecific suppressor cells for 35 days after transplantation.<sup>257</sup> Nonetheless, retina grafts in the anterior chamber do deteriorate in 35-day grafts suggesting that graft destruction is the result either of immune mechanisms not inhibited by cyclosporine and/or nonimmunologic factors. Independent of its effectiveness, systemic immune suppression can be complicated by side-effects such as nephrotoxicity, hypertension, risk of malignancy, susceptibility to infection, hepatotoxicity, seizures, and even anaphylaxis,

depending on the medications used.<sup>258</sup> Thus, local immune suppression has been considered. In one study, local immune suppression of rabbit eyes with cyclosporine prolonged cultured human fetal RPE xenograft survival in the subretinal space, but by 25 weeks, only ~10% of the green fluorescence protein-labeled grafted cells could be identified.<sup>230</sup> It may be that the viral vector used to introduce green fluorescence protein induced an inflammatory response. Sustained slow-release cyclosporine delivery was as effective at promoting transplant survival as repeated intravitreal injections of much higher doses. Thus, it is not clear that intraocular immune suppression with cyclosporine alone will prevent allogeneic RPE transplant rejection. High-dose dexamethasone therapy is known to be effective in preventing acute allograft rejection<sup>259,260</sup> although lymphocyte resistance to prednisolone can develop.<sup>261</sup> Repeated intravitreal injections of dexamethasone can be well tolerated by the retina,<sup>262</sup> which suggests that sustained intravitreal dexamethasone delivery may not be complicated by retinal damage. Use of the sustained dexamethasone delivery system has prevented allogeneic corneal transplant rejection in rats.<sup>263</sup> Currently, there are several intravitreal sustained-release steroid formulations that could be considered in human transplants.<sup>264,265</sup> Thus, if immune suppression of RPE grafts is necessary, this approach may also be effective in preventing RPE transplant rejection. Donor iPSC banks are being created and are targeted for individuals homozygous at some of the MHC loci.<sup>266-270</sup> Because disparities at minor histocompatibility loci can provoke immune rejection,<sup>271</sup> it is not clear how useful this approach will be. Supplementing MHC matching with immune suppression might be associated with an increased risk of ESC-derived tumor formation. Another strategy is to induce tolerance (i.e., absence of a destructive immune response to transplanted tissue without immune suppression).<sup>272</sup> Tolerance can be achieved via mixed chimerism or by inducing anergy through blockade of costimulatory signals that activate T cells (e.g., with belatacept). The combination of the immune privileged site of the transplant (i.e., the subretinal space) and the immune privileged tissue that is transplanted might result in the induction of ignorance (i.e., failure of the immune system to recognize transplanted tissue).

Photoreceptors, for example, have low MHC class I expression and express MHC class 1b antigens (HLA-G and HLA-E) that bind CD94-NKG2 and block NK cell-mediated lysis,<sup>272</sup> and RPE cells express Fas ligand.<sup>273</sup>

## Transplanted RPE Survival and Differentiation on Aged Bruch's Membrane

There is no fully validated animal model of AMD at present. In vivo and in vitro RPE wound healing and transplantation models exist, but they do not appear to be directly relevant to AMD patients. Previously reported successful in vivo RPE transplants involve attachment to normal Bruch's membrane or native RPE as noted above. Experiments using aged submacular human Bruch's membrane in organ culture indicate that aged human RPE do not adhere well to this surface unless they are cultured.<sup>177,178</sup> Cultured fetal RPE appear to adhere to aged submacular Bruch's membrane better than cultured aged RPE, but even in this case the cells do not appear to survive and differentiate well at 7 days in organ culture. It appears that aging changes in Bruch's membrane are responsible for this deleterious effect on the cells.<sup>180,274,275</sup> Thus, one approach to improving RPE transplantation success is to identify and manage these Bruch's membrane changes. Experiments in vitro have included "cleaning" Bruch's membrane with Triton X-100 (a detergent) and/or resurfacing the Bruch's membrane with extracellular matrix molecules, singly or in combination,<sup>276,277</sup> or resurfacing the Bruch's membrane with a cell-secreted matrix.<sup>180</sup> The latter has shown promise, but translation to clinical application remains a challenge. Another approach has included enhancing the expression of cell-matrix adhesion molecules, i.e., integrins, to improve RPE adhesion and survival.<sup>241,278</sup> Finally, it may be possible to enhance graft success through stimulation of the transplanted cells, for example, via trophic factors, to enhance long-term survival following transplantation onto diseased Bruch's membrane.<sup>148</sup>

As previously mentioned, cells introduced into the subretinal space on a scaffold could conceivably prevent deleterious effects from Bruch's membrane affecting the graft. Because cell-scaffold placement may require a larger retinotomy and a larger retinal

detachment, it may create more surgical damage than dispersed cell subretinal injections. In the case of patients undergoing CNV excision, however, scaffold-based cell delivery may be best because of the damage to Bruch's membrane generated by CNV removal. Tissue engineering and scaffold development is a rapidly evolving field, with sophisticated scaffolds manufactured that can reproduce properties of normal Bruch's membrane, allowing control over porosity and mechanical properties.<sup>152</sup> Pending and future clinical trials utilizing a variety of scaffolds will determine whether this approach is feasible.

## Native RPE Resurfacing of Aged Bruch's Membrane

An alternative to RPE transplantation is to stimulate RPE ingrowth from the edge of the dissection bed. Human pathologic studies indicate that RPE ingrowth following CNV excision in AMD patients is incomplete and aberrant.<sup>30,244,279</sup> Previously described cell culture RPE wound-healing models are associated with complete wound resurfacing, in contrast to the situation in AMD patients undergoing CNV excision.<sup>280–282</sup> In vivo RPE wound-healing models (e.g., rabbit, pig) are associated with complete resurfacing of the RPE defect<sup>283,284</sup> or involve administration of compounds (e.g., mitomycin C) that complicate further experimental study or have unclear relevance to resurfacing Bruch's membrane in AMD patients.<sup>217,285,286</sup> Experiments from a Bruch's membrane organ culture model indicate that resurfacing of ~65–85% of a ~3-mm-diameter circular RPE defect in aged submacular human Bruch's membrane occurs by approximately 10 days if RPE basement membrane or the superficial inner collagenous layer is present. If deeper defects are created, exposing deeper regions of the inner collagenous layer, significantly less resurfacing is observed (~54%) at day-10 indicating that one should expect less resurfacing with greater damage to Bruch's membrane.<sup>287,288</sup> However, these experiments were performed on aged (non-AMD) Bruch's membrane and therefore may be more relevant to cases in which the RPE are relatively healthy. Additional experiments are needed to determine whether one can alter the denuded Bruch's membrane

surface (or the RPE cells at the edge of the defect) so that resurfacing of the RPE defect occurs in situ.

Human clinical studies indicate that periods of macular detachment up to 2 weeks are compatible with recovery of visual acuity of 20/50 or better in a substantial number of patients.<sup>289</sup> Monkey and cat experiments indicate that many photoreceptors survive during retinal detachment periods of several weeks' duration, although some photoreceptors definitely die.<sup>290,291</sup> Approximately 80% of the cat outer nuclear layer survives during 3 days of detachment.<sup>292</sup> The numbers of photoreceptor nuclei in detached cat retina do not begin to decline significantly (i.e., >20% decline in density) until detachment periods longer than 13 days.<sup>293</sup> Data from cat retinal detachment studies indicate that 14-day detachments followed by 30-day reattachment is associated with rod and cone outer segment length similar to that observed after 5-day detachments.<sup>291</sup> The cat retina, however, is rod-dominated. Cones are more prone to apoptosis with detachment (versus rods)<sup>294</sup> although in one study, approximately 75% of S- and M-cones survived a 1-day detachment (followed by retinal reattachment) in the ground squirrel.<sup>295</sup> Thus, at this time, published experimental data do not indicate clearly what the exact survival of cones is after 2-week periods of retinal detachment, but clinical data indicate that it is good enough to warrant developing methods to promote RPE resurfacing. In addition to duration of detachment, the height of detachment influences photoreceptor survival.<sup>295,296</sup> The macular detachments that would arise from CNV excision are quite shallow (<1–2 mm height), which also favors photoreceptor survival during a 2-week RPE resurfacing period. Thus, we believe that the RPE resurfacing approach is feasible despite its possible association with photoreceptor death during the resurfacing process.

## **Background and Rationale for Photoreceptor Transplantation in Retinal Dystrophies**

Retinitis pigmentosa (RP) is a group of heterogeneous hereditary disorders with an estimated prevalence between 1 : 3000 and 1 :

5000, affecting 50, 000 to 100, 000 individuals in the United States and approximately 1.5 million people worldwide.<sup>297</sup> In the vast majority of cases, the condition results from mutations in photoreceptor cell genes encoding a myriad of structural and phototransduction proteins, and, to a lesser extent, from mutations in genes of the RPE.<sup>297</sup> Blindness ultimately results from rod and cone photoreceptor cell death.<sup>298</sup> Inner retinal layers remain relatively preserved, especially early in the course of the disease.<sup>299,300</sup> As degeneration progresses, however, extensive synaptic rewiring of the inner retina occurs.<sup>298,301,302</sup>

A variety of approaches to restore vision are under study, including gene therapy,<sup>303–307</sup> pharmacotherapy,<sup>308,309</sup> visual prostheses,<sup>310</sup> endogenous regeneration,<sup>311</sup> and transplantation.<sup>312–318</sup> The goal of retinal transplantation is to restore and/or maintain visual function by transplanting healthy donor photoreceptors that replace lost photoreceptors by integrating with the host inner retina to reconstruct a functional, neural retinal network. As noted above, this approach to sight restoration is termed “replacement.” Retinal transplantation may also slow down the progression of the disease by means of graft-released trophic substances that rescue residual host photoreceptors,<sup>319–322</sup> an approach termed “rescue.” A trophic effect would be most useful, however, only while the critical number of foveal cones required to support useful vision is present.<sup>323</sup> In late stages of the disease, when most photoreceptors have degenerated, replacement of lost photoreceptors probably would be more effective.

## Results of Photoreceptor Transplants in Experimental Animals

### Animal Models of Retinal Degeneration

Early studies of retinal transplantation utilized normal animals as hosts. Subsequently, investigators turned to animal models of retinal degeneration. Animal models became available either by discovery of naturally occurring genetic mutants, such as the retinal degeneration (*rd*) mouse,<sup>324</sup> the retinal degeneration slow (*rds*) mouse,<sup>325</sup> the RCS rat,<sup>6</sup> and the rod–cone dysplasia (*Rdy*) Abyssinian

cat,<sup>326</sup> or by experimentally induced degenerations such as photoreceptor degeneration induced by phototoxicity<sup>327</sup> and by intravitreal injection of a concentrated solution of human hemoglobin.<sup>328</sup> In addition, genetically engineered models of homologous human RP mutations such as the transgenic rhodopsin (Pro23His) mutant mouse<sup>329</sup> and the transgenic rhodopsin (Pro347His) mutant pig<sup>330</sup> were developed. The advantages of these models include the rapid and nearly total loss of target cells such as RPE or rod photoreceptor cells as well as their similarity (in some cases, equivalence) to human disease, allowing for the efficient study of retinal transplantation under more clinically relevant conditions. Most work to date has employed rodent models such as the light-damaged rat retina,<sup>14,331,332</sup> the *rd* mouse,<sup>314,333–337</sup> the P23H rhodopsin transgenic mouse,<sup>338</sup> and the RCS rat.<sup>339</sup> The small eye and large lens of the rodent favor transscleral rather than transvitreal graft delivery. Transvitreal delivery is a less traumatic and more pertinent technique to human retinal transplantation than the transscleral approach. Furthermore, the rod to cone ratio in rodent retina<sup>340</sup> differs from that of the relatively cone-rich human retina. To overcome these problems, animal models using larger eyes, such as the chemically ablated rabbit retina<sup>328</sup> and the Abyssinian *Rdy* cat,<sup>341,342</sup> have been employed as well as normal rabbits,<sup>328,343,344</sup> pigs,<sup>345,346</sup> and primates.<sup>347</sup> The pig may prove to be a valuable animal model because the anatomy and size of the porcine eye are closer to that of the human,<sup>348,349</sup> and the pig retina is well endowed with cones, has an area centralis, and is holangiotic.<sup>350</sup> In addition, Pro347His mutant pig<sup>330</sup> carries a mutation similar to that found in a form of human RP and is an animal model closest to human RP, especially with regard to refining surgical procedures.<sup>351</sup> However, the pig retina does not have a fovea.

## Graft Implantation Sites and Preparations

Retinal transplants have been placed in a surgically induced retinal lesion, in the vitreous cavity (i.e., epiretinally),<sup>13,352</sup> and into the host subretinal space.<sup>14,353</sup> Grafts from donors of the same species (i.e., allogeneic grafts) and from a different species (i.e., xenogeneic grafts)<sup>347,354,355</sup> have been transplanted with or without host immune

suppression.

Photoreceptor microaggregates, which are retinal fragments in which tissue integrity is disrupted by gentle trituration with cells remaining attached to each other in small clusters (<0.2 mm<sup>2</sup>), have been used in retinal transplantation.<sup>13</sup> Isolated cell suspensions obtained by mechanical and/or enzymatic dissociation of the retina also have been used.<sup>333,335,353,356</sup> Compared to microaggregates, isolated photoreceptors usually are more traumatized, frequently lose their outer segments, display less organization, and often are not properly oriented.<sup>313,356</sup> Both preparations often form spherical structures or rosettes, with photoreceptors oriented towards a central lumen similar to those seen in retinoblastomas and retinal dysplasias.<sup>13,352,354</sup> Outer segments of misoriented photoreceptors as well as those found in rosettes rapidly degenerate due to their failure to contact RPE cells.<sup>357</sup> In addition, both retinal microaggregates and cell suspensions frequently are contaminated with nonphotoreceptor retinal cells. Rosette formation prevents the reconstruction of the normal retinal anatomy and interferes with establishing contacts between graft photoreceptor terminals and host second-order neurons.<sup>35</sup>

To avoid these problems, Silverman and Hughes<sup>14</sup> introduced the photoreceptor sheet preparation, created by vibratome-sectioning of adult mammalian retina. Sheet preparations preserve the organization and polarity of grafted photoreceptors and maintain the densely packed arrangement of photoreceptors found in situ and thought to be critical for good visual acuity.<sup>358</sup> Furthermore, the inner retina, which could interfere with synaptic interactions between grafted photoreceptors and host second-order neurons, is removed. Sheets can be placed between the host retina and RPE in the proper orientation, and they show a much lower frequency of rosette formation.<sup>14,320,328,334</sup> This technique has been modified further to obtain photoreceptor sheets using both vibratome-sectioning and excimer laser ablation of the inner retina.<sup>359,360</sup> A similar approach has been used to transplant sheets of adult full-thickness retina, intact embryonic or fetal retinal sheets,<sup>332,339,344</sup> and vibratome-sectioned fetal retina. Aramant and coworkers introduced the approach of cotransplanting fetal neural retina with the adjacent RPE.<sup>339</sup> This approach might be advantageous in cases

of advanced disease where both retinal cell types have degenerated.<sup>316</sup>

Age is an important variable in the choice of donor tissue. Studies in neural retinal transplantation have utilized tissue from embryonic, early postnatal, late postnatal, and adult donors as well as transplantation of homo- and heterotypic neural progenitor cells (stem cells, see below). There are several advantages to transplanting embryonic or fetal retinal grafts.<sup>312</sup> Immature retinal tissue has a high potential for plasticity,<sup>361</sup> lacks immunogenicity,<sup>186</sup> and survives and differentiates well in the host.<sup>332</sup> However, it is extremely fragile, difficult to handle, and is undifferentiated, which makes obtaining pure photoreceptor sheets difficult or impossible. In one study, attempts to obtain photoreceptor sheets from embryonic retina using vibratome-sectioning resulted in abnormal morphology and poor survival.<sup>344</sup> Excimer laser was used to obtain a monolayer of human fetal cones, but the ultrastructure of their synaptic pedicles was disorganized.<sup>362</sup> Also, embryonic or fetal retinal grafts often are associated with rosette formation. Finally, obtaining embryonic or fetal tissue for transplantation has many logistical and ethical constraints. Adult retinal grafts seem to show normal morphology and organization in the host retina and are associated with minimal rosette formation, which might allow for better restoration of retinal anatomy,<sup>328,334,347</sup> especially if the outer blood–retina barrier remains intact.<sup>198</sup> Adult retinal graft preparations have been shown to yield good survival rates.<sup>328,334,347</sup> Furthermore, mature retinal tissue is easier to handle and, because it is fully differentiated, reliably yields pure photoreceptor sheets and can be obtained readily from eye banks.<sup>363</sup> Also, it seems that differentiated photoreceptors can integrate with host retina,<sup>313</sup> although the best integration seems to occur with cells that are developmentally committed to becoming photoreceptors but which have not yet matured morphologically (see below).

## **Transplantation Aimed at Photoreceptor Cell Rescue**

A wide variety of cells, including rod photoreceptors, RPE, IPE, and

even nonocular cells such as Schwann cells and olfactory ensheathing cells, as well as progenitor stem cells, have been used in transplantation paradigms aimed at rescuing host residual photoreceptors and retarding the progression of retinal degenerative diseases. The strategies employed, including the type of cells used, in these paradigms depend on the primary derangement that causes photoreceptor cell death. For example, Schwann cells, derived from peripheral nerves, have been used as autologous grafts to rescue photoreceptors. Schwann cells are known to produce growth factors such as ciliary neurotrophic factor (CNTF), glial cell line-derived neurotrophic factor (GDNF), and brain-derived neurotrophic factor (BDNF) and are therefore a source for sustained growth factor release. Schwann cells, however, do not phagocytose photoreceptor outer segments. Nevertheless, subretinal Schwann cell transplants have been shown to limit photoreceptor cell loss in RCS rats for as long as 9 months<sup>37,364</sup> and for up to 2 months in rhodopsin knockout mice (Fig. 128.5).<sup>365</sup> In addition, Schwann cells engineered to secrete GDNF or BDNF promote photoreceptor rescue in RCS rats to an even greater degree than that observed with parent Schwann cells.<sup>36</sup> Similar to Schwann cells, a mixture of adult olfactory ensheathing cells and olfactory nerve fibroblasts have been shown to produce nerve growth factor, basic fibroblast growth factor (bFGF), and BDNF, as well as restore recoverin expression and maintain ERG b-wave after subretinal transplantation in the RCS rat. However, in contrast to Schwann cells, olfactory ensheathing cells were shown to phagocytose porcine retinal outer segments in an in vitro assay.<sup>366</sup> Additional cell preparations considered for retina rescue therapy, particularly to treat patients with AMD, are discussed above (see Cell Selection for RPE Transplantation, Non-RPE Subretinal Cell Transplants).

**FIG. 128.5** Subretinal transplants of Schwann cells rescue photoreceptors in dystrophic Royal College of Surgeons (RCS) rats, the degree of rescue being greater with cells modified to secrete brain-derived neurotrophic factor (BDNF) or glial-cell-derived neurotrophic factor (GDNF). Toluidine blue-stained semi-thin sections of 16-week-old dystrophic RCS rats that had undergone sham surgery (A) or Schwann cell transplants (B–D) at the age of 4 weeks. (A) Retina after a sham surgery shows only occasional outer nuclear layer (ONL) nuclei. (B) Dystrophic rats that received Schwann cell transplants showed discontinuous regions of 2–3-cell-thick ONL. (C) Schwann cells secreting BDNF in the subretinal space resulted in more extensive preservation of ONL with some outer segment (*arrow*) and inner segment preservation. However, the debris zone is also quite extensive. (D) GDNF-secreting Schwann cells also led to anatomic rescue of photoreceptors greater than that caused by the parent Schwann cell line. *bv*, blood vessel; *DZ*, debris zone; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *IS*, photoreceptor inner segments; *ONL*, outer nuclear layer; *OPL*, outer plexiform layer; *RPE*, retinal pigment epithelium.

Transplantation of Schwann cell line clones secreting GDNF or BDNF into the retinas of dystrophic Royal College of Surgeons rats. *Invest Ophthalmol Vis Sci* 2004;45:267–74.)

Transplantation of rod photoreceptors with the goal of cone photoreceptor “rescue” has been undertaken because, in the vast majority of RP cases and related animal models, the disease-causing mutations are expressed exclusively in rods. Transplanted rods might rescue existing cones that would be lost secondary to rod degeneration.<sup>367</sup> Subretinal rod photoreceptor transplants have been shown to exert a protective effect on cone photoreceptors in animal models of retinal dystrophies, delaying photoreceptor degeneration and limiting cell death. Mohand-Said and coworkers<sup>320</sup> demonstrated that rod-rich retinal grafts transplanted into the subretinal space of *rd* mice, a strain with a naturally occurring

mutation in the gene encoding the  $\beta$ -subunit of rod cyclic guanosine monophosphate phosphodiesterase (cGMP), preserved cone cells, with cone density 30–40% greater than that of untreated *rd* retinas (Table 128.3). This rescue effect was observed at some distance from the grafted cells, suggesting the existence of diffusible trophic factor release by the transplant. These findings were substantiated by in vitro coculture studies in which significantly greater numbers of surviving cones were seen in mouse dystrophic retinas cultured with retinas containing normal rods compared to dystrophic retinas cultured in medium alone or with rod-deprived retinas.<sup>319</sup> Molecules mediating this paracrine effect have been identified.<sup>321,322</sup> Several growth factors, neurotrophic factors, and cytokines such as bFGF, acidic FGF (aFGF), CNTF, GDNF, BDNF, and IL-1 $\beta$  have been shown to exert robust survival-promoting effects in the retina when injected subretinally or intravitreally,<sup>308,368</sup> or when delivered by adenovirus gene therapy<sup>369</sup> in various animal models of retinal degeneration.<sup>370,371</sup> A similar rescue effect has been shown to occur by focal mechanical injury to the retina in light-induced retinal damage<sup>372–374</sup> as well as in sham-operated animals during transplantation studies.<sup>375,376</sup> This effect is probably mediated by injury-induced upregulation of neurotrophic factors.<sup>372,374</sup>

**TABLE 128.3**

**Quantitative Estimates of Effects of Tissue Transplantation on Host Retinal Degeneration (*rd*) Cone Numbers After 2 Weeks<sup>a</sup>**

	Nonoperated Controls ( <i>rd</i> )		C57 Outer Nuclear Layer		C57 Inner Retina		Entire <i>rd</i> Retina		Gelatin (Sham Control)	
	5 Week <i>rd</i>	7 Week <i>rd</i>	Grafted Eyes	Paired Controls	Grafted Eyes	Paired Controls	Grafted Eyes	Paired Controls	Grafted Eyes	Paired Controls
No. of eyes	10	42	12	12	12	12	11	11	7	7
Total no. cones	119,445	88,515	98,913	86,310	90,846	89,180	91,780	89,740	86,026	89,227

<sup>a</sup>Only rod transplantation leads to significant preservation of cone numbers ( $p < .001$ ).

Transplantation of rod-rich photoreceptors leads to rescue of cone photoreceptors. Five-week-old *rd/rd* mice received gelatin-encased subretinal transplants of one of the following in the right eye: sheets of rod-dominant (97%) photoreceptors from 8-day-old C57BL/6 mice, sheets of inner retina without photoreceptors from 8-day-old C57BL/6 mice, entire retina of 8-week-old *rd* mice, or gelatin sheet alone. The left eye served as unoperated control. Two weeks later, by which time *rd* mice lose 97% of rods, the mice were sacrificed, and the number of surviving cones in the host retina were labeled and counted in an unbiased manner. Five-week-old unoperated *rd* mice were used to determine the baseline rate of degeneration over the same 2-week period, and a loss of 30,000 cones was noted. Only those eyes receiving an outer nuclear layer transplant showed a statistically significant higher number of surviving cones ( $p < .001$ ).

SEM, standard error of mean.

Clinical trials involving encapsulation and intravitreal delivery of ARPE-19 cells transfected with a human *CNTF* gene (NT-501 cells) in patients with retinal degenerative diseases have been conducted.<sup>377–381</sup> Although reliable long-term intraocular release of CNTF was confirmed and despite several studies suggesting visual improvement in a select subset of patients, sustained long-term improvements in visual acuity, visual field sensitivity, or ERG responses have not been confirmed.

## Transplantation Aimed at Photoreceptor Cell Replacement

Various neural retinal transplantation paradigms have been developed in laboratory animals,<sup>312,382,383</sup> some of which have evolved into clinical trials in humans.<sup>316,347,384–387</sup> This work has documented the feasibility of retinal transplantation, with long-term survival of the transplant in both animals<sup>344,357</sup> and humans.<sup>316,347,384–388</sup> There is evidence that some degree of graft–host integration might occur after retinal transplantation,<sup>317</sup> but light and electron microscopy have not demonstrated unambiguous significant direct graft–host synaptic integration in all cases.<sup>13,14,332,334,335,339,344,389</sup> In many of these studies, a glial limiting membrane, derived from Müller cell processes, formed a barrier between graft and host retinas (reviewed in reference<sup>390</sup>). In areas

where this glial barrier was absent, the transplant and host retinas were in close apposition, and their cell processes intermingled indistinguishably.<sup>332</sup> Disruption of the outer limiting membrane seems to improve integration between transplanted photoreceptors and wild-type as well as degenerating retina.<sup>391,392</sup> In a study of rod photoreceptor integration in six different murine models of inherited retinal degenerations, Barber and colleagues found that (1) degree of integration related to disease progression but not severity, (2) integration was possible even in advanced disease, and (3) glial scarring and outer limiting membrane integrity significantly affected photoreceptor integration.<sup>393</sup> In addition, efficiency of integration may be related to tissue age and augmented by soluble factors.<sup>394-396</sup>

Ultrastructural analysis of full-thickness embryonic retinal sheets transplanted into the subretinal space of normal rabbits has shown bundles of nerve fibers containing mature neuronal processes and growth cones on either side of the graft–host interface in close association with intermingled graft and host Müller cell processes, which form a glial barrier.<sup>344</sup> Immunohistochemical analysis of these transplants showed some direct contact between processes of rod bipolar and AII amacrine cells as well as between a few cone bipolar and ganglion cell processes believed to be derived from both transplant and host retinas.<sup>344</sup> Identification of graft versus host cells was made based on location, however, not on specific cell markers. Under similar transplant conditions, a subpopulation of wide-field amacrine cells expressing neuronal nitric oxide synthase was found to extend processes from the graft into the host inner plexiform layer (IPL), but no direct contacts were observed.<sup>397</sup> Synaptic contacts between graft and host retinas are suggested by trans-synaptic tracing studies from the host brain to the transplant. A study conducted by Warre-Cornish et al. attempted to shed light on some of the changes that occur in photoreceptors after transplantation in the mouse retina by conducting a detailed histologic analysis. The sequence of events is as follows: transplanted cells migrate individually through the interphotoreceptor matrix into the host retina, localize to the ONL, form apical attachments, acquire mature rod structure, form synapses with resident neurons, and develop photoreceptor outer

segments.<sup>398</sup>

In an important study, MacLaren et al. showed that if donor cells isolated from retinas at the height of rod development were used for transplantation, integration can occur even if the host has a mature retina.<sup>399</sup> Using *rds*, *rd*, and rhodopsin knockout mouse models, MacLaren and colleagues demonstrated successful integration of postmitotic rod precursors by showing the presence of spherule synapse in donor cells (an essential component to communicate with inner retina), ganglion cell recordings in low light intensities that stimulate rods, and by restoration of pupillary light reflex. However, the cells were not morphologically mature even though they expressed photoreceptor markers. Similarly, when donor tissue was used during the development when retina was rich in rod-committed cells, similar integration into the mature retina was seen after transplantation.<sup>400</sup> As noted above, this integration is improved when outer limiting membrane is disrupted.<sup>391,392</sup> In addition to isolating photoreceptors at specific time points in development, another method that might improve photoreceptor cell integration involves isolating an enriched population of cells with the highest ability to integrate into host retina based on select molecular markers.<sup>401</sup> Gust and Reh have shown that adult photoreceptors can integrate into the host retina but have a higher transplant failure rate compared to less developmentally mature cells (Fig. 128.6).<sup>313</sup> Whether such integration can occur with human tissues is not known. Santos-Ferreira et al.<sup>402</sup> conducted a preclinical study specifically aimed at cone photoreceptor replacement. The team generated cone-like photoreceptors by crossing neural retina leucine zipper-deficient (*Nrl*<sup>-/-</sup>) mice with a GFP reporter line resulting in double transgenic mice. The cone-like photoreceptors were enriched by magnetic-activated cell sorting, transplanted into the subretinal space of *Nrl*<sup>-/-</sup> adult wild-type mice as well as cone photoreceptor function loss 1 mice, and were shown to integrate into the host retina, acquire photoreceptor morphology, express cone-specific markers, and survive for up to 6 months. Finally, retinal ganglion cell recordings demonstrated photopic responses in retinas with cone cell degeneration, implying restoration of visual function in this model system.<sup>402</sup> The number of integrated cones decreased

significantly during the first 6 months after transplantation, and CD68-positive monocytes/macrophages infiltrated the subretinal space. Lakowski et al.<sup>403</sup> used flow sorting to isolate Crx-expressing cells, which are committed to differentiate into cones and rods. Only embryonic-stage Crx-positive cells integrated within the ONL and differentiated into cones. Postnatal Crx-expressing cells generated primarily rods. Cone integration efficiency seemed to be highest in cone-deficient recipients (*Gucy2e*<sup>-/-</sup> mice) compared to *Crb1*<sup>rd8/rd8</sup> mice, which demonstrates that the recipient environment can have a profound impact on transplant outcome.

**FIG. 128.6** Dissociated retinal cells from green fluorescent protein-positive donor mice of ages postnatal day 5 and day 79 (fully mature adult) were transplanted into the subretinal space of adult wild-type C57/B16 mice. The hosts were sacrificed 2 weeks after transplantation, and the eyes were fixed, embedded in agar, and cut into 60- $\mu$ m sections. Cells from neonatal (A; P5) and mature (B; P79) donor mice (green) integrate into the unlabeled host outer nuclear layer

(ONL). Arrow points to an unintegrated clump of donor cells. Integrated mature rod photoreceptors exhibit complete morphology (C) including outer segment (OS); inner segment (IS); cell body (CB); and a spherule synapse (Sph). Outer segments of integrated cells express rhodopsin. Note that in an unintegrated cell, rhodopsin is present throughout the cell. INL, inner nuclear layer. Scale bars: 20  $\mu\text{m}$  (A,B); 10  $\mu\text{m}$  (C). (Republished with permission of the Association for Research in Vision and Ophthalmology from Gust J, Reh TA. Adult donor rod photoreceptors integrate into the mature mouse retina. Invest Ophthalmol Vis Sci 2011;52:5266–72.)

Although significant restoration of vision in humans after photoreceptor transplantation has not been documented (see below), there is some indication of improved visual function in laboratory animals.<sup>404,405</sup> Recovery of visual function is the goal of retinal transplantation, but it does not per se constitute evidence of graft–host synaptic connectivity sufficient to reestablish retinal neural circuitry since visual recovery might be due to a “rescue” effect rather than a “replacement” effect. Furthermore, accurate evaluation of visual function is a complex task, particularly in experimental animals. Simple reflexes, electrophysiologic testing, and visually guided behaviors have been used to evaluate visual function in laboratory animals. Silverman and coworkers<sup>334</sup> reported that visually evoked cortical potentials could be recorded over the retinotopic area that corresponded to the transplant. Light-elicited retinal ganglion cell responses and local light-driven electroretinograms (ERGs) have been recorded from host retina overlying transplants.<sup>336</sup> Visual-evoked potentials (VEPs) from areas of the host superior colliculus topographically corresponding to the transplant have also been recorded.<sup>317</sup> Recovery of the pupillary light reflex<sup>334</sup> as well as behavioral correlates, such as light-flash inhibition of the startle reflex<sup>331</sup> and light/dark preference behaviors,<sup>335</sup> have also demonstrated some degree of visual function restoration in animal models of retinal degeneration following photoreceptor transplantation. While the results of these tests are promising, the level of elicited responses was often less than that of normal controls.<sup>334,336</sup> Moreover, it is not clear that synaptic interactions between the transplant and host underlie the observed improvement in all cases.<sup>335</sup> A confounding factor in these

experiments is the possible trophic effect of the transplant,<sup>321,322,337</sup> and, to a lesser extent, of the surgery itself as a form of injury,<sup>372,374,375</sup> both of which have been shown to enhance residual host photoreceptor cell survival. A further difficulty is that the validity of some of these tests as accurate measures of visual function remains controversial. For example, Kovalevsky and coworkers<sup>406</sup> found no correlation between the intensity of the pupillary light reflex and the number of photoreceptor cells present in the host retina. This result limits the validity of the pupillary light reflex as an accurate tool for evaluating the extent of photoreceptor repopulation or the formation of functional contacts sufficient for the recovery of visual function following retinal transplantation. Approximately 120,000 functioning rods are required to generate a reproducible scotopic ERG response in preclinical models of RP.<sup>407</sup> (Restored visual behavior, however, can be detected with only 25,000 functioning photoreceptors in this model.)

## Stem Cells in Photoreceptor Transplantation

Stem cells that have been explored for possible retinal transplantation include brain-derived neural progenitor cells, embryonic stem cells, retinal stem cells, bone marrow-derived stem cells, and Müller cell-derived stem cells.

Given that the brain and retina are derived from neuroectoderm and that immature neuronal and progenitor cells are intrinsically capable of migrating and differentiating during neural development, it would appear that brain-derived neural progenitor cells could potentially differentiate into photoreceptors in the subretinal space. Several groups have examined this possibility<sup>408-411</sup> and noted that there was limited integration of neural progenitor cells into adult host retina,<sup>409</sup> but migration of transplanted cells was observed in all layers of a developing immature retina. However, these integrated cells did not express markers of mature retinal cells.<sup>408,411,412</sup> Perhaps this result reflects the fact that the lineage is restricted to brain-derived neural cells.<sup>413</sup>

Alternatively, retinal progenitors isolated from developing retina would not have the above-mentioned lineage restriction. Transplantation of such cells isolated from embryonic retina into young transgenic S334ter rats, an RP model, showed grafted cells forming a multilayered cellular sheet in the subretinal space and expressing retina-specific neuronal differentiation markers, e.g., recoverin and rhodopsin. Similarly, multipotent retinal stem cells isolated from adult mouse retina were able to successfully integrate, assume photoreceptor morphology, form synapses with host retinal neurons, and become functional based on electrophysiologic measurements in *rd1* and *rd7* mutant mice.<sup>414</sup> Human retinal progenitor cells isolated from fetal neural retina were transplanted into the subretinal space of an RCS rat, and 12 weeks later showed significantly better optokinetic response and superior preservation of the ONL thickness, spread distance, and cell count than vehicle controls.<sup>415</sup> In an effort aimed at photoreceptor rescue as well as restoration of retinal function, retinal progenitor cells were incubated with BDNF or GDNF slow-releasing microspheres and transplanted into the degenerating retina of S334ter line 3 rats.<sup>416</sup> In transplanted areas, there were RPE-photoreceptor outer segment interactions, rod and cone opsin immunoreactivity, preservation of amacrine and horizontal cells, and absence of glial hypertrophy allowing host-graft integration. Mouse retinal progenitor cells grown on a biodegradable thin-film polycaprolactone scaffold not only showed differentiation into photoreceptor lineage in vitro, but, when injected into the subretinal space of rhodopsin null mice, the cells localized in the ONL and expressed photoreceptor-specific markers.<sup>417</sup> A modification of the polycaprolactone scaffold by hybridizing it with the interphotoreceptor matrix may prove an even better platform for retinal progenitor cell transplantation.<sup>418</sup> Hyaluronic acid-based hydrogels may serve as a scaffold by which to reliably deliver retinal progenitor cells into the subretinal space.<sup>419</sup> Studies by MacLaren and Bartsch mentioned above also demonstrated survival, integration, and expression of mature photoreceptor markers when cells isolated at the peak of rod development were transplanted into the adult retina.<sup>400,420</sup> However, isolation of such cells from developing human retina would be unethical.<sup>421</sup>

Retinal progenitor cells exist in lower vertebrates in the ciliary margin zone, and similar cells have been isolated from adult human eyes.<sup>67,69</sup> Thus, human donor eyes might be used for isolation of retinal progenitor cells. These cells grow as neurospheres in culture and give rise to both glial and neural cells. Only a small fraction of cells express mature retinal cell types, however, and they do not completely differentiate into functional retinal cells.<sup>422,423</sup> These cells can be induced in culture by retroviral transduction of photoreceptor-specific transcription factors to express molecules such as transducin and recoverin, and they differentiate into light-sensitive rod phenotypes.<sup>424,425</sup> When transplanted into adult normal or degenerate retina, results have varied with some studies showing no differentiation or expression of mature retinal markers<sup>426</sup> and others showing differentiation of the cells with expression of mature retinal markers but without expressing mature retinal cell morphology or integration into host retina.<sup>408,427-429</sup> An additional problem with these cells is that they exhibit limited self-renewal in culture.<sup>422,430</sup> Despite the above mentioned limitations, clinical studies on intravitreal and subretinal injection of retinal progenitor cells in patients with RP are being initiated (NCT02464436, NCT02320812).

Müller cells are another potential source of stem cells.<sup>431</sup> Müller cells from mammalian retina possess stem-cell-like properties of growing in neurospheres and expression of neural stem cell markers, and they differentiate and express mature retinal markers including peripherin and opsin.<sup>432,433</sup> A spontaneously immortalized Müller cell line has been reported by Limb and coworkers.<sup>434</sup> Whether these cells can form fully differentiated retinal neurons is not known although, in contrast to retinal progenitor cells, they do not seem to have limited self-renewal. Transplants of Müller-cell-derived stem cells have shown limited integration,<sup>432</sup> but treatment of the host retina with chondroitinase (to break down proteoglycans prior to transplantation) resulted in better integration.<sup>435</sup> Human Müller glial cells were stimulated to differentiate into photoreceptors (showing upregulation of gene and protein expression of CRX, NR2E3, rhodopsin, and other phototransduction markers) that were transplanted into the subretinal space of the P23H rat. After transplantation, they migrated and integrated into

the ONL and increased the a-wave amplitude as measured by scotopic flash ERG.<sup>436</sup>

Embryonic stem cells can be cultured indefinitely and can be induced to differentiate into cell lineages of the three germ layers. Typically, culture of these cells requires the use of animal serum or coculture with animal-derived cells. Approval of use of such cells would be problematic due to potential contamination.<sup>421</sup> However, human ESCs have been cultured without use of such reagents, and cell lines have been established.<sup>437,438</sup> Efficient protocols for producing retinal cells from ESCs have been developed.<sup>94,95,395,439</sup> Transplants of precursors derived from ESCs via techniques prior to those developed by Lamba or Osakada have been shown to rescue photoreceptors in RCS rats<sup>440</sup> or migrate into rabbit retina and express S-opsin and rhodopsin.<sup>441</sup> Yanai et al.<sup>442</sup> recently reported on higher yield and quicker differentiation of human ESCs into photoreceptor precursor cells using size-controlled embryoid bodies, addition of triiodothyronine and taurine to the culture medium, and negative selection of undifferentiated cells. Hypoxia is another factor that increases photoreceptor differentiation from mouse ESCs.<sup>443</sup> It is not known if the newer techniques of deriving mature human retinal cells create cells that are able to survive, integrate, and function to a greater degree following transplantation. Early experiments in mice have been promising. ESC-derived retinal cells survived and were able to form functional photoreceptors after transplantation in *Crx*<sup>-/-</sup> mice,<sup>318</sup> a gene knockout animal model of Leber congenital amaurosis that is characterized by reduction or loss of components of phototransduction cycle including rhodopsin, cone opsin, transducin, cone arrestin, and recoverin. Thus, these mice do not have any ERG response. After transplantation, a small ERG response was detected. Human ESCs also replace photoreceptors in *mnd* mice<sup>315</sup> and in *rd1* mice.<sup>314</sup> Lakowski and colleagues showed that CD73(+)CD24(+)CD133(+)CD47(+)CD15(-) photoreceptor precursor cells isolated from three-dimensional self-forming retina differentiated from mouse ESC successfully integrated and matured into rod photoreceptors in adult mouse retina after subretinal transplantation.<sup>444</sup> Similarly, Eberle et al. showed a threefold higher retinal integration of CD73(+) magnetic-associate cell sorted

photoreceptor cells versus nonsorted cells when transplanted into the subretinal space of adult wild-type mice, as well as successful generation of photoreceptor outer segments.<sup>445,446</sup> Furthermore, Laver et al. visualized the location of transplanted stem cell-derived photoreceptor precursor cells after transplantation, which may aid our understanding of three-dimensional architecture, engraftment, and survival of such cells.<sup>447</sup>

iPSCs may be a good source of genetically matched stem cells whose isolation may not have the ethical complexity associated with the use of embryonic or fetal tissues. However, the efficiency of production is very poor. iPSCs have been induced to differentiate into photoreceptors and can generate cells that integrate into the host retina, express photoreceptor-specific markers, localize to the ONL, and improve ERG response.<sup>448,449</sup> Zhou and coworkers subjected pig iPSCs to a rod differentiation protocol and culture that resulted in rod-like cells that expressed rhodopsin and rod outer-segment-specific membrane protein 1.<sup>450</sup> These differentiated cells, when transplanted into the subretinal space of pigs treated with iodoacetic acid to eliminate photoreceptors, were noted in the outer nuclear layer, but only a few of the cells expressed projections resembling outer segments at 3 weeks. Similarly, Lamba and coworkers showed that such cells were able to integrate into mouse retina.<sup>448</sup>

Following reports of bone marrow-derived stem cells integrating into the retina and differentiating into photoreceptors in rat eyes,<sup>451</sup> attempts have been made to induce these cells to develop into retinal cells in vitro.<sup>452,453</sup> Injection of bone marrow-derived mesenchymal stem cells into the subretinal space appears to have a rescue effect on photoreceptors.<sup>454,455</sup> However, the outcome may be due to a trophic effect rather than a result of transplanted cells differentiating into photoreceptors. As noted above, intravitreal bone marrow-derived lineage-negative hematopoietic stem cells rescue photoreceptors (primarily cones) in *rd1* and *rd10* mice.<sup>337</sup> Peripheral blood mononuclear cells, a population of cells believed to include a small proportion of pluripotent stem cells, have shown results similar to bone marrow-derived stem cells in terms of survival after subretinal transplantation, intraretinal migration, and expression of photoreceptor-specific markers.<sup>456,457</sup>

## Results of Photoreceptor Transplants in Humans

Neural retinal transplantation has been performed in human volunteers with RP and AMD.<sup>316,347,384-387</sup> In these studies pre- and postoperative visual acuity and evaluation of retinal function were done using a variety of psychophysical, electrophysiologic, and clinical tests, including macular perimetry, full-field and focal ERGs, fundus examination, fundus photography, and fluorescein angiography. Kaplan and coworkers<sup>347</sup> reported the transplantation of vibratome-sectioned adult cadaveric photoreceptor sheets into the subretinal space of two patients with advanced RP and visual acuity of no light perception (NLP). The patients were not immune-suppressed and showed no signs of graft rejection (e.g., focal chorioretinitis, macular edema, vitritis) for up to 12 months after surgery. However, no improvement of visual function was attained. Das and coworkers<sup>384</sup> transplanted fetal neuroretinal cells into the subretinal space of one eye in 14 RP patients, temporal or superotemporal to the macula. Patients were followed for as long as 44 months after surgery with no apparent signs of rejection in the absence of immune suppression. Visual improvement was reported in five transplant recipients but was based solely on subjective testing (i.e., improved visual acuity in five patients and a detectable narrow visual field in two patients). Moreover, these patients had some degree of visual perception preoperatively, which may have been underestimated resulting in an apparent increase in visual function after surgery. No improvement of results from more objective tests, such as a full-field ERG or VEPs, was observed. In another study, two patients with advanced RP received subretinal transplants of intact fetal retina.<sup>458</sup> Patients were followed for 12 months after surgery with no clinical signs of rejection. Both patients reported subjective visual improvement (new visual sensations), and one patient showed a transient faint positive response during a multifocal ERG that was later undetectable. The same authors cotransplanted sheets of fetal retina together with the adjacent RPE unilaterally into the subretinal space near the fovea in five RP patients with visual acuity of light perception (LP).<sup>386</sup> After 6 months follow-up, there was no evidence of rejection, but no

visual improvement was observed. Although, in another patient with autosomal dominant RP, cotransplantation of fetal retina with RPE resulted in long-term improvement of visual acuity (from 20/800 to 20/270) and visual field.<sup>459</sup> This group subsequently reported on 10 patients (6 RP, 4 AMD) who received retinal implants in one eye and were followed in a phase II trial conducted in a clinical practice setting.<sup>316</sup> Seven patients (3 RP, 4 AMD) showed improved EDTRS visual acuity scores. Three of these patients (1 RP, 2 AMD) showed improvement in both eyes to the same extent. In 1 RP patient, vision remained the same, but in 2 RP patients, vision decreased. One RP patient maintained an improvement in vision from 20/800 to 20/320 at the 6-year follow-up, while the nonsurgery eye had deteriorated to hand motion vision. This patient also showed a 23% increase in light sensitivity at 5 years compared to microperimetry results at 2 years; the other patients showed no improved sensitivity. Although no HLA match was found between donors and recipients, no rejection of the implanted tissue was observed clinically. Humayun and coworkers<sup>385</sup> transplanted fetal retinal microaggregates into the subretinal space of 8 patients with advanced RP and visual acuity of LP, as well as a fetal retinal sheet plus microaggregates in 1 patient (in two separate locations) with advanced neovascular AMD and visual acuity of NLP. Patients were followed for as long as 13 months after surgery with no signs of rejection in the absence of immune suppression. Three patients showed a decline in visual function, and 3 others showed a transient improvement. The patient with AMD died from an unrelated cause 3 years after receiving the transplant. Ultrastructural and immunocytochemical studies of the eye revealed survival of at least some of the transplanted cells in the subretinal space with no signs of inflammation.<sup>388</sup> Although the host retina and transplant were separated in some areas by a fibrocellular membrane composed of Müller cell processes, cellular debris, and collagen, a few GABA-positive and synaptophysin-positive cell processes extended between the transplant and the host retina. However, no synaptic contacts involving these processes were found. In another study, adult human cadaveric photoreceptor sheets harvested with the excimer laser were transplanted into 8 patients with advanced RP.<sup>387</sup> Subjects were

followed for 12 months, but no improvement in visual function was recorded. Siqueira and coworkers<sup>460</sup> reported the results of a prospective phase I, nonrandomized open-label study of autologous bone marrow-derived mononuclear cell transplants in RP patients with best-corrected ETDRS visual acuity worse than 20/200. Patients (3 with RP, 2 with cone-rod dystrophy) received intravitreal injection of  $10^4$  autologous bone marrow-derived stem cells/0.1 mL, 3–3.5 mm posterior to the limbus with a 27-gauge needle. No adverse effects occurred (e.g., teratoma, visual loss, intraocular inflammation), but there was no documented benefit (e.g., visual acuity, visual field, ERG, optical coherence tomography) at 10-months follow-up. In a similar study, Park et al.<sup>461</sup> injected a mean of 3.4 million human autologous bone marrow CD34<sup>+</sup> stem cells into the vitreous of 2 patients with SMD, 2 patients with AMD, and 1 patient with RP (VA <20/200 in all patients). Although VA improved in 4 (80%) of 5 patients during 6 months of follow-up and no long-term ocular or systemic side-effects were observed, progression of geographic atrophy was evident in both patients with AMD (along with decline in ERG and microperimetry) despite the suggestion of stem cell integration into the host retina as assessed by adaptive optics OCT. While these studies have established the feasibility and safety of retinal transplantation in humans as well as the survival of the transplants, additional work remains to achieve long-term preservation of visual function.

## Immune Response to Photoreceptor Transplants

Photoreceptor cells are probably minimally immunogenic due to very low levels of expression of MHC class I molecules.<sup>462</sup> Most neural retinal transplantation studies in animal models have employed allografts and, to a lesser extent, xenografts with or without host immunosuppression. In humans, allografts have been used almost exclusively.<sup>347,384–387,458</sup> The occurrence of cell-mediated delayed hypersensitivity rejection following retinal transplantation was only reported in a few studies involving xenografts.<sup>355</sup> Two distinct aspects of immune privilege may play a role in retinal

transplantation. First, immature neural retina is immune privileged tissue,<sup>463</sup> and second, the subretinal space is an immune privileged site.<sup>188</sup> So far, it is not clear whether adult neural retina also behaves as immune privileged tissue.<sup>186</sup> Neural progenitor cells behave like immune privileged tissue as well.<sup>464</sup> As noted above, however, neural tissue derived from iPSCs may not be immune privileged because abnormal gene expression in some cells differentiated from iPSCs (both via a retroviral and episomal approach) can induce a T-cell-dependent immune response in a syngeneic recipient.<sup>84</sup>

Although the majority of neurons, including retinal neurons, do not express MHC molecules, they may express minor histocompatibility antigens.<sup>186</sup> These antigens are not displayed in the absence of MHC class I expression, but if cells die, minor histocompatibility antigens can be released, phagocytosed by antigen-presenting cells, and presented to T-lymphocytes.<sup>186</sup> Furthermore, retinal glial cells, including Müller cells and astrocytes, constitutively express class I and II MHC molecules.<sup>465,466</sup> Neural retinal microglia may also play a major role in the expression of transplantation antigens. Microglia can localize in the lumen of graft rosettes as well as within and surrounding retinal grafts, especially those undergoing rejection.<sup>467</sup> Ma and Streilein<sup>468</sup> have shown that these cells become activated after transplantation of neural retina into the subretinal space and display upregulated expression of both class I and class II MHC molecules. Donor-derived, activated microglia are thought to act as antigen-presenting cells that initially induce ACAID in their recipients following subretinal transplantation but eventually mediate an atypical delayed hypersensitivity reaction in which slow rejection of the graft takes place instead of the acute graft rejection seen in typical delayed hypersensitivity. In addition, Xu et al.<sup>469</sup> showed that conditioned medium from CD11b(+) interferon-gamma and lipopolysaccharide activated microglia was able to influence retinal progenitor cells to differentiate into neuron-like cells expressing the photoreceptor marker recoverin. These results imply that microglia are an important population of cells that may affect photoreceptor cell survival and may represent an additional target in an effort to optimize retinal cell transplantation and integration.

As noted previously, the immune privilege of the subretinal

space is not absolute. Whereas gross infiltration by lymphocytes is seen rarely after transplantation into the subretinal space and graft survival is prolonged, tissue rejection still may occur.<sup>198,463,470</sup> The underlying mechanism of graft rejection in this immune privileged site is not understood fully. However, it appears to involve an unconventional pattern of immune response that comprises only minimal lymphoreticular cell infiltration with gradual rather than acute graft deterioration.<sup>463</sup> Exposure of the subretinal space to systemic immunity, which occurs if the integrity of the blood–retina barrier is compromised due to surgery and/or disease such as RP or AMD, can contribute to graft rejection.<sup>198</sup> Breach of the host blood–retina barrier may allow MHC-expressing cells, e.g., dendritic cells from the systemic circulation, to invade the subretinal space and present the transplant antigens to T-lymphocytes. Immune suppression may be needed to prolong the survival of the graft.<sup>470</sup>

## Photoreceptor Transplantation: Future Directions

Studies in experimental animals and humans indicate that absence or paucity of graft–host synaptic interactions remains an unsolved obstacle to successful neural retinal replacement. The retinal and subretinal microenvironment can influence the differentiation and functionality of transplanted cells. Photoreceptor morphology and the degree of integration can vary depending on the state of the recipient.<sup>395</sup> Although synapse formation between donor and host tissue has been documented as has recovery of visual function (in preclinical models), the overall efficiency of photoreceptor transplantation currently is poor with 0.1–1% of transplanted cells surviving long term after transplantation.<sup>395,471–473</sup>

Reactive glial cells may constitute a barrier between the host retina and the grafted cells.<sup>389</sup> Following retinal transplantation, astrocytes and Müller cells become reactive and upregulate expression of the intermediate filament proteins, glial fibrillary acid protein (GFAP), and vimentin.<sup>345</sup> Reactive gliosis can create a barrier that separates the area of injury from surrounding healthy tissue,<sup>474</sup> which may explain the consistent finding that neuritic

processes extend between the graft and the host only in areas of the transplant where the glial barrier is absent<sup>332,344</sup> or where the host outer limiting membrane, rich in adherens junctions involving Müller cell processes, is disrupted.<sup>389</sup> In an in vitro study, neuronal cell processes extended between two pieces of retina placed adjacent to each other in culture. However, processes did not appear to grow if they encountered glial structures such as the outer or inner limiting membranes.<sup>389</sup> In contrast, robust neurite outgrowth was seen in immature isolated retinal cells transplanted into the subretinal space of mutant mice deficient in GFAP and vimentin.<sup>475</sup> Disruption of the outer limiting membrane, breaking down the glial barrier using matrix metalloproteinase delivered through biodegradable polymers, as well as selecting specific cells based on cell surface markers, has been shown to improve graft migration and integration into host retina.<sup>391,392,401,476</sup>

Alternatively, scarcity of graft–host synaptic integration may involve factors intrinsic to the transplant itself. Retinal neurons, including photoreceptors, display synaptic plasticity during injury or disease<sup>301,477–481</sup> and in culture.<sup>482,483</sup> This potential for structural plasticity can be geared towards enhancing synaptic interactions between the graft and the host after transplantation. Photoreceptor sheets prepared by vibratome-sectioning undergo significant morphologic changes, including rapid retraction of axonal terminals towards their cell bodies in culture.<sup>484</sup> This phenomenon has also been seen in studies of experimental retinal detachment<sup>293,477</sup> and may be due to separation of photoreceptors from adjacent RPE cells. Retraction of photoreceptor terminals is likely to interfere with synaptic integration following transplantation since physical proximity is required for synaptogenesis to occur between pre- and postsynaptic elements. One can prevent retraction by increasing intracellular cAMP levels in photoreceptor sheets<sup>485</sup> or by inhibiting RhoA,<sup>486,487</sup> which may help improve synaptic interactions between pretreated photoreceptor grafts and host bipolar and horizontal cells.

Identification of the optimal parameters for successful retinal transplantation, such as the source of cells (e.g., human ESCs versus iPSCs versus mature dispersed photoreceptors) or the surgical procedure (e.g., sheets on a biodegradable membrane versus

dispersed cells), as well as resolving issues of tissue rejection, are important goals, regardless of whether the objective of surgery is “rescue” or “replacement.” We anticipate tremendous progress in generating photoreceptors from stem cells (induced pluripotent, embryonic, bone marrow, or peripheral blood) and identification of which cell is most capable of integrating and differentiating in a diseased microenvironment during the next decade. Additional studies on modification of the host transplantation microenvironment in order to optimize cell integration may also be pursued.<sup>394,396</sup> Restoration of a functional neural retinal network capable of mediating visual perception, which is a goal unique to “replacement” therapy, depends primarily on establishing graft–host synaptic integration sufficient to rectify the damaged neural circuitry resulting from cell loss. Preclinical studies have shown that it may be possible to restore transmission of visual stimuli between damaged retinas and higher-order areas of visual processing (i.e., V1 cerebral cortex) in select animal models of retinal degeneration.<sup>407</sup> To achieve neural reintegration, additional experimental studies (e.g., identification of molecules that foster synapse formation, development of means to unambiguously identify donor and recipient neurons, identifying methods to manage the synaptic rewiring that accompanies photoreceptor degeneration) and clinical studies must be done. Initial efforts to visualize integrating tissue reliably are underway. In addition, more rigorous functional tests must be developed to aid in the accurate, objective assessment of incremental changes in vision (particularly for low levels of visual function) following retinal transplantation. Since photoreceptor death is associated with synaptic remodeling in the local retinal circuitry<sup>298,301,302,478,488</sup> and may cause transneuronal cell death of inner retinal neurons, relatively early intervention (i.e., before foveal cone cell loss is profound) may play a significant role in the success of retinal transplantation.

## Conclusions

In principle, RPE and retinal cell transplantation offer the possibility of sight-restoring therapy for blindness due to age-

related macular degeneration, retinitis pigmentosa, and allied diseases. Extensive research has led to the identification of several obstacles to success, namely graft survival and differentiation (in the case of RPE and photoreceptors), graft integration with the host (in the case of photoreceptors), and immune rejection (at least in the case of RPE cells). Additional progress in this new field of ocular surgery will occur through an iterative process comprising the development of suitable in vitro and animal models, refinement of immune-suppressive therapy, development of a noncontroversial source of safe and unlimited donor cells from stem cells, improved in vivo imaging technologies for in situ assessment of the transplant anatomy and function in human patients, and carefully designed clinical experiments. The unique anatomy of the eye, including the laminar organization of retinal neurons, the immune-suppressive environment of the subretinal space, and the immune-privileged nature of RPE cells and retinal neurons, combined with straightforward surgical access to the subretinal space, augur well for the ultimate success of these efforts.

## **Introduction**

More than 1 million Americans are legally blind, 10% of whom have no light perception.<sup>1</sup> Certain approaches, such as gene and drug therapy (see [Chapter 36](#), Gene therapy for retinal disease), may be preventative or therapeutic options for blindness.<sup>2,3</sup> However, once photoreceptors are nearly completely lost, such as in endstage retinitis pigmentosa (RP) (see [Chapter 42](#), Retinitis pigmentosa and allied disorders) or age-related macular degeneration (AMD) (see [Chapter 64](#), [Chapter 65](#), [Chapter 66](#), [Chapter 67](#) on epidemiology/risk factors for AMD, pathogenesis, and diagnosis and treatment of dry and wet AMD, respectively), very few interventions<sup>4</sup> can restore useful vision to blind patients. Retinitis pigmentosa (RP) is the leading inherited cause of blindness, with 1.5 million people worldwide affected and an incidence of 1 in 3,500 live births.<sup>5</sup> AMD is the leading cause of visual loss among adults older than 65, with 700,000 newly diagnosed patients annually in the United States, 10% of whom become legally blind each year.<sup>6</sup> With an increased average lifespan, particularly in the developing world, the number of people with age-related eye disease and resulting visual impairment is expected to double during the next three decades.<sup>7</sup> Blindness imposes major economic and social consequences on affected persons, their caregivers, and society at large. The mean annual expense for patients with visual impairment and blindness is found to be two times the cost for nonblind patients. Time spent by caregivers to care for the visually impaired and other indirect costs due to productivity losses and premature mortality are additional considerable burdens.<sup>8</sup>

Few treatment options exist for outer retinal degeneration. Anti-VEGF therapy is very effective for the treatment of neovascular-AMD by inhibiting the growth of abnormal new blood vessels. This therapy is capable of preventing visual loss and even returning vision to patients treated in the initial phases.<sup>9-11</sup> Nevertheless, like most new therapies, it has limitations and drawbacks, and there is some evidence that there is disease progression in spite of injections, especially in polypoidal choroidal vasculopathy.<sup>12</sup> Moreover, a number of patients seek consultation when the neovascularization is advanced and irreversible vision loss has already occurred. Non-neovascular AMD can also become

advanced, leading to atrophic AMD (e.g., geographic atrophy). There is no approved therapy for atrophic AMD, albeit many companies are trying to develop a therapy for this slowly progressive variant of AMD. Replacement of atrophic retinal pigmented epithelium (RPE) with stem cell-derived RPE cells is being tested in multiple clinical trials;<sup>13</sup> however, it is not clear if patients with endstage macular degeneration with advanced loss of photoreceptors benefit from this method. Combined stem cell-derived RPE and photoreceptor progenitor cell implantation is proposed for such patients, but the safety and efficacy of such interventions have yet to be proven in clinical trials. Gene therapy has shown some success in Leber congenital amaurosis by targeting a specific mutation of the *RPE65* gene.<sup>14-17</sup> This is a tremendous scientific breakthrough, but the impact is limited, since this specific type of retinal degeneration is rare and the total number of eligible patients is small (approximately 1000). Neither anti-VEGF nor many of the proposed pharmacologic treatments or gene therapy can address lost vision due to photoreceptor loss, since photoreceptors are not regenerated by these approaches. Artificial vision, the novel concept of restoring vision by electrically stimulating the surviving retinal cells in a person who has lost vision due to advanced photoreceptor damage, has created hope for treating blindness.

This chapter will briefly summarize the history and evolution of electronic visual prostheses with an emphasis on retinal implants and will present the current state of the field with remaining challenges that lie ahead.

## **Background and History of Artificial Vision**

The concept of electrically stimulating the nervous system to create artificial vision was first introduced in 1929, when Foerster, a German neurosurgeon, observed that electrical stimulation of the visual cortex caused his patient to detect a spot of light (phosphene). He further demonstrated that the perceived location of this phosphene depended on the location of the stimulating

electrode over the cortex.<sup>18</sup> The first effort towards an electrical artificial vision device was undertaken 50 years ago by Giles Brindley. Brindley's implantation of an 80-electrode device onto the visual cortex of a blind patient revealed the possibilities of electrical stimulation to restore vision and the implementation barriers of a suitable device. Limitations of the available technology prevented the realization of a clinically deployed device, but Brindley's pioneering work influenced all subsequent major efforts in the area of electronic visual prostheses. In the past 50 years, exponential advances in our understanding of electronics, physiology, and medicine have enabled the development of implantable microelectronic systems that overcome the shortcomings of Brindley's large, immobile visual cortex stimulator.<sup>19</sup>

Examples of such advances have been noted in the fields of electrical engineering, computer sciences, and micromachining technology. For instance, very large-scale integration (VLSI) circuits and microelectromechanical systems (MEMS) technology have all contributed to the evolution of the field of visual prostheses by allowing for the creation of both smaller electronics and smaller neural interfaces. These technological advancements, coupled with recent scientific investigations, have transformed the focus of the field from that of whether it is possible to create visual sensations through electrical stimulation to the more important question of how to optimize the perceptions for maximum benefit. Current questions being considered are related to the quality of images created by stimulation of many small areas of neuronal tissue as well as the mechanical and electrical biocompatibility of the microelectronic implants.

Whether a useful vision can be rendered via an artificial visual prosthesis depends in part upon establishing a definition of useful vision that is based on the minimum number of pixels required for people to accomplish activities of daily living. Psychophysical experiments were conducted to estimate the number of the pixels needed for specific tasks. Brindley originally suggested that 600 points of stimulation (pixels) would be sufficient for reading ordinary print.<sup>19</sup> Recent studies have tested humans with normal visual function by pixelating their vision via a portable phosphene simulator, consisting of a small head-mounted video camera and

monitor. Patients then walked through an obstacle course and read pixilated text. In this fashion, it was determined that 625 electrodes implanted in a 1-cm<sup>2</sup> area near the foveal representation in the visual cortex could produce a phosphene image with a visual acuity of approximately 20/30 and reading rates near 170 words/minute with scrolled text and 100 words/minute with fixed text.<sup>20-23</sup> Furthermore, a degree of learning was noted as walking speeds increased fivefold during 3 weeks of training.<sup>22</sup>

Studies simulating electrodes placed over the entire macula rather than concentrated on the fovea have assessed the ability of subjects to recognize faces with artificial vision. Parameters included grid size (10 × 10 to 32 × 32 pixels), pixel size, gap width, pixel dropout rate, and grayscale resolution. The subjects achieved highly significant facial recognition accuracies in both high- and low-contrast tests with a marked learning effect documented. These results suggest that reliable facial recognition is possible even with crude visual prostheses, and possibly makes the task of engineering the implant easier as it would require fewer data/stimulation channels.<sup>23</sup> The ability of subjects to read using a pixilated visual simulator has been evaluated in a separate cohort which demonstrated that most subjects are able to read fonts as small as 36 point (with all at 57 point) using a 16 × 16 pixel array.<sup>24,25</sup>

## Visual Prostheses

Visual prostheses are based on neuronal electrical stimulation at different locations along the visual pathway (i.e., cortical, optic nerve, thalamus, epiretinal, subretinal). With the exception of thalamic prosthesis, prototype implants have been tested in humans in each location listed above, with varying results. Each approach has advantages and disadvantages. The main advantage of a cortical implant is that many types of blindness can be treated, including optic nerve disease. The main disadvantage of a cortical implant is that significant neural processing that normally occurs at the retinal and thalamic levels are missed with cortical implants. Retinal implants are applicable only in photoreceptor disease but tap into the visual pathway closer to the photoreceptors, thus most of the neural signal processing is preserved, albeit significant

processing in the retina may need to be replicated. The thalamic approach balances these concerns but is difficult to access surgically. In this chapter, the different types of implants, their position in the visual system, and recent results are discussed, but special emphasis is given to retinal implants.

## Cortical Prosthesis

Building upon earlier observations of phosphene perception with cortical stimulation, Brindley and Dobbie began work in the 1960s towards functional, visual cortex prosthesis. They demonstrated the ability to evoke phosphenes and patterned perceptions by electrically stimulating the occipital cortex via permanently implanted electrodes.<sup>19,26-32</sup> Both groups used implanted arrays with over 50 electrodes placed subdurally over the occipital pole, thus providing evidence of the ability to return the sensation of vision to individuals who had a severed visual pathway anterior to the visual cortex. Dobbie's 64-channel platinum electrode surface stimulation prosthesis allowed blind patients to recognize 6-inch characters at 5 feet (approximately 20/1200 visual acuity).<sup>29,31,33</sup> Difficulties encountered in these experiments included the following: (1) controlling the number of phosphenes induced by each electrode; (2) interactions between phosphenes; (3) use of high currents and large electrodes that induced pain from meningeal stimulation; and (4) occasional focal epileptic activity following electrical stimulation.<sup>29,34,35</sup> Patients in these initial experiments complained of not being able to appreciate distinct phosphenes, but rather reported seeing "halos" surrounding each phosphene.<sup>36</sup>

Since most of the visual cortex is deep within the calcarine fissure and inaccessible to cortical surface electrodes, intracortical stimulation via penetrating electrodes was introduced in hopes of remedying the shortcomings of surface cortical stimulation. The intracortical devices employed smaller electrodes closer to the target neurons, thus requiring less current and resulting in a more localized stimulation. The stimulus threshold was 10–100 times lower for intracortical prosthesis as compared to surface stimulation. Further, this approach allowed for closer spacing of electrodes at 500  $\mu\text{m}$  apart and thus possibly higher resolution.

Initial studies, during which the intracortical prosthesis was implanted in humans for a period of 4 months, demonstrated the ability to produce phosphenes that usually had color.<sup>37</sup>

Documented advantages of the intracortical versus surface cortical implants included (1) predictable forms of elicited phosphenes; (2) absence of flicker phenomenon; (3) reduction in phosphene interactions; (4) increased number of electrodes; (5) reduced overall power requirement.<sup>35,37-39</sup>

Current models of the intracortical prosthesis include the Utah electrode array. This device consists of multiple silicon spikes organized in a square grid measuring 4.2 mm by 4.2 mm.<sup>38</sup> A platinum electrode is at the tip of each spike. A pneumatic system, which inserts a 100-electrode device into the cortex in about 200 ms, is designed for minimal trauma during insertion of this array.<sup>40</sup>

The cortical visual prosthesis is advantageous over other approaches because it bypasses all diseased visual pathway neurons rostral to the primary visual cortex. As such, this approach has the potential to restore vision to the largest number of blind patients. There are some limitations to the cortical visual prostheses. First, histologic changes for chronically implanted prostheses need to be further investigated.<sup>41-43</sup> In the case of silicon-doped penetrating electrodes, such as Utah electrode array, tissue reaction has ranged from none to a thin capsule around each electrode track to gliosis and buildup of fibrotic tissue between the array and meninges.<sup>44</sup> Second, the organization of the visual field is markedly more complex at the level of the primary cortex than at the retina or optic nerve and is not easily reproducible between various patients.<sup>36</sup> Next, there is a high level of specialization of every area of cortex for various parameters including color, motion, and eye movement, making it unlikely to garner simple phosphenes from stimulation.<sup>45</sup> Finally, surgical complications of this approach carry significant morbidity and mortality for the patient. The future success of the intracortical prosthesis requires further investigation of these areas.

## Optic Nerve Prosthesis

Investigators have targeted the optic nerve as a potential site for the

implementation of a visual prosthesis.<sup>46</sup> Veraart et al. was the most recent of such groups attempting this method, employing the concept of a spiral nerve cuff electrode.<sup>47-50</sup> An electrode cuff is surgically implanted circumferentially on the external surface of the optic nerve. As this device does not penetrate the optic nerve sheath, it relies on the principle of retinotopic organization within the optic nerve. A volunteer with retinitis pigmentosa and no residual vision was chronically implanted with an optic nerve electrode connected to an implanted neurostimulator and antenna. An external controller with telemetry was used for electrical activation of the nerve that resulted in phosphene perception. Open-loop stimulation allowed the collection of phosphene attributes and the ability to elicit perception of simple geometric patterns. Low perception thresholds allowed for large current intensity range within safety limits. In a closed-loop paradigm, the volunteer was using a head-worn video camera to explore a projection screen. The volunteer underwent performance evaluation during the course of a training program with 45 simple patterns. Multiple bars (each 320 × 22 mm when projected on a screen) were combined to form letters on a 1 × 1-m screen, with the patient at 0.5 m from the screen. After learning, the volunteer reached a recognition score of 63% with a processing time of 60 seconds. The results were encouraging in that the blind volunteer was able to adequately interact with the environment while demonstrating pattern recognition and a learning effect for processing time and orientation discrimination.<sup>51</sup>

The optic nerve is an appealing site for the implementation of a visual prosthesis, as the entire visual field is represented in this small area. This area can be reached surgically and presents a viable anatomic location for an implant; however, there are several hurdles to overcome regarding this approach. First, the optic nerve is a densely consolidated neural structure with approximately 1.2 million axons in a 3-mm-diameter cylinder. While this allows for the entire visual field to be represented in a relatively small area, it is difficult to achieve focal stimulation of neurons and to replicate the exact retinotopy of the optic nerve. The dense packing of neurons requires a large number of electrode contacts from the prosthesis in a small area, increasing the risk of damage to the

nerve.<sup>52</sup> Surgical manipulation of this area requires dissection of the dura mater, creating possible harmful CNS effects including infection and possible interruption of blood flow to the optic nerve. Intervention at this point within the optic pathway requires intact retinal ganglion cells (RGC) and therefore is limited to the treatment of outer retinal (photoreceptor) degenerations. The optic nerve and RGC represent higher-order structures than the bipolar cells targeted by the retinal prosthesis. As such, the processing power of the bipolar, horizontal, and amacrine cells is lost, and therefore much more image processing must be achieved by the implant rather than relying on intact human physiologic pathways. Last, the nerve fibers from the macula lie most centrally within the optic nerve. Cuff electrodes, thus, are farthest away from macular fibers, and this will dramatically limit the use of this approach, especially for AMD, as the peripheral fibers will get stimulated along with the central macular fibers. Future development of this technology must address the above issues. Investigators have also proposed intraneuronal stimulation devices in order to more accurately target individual neurons within the optic nerve.<sup>53</sup>

## Retinal Prostheses

The pathobiology of disorders causing blindness must be considered in discussions of visual prostheses.

### Pathology of Retinitis Pigmentosa and Selected Macular Disorders

Potts and Inoue, over 45 years ago, demonstrated the ability to evoke an electrically elicited response (EER) via ocular stimulation using a contact lens as a stimulating electrode.<sup>54-56</sup> This discovery was expounded upon by Knighton, who demonstrated that inner retinal layers could be electrically stimulated to elicit an EER.<sup>57,58</sup>

For a retinal prosthesis to function properly, the retina must not be affected by disease to the point where few viable cells remain to initiate a neural signal. Postmortem morphometric analysis of the retina of patients with endstage RP has revealed that 78.4% of inner nuclear and 29.7% of ganglion layer cells (RGC) were retained compared to only 4.9% of photoreceptors.<sup>59</sup> Also, 93% of RGC were

spared and an increase in inner nuclear layer cells (by 10%) was noted in legally blind neovascular AMD patients.<sup>60,61</sup> Furthermore, no statistical significance was noted in the number of inner nuclear layer cells between non-neovascular eyes with geographic atrophy and age-matched controls.<sup>60,61</sup> This demonstrated limited trans-synaptic neuronal degeneration in the aforementioned retinopathies, and as such, showed that it is theoretically possible to electrically stimulate the remaining retinal neurons to elicit useful visual perceptions. However, it is important to understand the stages of outer retinal degeneration and the associated anatomic and physiologic changes that occur. A comprehensive study by Marc et al. has characterized the three phases of retinal neuronal degeneration and remodeling.<sup>62</sup> In the first two phases, photoreceptor stress and death, and associated loss of trophic transport are observed. Both bipolar and horizontal cells can actually retract dendrites, while the latter can sprout axonal and dendritic processes that can reach the inner plexiform layer. Müller cells can form a dense fibrotic layer and seal off the subretinal space, electrically isolating implants placed there via the choroid. In phase 3, the number of viable cells of all classes is depleted. In this phase, bipolar and amacrine cells migrate up to the ganglion cell layer and undergo neural rewiring.

Such anatomic changes manifest physiologically. Using a patch clamp technique in a retinal degeneration mouse model, it has been shown that rod bipolar cells lose their sensitivity to the excitatory neurotransmitter glutamate while they increase their response to the inhibitory horizontal cell neurotransmitter GABA.<sup>63</sup> In addition, oscillatory fluctuations in membrane potential, originating in AII amacrine cells, have been noted in animal models of retinal degeneration.<sup>64</sup> Thus, the retinal circuitry is altered both anatomically and physiologically by degeneration.

In spite of these well-documented changes in the inner retina after photoreceptor loss, numerous studies have established the safety and efficacy of electrical stimulation of the retina. Early studies by Humayun and colleagues established the feasibility of electrical stimulation of the retina.<sup>59,65,66</sup> In an operating room setting, handheld electrodes were inserted into the eye of blind test subjects. The test subjects reported the appearance of small spots of

light when the electrodes were activated. The apparent location of the spot of light in general corresponded with the retinal area stimulated. Similar experiments were repeated by other groups.<sup>67,68</sup> While these experiments only allowed a few hours of testing in each subject, the critical findings led to the development of a chronic implant system.

## **Epiretinal Prostheses**

Epiretinal implants rely on external cameras to capture images and then transform this visual information to patterns of electrical stimulation to excite remaining retinal neurons. Designs tend to vary in terms of how much required electronic circuitry is contained in an intraocular device versus extraocular elements. Powering and signal transmission may be accomplished by induction coils, penetrating wires, or lasers.

The advantages of the epiretinal approach include the following: (1) the epiretinal placement allows for surgical access that follows standard vitrectomy procedures; (2) a minimal number of microelectronics are incorporated into the implantable portion of the device since image processing is external to the body; (3) the wearable portion of electronics allows for easy upgrades without requiring subsequent surgery; and (4) the electronics allow the user and the doctor full control over every electrode and image processing parameters, allowing the implant to be customized for each patient. The disadvantages to this approach include (1) requirement of techniques that will provide prolonged fixation of the device near the inner retina and (2) further distance of the epiretinal device to the target bipolar cells than the subretinal device requires increased current.

### **ARGUS I.**

The ARGUS I system consists of a 16-channel stimulator, based on a commercial cochlear implant, positioned behind the ear, and attached to a cable that terminates at an electrode array on the epiretinal surface. The electrode array is a 4 × 4 grid of platinum disk electrodes, either 260 μm or 520 μm in diameter. The overall size of the ARGUS I retinal array is 3 × 3 mm. An inductive coil link is used to transmit power and data to the internal portion of the

implant from an external video processing unit (VPU), and a miniature camera that is mounted on a pair of glasses. The video camera captures a portion of the visual field and relays the information to the VPU. The VPU digitizes the signal in real time, applies a series of image processing filters, down-samples the image to a  $4 \times 4$  pixelated grid, and creates a series of stimulus pulses based on pixel grayscale values and conversion tables (from grayscale value to pulse amplitude) customized for each subject. The data are delivered via an inductive RF coil link and the application-specific circuitry to the pulse generator.

The surgical procedure for the ARGUS I system implantation included a botulinum toxin injection 2 weeks prior to the surgery, in the superior, inferior, medial, and lateral rectus muscles, due to the concern that the subject's eye movement might break the cable connecting the intraocular electrode array to the extraocular electronic case. Two weeks post-injection, under general anesthesia, the implant was placed in a recess well created in the temporal skull, similar to cochlear implant surgery.<sup>69</sup> To secure and protect the cable, a shallow groove was created along the temporal skull. The cable was then placed in the groove and delivered through a lateral canthotomy into the periorbital space. Next, the cable and electrode array were implanted under the four rectus muscles. A complete pars plana vitrectomy was performed and the array introduced to the eye through a 5-mm scleral incision placed 3 mm posterior to and parallel to the limbus. The array was placed temporal to the fovea, and a single retinal tack was inserted to secure the array in place.<sup>70</sup> A clinical trial of the ARGUS I device began in 2002 and enrolled six RP patients.

Subjects were able to discriminate between different electrodes, identify everyday objects such as a knife, a plate or a cup, and detect the direction of motion. Perceptual thresholds were within safe limits and were stable over time.<sup>71,72</sup> Perceptual thresholds correlated with separation (i.e., lift-off) between the electrode array and the retina.<sup>71,73</sup> In addition, increasing frequency of pulses lowered the charge per pulse in a predictable way.<sup>74</sup>

The best visual acuity using the ARGUS I was the maximum allowable by the spacing of electrodes on the array (i.e., 20/4000), but this was only demonstrated in one test subject.<sup>75</sup> Adverse events

included erosion of the conjunctiva over the cable at the sclerotomy and detachment of one array after one subject incurred blunt ocular trauma (subsequent re-tacking was successful).

## ARGUS II.

The ARGUS II system (Fig. 129.1) is the first FDA approved and CE Mark certified artificial vision device for human use. It uses an external camera system very similar to ARGUS I, but the implanted part of the device is completely different. The ARGUS II system comprises an encircling band (sclera buckle), an inductive coil, and a case containing the electronic components attached to the band, and an integrated ribbon cable and electrode array. The electrode array spans 20° of visual field corner-to-corner. All components fit inside the orbit.

**FIG. 129.1** ARGUS II System. (A) Schematics of the ARGUS II system and the eye. (B) ARGUS II 60 electrode array placed in the surface of the retina with tack in place.

The implantation procedure is similar to a pars plana vitrectomy with an encircling buckle. The device is placed under the four rectus muscles, with the implanted electronic components sutured on the superior temporal quadrant, with the anterior edge of the case 7 mm posterior from the limbus, and sutures around the encircling band on the other four quadrants. The cable and array

are then inserted through a 5-mm incision at 3.5 mm posterior to the limbus. The incision is sutured watertight, and then a retinal tack is used to fix the array to the retinal surface. The optimal placement of the array is over the macular area. External components of the system are similar to ARGUS I and the basis of operation is the same.

More than 200 patients worldwide have received the ARGUS II implant.<sup>76-78</sup> Long-term safety and efficacy were evaluated in 30 subjects in a multicenter clinical trial.<sup>77</sup> Of these 30 subjects who were enrolled between June 2007 and August 2009 at 10 clinical centers, 29 had RP (including one with Leber congenital amaurosis) and one patient had choroideremia.<sup>78</sup> All subjects were able to perceive light during electrical stimulation. Experiments documented improvement in object localization. Using a target of a 7-cm white square on a black LCD screen at 30 cm distance, 27 out of 28 subjects (96%) performed better in localizing the object with System on versus off. No subjects performed significantly better with the System off.<sup>74</sup> At 3 years, 89.3% of the subjects continued to demonstrate improved visual task performance with the system on versus system off.<sup>77</sup> Motion detection improved too, but to a lesser extent as this was a more difficult task. Using a target of a white bar moving across a black LCD screen, 63% and 56% of the subjects performed this test better with the System on versus off at the end of year 1 and 3 respectively.<sup>77,78</sup> Some subjects reported the perception of color, which could be reliably produced under certain conditions.

All subjects' acuity was measured at worse than 2.9 logMAR in both eyes before implantation. To date, none of the subjects has been able to reliably score on the visual acuity scale in either eye with the System off. At the end of year 1, seven subjects were able to reliably score on the scale with the System on in at least one follow-up time point. At year 3, 33% of the subjects scored 2.9 logMAR or better with the system on.<sup>77</sup> The best result to date has been 1.8 logMAR (equivalent to Snellen 20/1262).<sup>78</sup> Subjects performed better using their Argus II systems in orientation and mobility functions as measured by door and line recognition tasks. Activities of daily living and quality of life was overwhelmingly rated better with system on.<sup>77</sup>

Letter reading was tested in 22/30 subjects. Six of these subjects were able to identify any letter of the alphabet at a 63.5% success rate (vs. 9.5% with the system off). In all 22 subjects, a small set of eight letters was identified 72.5% correctly, versus 16.8% with the system off. Subjects were free to take as much time as needed to make a judgment. Subjects provided answers after 100 seconds in the full alphabet and 44 seconds in the limited letter set.<sup>76</sup> Seventy percent of the patients could recognize letters with only horizontal and/or vertical components and about half of the patients were able to read letters that had oblique or curved components.<sup>76</sup> Some subjects were able to put the letters together into words and read sentences.<sup>78</sup>

Twenty-nine subjects had functional devices 3 years after implantation. Of the 30 subjects, 19 subjects (61%) had no serious adverse events (SAE) and none had any unanticipated adverse events at the end of 3 years' follow-up. After 3 years of implantation, four subjects experienced conjunctival erosion due to the extraocular device, this being the most common SAE. All but one were successfully repaired. One device was explanted for SAE management, rather than device failure. This patient had recurrent erosions of conjunctiva over the extrascleral elements of the prosthesis and decided to have the device explanted after three attempted repairs. Other SAEs included three cases of presumed endophthalmitis; each was treated with intravitreal antibiotics, and the devices were not explanted and remain functional. There were four cases of hypotony that were resolved with surgical intervention. There was one intraoperative retinal tear treated successfully during surgery with laser retinopexy and two retinal detachments that required subsequent surgery to reattach the retina.<sup>78</sup> Keratitis, corneal opacity, and corneal melt each occurred in one patient and were treated medically.<sup>77</sup>

Based on these results, and manufacturing details provided by Second Sight Medical Products Inc., the ARGUS II received a CE Mark in March 2011 and FDA approval in 2013, making it the first retinal implant to be sold as a medical device in Europe and the United States. This has been a major milestone in the field of artificial vision and would allow more patients to be implanted and allow further postmarket studies.

## IRIS Epiretinal Implant.

The IRIS (Intelligent Retinal Implant System) epiretinal implant (Pixium Vision, France) is under clinical trial in multiple centers in Europe at the time of this writing. The device has evolved from the experimental prosthesis developed by Intelligent Medical Implant AG (IMI), a Switzerland-based company. Similar to Argus II, the IRIS epiretinal implant includes three components: (1) an implant with extraocular electronics, an induction coil, a transscleral cable, and an epiretinal array; (2) a body-worn processing unit; and (3) a glasses-mounted camera. In preparation for chronic implant testing, acute stimulation tests of the intraocular array were performed in 20 human subjects with RP.<sup>79</sup> The acute testing surgery was performed under subconjunctival anesthesia. The four rectus muscles were fixed, and a pars plana vitrectomy with complete removal of the vitreous and posterior hyaloid was performed. Afterwards, the electrodes were introduced into the eye using the MESE 12 system (Fig. 129.2), a handheld surgical instrument for controlled positioning of a microcontact film on the surface of the retina. The system must be held by the surgeon during the entire procedure. Most subjects were able to recognize objects as small as a coin at 1 meter.<sup>79</sup>

**FIG. 129.2** MESE 12 handheld system.

A 49-electrode IRIS epiretinal implant has been tested in eight subjects. Most implants were removed after a few months, but some

have stayed in place for several years. The main findings of the chronic implant clinical trial were low thresholds to elicit visual perceptions and that the implant was reasonably well tolerated by the eye. The device was only activated in the clinic and was directly controlled by computer (i.e., no camera), therefore visual performance results were limited. Thresholds in one subject were measured for an extended period and ranged from 8.0 and 35.9 nC (which corresponds to single  $\mu\text{A}$  of current for 1–2 ms) and were reported as stable over an extended period of testing. The subjects reported that the phosphenes had different appearances, point-to-point relative location was possible, and simple shapes such as a horizontal bar were recognized when presented.<sup>80</sup>

In 2014, Pixium Vision (Pixium Vision, SA, Paris, France) acquired IMI's technology to develop the IRIS V1 implant. A multicenter clinical trial involving IRIS V1 is scheduled for completion in June 2017 ([www.clinicaltrials.gov](http://www.clinicaltrials.gov), NCT01864486). Twenty patients are expected to enroll in the study. The commercial version of the device will have 150 electrodes. A superior image processing system is claimed as the main feature of the IRIS V1 device. The processing unit encompasses the “retina encoder” that modifies each patient's settings until he/she is able to perceive the image. For example, if a square is shown to the patient, the algorithm will adjust the settings until the patient perceives a square.<sup>81</sup> It is shown that less than 100 iterations are necessary to calibrate and personalized the system to the needs of an individual patient.<sup>82</sup> Pixium Vision is also collaborating with Stanford University to develop PRIMA Vision Restoration System, a subretinal implant currently in preclinical phase.

Epi-Ret 3 is the third epiretinal device that was implanted in six test subjects in 2006. This unique implant was designed to fit entirely inside the eye yet had a provision for external power via an inductive wireless link. The electrode array had 25 electrodes that were slightly protruding from the substrate (Fig. 129.3).<sup>83</sup>

**FIG. 129.3** Fundus photos of all six chronic implants to date: (A) Artificial Silicon Retina (*white arrow*); (B) ARGUS I; (C) Active subretinal device; (D) Epi-ret 25 electrode device; (E) 49-electrode epiretinal device; (F) ARGUS II (A, courtesy Optobionics/ASR, Dr John Pollack; B, courtesy Second Sight Medical Products, Inc.; C, courtesy Retina Implant, GmbH, Prof. Eberhart Zrenner; D, courtesy Prof. Peter Walter); E, courtesy Intelligent Medical Implants, Prof. Gisbert Richard); F, courtesy Second Sight Medical Products, Inc.)

The implantation procedure required a pars plana vitrectomy and removal of the lens or intraocular lens (IOL) and the capsular remnants. An 11-mm corneoscleral incision was performed for the insertion of the device, and transscleral 10.0 sutures were utilized for the stabilization and placement of the inductive coil and electronics module right behind the iris, resembling an IOL scleral fixation. A micro cable acted as a substrate for microelectronic components, and its flexibility allowed it to bend and follow the eye curvature. After the corneoscleral incision was closed, the stimulation electrodes were fixed on the surface of the retina with two retinal tacks. The implants were removed after 28 days in the first clinical trial.<sup>83</sup>

Tests during implantation showed that the device remained in position for the entire implant period. Consistent with the other epiretinal implant studies, low perceptual thresholds (i.e., single  $\mu\text{A}$  of current) were reported.<sup>83,84</sup> Exams 6 months after explantation

showed only some proliferation around the retinal tacks, which were left in place.<sup>83</sup>

## **Subretinal Prosthesis**

The subretinal approach to the retinal prosthesis involves implanting a microphotodiode array between the bipolar cell layer and retinal pigment epithelium. This is accomplished surgically either via an intraocular approach through a retinotomy site (*ab interno*) or a transscleral approach (*ab externo*).

A subretinal prosthesis that uses microphotodiodes (solar cells) to convert light into electrical stimulation signals appears as an elegant solution to replace photoreceptor function.<sup>85</sup> However, several limitations currently hinder this technology from realizing its goal of providing artificial vision. Of primary concern is the inefficiency of current photodiode technology.<sup>86</sup> The illumination levels required in order to achieve adequate electrical current generation are not realistically attainable as the solar cells will need to generate electrical energy many orders of magnitude greater than that which is currently viable.<sup>87-89</sup>

This limitation jeopardizes the passive, all-inclusive nature of the subretinal prosthesis, which more than likely will require an external power source to amplify photocurrent. A device based solely on microphotodiodes (solar cells) is very unlikely to be a prosthesis, since it cannot directly produce phosphenes via electrical stimulation. This section will only focus on subretinal prostheses that have enough power to function as such. A clinical trial of passive subretinal devices is discussed in the section on electrotherapeutics (below).

There are distinct advantages and disadvantages to the subretinal prosthesis approach. Advantages include closer proximity to the next surviving neuron in the visual pathway (i.e., bipolar cell), and therefore less current requirement, and a more stable means of mechanical fixation. The disadvantages include the limited subretinal space to place electronics as well as the close proximity of the retina to the electronics, which would increase the likelihood of thermal injury to the neurons. If the subretinal implant is comprised as an electrode array with the electronics outside the eye (*ab externo* approach), then the implant will have a cable piercing

the sclera. Issues related to such a surgical approach include long-term tethering effects because of the cable and a transchoroidal incision resulting in a greater likelihood of subretinal hemorrhage as well as possible retinal detachment either total or localized. In the latter case, the subretinal fluid would increase the distance between the underlying electrode and the retinal neurons and therefore increases the current requirements.

**Alpha IMS:** In 2009, Retina Implant AG (RI), Reutlingen, Germany, started a clinical trial on a prototype subretinal prosthesis, now called Alpha-IMS. The first prototype implant had an intraocular part, comprising the subretinal chip, a flexible substrate to hold the chip and an additional test electrode array, and a cable to connect the chip and array with the supporting electronics (Figs. 129.4A–B). The subretinal chip had 1500 pixels elements, each with a photo diode detector, circuitry to amplify the detected signal, and an electrode to stimulate the retina. The test electrode array had 16 individual electrodes and was included to provide a means for direct stimulation tests via external test equipment (Fig. 129.4A). The chip/array assembly was placed subretinally, and the cable exited the eye through the pars plana and followed an intraorbital, subcutaneous path to a point behind the ear, where the cable crossed the skin. This transcutaneous connection allowed direct access to the subretinal chip for power, measurement, and configuration as well as direct access to the test electrode array (Fig. 129.4B). The implant was designed to give a diamond-shaped visual field of  $10^\circ \times 10^\circ$ , diagonally  $15^\circ$ .

**FIG. 129.4** Alpha IMS subretinal implant and cable.

The direct stimulation electrodes with some of the test patterns of stimulation are shown in [Figs. 129.4C–F](#). Also the microphotodiode array is shown magnified, with its rectangular photodiodes above each squared electrode ([Fig. 129.4G](#)). The implantation can be theoretically performed through either a pars plana vitrectomy (PPV) and retinotomy (ab interno), or PPV and a transscleral approach (ab externo);<sup>85,90</sup> however, to date, only the ab externo approach has been used in the patients. Multiple publications have detailed the procedure and long-term outcome of Alpha-IMS implantation in humans.<sup>91–95</sup> Hypotensive anesthesia has been used to prevent the risk of excessive choroidal bleeding when a 5-mm incision is made in the sclera and choroid to introduce the array into the subretinal space. A guide was used to help slide the electrode array under the retina, and the placement was controlled with indirect ophthalmoscopy during the surgery. A silicone oil tamponade was used to prevent retinal detachment. Preoperative topographic mapping of the macula was carried out in some

patients to find the optimal macular position.<sup>90</sup> Comparing functional status of the implant in “subfoveal” versus “parafoveal” position showed a remarkable advantage for subfoveal implantation.<sup>95</sup> It should be noted that finding functional fovea can be a challenge in many patients with advanced RP due to extreme retinal atrophy. A fundus photo and the placement of the device on the skull are shown in [Fig. 129.5](#).

**FIG. 129.5** Alpha IMS subretinal implant in a retinitis pigmentosa patient. (A) Electrode placed on the subretinal space. (B) Trajectory of the cable from the eye to the external connector. (Panel A with permission from Zrenner E, Bartz-Schmidt KU, Benav H, et al. Subretinal electronic chips allow blind patients to read letters and combine them to words. *Proc Biol Sci* 2011;278:1489–97, with permission from *Proc R Soc B*, published online, November 3, 2010.)

The first set of studies were semichronic, by design and largely due to the infection risk of a transcutaneous cable, with planned explantation several weeks to 3 months later. Twelve subjects were enrolled in this study. Of the first seven subjects, four had electronic hardware problems that precluded further testing of the implanted active chip. For the first nine subjects, implants were removed after 1 month while the last three subjects had longer period of implantation (3 months). One subject refused to have the implant removed. Functional testing of the active subretinal implant

demonstrated the ability to see lines and determine the correct orientation of these lines. A scanning laser ophthalmoscope was used to directly activate the subretinal chip, and a laser spot as small as 100  $\mu\text{m}$  produced a visual perception.<sup>85</sup> Because the device required an external connection to function, it was only operated in a clinic setting and the patients did not use the device outside the clinic.

The group published detailed results from the last three (of 12) subjects in 2011.<sup>85</sup> Having gained experience from the first nine subjects, hardware problems were largely avoided in the last three. Also, placement of the subretinal array was more consistent in the macula. Results from these three subjects showed that one patient could identify the direction of the letter “U” when presented in one of four orientations (20/24 times correct), when using the DS electrodes. Patient two of this group could identify letters and combine these into words. All three patients could detect the orientation of gratings, with patient two achieving a visual acuity of logMAR 1.74. This study was the first to report letter reading, providing strong support for functional vision via electrical stimulation. The short duration of implantation (1 or 3 months) limited the amount of data available from these tests. The robustness of this system needs to be improved. The device experienced technical failures at a rate unacceptable for a clinical implant, although fewer problems were noted in later implants.

The percutaneous connector is eliminated in the newer version of the device by adding a power module which is implanted behind the ear and receives power and controls signals wirelessly.<sup>85,92-95</sup> This change and the addition of a portable, external power supply, allow patients with this device to use it outside the clinic. Other features of the implant are similar to the first prototype described above. A cable connects the power module behind the ear to the subretinal chip. But no direct stimulation electrodes are included in the latest version of the Alpha-IMS. Recent publications reporting long-term outcomes of the Alpha-IMS implant encompass patients implanted with both versions of the device.<sup>94</sup> Of 29 patients included in the 2015 report, 21 subjects (72%) met the primary endpoint of the study at the end of 12 months follow-up. The primary endpoint of the study was significant improvement of

activities of daily living and mobility as determined by daily living tests, recognition tests, or mobility tests. Thirteen participants (45%) reported restoration of visual function to the point to be used in daily life. Twenty-five participants (86%) reached the secondary endpoints of significant improvement of visual acuity/light perception and/or object recognition. One patient achieved Snellen visual acuity of 20/546 using Landolt C charts. Maximal motion perception ranged from 3 to 35 degrees per second. Additionally, detection, localization, and identification of objects were reported significantly better with the implant power switched on in the first 3 months.<sup>94</sup> Four out of 29 patients were never able to perceive any light with the subretinal implant. The inability for light detection in these cases was attributed to (1) intraoperative touch of the optic nerve; (2) retinal edema over the implant; (3) suspected retinal ischemia; and (4) technical failure of the implant. Two SAEs included increased intraocular pressure and retinal detachment immediately after the implantation were reported in this cohort. Both patients were managed with standard methods.<sup>94</sup> An earlier study from the same group focused on the safety of the Alpha-IMS implantation in nine patients implanted in a single center reported a wider range of minor and major SAEs.<sup>92</sup>

The Alpha-IMS's higher photodiode density, subretinal placement, and use of optical properties of the operated eye are main advantages of this subretinal implant. The device harnesses the benefits of eye movements to scan scenes and fixate, and utilizes natural ocular microsaccades for refreshing the perceived images.<sup>93</sup> In addition, visual signal processing by bipolar and amacrine cells may enhance motion and contrast perception in subretinal implants such as the Alpha-IMS. Supported by angiographic and psychophysical evidences, it is proposed that inner retinal function may recover above the baseline after a period of stimulation by subretinal implantation.<sup>95,96</sup>

The Boston Retina Implant Project (BRIP) has been developing a device with more than 200 individually controlled stimulating electrodes.<sup>98</sup> The new-generation implants have the power and data receiver coils that are implanted in the anterior part of the eye, circumferential to the cornea, just posterior to the limbus. The electronics enclosure is made of titanium. The electrode

implantation is in the same quadrant as the electronics facilitating surgical access to the subretinal space via a scleral flap.<sup>10,99</sup> Like the Argus II, the BRIP implant utilizes an external camera to provide wireless, real-time video data to the stimulator. The device is not yet in clinical trial.

Palanker et al. have developed a wireless photovoltaic retinal prosthesis system, in which camera-captured images are projected onto the subretinal implant using pulsed near-infrared (IR) light (~900 nm).<sup>100,101</sup> This architecture seeks to minimize the size and complexity of the implant. To accomplish this goal, the system requires a head-worn display that can display IR light in front of the eye with a subretinal implant. Each pixel in the subretinal implant directly converts pulsed light into local electric current to stimulate the nearby inner retinal neurons. Each single pixel has three photodiodes in series connected between the active central and peripheral return electrodes. Several versions of the subretinal array have been fabricated, with pixel sizes from 100 to 25  $\mu\text{m}$ , corresponding to 640–10,000 pixels on an implant 3 mm in diameter (corresponding to a maximum theoretical visual acuity of 20/80).

This group has evaluated two basic geometries to improve proximity to retinal neural cells: perforated membranes and protruding electrode arrays.<sup>102</sup> In an in vitro experiment placing retinas with the photoreceptor side down in contact with a 13- $\mu\text{m}$  implant with 40- $\mu\text{m}$  apertures, retinal tissue migration was observed in all samples of rat, chicken, and rabbit retinas (Fig. 129.6). Migration occurred through pores  $>5 \mu\text{m}$ . Implantation in rat and pig eyes has showed good integration of the implant in the subretinal space ensuring long-term biostability as well as robust cortical responses upon stimulation with pulsed near-IR light.<sup>100,101,103–105</sup> Two different designs of the device each with 5- or 10- $\mu\text{m}$  wide perforations were implanted in rats and pigs. Subretinal placement was verified with optical coherence tomography, and retinal perfusion was studied with fluorescein angiography. Regardless of implant design, retinas of both species showed normal vasculature. Rat retinas showed significant migration of inner nuclear layer (INL) cells through the perforations, INL thinning, and pseudo-rosette formation. Pig retinas maintained photoreceptors, showed no migration, and less

pseudo-rosette formation, but more fibrosis formation in 8 weeks compared with implanted rat retinas.<sup>103</sup> In addition, implantation in rats showed robust cortical responses that could be modulated by irradiance, pulse duration, and frequency, with stimulation thresholds well below the ocular safety limits up to 6 months after implantation.<sup>105</sup> The developers are collaborating with Pixium Vision, France, to rebrand this implant as PRIMA Vision Restoration System. First human trials were planned to start in 2016.

**FIG. 129.6** (A) Three-layered membrane with channels on top, inner chambers, and a fenestrated membrane at the bottom. Voltage can be applied across the two

electrodes (*horizontal blue lines*). Current flow between the two electrodes is indicated by the *red lines with arrows*. 2' indicates electrode interface with inner retina. (B) Rat retina grown on the structure after 7 days in vitro, with migration of retinal cells through the 20- and 35- $\mu\text{m}$  holes into the middle chambers, but not through the 3- $\mu\text{m}$  holes in the lower membrane. GC, Ganglion cells; IN, inner nuclear layer; ON, outer nuclear layer. (Reproduced with permission from Palanker, et al. Attracting retinal cells to electrodes for high-resolution stimulation, Vol. 5314. San Jose, CA: SPIE; 2004.)

Some questions arise from this approach, mainly if the retinal tissue will remain viable after migrating through the pores, if the circuitry will be kept functional given the lack of a proven hermetic coating and lastly, if the migrated tissue will differentiate into fibrous tissue. Another approach consists of subretinal implants with protruding electrodes so that cells can migrate to the spaces between the electrodes, similar to the migration observed in the perforated membrane. In vivo implantation on Royal College of Surgeons (RCS) rats of 70  $\mu\text{m}$  in height with 10  $\mu\text{m}$  in diameter arrays showed penetration of the pillars into the inner plexiform layer and the retina well preserved ([Fig. 129.7](#)).<sup>106,107</sup>

## Suprachoroidal and Transscleral Retinal Prostheses

Two groups of investigators from Japan and Australia have recently moved to in-human trial of a suprachoroidal approach of retinal

stimulation. A suprachoroidal-transretinal stimulation (STS) implant has been developed and tested in human at the Osaka University in collaboration with Nidek Inc., Osaka, Japan (Fig. 129.8). The suprachoroidal approach is based on the premise that placing a stimulating electrode in the suprachoroidal space or in the fenestrated sclera along with a ground electrode in the vitreous cavity may allow for a less-invasive method to achieve visual percepts. The advantages of this approach are multiple. First of all, the surgery is less complicated. Second, the electrodes are less invasive to the retina. Third, the electrodes are relatively easy to remove or replace if damaged.<sup>108,109</sup>

**FIG. 129.8** Suprachoroidal-transretinal stimulation (STS) prosthesis. (A) Internal part of the STS system. (B) Electrode array ( $6 \times 6 \times 0.5$  mm) with 49 platinum electrodes in a  $7 \times 7$  array. (C) Return electrode and extraocular microelectronic simulator. (D) External transmitter and processor of the STS system. (E)

**Microstimulator.** (Reproduced with permission from Morimoto T, Kamei M, Nishida K, et al. Chronic implantation of newly developed suprachoroidal-transretinal stimulation prosthesis in dogs. *Invest Ophthalmol Vis Sci* 2011;52:6785–92.)

Because the electrodes are further from the target neurons, they will need to deliver higher currents and the current spread should be greater, therefore limiting the resolution.<sup>108,109</sup> Although no damage was seen at the light microscopic level to the retinal tissue around the area of stimulation in the short term in rabbits implanted with STS devices,<sup>110</sup> this approach remains to be proven safe over long-term implantation.

Initially, STS was investigated in the RCS rats and rabbits. In the RCS rats, the investigators studied threshold intensities of electrically evoked potentials (EEPs) from the superior colliculus (SC). It was found that the response to the STS was recorded in the localized retinotopically corresponding SC areas, suggesting that the focal stimulation to the degenerated retina effectively elicits artificial vision in the RCS rats. Similar findings were noted in rabbits. The threshold intensity of the EEPs was 5–10 nC of electrical charge, suggesting that stimulation via STS may be attained with relatively low stimulating current.<sup>108</sup> However, it should be noted that rabbit sclera and retina are thinner than in humans, thus partially accounting for the relatively low stimulating current in this study.

The results from a long-term implantation in canines were published in 2011.<sup>109</sup> STS microelectrode arrays were implanted in a scleral pocket and were kept in place for 3 months. The electrode array and the return electrode were connected to the extraocular stimulator by a multiwire cable, connected wirelessly to an extracorporeal processor and transmitter. The electrode array measured  $6 \times 6 \times 0.5$  mm, with 49 platinum electrodes in a  $7 \times 7$  arrangement fixed in a clear silicone rubber platform coated with Parylene. The stimulating electrode was 0.5 mm in diameter and 0.5 mm in length and the distance between the centers of the electrodes was 0.75 mm, and the return platinum electrode placed in the vitreous cavity was 6.5 mm in length and 0.5 mm in diameter. Nine of the electrodes on the array were electrically active for this experiment, which was performed in three animals. After 3 months,

the devices were safely explanted with no intraoperative complications, the position of the eyes was maintained orthophoric without proptosis during the follow-up period, and all the wounds healed properly with no sign of infections or wound dehiscence. The ERGs had the normal a-wave and b-waves, and the shape did not differ from the ERGs recorded from the unoperated fellow eye 3 months after the implantation in all three animals. Histologic sections from two implanted and control eyes showed no obvious changes in the structure of retina and choroid beneath the electrode array in two dogs; however, pathologic changes were detected in one dog (Fig. 129.9). The retinal and choroidal architecture was destroyed due to the mechanical pressure, according to the authors.<sup>109</sup>

**FIG. 129.9** Light microscopic photographs of the retina and sclera from the implanted eyes of two dogs. (A,C)

Photographs of the retina and sclera around the electrode array from dog one. No damage of the retina is visualized. (B,D) Photographs of the retina and sclera around the array from dog two. Local damage of the retina and choroid at the site of the implanted electrode array can be seen (*arrowheads*); however, the other area of retina on the array is intact (*arrows*).

(Reproduced with permission from Morimoto T, Kamei M, Nishida K, et al. Chronic implantation of newly developed suprachoroidal-transretinal stimulation prosthesis in dogs. *Invest Ophthalmol Vis Sci* 2011;52:6785–92.)

In 2011 Fujikado et al. reported results of semi-chronic, suprachoroidal implantation of Nidek Visual Prosthesis in two patients with RP. The visual acuity of the patients before implantation was light perception. A 49-electrode array (5.7 × 4.6 × 0.5 mm) was placed in the suprachoroidal space without causing retinal detachment or vitreous hemorrhage, and the internal electronics of the implant were implanted under the skin on the temporal side of the head. The implants remained functional for the 4 weeks of the study. After 5 and 7 weeks the implants were surgically removed (first and second patient, respectively).<sup>111</sup>

Phosphenes were elicited by currents delivered through six electrodes in patient one and through four electrodes in patient two. The success of discriminating two bars was better than the chance level in both patients. In patient two, the success of a grasping task was better than the chance level, and the success rate of identifying a white bar on a touch panel increased with repeated testing.<sup>111</sup> Chronic implantation of a wide-field implant with the same technology has been tested in middle-size and large mammals.<sup>109,112</sup> However, the group has not yet announced its plan for chronic implantation of human subjects with the wide-field implant.

The Australian group has published in-human feasibility study of a similar approach with suprachoroidal placement of Bionic Vision Australia electrode array (Fig. 129.10).<sup>113,114</sup> Unlike the Japan group's approach for implanting the electrode array within a scleral pocket, the Australian group implanted the device between the choroid and sclera. Preclinical animal studies determined stimulation parameters after acute and chronic implantation of the suprachoroidal array.<sup>115</sup>

**FIG. 129.10** Suprachoroidal artificial vision implant tested by Bionic Vision Australia. The electrode array (A) and the entire device (B). The array is connected to the percutaneous connector via a helical lead wire. The electrodes number 1–20 on the intraocular array (C) perform visual signal transduction and the black electrodes (21a to 21m) are ganged to provide an external ring for common ground and hexagonal stimulation parameter testing. The percutaneous connector protruded through the skin behind the ear (D), allowing direct connection to the neurostimulator via a connecting lead (E). Surgical implantation through scleral incision (F). (Reproduced with permission from Ayton LN, Blamey PJ, Guymer RH, et al. First-in-human trial of a novel suprachoroidal retinal prosthesis. PLoS ONE 2014;9(12):e115239.)

The surgical procedure that was developed in animal and cadaver eyes consisted of lateral canthotomy followed by disinsertion of lateral rectus muscle and creating a full-thickness sclerotomy and exposing the choroid.<sup>113,116,117</sup> A “pocket” was created in the suprachoroidal space for the insertion of a flexible electrode array 15–17 mm toward the posterior pole, beneath the

area centralis. The array was then sutured in place, and platinum ball electrodes (1.5 mm diameter) were placed in the vitreous cavity and in the suprachoroidal space, next to the electrode, to act as return electrodes for electrical stimulation. A “trapdoor” sclerotomy was described to disinsert short posterior ciliary vessels behind the macula in order to avoid hemorrhage during the implantation.<sup>113,117</sup>

Three patients with long-standing RP with 8 to 20 years of light perception vision were included in the clinical trial of Australian suprachoroidal retinal prosthesis.<sup>117</sup> Implantation was carried out as described above and took 3–4 hours. No complications occurred during the surgery. Due to submacular hemorrhage seen in the first patient, the investigators attempted to decrease eye movement immediately after the surgery by injecting botulinum toxin in all four recti muscles at the end of surgery. This proved to be not effective, as patients two and three experienced submacular hemorrhage 3–4 days after the surgery. Patients were assessed for safety and efficacy of surgical procedure and the functional efficacy of suprachoroidal visual prostheses.<sup>117</sup>

The electrode array was easily visible with indirect ophthalmoscopy during the surgery because of the choroidal atrophy. Postoperative period was uneventful. All three subjects experienced a combined subretinal and suprachoroidal hemorrhage 3–4 days postoperatively, which resolved without any complications in two patients. In one patient with a larger hemorrhage than the others, a fibrotic tissue reaction formed at the temporal edge of the implant following hemorrhage resolution. The fibrotic tissue did not affect device efficacy nor caused complications such as retinal detachment. The electrode arrays remained stable during 1-year follow-up. All subjects were able to experience visual percepts within a safe charge limit. In addition, all subjects showed improved light localization with the device on compared to the device off.<sup>117</sup> This proof of concept study served to optimize stimulation parameters and showed that the suprachoroidal anatomic position was a less invasive method with acceptable complication profile, excellent lateral device stability, and successful stimulation of visual percepts. The group is aiming at improving functional efficacy in newer versions of the device.

The transchoroidal systems described above represent a new

approach that has some advantages compared with the subretinal and epiretinal approaches. For example, the ab externo approach through the sclera, potentially less complicated than the ab interno approach, along with a more stable positioning of the electrode on the suprachoroidal space, decrease the risk of retinal detachment. However, given the distance between the retina and sclera (204–490  $\mu\text{m}$  in humans),<sup>118</sup> it is suggested that such prosthesis will not achieve the same resolution as the epiretinal or subretinal prostheses.<sup>119</sup> Also, higher currents are required for stimulation due to the tissue layers interposed between the array and the ganglion/bipolar cells. However, animal studies have shown the ability to evoke cortical potentials using suprachoroidal stimulation of the outer nuclear layer, outer plexiform layer, and inner nuclear layer.<sup>110,120–123</sup> In addition, human trials using suprachoroidal implants have shown functional improvement, indicating adequate stimulation of the retinal ganglion/bipolar cells, with stimulation thresholds well below the safe levels for retina.

The Microfluidic Retinal Prosthesis is an alternative approach that will mimic normal chemical signaling between neurons in the retina and brain.<sup>124–126</sup> The overall hypothesis is that digital images may be transposed into neurochemical signals through a microfluidic chip, implanted in the subretinal space. A neurotransmitter-based visual prosthesis utilizes a multitude of microfluidic orifices that create a two-dimensional array of “chemical pixels,” arranged to create an image analogous to an inkjet printer, delivering neurotransmitter to the retina or brain. While conceptually interesting, this approach has not developed into a viable implant, due to the complexity of routing and control of small amounts of neurotransmitter delivered to precise locations in the retina, and due to concerns about potential toxicity of excess neurotransmitters.

## Electrotherapeutics

The Optobionics Artificial Silicon Retina (ASR) has shown some efficacy in improving vision, not through direct action of the device, but instead, through a neurotrophic effect. Initially developed as a retinal prosthesis, the ASR was implanted (subretinal and

extramacular) in ten patients in a single-center study and then in 20 subjects in a multicenter study. The 3-mm-diameter implants had 3500 microphotodiodes that generated stimulating current in response to incident light (Fig. 129.3). Results from the first six subjects were published in 2004, reporting that all six described subjective improvements in vision. Three of the six had improved early treatment diabetic retinopathy study (ETDRS) scores, while one in six had an enlarged visual field postoperatively. However, the improved vision included areas of the visual field far from the implant location. The authors concluded that the subretinal ASR implant was not directly mediating artificial vision (i.e., electrical stimulation via the ASR did not directly affect visual perception). Instead, the ASR's presence in the subretinal space was acting via an indirect effect, possibly through release of growth factors, and improving the health of the retina.<sup>127</sup>

The theoretical current output of a subretinal microphotodiode in a sunny environment is <1 nA (nano Ampere) ( $10^{-9}$  amperes),<sup>101</sup> or about 1/10,000 of what is required typically for electrical activation of nerves. This estimation explains the lack of direct activation of the retina by a subretinal implant that relies solely on incident light as a power source. The multicenter study provided additional results from visual task performance and more detail on the surgical procedure. Adverse events included three cases of ASR migration, two incidences of fracture of the device during implantation (the damaged device was easily removed), and six visually significant cataracts (versus three in the fellow eyes).<sup>87</sup> The most recent report from the group states that visual improvements are maintained in the original six implant subjects from the single-center trial.<sup>128</sup>

## Optogenetics

An alternative to an implanted bioelectronic device is the “optogenetic” approach. Pioneered by Deisseroth,<sup>129–131</sup> the optogenetic technique modifies retinal neurons to express light-sensitive ion channels, the most common being channel rhodopsin 2 (ChR2). When high-intensity light is used, enough ChR2 channels open to depolarize a cell and trigger an action potential. Viral

vectors such as adeno-associated virus are used to introduce ChR2 gene into retinal cell. Bi et al. first demonstrated that this method could be used to modify retinal ganglion cells, showing that light-evoked neural responses were present in a mouse model of retinal degeneration after the mouse RGCs expressed ChR2.<sup>132</sup> Others have extended this initial work to show that behavioral responses were preserved in rd1 mice<sup>133</sup> and that photoreceptor nuclei cell bodies could be modified and initiate a neural response even in the absence of outer segments.<sup>134</sup> Incorporating a second light-sensitive channel (halorhodopsin) into the dendrites of a retinal ganglion cell and ChR2 into the soma, to enable a center-surround response dependent on the wavelength of light, the optogenetic approach has showed significant advantages over the bioelectronic approach. By making each cell light-sensitive, vision can potentially be restored to near normal acuity. Also, using light as the activating signal allows the optics of the eye to be used to focus the image on the retina. In other words, the optogenetic approach can come much closer to restoring natural vision versus artificial vision provided by bioelectronic approaches. However, many potential challenges must be overcome before optogenetic approaches can be clinically viable. The main issue relates to sensitivity. Currently, modified cells require bright blue light to be activated, roughly four orders of magnitude above cone light sensitivity threshold in normally sighted people.<sup>135</sup> It is not clear how such intense light would interact with a diseased retina with minimal light sensitivity. Given that photophobia is sometimes a symptom of RP, a therapy that requires directing a bright light into the photophobic patient's eye is unlikely to provide a benefit. In addition, it is unclear if the modified cells permanently maintain this light sensitivity or if reinjection is required.

## Conclusions From Clinical Trials

Both the subretinal and epiretinal artificial vision prostheses have demonstrated feasibility and a reasonable safety profile. Both implants have also demonstrated the ability to restore vision through electrical stimulation of the retina in endstage outer retinal degenerations. However, there are important differences between

the two approaches. The surgical procedure for the subretinal approach is more complex, although it has the potential advantage of stimulating the next layer of neuron after the photoreceptor (i.e., the bipolar cell). However, this advantage may not be present in a severely reorganized retina secondary to chronic endstage outer retinal degeneration. Using a camera to capture visual information is also a theoretical advantage in that it could provide a wider bandwidth of data. On the other hand, using the blind eye's optical system to stimulate subretinal Alpha-IMS implant allows for eye's micro-saccade movement to overcome the "image fading" described as the Troxler phenomenon. ARGUS II implant, that utilizes a glasses-mounted camera to capture the images, obviates the need for clear media and also can overcome image blur caused by nystagmus. Lastly, the size of the clinical trials and the number of years the implants have been in use vary dramatically. The ARGUS II is the largest study of a retinal prosthesis to date with over 200 patients implanted and with the longest follow-up over 8 years as of the writing of this chapter. The Alpha-IMS has fewer cumulative years of testing due to fewer implantations and the limited longevity of the device.

Retinal prostheses have achieved major milestones in recent years. With both ARGUS II and Alpha-IMS retinal implants, we have seen continued improvement in visual acuity with increasing number and density of electrodes. Simulations of artificial vision<sup>19,26</sup> have predicted that 600–1000 individual pixels may be needed to enable face recognition and large font reading (Figs. 129.11 and 129.12). Even though the visual acuity is still poor relative to normal vision, the subjects with either the ARGUS or the Alpha-IMS device can read large letters and do better with daily life activities. Continuing this forward momentum to enable implant recipients' benefit through the use of retinal prostheses in their activities of daily living is the main challenge ahead. Moreover, another major challenge for future implants is to provide color vision for implanted patient. If optogenetic therapies can be made more sensitive, they may provide restoration of near natural vision. The development of retinal prostheses to generate artificial vision for the blind is a complex, long-term, expensive, and interdisciplinary undertaking, but the data from new clinical trials provide hope that

in the near future, doctors can present the long-awaited “good news” to their patients.

**FIG. 129.11** Examples of pixelated vision. Lower resolution may allow crude shape recognition, but increasing resolution can lead to (A–C) reading letters on an eye chart and (D–F) face recognition (rectangle added on last image to protect identity). ## Introduction

Within the last years many technical developments in the field of vitreoretinal surgery were introduced. We experienced not only improvements of vitrectomy machines (increased cut rates, improved pumps, improved fluidics, etc.), but also a continuous miniaturization of the surgical instruments such as cutters, forceps, and scissors from 20-gauge to 23- or 25-gauge, and even 27-gauge. In addition, improved illumination and viewing systems allow for a better visualization. All these refinements greatly helped to reduce surgical trauma, facilitate surgical maneuvers, and improve postoperative comfort for the patient. Thus mechanical means of vitrectomy have constantly been optimized during the years. Recent developments have added pharmacologic options to the surgical possibilities in vitreoretinal surgery.

Meanwhile new pharmacologic treatment strategies for many retinal diseases including diabetic retinopathy, age-related macular degeneration, and retinal vein occlusion have been discovered and have opened a perspective of significant visual improvement for many patients. As a consequence of these developments, a pharmacologic option is beginning to be added to the vitreoretinal surgical armamentarium.

In vitreoretinal surgery, pharmacotherapy at the time of surgery formerly mainly played a role in experimental studies addressing the issue of prevention of proliferative vitreoretinopathy, a major sight-threatening complication of vitreoretinal procedures. In addition pharmacotherapy was used routinely when surgery was necessary in cases of severe endophthalmitis. Meanwhile, as pharmacotherapy of retinal diseases has become an essential

standard in the specialty of medical retina, new ideas and concepts regarding this field have also emerged in the field of vitreoretinal surgery.

The following chapter will discuss some of these developments with special emphasis on aspects of relevance as an adjunct for vitreoretinal surgery.

## Pharmacologic Vitreolysis

### Rationale for Pharmacologic Vitreolysis

Posterior vitreous detachment (PVD) is a progressive physiologic process, involving both syneresis (liquefaction) and sychysis (separation). However, spontaneous PVD is very often incomplete and remnants of the vitreous adhere firmly either to areas in the periphery of the retina or to the macular area. Tractional forces exerted by vitreous collagen fibers and/or cellular proliferations at the vitreoretinal interface also play an important role in the pathogenesis of tractional maculopathies such as macular holes, vitreomacular traction syndrome, or epiretinal membranes. In addition, focal abnormal vitreoretinal adhesions may be implicated in certain types of diabetic macular edema and exudative age-related macular degeneration<sup>1,2</sup> and may have an impact on the effectiveness of the pharmacologic treatment applied in these conditions.<sup>3</sup>

Our present therapeutic approach in these tractional maculopathies is to relieve tractional forces surgically by mechanical means, inducing a more or less complete PVD using suction exerted by the vitrectomy probe followed by a removal of remnants of vitreous collagen fibers and cellular proliferations using an endgripping forceps. As we have learned that cellular proliferations tend to recur using remnants of collagen at the internal limiting membrane (ILM) as a scaffold, most surgeons tend to remove the ILM during the surgical intervention as well, in order to remove all epiretinal tissue. However, it may be hypothesized that direct manipulation in the area of the macula and the removal of the ILM itself may somehow have an impact on function in the macular area or interfere with the morphologic integrity of the

retinal layers, especially when being removed with the aid of visualizing agents.<sup>4</sup> Therefore, although ILM peeling appears safe from a clinical point of view, it may not be the optimum treatment option with regard to the best possible functional results.

Given this background, a pharmacologic liquefaction of the vitreous gel and simultaneous enzymatic separation of vitreous fibrils from the inner aspect of the ILM may result in a resolution of focal vitreomacular adhesions, representing an alternative approach to treat traction-related retinal and macular diseases. Leaving the ILM in place and cleaving the vitreoretinal interface at the vitreal side of the ILM may offer a more complete PVD, and be less traumatic as compared to vitrectomy. This pharmacologic induction of a PVD, if achieved early in the course of retinal or macular diseases, may have also a potential as a prophylactic treatment against advanced stages of potentially sight-threatening conditions such as diabetic retinopathy or age-related macular degeneration (AMD).<sup>3</sup> This concept is referred to as “pharmacologic vitreolysis,” and was initially introduced by Sebag in 1998.<sup>5</sup> Additional potential indications theoretically include vitreoretinal procedures for retinal detachment in children, in whom firm adherences of the vitreous often complicate surgery, especially in retinopathy of prematurity (ROP) or ocular trauma with intraocular foreign body. The hope is to make vitreoretinal surgery procedures more safe and effective using the concept of pharmacologic vitreolysis.

The following substances have been evaluated or are currently under investigation.

## Enzymatic Vitreolysis – Microplasmin, Plasmin, and Others

A variety of intravitreally applied enzymes has been investigated in animal studies so far and some of them have even progressed to clinical trials in humans. Based on the present published data, plasmin and microplasmin seem to be the most promising substances.

**Microplasmin** represents a recombinant protein that contains the catalytic domain of human plasmin but is much more stable as compared to the latter; both plasmin and microplasmin are

nonspecific serine proteases cleaving a variety of glycoproteins such as fibronectin, laminin, fibrin, and thrombospondin.<sup>6</sup> These glycoproteins are involved in the adherence of the vitreous cortex to the ILM. Thus cleavage of these enzymes potentially induces a PVD: Experimentally, microplasmin has been shown to increase vitreous diffusion coefficients *in vitro* using the noninvasive technique of dynamic light scattering<sup>7</sup> and caused simultaneous vitreolysis and posterior vitreous separation in *ex vivo* and *in vivo* animal eye models in an apparent dose- and time-dependent fashion<sup>8,9</sup> without morphologic alterations in the retina.<sup>10</sup> In a human, double-masked, phase II trial 60 patients were randomized in four treatment cohorts either receiving increasing doses of microplasmin (75, 125, and 175  $\mu\text{g}$ ) or an initial injection of 125  $\mu\text{g}$  followed by an injection of 125  $\mu\text{g}$  if no release of adhesion occurred 1 month later or after sham injection.<sup>11</sup> The study revealed that within 28 days of sham 75, 125, and 175  $\mu\text{g}$  microplasmin administration, a nonsurgical resolution of vitreomacular adhesion was observed in 8, 25, 44, and 27% of patients; when the 125- $\mu\text{g}$  dose was repeated up to three times, adhesion release was observed in 58% of patients 28 days after the final injection.<sup>11</sup> Another phase II, placebo-controlled, double-masked, dose-ranging clinical trial analyzed the effect of a single injection of microplasmin (25, 75, or 125  $\mu\text{g}$ ) 7 days prior to scheduled vitrectomy for vitreomacular traction and reported that 125  $\mu\text{g}$  microplasmin was associated with a greater likelihood of induction and progression of PVD than placebo injection.<sup>12</sup> Randomized clinical trials have been published suggesting microplasmin as a monotherapy replacing the need for surgical intervention in some patients with small macular holes less than 250  $\mu\text{m}$  and patients with vitreomacular traction up to 1500  $\mu\text{m}$ <sup>13</sup> (Fig. 130.1). The success of enzymatic vitreolysis in these cases is negatively correlated with the presence of epiretinal membranes.<sup>13,14</sup> It has also been shown that intravitreal injections of microplasmin may increase vitreal  $\text{O}_2$  levels, increase the rate of  $\text{O}_2$  exchange within the vitreous cavity, and increase vitreous diffusion coefficients *in vitro*.<sup>15,16</sup> The vitreous detachment induced by microplasmin may lead to a distribution of oxygen to ischemic retinal areas and help to reduce the VEGF concentration at the retinal surface. This may be beneficial in ischemic retinal diseases

such as proliferative diabetic retinopathy or retinal vein occlusion.<sup>17</sup>

**FIG. 130.1** (A) Optical coherence tomography (OCT) demonstrating a small full-thickness macular hole with vitreomacular adhesion visible at the edge of the macular hole. (B) OCT 5 weeks after treatment with 125- $\mu$ g microplasmin showing the resolution of the vitreomacular adhesion and associated macular hole closure without vitrectomy. Subfoveal fluid is still present, which dissolved over the next few weeks.

Microplasmin has been approved under the generic name “ocriplasmin” since 2012 by the United States Food and Drug Administration as a drug approved to treat symptomatic vitreomacular adhesion (VMA). In Europe the approval by the European Medicines Agency in 2013 included the indications vitreomacular traction, also in association with a macular hole smaller or equal to 400  $\mu$ m diameter. New data discuss potential side-effects including an assumed ocriplasmin-induced retinopathy.<sup>18</sup> From current surveys it is concluded that further studies are needed to better understand the pathophysiology and

clinical relevance of adverse events after the use of ocriplasmin.<sup>19</sup>

**Plasmin** was initially used by Verstraten and coworkers to facilitate a PVD during vitrectomy in rabbit eyes. They found a positive effect but also mentioned a transient reduction of the b-wave amplitude in the electroretinogram as a potential adverse effect.<sup>20</sup> This study was followed by other experimental trials confirming the proteolytic activity of plasmin on the vitreoretinal junction. Autologous plasmin was then used in clinical case series investigating the effect of a single injection without vitrectomy as a treatment for refractory diffuse diabetic macular edema,<sup>21</sup> tractional diabetic macular edema,<sup>22</sup> or macular edema associated with branch retinal vein occlusion.<sup>23</sup> The reduction of retinal thickness and improvement of visual acuity in these series supported an effectiveness of plasmin and the need for further trials. Autologous plasmin-assisted vitrectomy was performed for stage 3 macular holes, traumatic macular holes, diabetic macular edema, and stage 5 ROP,<sup>24-29</sup> and all of these trials underlined the potential of plasmin to facilitate vitrectomy and its good safety profile.

Other enzymes investigated included **hyaluronidase** and **dispase**. While the first liquefied vitreous but did not induce a PVD and was therefore not suitable to release traction, the latter showed evidence for retinal bleedings, epimacular membrane formation, abnormalities in the electroretinogram responses, and ultrastructural retinal damage, and it was not further evaluated for clinical use.

## Antiproliferative Agents in the Management of Proliferative Vitreoretinopathy

Proliferative vitreoretinopathy (PVR) is a serious and major complication of primary rhegmatogenous retinal detachment, severe diabetic retinopathy, and severe intraocular trauma. The pathophysiology of this disease implies a very complex cascade of events resulting in a subsequent proliferative response within the retina (see [Chapter 101](#), Pathogenesis of proliferative vitreoretinopathy). Experimental studies described an intraretinal

cellular response to retinal detachment which is triggered by serum and growth factors present in the vitreous cavity<sup>30</sup> and includes all types of non-neural cells such as RPE cells, astrocytes, microglia, macrophages, but predominantly Müller cells,<sup>31-34</sup> which is then followed by a fibrocellular growth on the subretinal or epiretinal surface.<sup>35</sup> Both subretinal fibrosis and epiretinal proliferation have an impact on functional results and anatomical failure of retinal detachment surgery.<sup>35,36</sup> The facts that these cellular responses to retinal detachment may occur early in the development of the disease and may continue even in the longer term following (successful) surgical intervention, point to the need for an early pharmacologic intervention and a long-term drug release or pharmacologic effect,<sup>37</sup>

Other contributing factors include a relative hypoxia due to the distance between the neurosensory retina and the choriocapillaris<sup>38</sup> which leads to glial changes and photoreceptor deconstruction. These mechanisms are the target of recent and current approaches for an adjuvant pharmacologic intervention in PVR as these cellular responses cannot be controlled by surgery alone.

Antiproliferative and antiinflammatory agents have been subjects of in vitro investigations including substances such as colchicine, daunomycin, and 5-fluouracil.<sup>39,40</sup> However, none of these agents has become part of any standardized procedure to treat or prevent PVR. Only daunomycin and 5-fluouracil combined with low-molecular heparin were tested in clinical studies, and these revealed no clinically relevant impact on PVR.<sup>41</sup>

Several years ago steroids applied intravitreally were used to suppress the process of PVR in clinical settings and in experimental studies.<sup>42</sup> However, the effect was not sufficiently long-lasting to prevent PVR.

New concepts include other agents such as alkylphosphocholines (APCs), which are synthetic phospholipid derivatives that have been shown to effectively inhibit cellular proliferation.<sup>43</sup> Their mechanism of action involves binding to the membrane-bound G-protein PKC (protein kinase C), which is part of a major intracellular second-messenger system that regulates cell attachment, spreading, migration, and proliferation. As described in the literature, APCs have a potential to inhibit RPE cell spreading

and migration as well as proliferation and cell-mediated membrane contraction at nontoxic concentrations in vitro, and they did not display any toxic effects upon retinal tissue in in vivo animal models.<sup>44</sup> Besides prevention and treatment of PVR, APCs might have the potential for topical application as a single-dose agent to prevent posterior capsule opacification following cataract surgery.<sup>45</sup>

In addition to these above-mentioned substances a variety of other drugs are currently evaluated. However, none so far has reached a clinically relevant potential.

## Tissue Plasminogen Activator in Vitreoretinal Surgery

AMD is one of the leading causes of blindness in the Western world. New pharmacologic treatment options have revolutionized the treatment armamentarium and provided true functional improvement in neovascular forms of the disease. However, complications of neovascular AMD such as major subretinal hemorrhages are still associated with a limited visual prognosis that could require vitreoretinal intervention.

This problem may be related to toxic effects of iron released from subretinal hemoglobin as well as an increased physical barrier for retinal diffusion and fibrotic changes.<sup>46-48</sup> Up to now, there is no consensus regarding how to treat subretinal hemorrhages associated with neovascular AMD, and most surgical treatment strategies seem not efficient in restoring or improving vision.<sup>49</sup>

A displacement of the hemorrhage may be achieved by intravitreally applied expansile gas combined with intravitreal injection of recombinant plasminogen activator (rTPA). However, the subretinal lytic effect of intravitreally applied rTPA was challenged by some authors due to its molecular size and the reduced retinal diffusion.<sup>50,51</sup> Therefore, a combination of intravitreal VEGF inhibitors to treat the underlying neovascular process combined with an injection of expansible gas is favored by some authors.<sup>52</sup>

There is clinical evidence that intravitreal rTPA in combination with expansile gas was in the long term more effective if combined

with subsequent anti-VEGF treatment than intravitreal bevacizumab in combination with expansile gas alone.<sup>53</sup> Other groups have suggested triple therapies using using rtPA, bevacizumab or ranibizumab, and have shown a successful management of the disease with this approach.<sup>54</sup> If rTPA and pneumatic displacement combination is contraindicated, an anti-VEGF monotherapy may be performed to prevent further visual loss.<sup>55</sup> However, after intravitreal injection of any agent combined with expansible gas a vitreous hemorrhage may occur, very often due to a displacement of the subretinal blood into the vitreous cavity. In these cases vitrectomy is indicated and may lead to good functional results.

An additional strategy is to perform a vitrectomy and apply rtPA subretinally followed by fluid gas exchange<sup>56</sup> to displace the hemorrhage. This approach led to visual improvement in some cases. The authors also reported that vitrectomy with subretinal injection of rtPA and intravitreal gas tamponade was more effective than vitrectomy with intravitreal injection of rtPA and gas in terms of complete displacement of the submacular blood.<sup>57</sup> Although functional improvement in the majority of patients suggests the absence of direct retinal toxicity of subretinally applied rtPA, vitrectomy and subretinal injection of rtPA carry a greater risk for postoperative complications.<sup>57</sup>

Despite good experiences in clinical use, experimental studies demonstrated dose-dependent negative effects of rtPA as seen by a significant and potentially irreversible reduction of the b-wave amplitude in ERG examination in bovine retinas.<sup>58</sup>

## Visualization of the Vitreoretinal Interface

The application of vital dyes to visualize transparent and sometimes barely visible target structures such as the internal limiting membrane (ILM), epimacular membranes or vitreous has become very popular among vitreoretinal surgeons. The ILM is the main target structure for “chromodissection.” This is related to the fact that the ILM has been identified as an important scaffold for

cellular proliferation. In order to remove all cellular proliferations, vitreous collagen remnants, and relieve all relevant tractional forces, the ILM is dissected from the underlying tissue using the retinal surface of the ILM as a cleavage plane. The ILM can be removed without further visualization. A slight whitening of the retinal surface can be used as an indicator where ILM has been successfully peeled. However, this manoeuvre requires a lot of surgical experience and skills. The introduction of visualizing agents has made ILM peeling accessible even to the less experienced surgeon. Several dyes are in clinical use and can be applied to selectively visualize the target structure (Table 130.1).

**TABLE 130.1**

**Dyes in Clinical Use That Can Be Applied to Selectively Visualize the Target Structure<sup>a</sup>**

Dye	Epiretinal Membrane	ILM	Vitreous	Application <sup>b</sup>	Comments
Indocyanine green (ICG) (0.5%)	—	Selective +++	—	Usually fluid-filled globe	Question of toxicity, off-label
Brilliant blue G (BBG) (0.025%)	—	Selective ++	—	Fluid filled-globe (if heavy BBG is used)	Approved in Europe
Trypan blue (TB) (0.15%)	+++	(+)	(+)	Fluid- or air-filled globe	Approved in Europe
Bromophenol blue	+++	—	+	In combination with BBG	Approved in Europe
Triamcinolone (TA)	—	Non selective (+)	+++	Fluid filled-globe	No dye, pharmacologic properties
Fluorescein	—	—	+	Intravitreal, intravenous or peroral application	

<sup>a</sup>Several staining substances are available at present. There are differences mainly with regard to their selectivity and biocompatibility.

<sup>b</sup>Surgical techniques may vary depending on individual preference.

The dyes are either injected into the fluid-filled or air-filled globe and different concentrations are used. Fluid–air exchange can especially be avoided if the dye solution is heavier than water, which can be achieved with specific solvent media such as glucose 5% or deuterium oxide.<sup>59</sup>

## Current Dyes for Epiretinal Membranes and the Internal Limiting Membrane

Epiretinal membranes can be stained using the anionic disazo dye trypan blue, which is commercially available in a concentration of 0.15% for that purpose. The contrast at the level of the ILM using trypan blue is quite poor. Bromophenol blue<sup>60</sup> is also approved for ERM staining, but is only available as a combination with brilliant blue (see below) as a dual stain. Two other dye classes are currently predominantly used for ILM peeling: The cyanine dye indocyanine green (ICG) and the triarylmethane dye brilliant blue G (BBG). Due to tissue dye interactions and alterations of its collagen structure, the stained ILM can be peeled off more easily and, postulating that the dye used provides a high biocompatibility, with less damage to underlying retinal structures such as the nerve fibres and Müller cell end feet. Both dyes selectively stain the ILM,<sup>61</sup> although the staining effect seen after ICG use appears more pronounced compared to BBG. In contrast to the good biocompatibility of BBG,<sup>62</sup> ICG has revealed toxic effects in some studies which underline the narrow safety margin of this dye.<sup>63</sup> Postoperative visual field defects and less favourable functional outcome have been described in the literature.

In addition, ICG appears not as an ideal candidate for ILM staining as its maximum absorption is in the near infrared and not within the spectral sensitivity of the human eye,<sup>64</sup> meaning that the majority of light absorption of ICG is useless or of low value during vitreoretinal surgery because it is in the invisible NIR and in the bathochromic region of the visible spectrum. As a consequence, relatively high dye concentrations of 0.5% are required and were used to achieve a sufficient contrast on the vitreoretinal interface in contrast to BBG, where concentrations of 0.025% are sufficient for ILM staining.

The availability of different dyes with selective staining properties allows for variable operative techniques and sequential “chromodissection” of the tissue. In theory, one could stain the vitreous using triamcinolone and stain epiretinal membranes using trypan blue, followed by ILM staining using BBG. In epiretinal membrane surgery, where the vitreous is detached already in most

cases, a reasonable approach is to peel the epiretinal membrane without adjuncts first, and then visualize the ILM and peel areas where ILM can be detected (Fig. 130.2). In macular hole surgery, the ILM can be stained without prior removal of epimacular tissue. However, some manufacturers offer combinations of ERM-staining dyes such as trypan blue or bromophenol blue and ILM staining dyes such as BBG suggesting that repeated dye injections can be avoided and potential toxicity can be thereby limited.

**FIG. 130.2** (A) Preoperative fundus picture showing the epimacular membrane which is removed with an end-gripping forceps. (B) Heavy brilliant blue (BBG) is now applied over the macular area. (C) After removal of excessive dye, the internal limiting membrane (ILM) is easily detectable due to the selective staining

properties of BBG. (D) The stained ILM can be peeled off safely.

## Perspectives

In general, any dye should be used with care as long as the tissue–dye interactions are not completely understood. There is an ongoing effort to identify better dyes with appropriate staining properties and a high biocompatibility. It seems that an ideal candidate dye would be a dye incorporating the excellent contrast provided by ICG and the high biocompatibility of BBG (i.e., strongly absorbing at visible wavelengths, conveniently binding tissue, non toxic, and physiologically degradable at a practical time scale). This may be reached by synthesizing new cyanine dyes and thereby improving the absorption qualities and the affinity of the dye molecule to the target structure.<sup>65</sup>

These new molecules provide improved absorption and fluorescent qualities and equal staining properties but potentially a better safety profile compared to ICG as it is adapted to the spectral sensitivity of the human eye and to the standard illumination used during surgery. In addition, the contrast is thereby enhanced as it implies both the blue absorption colour and an even stronger purple fluorescence colour. Additionally, several other absorbent dyes have been subjects of experimental in vivo and ex vivo experiments, including among others methyl violet, crystal violet, eosin Y, Sudan black B, methylene blue, toluidine blue, light green, indigo carmine, fast green, Congo red, evans blue, and lutein.<sup>66–68</sup>

## VEGF Inhibitors in Vitreoretinal Surgery

### Proliferative Diabetic Retinopathy and Macular Edema

The development of diabetic retinopathy is a multifactorial process. Much of the retinal damage that characterizes the disease is understood to result from retinal vascular leakage and

nonperfusion, mediated by numerous growth factors including vascular endothelial growth factor (VEGF).<sup>69</sup> High concentrations of VEGF have been identified in the vitreous of patients with proliferative diabetic retinopathy<sup>70</sup> indicating that VEGF plays a major part in mediating active intraocular neovascularization in patients with ischemic retinal diseases. The upregulation of VEGF is not only associated with a breakdown of the blood–retina barrier resulting in retinal edema, but also with a stimulation of endothelial cell growth and neovascularization.<sup>71</sup> Therefore, the inhibition of VEGF has become a widely used treatment option in these conditions. Available VEGF inhibitors include bevacizumab, ranibizumab, and aflibercept. For intraocular application, the drug is administered via the pars plana using a sterile 27- or 30-gauge needle.

The intravitreal injection of VEGF inhibitors is approved to treat center-involving macular edema associated with retinal ischemic disease such as diabetic macular edema or retinal vein occlusion. Nevertheless, another (at present “off label”) indication for the intravitreal application of VEGF inhibitors might be the treatment of proliferative diabetic retinopathy,<sup>72</sup> resulting in a marked regression of neovascularization and possibly a resolution of vitreous hemorrhage within a short period of time in some cases. This treatment effect may be of relevance for patients awaiting vitrectomy for dense vitreous hemorrhage or traction retinal detachment associated with active proliferative vascular diseases (Fig. 130.3). The injection of VEGF inhibitors prior to vitrectomy does help to minimize the risk of perioperative bleeding from active neovascularization and reduces the incidence of postoperative intraocular hemorrhages.<sup>73</sup> It has been shown that the vascular component of proliferation is markedly reduced by day 10 post injection, whereas the contractile components are not yet impacted.<sup>74</sup> Therefore, patients having been treated with intravitreal injections of VEGF inhibitors before surgery should be followed on a daily basis, as an exacerbation of the tractional forces may occur due to fibrotic changes of the neovascularization and require immediate intervention. In clinical practice, vitrectomy could be scheduled 2–7 days after intravitreal injection since in most instances the marked reduction of neovascularization is usually

seen within 48 hours. This holds true for retinal neovascularizations as well as iris neovascularizations.

**FIG. 130.3** (A) Preoperative fundus of a young female patient with proliferative diabetic retinopathy and massive traction at the posterior pole. Note the intensive vascularization within the fibrovascular membrane. Prior to scheduled vitrectomy bevacizumab (1.25 mg) was injected intravitreally. (B) Two days after intravitreal injection a marked regression of the vascularization was seen and vitrectomy was performed.

With this option of anti-VEGF-assisted vitrectomy, the surgical procedure in patients with active neovascularization at the retina or at the iris becomes safer and more controlled, since the danger of major intraoperative bleeding is markedly reduced.

In addition, some case reports have demonstrated that injection of bevacizumab at the end of vitreous surgery can reduce the recurrence of hemorrhages after vitrectomy.<sup>75</sup>

## Retinopathy of Prematurity

Retinopathy of prematurity is a disease of the immature retina affecting children before 31 weeks' gestational age (see [Chapter 65](#), Telescreening for retinopathy of prematurity). It represents one of the three leading causes of legal blindness in childhood in the developed countries. The pathophysiology of the disease implies tissue hypoxia resulting in an upregulation of VEGF and the development of abnormal retinal fibrovascular tissue leading to

tractional retinal detachment and vision loss in progressive stages. The well-established treatment option for this condition is peripheral retinal ablation with conventional (confluent) laser therapy. However, laser photocoagulation is destructive and may cause complications later on. In addition, it does not prevent all vision loss, especially in cases of ROP affecting zone I of the eye.<sup>76</sup> Since the introduction of VEGF inhibitors for the treatment of neovascular diseases, such as AMD, diabetic retinopathy, or retinal vein occlusion, case series described a positive effect of single injections of the VEGF inhibitor bevacizumab in ROP,<sup>77</sup> indicating that this agent may be a useful alternative to laser ablation, especially as it is not destructive to retinal tissue. As a rule this agent is applied only once in these diseases.

A recent prospective, controlled, randomized, multicenter trial compared the effect of a 0.625-mg intravitreal bevacizumab monotherapy for zone I or zone II posterior stage 3+ (i.e., stage 3 with plus disease) to conventional laser therapy.<sup>78</sup> The recurrence of ROP in one or both eyes requiring retreatment before 54 weeks postmenstrual was the primary ocular outcome. The study revealed that intravitreal bevacizumab monotherapy, as compared with conventional laser therapy, in infants with stage 3+ ROP is associated with a significant benefit for zone I but not zone II disease. While development of peripheral retinal vessels continued after treatment with intravitreal bevacizumab, conventional laser therapy led to permanent destruction of the peripheral retina. However, as compared with conventional laser therapy in treating patients with zone I retinopathy of prematurity, intravitreal bevacizumab represents a true breakthrough in disease management of ROP.

Therefore, based on the current literature, the use of VEGF inhibitors in retinopathy of prematurity may provide an advantage compared to laser treatment for acute zone I or zone II posterior stage 3+ disease. A monotherapy using VEGF inhibitors appears advantageous when media opacities such as a tunica vasculosa or hemorrhages in the anterior or posterior segment preclude diode laser photocoagulation.<sup>79</sup> In contrast, the treatment with VEGF inhibitors should be avoided in stage 4 or 5 disease, as fibrotic changes may be accelerated leading to traction retinal detachment.

Whether a combination of anti-VEGF treatment in combination with vitrectomy in stage 4 or 5 disease in ROP has advantages has not yet been examined. Also, it is not known whether the combination of bevacizumab and laser treatment has advantages.

As intravitreal bevacizumab reaches the systemic circulation<sup>80</sup> of the infant there are concerns of negative systemic effects, which have not been demonstrated up to now. However, vigilance is mandatory, and a longer follow-up of patients will help us to outline the best concentration of the agent and the indications (and relative contraindications) for the use of VEGF inhibitors for retinopathy of prematurity.

## Neovascular Glaucoma

Another indication for the use of VEGF inhibitors is neovascular glaucoma. Neovascular glaucoma is still a sight-threatening complication of retinal ischemia as seen in a variety of diseases such as diabetic retinopathy or retinal vascular occlusion. Vitrectomy for conditions associated with neovascular glaucoma has been considered, resulting in very bad results. Therefore neovascular glaucoma has to be controlled before vitrectomy. The first-line treatment is laser photocoagulation of ischemic areas of the retina in order to prevent a progression of the neovascularization and to finally stop neovascularization at the iris. In cases where the retina cannot be visualized due to media opacities such as corneal edema or vitreous hemorrhage, transscleral retinal cryotherapy can be performed instead.<sup>81</sup> Vitrectomy and endolaser photocoagulation is indicated in the presence of retinal detachment, progressive disease, or in the presence of vitreous hemorrhage. While filtration surgery often fails in neovascular glaucoma, laser cyclophotocoagulation or cyclocryotherapy are effective means to lower intraocular pressure (IOP) with fewer complications seen after laser cyclophotocoagulation. Vitrectomy with peripheral retinectomy had also been suggested as a treatment for neovascular glaucoma, but retinal complications are frequent.<sup>82</sup> However, despite several treatment modalities being available functional outcome is often unfavourable. Therefore the addition of pharmacotherapy to vitreoretinal surgery in such cases is almost mandatory today.

Again anti-VEGF substances are used.

Several studies<sup>83</sup> have shown that the monoclonal antibody bevacizumab can be used intravitreally as well as intracamerally to reduce not only retinal, but also iris and anterior chamber angle neovascularization (Fig. 130.4). Often, the regression of iris and chamber angle neovascularization is followed by a fast and effective decrease of IOP. However, recurrence of increased IOP is frequent.<sup>84</sup> Therefore, the intracameral application of VEGF inhibitors may extend our therapeutic options in the management of neovascular glaucoma, especially as other options such as photocoagulation of ischemic retinal areas alone may not be sufficient to prevent the progression of neovascular glaucoma, and reduce the need for IOP-lowering drugs. The early treatment effect seen after intracameral application of VEGF inhibitors may also help to bridge the time until the treatment effect of other strategies, such as laser photocoagulation, is noted. Almost as a rule, iris neovascularization is gone within 24 hours after intraocular injection of bevacizumab, and necessary vitreoretinal surgery can be performed one day after injection if needed.

**FIG. 130.4** (A) Rubeosis iridis seen in a patient with neovascular glaucoma. (B) Five days after intracameral injection of bevacizumab a marked regression of the neovascularization is seen and a drop of intraocular pressure occurred.

## Endophthalmitis

Endophthalmitis is a serious intraocular inflammatory condition

sometimes requiring immediate vitreoretinal intervention. It can be the result of exogenous or endogenous spread of infecting organisms into the eye (see [Chapter 125](#), Infectious endophthalmitis). The prognosis for visual function is often poor independently from the etiology of the disease. Exogenous endophthalmitis is mostly seen after ophthalmic surgical procedures. As cataract surgery is the most frequently performed surgery in ophthalmology, 90% of exogenous endophthalmitis cases are related to this operation.<sup>85</sup> The incidence is reported to range between 0.08% and 0.7%.<sup>86,87</sup>

Endogenous endophthalmitis is less common. It results from secondary hematogenous dissemination and spread from a distant infective source in the body. Therefore, predisposing risk factors should be carefully evaluated when checking the patient's medical history.

Although the incidence of endophthalmitis has decreased over the years due to continuous improvement of preoperative disinfection<sup>88</sup> and perioperative prophylaxis, endophthalmitis is still a very severe disease with indistinct prognosis and requires immediate intervention to maintain at least a possibility of visual recovery. Early diagnosis and treatment with antimicrobial therapy are crucial. Therapy is usually initiated empirically while microbiologic testing of intraocular samples, obtained for example during vitrectomy in severe cases, is being performed. After culturing and identification of the causing organism the spectrum of the antimicrobial therapy may be altered according to the sensitivity of the pathogen. However, unless there is no other unequivocal result from culturing, endophthalmitis therapy should cover both gram-positive organisms, which play a predominant role in exogenous endophthalmitis, and gram-negative organisms, as they are associated with higher virulence and poorer outcome. According to the literature, current antibiotic standard protocols for intravitreal application include the peptide antibiotic vancomycin (1.0 mg/0.1 mL) for gram-positive coverage<sup>89,90</sup> in combination with the  $\beta$ -lactam antibiotic ceftazidime (2.25 mg/0.1 mL) for gram-negative coverage. In patients hypersensitive to  $\beta$ -lactam drugs, amikacin (400  $\mu$ g/0.1 mL), an aminoglycoside antibiotic, might be considered instead of ceftazidime.<sup>89</sup>

Other antibiotics such as fluoroquinolone, especially the recently developed third- and fourth-generation such as levofloxacin and moxifloxacin, have been discussed as a potential alternative treatment for gram-positive pathogens due to their enhanced activity.<sup>89</sup>

In addition to antibiotics, corticosteroids are commonly used as adjunctive treatment both in bacterial as well in fungal endophthalmitis. The antiinflammatory properties of these drugs may help modulate the inflammatory response to the infection itself and decrease secondary damage. They may be applied topically, under the conjunctiva, intravenously, or intravitreally. However, their use and mode of application in endophthalmitis remains a subject of debate. If surgery is required for such cases in all instances a combination of surgery and intraocular pharmacotherapy is standard of care.

## Conclusion

Pharmacologic therapy has become an important field in ophthalmic surgery. Recent developments include microplasmin as an adjunct in vitreoretinal surgery to induce a posterior vitreous detachment and release traction at the vitreoretinal interface, as well as the inhibition of VEGF to prevent vitreal hemorrhages as a result of vitreoretinal surgery in proliferative vitreoretinal diseases, such as diabetic retinopathy, and to prevent progression and sight-threatening complications of retinopathy of prematurity as well as to treat neovascular glaucoma. Tissue plasminogen activator can be used as an adjunct in the treatment of submacular hemorrhages. Recent developments also include the introduction of vital dyes to selectively visualize layers of the vitreoretinal interface in macular surgery. Intravitreal application of antibiotics and steroids have become a standard treatment for intraocular infections such as endophthalmitis. Despite these refinements no effective pharmacologic treatment options are currently available for other blinding conditions such as proliferative vitreoretinopathy.

**Removal of a Large Glass Intraocular Foreign Body**

A complication is an unanticipated event that arises either from the original disease, the treatment, an independent cause, or a combination of above. As surgeons we are trained to predict and treat expected events during surgery. However, unexpected events are the ones that are most dangerous and usually lead to undesirable outcomes. In general, the question is not whether an unexpected event will happen but when it will occur. The early recognition of an impending unexpected event is crucial for its successful management.

The knowledge of how to predict, treat, and prevent unexpected events during surgery is extremely valuable and would make vitreoretinal surgery safer, leading to improved visual outcome for patients. The more one is acquainted with unexpected events the less they are considered “unexpected” since one has already seen these events happen and knows how they were handled and therefore the factor of surprise is eliminated.

In this chapter, experienced surgeons from around the world share with you their unexpected experiences during retinal surgery and show how they handled some of the most unusual surgical cases. Further, they share their surgical pearls on how to predict, prevent, and treat these unusual surgical situations.

## **Subluxated Intraocular Lens Without Haptics**

Renaud Duval

Removal of intraocular foreign bodies usually relies on the use of forceps or magnets (in the case of magnetic objects). Removing a round, smooth optic of an intraocular lens (IOL) that is missing both haptics cannot be done in the usual fashion. Using forceps

would damage the underlying macula. However, a 25-gauge (G) soft-tip cannula placed on the extrusion line can induce sufficient vacuum to lift the IOL to a position where it can be grasped safely. This technique should be kept in mind when dealing with light foreign bodies that lack grasping points.

In Video 131.1 , a 72-year-old patient is presented with a history of blunt trauma to the left eye leading to superior iris loss and IOL expulsion from the globe through a superior sclerolimbic rupture. Following primary repair by a general ophthalmologist, the patient was referred for management of aphakia and vitreous hemorrhage. The hemorrhage cleared over the ensuing weeks, and the patient was reoperated for peeling of an epiretinal membrane followed by correction of aphakia with a scleral-fixated IOL.

After removal of the vitreous hemorrhage and indocyanine green-assisted peel of the epiretinal membrane, a three-piece IOL was injected into the eye through a 2.75-mm clear corneal incision and the haptics were externalized through sulcus-based sclerotomies. While attempting to tuck the second haptic into its intrascleral tunnel, sudden motion of the forceps caused by forcing against an overly tight tunnel led to separation of the haptic from the optic. Subsequent maneuvers to cut the IOL and remove it by the “pacman” technique led to the separation of the second haptic and complete dislocation of the now haptic-less optic on the macular surface. Creating a wider scleral pocket and avoiding the use of the haptics to stabilize the IOL while cutting it for explantation may have minimized the risk of haptic separation.

## **Posterior Synechiae and Small Pupil During Vitrectomy**

Ehab El Rayes

Posterior synechiae secondary to inflammation may lead to miotic pupil and limit visualization during vitrectomy surgery. Additional pharmacotherapy may be applied for dilation; however, it has a limited role when posterior synechiae are present. Mechanical stretching of the pupil would be the next option. To safely dilate the pupil one may either use iris hooks or iris

stretching rings such as the Malyugin ring (MicroSurgical Technology (MST), Redmond, WA) or the Morcher ring (FCI Ophthalmics, Pembroke, MA).

In this Video 131.2 a Morcher ring, a 7-mm PMMA ring, is introduced into the anterior chamber by dialing it in through a 2-mm corneal incision. The inferior pupillary margin is engaged first, thus providing a 6-mm opening for visualization. Viscoelastic is injected into the anterior chamber to maintain the depth and to keep the media clear. Removing the cataract can easily be performed through the ring which maintains a dilated pupil (even in cases with floppy iris). Phacoemulsification and IOL implantation are performed. Identifying the tip of the infusion cannula before starting the vitrectomy is important and can now be easily achieved through a dilated pupil and clear media. Vitrectomy is carried out in the usual manner. Once the posterior segment procedure is completed, the Morcher ring will be removed by dislodging it from the pupillary margin and then dialing it clock- or anticlockwise, via the corneal incision, to exit the eye.

## Induction of PVD in Retinal Detachment

Andre Gomes

Inducing posterior vitreous detachment (PVD) is a key step during vitrectomy surgery for retinal detachment. Induction of PVD; however, is not always easy and the strong vitreoretinal adherence especially in young patients can make this step challenging.

The patient in Video 131.3 presented with strongly adherent posterior hyaloid and a thin and mobile retina. The induction of PVD was first attempted in the usual manner by applying suction over the peripapillary area followed by suction at more peripheral areas of the fundus. These attempts were followed by using microserrated forceps and end-grasping forceps in an attempt to peel the internal limiting membrane (ILM) while the posterior hyaloid was still attached. To improve the visualization of ILM, brilliant blue dye was injected into the eye. Attention was given to

prevent any subretinal exposure. Inducing openings in the posterior hyaloid/ILM/retina interface allowed fluid to gain access underneath the posterior hyaloid and make the induction of PVD easier. Peeling the ILM in patients with adherent posterior hyaloid can make the induction of PVD easier and safer.

## Induction of PVD in High Myopia

Ramin Tadayoni

One surgical challenge during vitrectomy for retinal detachment in high myopia is the induction of posterior vitreous detachment, which is one of the initial steps of the surgery. Missing this step may cause postoperative complications including increased risk for retinal redetachment.

This technical difficulty in high myopia is generally a combination of poor visualization of the posterior hyaloid, presence of vitreoschisis, and the strong adhesion of the posterior hyaloid to the surface of the retina, particularly in younger patients. The strongly adherent posterior hyaloid associated with large pockets of liquefied vitreous may make the usual techniques used for the PVD induction not very successful. Further, in high myopia the presence of vitreoschisis may give the appearance of posterior hyaloid separation while in fact the hyaloid is still attached. Visualizing the vitreous with triamcinolone acetonide suspension may help identifying the posterior hyaloid during surgery. It is usually diluted with balanced salt solution (BSS) to a lower concentration (typically 1/5) before injection into the eye. Further, new imaging technologies such as intraoperative optical coherence tomography (OCT) may help identify the status of the posterior hyaloid during surgery.

In Video 131.4  a complex situation is presented: an attached posterior hyaloid is identified by intraoperative OCT (RESCAN 700®, Carl Zeiss Meditec, Germany) during a 25G vitrectomy (Constellation®, Alcon, TX, USA) for a posterior retinal detachment secondary to macular hole in high myopia. The vitreous cannot be visualized by the surgeon through the microscope (without OCT). Diluted triamcinolone acetonide suspension is injected over the optic nerve to visualize the posterior hyaloid and allow its safe

peeling.

## Iatrogenic Retinal Breaks During Peeling

Manish Nagpal

One of the risks involved during membrane peeling is the formation of iatrogenic breaks. Their immediate detection and management is crucial to prevent a negative outcome.

The following tips may help avoid making an iatrogenic break during peeling and also help their management if formed.

1. Use a wide-angle viewing system during vitrectomy surgery to be able to evaluate optimally the periphery of the retina.
2. Peel membranes in a radial fashion and avoid anteroposterior pulling.
3. If iatrogenic breaks are formed, assess the location and extent of the break, mark the edges, and assure adequate endolaser when the retina is reattached.

In Video 131.5  a patient is presented with a semiopen funnel retinal detachment with proliferative vitreoretinopathy (PVR). Core vitrectomy is performed and perfluorocarbon liquid (PFCL [AuroOctane, Aurolab, India]) is injected over the disc to stabilize the retina. A circumferential membrane over the disc is gradually peeled to allow the flattening of the posterior pole under the PFCL liquid.

The residual inferior traction is reassessed, and the responsible epiretinal membrane is peeled to release this traction. During the peel the peripheral inferior retina is stretched and an iatrogenic break is formed. A wide-angle viewing system allowed the immediate detection of the break. The extent of the break and its location is assessed, and diathermy is applied to mark the edges and to control the bleeding. Fluid–air exchange is performed, and subretinal fluid is drained through the break. Once the retina is flattened, laser endophotocoagulation is applied around the break

to assure adequate retinopexy.

## Internal Limiting Membrane Peeling

Sjakon Tahija

Creating an edge of the ILM at the beginning of its peeling is the part of the procedure that is associated with the highest risk for retinal bruising and damage. In Video 131.6, the surgeon is performing pars plana vitrectomy for proliferative diabetic retinopathy in a type 1 diabetic patient. After removing the vitreous hemorrhage, endolaser photocoagulation was applied to the retina. Since macular striae were present, it was decided to peel the ILM, which was stained with brilliant blue dye. The ILM appeared very adherent and frequent regrasping of the edge became necessary. When grasping the edge of the ILM nasal to the fovea, one of the retinal folds was pinched, causing retinal bruising and hemorrhage. The intraocular pressure (IOP) was raised to prevent further bleeding and the ILM peeling was completed. The blood clot could not be removed using the back flush technique, so it was gently massaged away from the fovea using the silicone tip of a flute needle.

To avoid this complication, it is best to initiate the ILM peeling inferiorly and further away from the center of the macula. Any visual field defect caused by the peeling would be in the superior field and less noticeable by the patient. Good staining, high magnification, and slow motion peeling would also minimize iatrogenic trauma during ILM peeling.

## Subretinal Injection of Brilliant Blue

Arturo Alezzandrini, Francisco Rodriguez

In vitreous surgery, staining of the ILM with vital dyes is widely performed, and surgical outcomes have improved in many vitreoretinal disorders such as macular holes and epiretinal membranes. The dyes currently utilized for different steps during vitrectomy surgery are triamcinolone acetonide for vitreous visualization; indocyanine green (Diagnostic Green LLC, Powell, OH), infracyanine green (SERB Laboratories, Paris, France), and

brilliant blue (DORC, Zuidland, The Netherlands) for ILM staining; and trypan blue (Dutch Ophthalmic USA, Exeter, NH) for epiretinal membrane identification. One of the main complications that is observed during injection is the subretinal injection of the dye.

In Video 131.7, a series of steps are demonstrated to prevent this complication:

1. Dye is injected away from the fovea while the IOP is decreased.
2. A dual-bore cannula with multiple fluid egress vents is used to allow faster pressure relief during injection, eliminating the fluid jet stream.
3. Dye is injected over the light pipe, thus avoiding direct impact of the dye on the macula.

## Reopening of Peripheral Retinal Breaks During Surgery for Submacular Hemorrhage

Carl Regillo

Submacular hemorrhage secondary to neovascular age-related macular degeneration (AMD) is a treatment dilemma for physicians and patients.

The patient in Video 131.8, with submacular hemorrhage secondary to neovascular AMD, was managed with subretinal tissue plasminogen activator (tPA) and pneumatic displacement as described by Tamer Mahmoud and colleagues.<sup>1</sup> During the initial core vitrectomy, there was evidence of a previously partially treated horseshoe retinal tear, and the posterior lip of the tear did not appear to have laser marks. We proceeded with submacular tPA injection (25 mcg/0.1 ml tPA [alteplase, Genentech, South San Francisco, CA]). This was followed by injection of filtered subretinal air, resulting in bullous elevation of the retina. In fact, the air made the retina too bullous and actually displaced it temporally towards the tear. When we tried to subsequently laser the break, the detached retina was in the way, making the view extremely

difficult. The air bubbles migrated towards the break and opened it up. The solution to the problem was to go to air and perform an air–fluid exchange, which helped to tamponade the retina so that we were able to aspirate over the break and flatten this area out so that it could be successfully lasered.

There are several potential ways to prevent opening up existing peripheral breaks in such cases. If breaks are found to be present preoperatively, they can be reinforced in the office a week or two ahead of time. Intraoperatively, if extensive subretinal fluid or air injection is being planned, it may be best to inspect the peripheral retina before the injection and, if breaks present, laser the breaks upon identifying them and minimize the volume of fluid or air subsequently injected under the retina.

It should be noted that the use of air in addition to a solution of tPA has not been proven to enhance or aid in the displacement of macular subretinal hemorrhage. A more conservative, safer approach utilizing just the subretinal tPA solution without subretinal air may be preferred approach. Further studies are warranted before routinely adopting the subretinal air technique.

## **Surgical Management of Hypotony Maculopathy**

Jose Garcia Arumi

Low intraocular pressure after vitrectomy surgery (postoperative hypotony) is generally due to the failure of the ciliary body to produce aqueous humor. This may be due to fibrous traction from anterior PVR, cyclodialysis, or ciliary body detachment. A diagnosis can be made with ultrasound biomicroscopy (UBM) that visualizes the ciliary body and tissues around it.

Video 131.9  presents a 54-year-old patient with a history of vitreous hemorrhage after trauma who had undergone a 23G vitrectomy procedure elsewhere. Three months later he developed hypotony maculopathy and was referred for evaluation. Upon examination the best corrected visual acuity was 20/400 and intraocular pressure was 4 mmHg. The UBM suggested a cyclodialysis cleft and ciliary body detachment extending 360°. The

OCT scan indicated increased macular thickness associated with hypotony maculopathy and chorioretinal folds, which were visualized on fluorescein angiography.

The patient underwent a 23G pars plana vitrectomy surgery followed by posterior hyaloid separation, brilliant blue dye staining, and removal of the internal limiting membrane (ILM) in the macular area. Peeling the ILM decreases the rigidity of the retina and eases the opening of the macular folds once the hypotony is resolved. Transconjunctival cryotherapy was applied to the sclera 2.5 mm posterior to the limbus using a curved spherical retinal probe. Eight spots were applied: two spots per quadrant, each with a duration of 10 seconds and a temperature of  $-80^{\circ}\text{C}$  (avoiding the ciliary body). Following cryopexy, fluid–air exchange is performed and 6%  $\text{C}_3\text{F}_8$  gas was injected into the eye for tamponade. The postoperative course was unremarkable. Two weeks after surgery the best corrected visual acuity improved to 20/25 and IOP was 15 mmHg. Ultrasound biomicroscopy indicated that the ciliary body had reattached to the scleral spur, closing all the clefts.

Key steps in the management of hypotony maculopathy are:

- Performing preoperative UBM.
- Peeling the ILM during the surgery.
- Applying transscleral cryotherapy to the pars plana (avoiding the ciliary body).
- Gas tamponade.

## Intraoperative Choroidal Detachment

Homayoun Tabandeh

Intraoperative choroidal detachment may occur as a result of displacement of the infusion cannula into the suprachoroidal space, or it may represent suprachoroidal hemorrhage. Furthermore, continued infusion into the suprachoroidal space from a displaced infusion cannula could result in stretching and subsequent rupture of blood vessels traversing this space causing the additional suprachoroidal hemorrhage. Conversely, intraoperative suprachoroidal hemorrhage may result in displacement of the

infusion cannula into the suprachoroidal space, further exacerbating the choroidal detachment.

Early detection is an important first step. Intraoperative visualization of ora serrata in the absence of scleral depression may be an early warning sign indicating choroidal detachment. Once a choroidal detachment is suspected, surgery should be stopped and the situation assessed, establishing the possible cause.

Intraoperative displacement of infusion cannula can be identified by inspection of the infusion cannula internally and externally. Risk factors for infusion cannula displacement include intraoperative manipulations, oblique placement of the cannula, preoperative choroidal detachment, and hypotony. Visualizing the tip of the cannula prior to opening the infusion flow at the beginning of the surgery is an important step that helps in identifying a misplaced cannula in the suprachoroidal space. In eyes with preexisting choroidal detachment, a straight cannula entry aiming towards the center of the vitreous cavity (instead of beveled incision) reduces the chance of suprachoroidal placement of the infusion cannula. Securing the infusion line by a tape helps reduce the chances of cannula displacement during surgical manipulations.

Once a displaced infusion cannula is recognized, the infusion flow should be closed immediately. The infusion line is disconnected from the cannula (leaving the cannula in place) and immediately reinserted through one of the other available cannulas (the tip needs to be visualized prior to reopening the infusion), therefore maintaining the intraocular pressure. The original infusion cannula will be left in the original location to allow drainage of fluid from the suprachoroidal space. Once the choroidal detachment is reduced, an attempt may be made to reposition the displaced cannula. Alternatively the cannula may be removed and a new cannula may be inserted, utilizing a straight entry, aiming towards the center of the vitreous cavity. A modified version of this technique may be used in the management of intraoperative suprachoroidal hemorrhage.

In Video 131.10 , a patient with diabetic retinal detachment underwent pars plana vitrectomy. Towards the end of surgery, progressive choroidal detachment was noted. The infusion cannula was inspected and was noted to have been displaced into the

suprachoroidal space. The infusion line was disconnected from the cannula, leaving the displaced cannula in place. The infusion line was immediately reinserted through one of the remaining cannulas, maintaining the IOP. The displaced cannula was left unplugged in the suprachoroidal space to allow drainage of fluid. The posterior segment was inspected. The choroidal detachments were found to have subsided. An attempt was made to reposition the cannula, without success. Subsequently the cannula was removed and a new cannula was inserted with a straight entry, aiming towards the center of the vitreous cavity. The infusion line was relocated, and the surgery was continued uneventfully.

## **Massive Suprachoroidal Hemorrhage (SCH)**

Jose Garcia Arumi

Massive suprachoroidal hemorrhage generally implies the rupture of the short or long posterior ciliary artery branches during intraocular surgery or after penetrating trauma. The incidence of suprachoroidal hemorrhage in vitreoretinal surgery is low. Systemic risk factors include advanced age, hypertension, atherosclerosis, diabetes, and bleeding disorders. Ocular risk factors include high myopia (decreased scleral rigidity and the increased fragility of the choroidal vasculature), prior history of retinal detachment surgery, preoperative hypertension, and intraocular inflammation. Main intraoperative risk factors are elevated blood pressure or heart rate during surgery, prolonged intraocular hypotony, scleral manipulation, and extensive cryopexy.

The goal in the management of suprachoroidal hemorrhage during surgery is to stop the bleeding by increasing the intraocular pressure, closing the surgical wound, and lowering the systemic blood pressure. Emergency drainage sclerotomies may induce transient hypotony and stimulate rebleeding. Further, they increase the risk of retina/uveal tissue incarceration due to the high pressure.

Suprachoroidal blood may not necessarily require drainage. This particularly applies to sectorial hemorrhages that do not involve the posterior pole and the macula. During the follow-up, dynamic B-

scan ultrasound can help in assessing the degree of liquefaction of the suprachoroidal blood clot and indicate the adequate timing for the drainage procedure, which is usually 10–14 days after the incident.

In Video 131.11, a 25G infusion cannula is placed into the anterior chamber through the inferior limbus and the IOP is set at 30 mmHg. A radial sclerotomy is performed parallel to the rectus muscle in the quadrant with the most suprachoroidal hemorrhage. The infusion pressure allows a controlled drainage of the liquefied blood through the sclerotomy. After a partial drainage, 23G cannulas are inserted into the eye through the pars plana and a limited vitrectomy is performed followed by removal of the posterior hyaloid. Injection of PFCL into the vitreous cavity induces an internal tamponade which further displaces the liquefied blood towards the periphery and allows its drainage through the sclerotomy. The eye may then be filled with gas or silicone oil.

## Suprachoroidal Hemorrhage During Cataract Surgery

Kazuaki Kadonosono

Suprachoroidal hemorrhage is a rare but severe complication that usually results in poor vision. Intraoperative hypotony is one of the main risk factors resulting in choroidal effusion with subsequent rupture of small arteries traversing the suprachoroidal space. In addition, prolonged hypotony may directly result in rupture of the short or long posterior ciliary arteries or vortex veins. The greatest risk for suprachoroidal hemorrhage during cataract surgery occurs immediately after nucleus removal, when the eye is at greatest risk of prolonged hypotony.

The 73-year-old patient presented in Video 131.12 had had phacoemulsification elsewhere. While aspirating the cortex, the posterior capsule was ruptured with subsequent vitreous loss. Effort was made to implant the IOL into the bag; however, suddenly the choroid became elevated, and suprachoroidal hemorrhage was recognized and surgery was stopped. The patient was referred for evaluation and management to our clinic. One

week after the original surgery, the patient was brought back to the operating room for drainage of the suprachoroidal blood. Iris retractors were placed to have a better visualization of the anterior chamber. An infusion cannula was inserted into the anterior chamber to maintain the IOP. It was noted that patient still had a large blood clot in the suprachoroidal space. A scleral cutdown was performed superotemporally, and tissue plasminogen activator (0.4 ml volume at a concentration of 62.5 µg/0.1 ml [Monteplase, Eisai Co., Tokyo, Japan]) was injected into the suprachoroidal space to dissolve the clot. The sclera was depressed with a cotton swab to aid its removal. An infusion cannula could now be placed through the pars plana into the vitreous cavity and vitrectomy was performed.

## **Subretinal Perfluorocarbon Bubble**

Maria H. Berrocal

Subretinal perfluorocarbon liquid (PFCL [Alcon Laboratories, Fort Worth TX]) after vitrectomy surgery is one of the most dreaded complications of its use. The risk factors for subretinal migration of PFCL include:

1. Large breaks.
2. Posterior breaks.
3. Residual traction on the breaks.
4. Multiple small bubbles during injection.
5. Turbulence during injection.
6. Injecting directly in the direction of the break.

Although extrafoveal subretinal PFCL bubbles could be monitored (although it has been reported that they can migrate inferiorly and if close to the fovea would need to be removed), submacular PFCL bubbles would have adverse impact on visual acuity and need to be removed.

To decrease the likelihood of getting subretinal/submacular PFCL bubbles, one may relieve all traction on the breaks prior to the injection of PFCL into the eye; use a dual-bore cannula (MedOne Surgical Inc, Sarasota, FL) for PFCL injection or use an aspirating instrument (in the other hand) during the injection (in valved trochar systems); inject with a slow speed over the optic nerve to form a single bubble and inject inside the forming PFCL bubble; use valved cannulas to decrease the amount of turbulence during the injection procedure; and keep the PFCL level below the peripheral breaks. Washing out the residual PFCL bubbles with balanced salt solution (BSS [Alcon Laboratories, Fort Worth TX]) or infusion fluid after the removal of the main bubble may avoid having residual PFCL bubbles inside the vitreous cavity after surgery.

Utilizing a dual-bore cannula that has a side port for injection may prevent damage to the retina from the PFCL jet stream during the injection procedure. This may particularly be an issue when utilizing 25- and 27G vitrectomy systems.

Very small amounts of residual PFCL bubbles inside the vitreous cavity may be tolerated although the patient may complain of seeing the bubble when laying on their back. Larger amounts of PFCL in the vitreous can cause inflammation and may need to be removed.

In Video 131.13, the patient presents with a rhegmatogenous retinal detachment with star fold and inferior PVR. An encircling no. 41 band was placed and tied superonasally; 27G vitrectomy was performed with complete vitreous removal. PFCL was injected into the eye to flatten the retina, and subretinal fluid was drained through the superior retinal tear. The PFCL was injected with a 30G needle. Multiple PFCL bubbles were dispersed inside the vitreous cavity. Air–fluid exchange was performed, and laser endophotocoagulation was applied around the break and the lattice degeneration inferiorly. Residual PFCL bubbles were washed out multiple times and no residual bubbles were visible. Air–gas exchange was performed, and the eye was filled with 14% C<sub>3</sub>F<sub>8</sub> gas (Alcon Laboratories, Fort Worth TX).

Postoperatively, a small subretinal PFCL bubble was detected near the peripheral break on the buckle. Laser was applied around the bubble to prevent its migration towards the posterior pole. The

retina has remained attached, and the subretinal PFCL bubble has not moved for over a year.

## **Perfluorocarbon-Induced Macular Hole**

Yusuke Oshima

Perfluorocarbon (PFCL [Alcon Laboratories, Fort Worth TX]) liquid is a very useful tool for flattening the detached retina during vitrectomy, especially in giant retinal tear detachment or detachment associated with proliferative vitreoretinopathy. Special attention should be given to PFCL injection during surgery, especially in small-gauge surgery where resistance to the injection is increased due the narrower size of the injection lumen.

In Video 131.14  PFCL is injected over the macula. A macular hole is formed due to the pressure caused by the injection stream. The surgeon should keep in mind to gently inject PFCL over the optic nerve (or nasal to it) and avoid injecting it directly over the macular area. Further, the injection should be done by the surgeon (rather than an assistant), and a safe distance from the surface of the retina should be kept during the injection procedure (one has the tendency to move closer to the surface of the retina during the injection). If any resistance is felt during the PFCL injection, the cause needs to be evaluated outside the eye instead of applying additional pressure. In this case a standardized macular hole surgical technique was performed including peeling the ILM followed by fluid–air exchange and gas tamponade.

## **Giant Retinal Tear With Slippage on Encircling Scleral Buckle**

Carl Regillo

A combined pars plana vitrectomy (PPV) with encircling scleral buckle (SB) was being performed for a giant retinal tear (GRT) extending approximately 180° in a phakic patient. Despite meticulous drying of the edge of the retina during fluid–air

exchange, when the perfluorocarbon liquid (PFCL) was completely removed, there was posterior slippage of the retina. Another attempt with the same technique, again paying close attention to patiently removing as much fluid over the PFCL as possible, yielded the same results. The scleral buckle was then loosened significantly, and the same technique was attempted. This time, the retina did not slip. We hypothesize that excessive cerclage effect of the encircling scleral buckle promoted posterior slippage which was resolved by loosening the buckle (Video 131.15).

Posterior slippage of the retina in the setting of a GRT-related retinal detachment is generally from anterior fluid (i.e., the layer of fluid between the PFCL and the infused air) displaced posteriorly through the large break. To minimize this effect, it is important to remove all of the anterior fluid in the vitreous cavity before removing the PFCL under air along with any anterior subretinal fluid above the PFCL meniscus by extruding over the break.

In this case, presumably there was the additional factor of excessive 360° of scleral buckle indentation. A “high” indentation may be undesirable and, therefore, best avoided to minimize slippage. Furthermore, there is no proof that encircling significantly enhances the success rate of vitrectomy for retinal detachment repair, with or without GRT. Many surgeons would argue that this combined approach (i.e., PPV plus SB) is not necessary and only adds to the surgical morbidity.

## **PVR and Subretinal Membrane**

Stanislao Rizzo

Subretinal membranes are associated with rhegmatogenous retinal detachment due to proliferative vitreoretinopathy (PVR). Several surgical techniques are available for the removal of subretinal membranes during PVR surgery.

When the subretinal membrane is in the form of branching bands and the extent of the membrane can be visualized through the retina, the membrane can be removed using forceps passed through preexisting retinal breaks or small retinotomies. However, if the membrane is in the form of diffuse sheets or the extent of subretinal membrane cannot be visualized, peripheral retinotomy may

become necessary followed by folding the retina and removal of the subretinal membrane under direct visualization.

In Video 131.16, after performing core vitrectomy and meticulous peripheral vitreous shaving with 360° scleral depression, attention is directed towards the proliferative membranes. Intravitreal triamcinolone acetonide suspension was used to highlight these membranes. Mature preretinal membranes were peeled with forceps and a pick in a bimanual fashion using chandelier light for illumination. The removal of subretinal membranes was attempted through a small access retinotomy. However, the retinal folds still remained, indicating the presence of residual subretinal membranes inducing traction and folding of the retina. The small retinotomy was not sufficient to visualize and remove all the subretinal membranes. It was decided to perform an inferior 180° retinotomy to relieve the traction and to visualize and remove all the residual subretinal membranes. Subsequently perfluoron was injected into the eye to flatten the retina, and endolaser photocoagulation was applied around the edges of the retinotomy. The eye was filled with silicone oil up to the posterior iris plane.

## A Problem During 27G Vitrectomy

Carl Claes

Constant monitoring and visualizing the instruments (specially their tips) during surgery is very important to detect any breakage while operating. In Video 131.17 a 27G pars plana vitrectomy is performed with a valved trochar system. A posterior vitreous detachment was induced and core vitrectomy was completed. During the ILM peeling a small retinal hemorrhage was passively aspirated with the 27G silicone-tipped flute needle, after which the ILM peeling continued unremarkably.

Suddenly a foreign body was visualized superior to the optic nerve: a barely visible transparent silicone tip of the flute needle. It probably got stuck in the 27G valved trochar and detached from the flute needle. During consecutive instrument exchange through the trochar, the silicone tip was inadvertently mobilized into the eye and fell on the retina.

An attempt was made to remove the silicone tip by slipping it into the tip of 27 G forceps as a sleeve covering the forceps arm. This maneuver unfortunately widened the diameter of the 27G forceps, and the sleeve got stuck in the valved trochar. To overcome this problem, the silicone tip was regrasped and in a bimanual fashion the silicone tube was pulled over one of the arms of the forceps. The silicone tip was pulled upwards to the shaft of the forceps, allowing the forceps to secure the silicone tip and remove it.

## **Vitreous Incarceration in the Sclerotomy Sites**

Maria H. Berrocal

Vitreous incarceration may occur at the sclerotomy sites and can cause traction and peripheral retinal breaks. There has been a decrease in the incidence of this complication due to a decrease in size of the sclerotomies and the use of trocar cannulas.

Nevertheless, it can still occur, particularly if a significant amount of peripheral vitreous remains near the sclerotomy sites. Additional predisposing factors for vitreous incarceration into the sclerotomy sites include elevated intraocular pressure during trocar removal, not using valved cannulas, and removing the trochars without an instrument inside their lumen.

Vitreous incarceration may be avoided by:

1. Thorough removal of the peripheral vitreous around the sclerotomy sites.
2. Careful examination of the peripheral retina around sclerotomy sites using scleral depression.
3. Avoiding increased IOP during trocar removal.
4. Performing a partial air–fluid exchange to have air seal the sclerotomies.
5. Placing the light pipe inside the cannula during its removal

(pushing back incarcerated vitreous).

6. Inspecting the sclerotomy sites for vitreous strands.

7. Suturing the leaking sclerotomies.

Vitreous incarceration does not always cause peripheral breaks or detachments but can potentially be a tract for entry of bacteria into the eye and consequent endophthalmitis as well. During the postoperative period it can only be detected if the peripheral retina is visualized and a peripheral break or detachment occurs. The management is to treat the secondary complications that ensue, namely new breaks, opening of existing breaks, and redetachment.

The 62-year-old female patient in Video 131.18<sup>6</sup> presented with a pseudophakic total rhegmatogenous retinal detachment with one tear identified at 11 o'clock. Since the patient had to travel by air, she did not want a gas bubble in the eye. It was decided to proceed with a scleral buckling procedure, and an encircling scleral buckle with a no. 41 band was placed around the eye under visualization with microscope. The band was measured and was left with a circumference of 70 mm. A trochar-cannula with a chandelier light was inserted into the eye to serve as light source. The fundus was visualized under the microscope using the wide-angle viewing system. A vitrectomy was not performed.

External drainage was performed by scleral cutdown: applying cautery to the scleral edges and choroidal bed, and puncturing the choroid with a 30G needle under direct visualization with the microscope. The chandelier light was removed, and an illuminated endolaser probe was inserted into the eye through the same cannula to laser around the break. The cannula was removed, the sclerotomy site was not sutured, and the conjunctiva was closed. On the first postoperative day the retina was completely attached. A week later the patient returned with a recurrent retinal detachment and a break near the sclerotomy site (for chandelier light) with vitreous strand visible incarcerating into the sclerotomy. A reoperation was recommended, and pars plana vitrectomy was performed with SF<sub>6</sub> gas (Alcon Laboratories, Fort Worth, TX) and additional laser treatment. The retina has remained attached.

## Argus II Array Implantation

J. Fernando Arevalo

In Video 131.19, an Argus II array (Second Sight Medical Products, Inc, Sylmar, CA) was implanted in the usual manner in a retinitis pigmentosa (RP) patient with bare light perception vision. Core and peripheral vitrectomy was performed with the assistance of triamcinolone acetonide. The microelectrode array was then inserted through a temporal sclerotomy (5.2 mm). The array was positioned over the macula and then tacked using a custom retinal tack (Second Sight Medical Products, Inc, Sylmar, CA). However, the retinal tack dislodged from the implant and fell into the vitreous cavity. The retinal tack needed to be removed, similar to an intraocular foreign body (IOFB). The microelectrode array was then placed again over the macula and was stabilized using a new retinal tack without any further issues.

Pearls on how to avoid this complication:

- Open a large inferonasal sclerotomy to tack the array and enlarge it further if necessary (19G).
- Assure that the tack is engaged perpendicular to the tack holder.
- When using bimanual techniques to place the array over the macular area, make sure that the tack does not move from its proper position. If it does, exchange it for a new tack before attempting to tack the array.
- Practice the tacking procedure before the surgery. This is a unique maneuver that is only performed during the Argus II surgery.

## Subretinal SF<sub>6</sub> Gas After Retinal Detachment Surgery

Stratos Gotzaridis

Postoperative subretinal SF<sub>6</sub> gas is a rare finding after retinal detachment surgery. It may occur due to the turbulence during the injection of gas near a large retinal break, especially if there is persistent subretinal fluid keeping the break open. The positioning of the patient, location, and size of the break may worsen the

situation during the postoperative period.

The patient in Video 131.20 presented at postoperative day 1 with subretinal gas and total retinal detachment. The patient was brought back to the operating room. A 25G trocar was placed through the corneal limbus into the anterior chamber and was attached to the infusion line. Through a corneal tunnel the endodiathermy probe was introduced into the eye and an anterior retinotomy was made to allow the aspiration of the gas with the vitreous cutter. The infusion fluid pushed the retina back to its original position, allowing the insertion of an infusion cannula through the pars plana.

A new retinotomy was created for further drainage of subretinal gas/ fluid and allow the flattening of retina. Once the retina was flattened, endolaser was applied around the retinotomies, followed by intravitreal gas injection. The patient was asked to maintain a face-down positioning posture for 7 days.

## **Removal of a Large Glass Intraocular Foreign Body**

Grazia Pertile

The patient in Video 131.21 suffered penetrating ocular trauma with a large piece of glass from a broken bottle. During the initial surgery the lens remnants were removed and the corneoscleral wound was sutured with 10-0 nylon sutures, but the foreign body was left behind, and the vitreous hemorrhage prevented the direct visualization of the fundus. Postoperatively, the vitreous cavity and retina were monitored with B-scan ultrasonography. After a couple of weeks a retinal detachment developed. Vitrectomy was performed with the purpose of removing the blood and intraocular foreign body and reattaching the retina. The surgeon who performed the surgery reported that the repeated attempts to remove the glass from the vitreous cavity were unsuccessful due to the very large size of the foreign body, which was irregular in shape and slippery. Different types of intraocular forceps were tried but none were able to grasp the foreign body to remove it.

At this point the patient was referred for second opinion. The

visual acuity was light perception. The cornea was reasonably clear, but there was a large corneoscleral wound involving the center. The temporal half of the iris was missing, and nasally there were points of iris root disinsertion with a mild hyphema. B-scan ultrasonography confirmed the diagnosis of a total retinal detachment.

Twenty-gauge vitrectomy was started by inserting an illuminated infusion cannula. After the removal of the blood, a total retinal detachment with extensive proliferative vitreoretinopathy and multiple posterior retinal breaks was visualized; these perhaps resulted from multiple unsuccessful attempts to remove the large piece of glass. The foreign body was located in the inferonasal quadrant, with an irregular triangular shape. The length was around 15 mm and the width was 9 mm.

A basket (Nitinol Tipless Stone Extractor [G46206] COOK MEDICAL, Bloomington, IN) that is generally utilized by the urologists for the removal of kidney stones was used to remove the foreign body. This retractable instrument with a diameter of 1.1 mm was introduced through an enlarged sclerotomy site. With this device, a thin network made of memory metal was then extruded inside the eye, paying attention not to touch the retina while trying to engage the object with the basket. The large piece of glass is gently moved inside the basket with the help of an illuminated spatula, which permitted us to lift it up from the retina and guide it toward the metal network. The illumination from the spatula allowed us to overcome the shadow that was projected by the large foreign body. (When the object is large, it is crucial to start the maneuver from the most posterior part. In this way, you promote a spontaneous movement inside the basket due to the gravity and prevent it from rotating and getting stuck in the retina.) Finally, the metal network was retracted with the object inside. Once brought behind the iris plane, the large size of the foreign body could be appreciated. The next step was to find the least invasive method of taking the basket with the object inside it out of the eye. In general, when the foreign body is firmly held with an instrument, it is best to enlarge the same sclerotomy with the other hand and remove it through a scleral incision at 3–4 mm posterior to the limbus. However, in this case we would have cut the sclera for more than

one quadrant in addition to the extensive corneal wound and the corneoscleral incision already present in the superonasal quadrant. We chose to reopen the corneoscleral incision used during the previous operation. But this approach was tricky because the slippery foreign body needed to be regrasped. In order to reduce the risk of dropping the foreign body, the basket was directed toward the corneoscleral incision that was kept open with a spatula and then the basket was slowly opened while grasping the piece of glass with forceps in the other hand. The basket was retracted after at least one-third of the foreign body was extruded with forceps. The wound was sutured, the membranes were removed, the retina was flattened, and silicone oil tamponade was injected.

## **Introduction**

The quote from retinoblastoma pioneer Alfred G. Knudson Jr. is as true today as it was in 1976.<sup>1,2</sup> We now know a great deal more about the molecular basis of the mutations in cancer cells than Knudson knew when he was writing, but we have made distressingly little progress towards Knudson's admonishment to clinicians that early diagnosis and treatment is essential for the successful management of this disease. This chapter on

retinoblastoma (RB) emphasizes the need for pediatricians and other healthcare professionals who must listen and take action when parents report seeing “something in my child's eye.” We continue to emphasize what Nancy Mansfield taught us about the importance of recognizing signs and symptoms of classic posttraumatic stress disorder in children undergoing prolonged treatment and multiple anesthetics for intraocular retinoblastoma.

## Clinical Advances

Since the fifth edition of this publication in 2012, the most significant addition to the clinical management of children with retinoblastoma is the emergence of local or regional therapies such as intraarterial chemotherapy and intravitreal chemotherapy. Intraarterial ophthalmic artery chemotherapy infusion is a more selective adaptation of the Japanese experience in the use of regional intraarterial chemotherapy.<sup>3,4</sup> Like many other new treatment approaches, the initial excitement of intraarterial chemotherapy has been tempered somewhat as rare but significant complications have been encountered (including choroidal artery occlusion, local orbital recurrence, and metastatic disease).<sup>5-8</sup> Intravitreal chemotherapy has emerged as an effective modality for treating vitreous seeding, and appears to offer a high globe salvage rate and a negligible risk of side-effects as long as the clinician adheres to a strict protocol and dose range.<sup>9-11</sup> The pros and cons of these new approaches to the treatment of retinoblastoma are discussed later in this chapter.

## Basic Science Advances

In the previous edition, we cited three advances: (1) the definition of the three-dimensional structure of the retinoblastoma protein (pRB), providing new insights into how it works; (2) the fact that pRb can simultaneously bind to multiple proteins, acting as a coupling factor to recruit proteins to specific genes; and (3) an improved understanding of low-penetrance retinoblastoma.<sup>12</sup>

## Genetics of Retinoblastoma

## Clinical Genetics

Study of retinoblastoma has been critical to understanding the genetic basis of cancer in general. Although retinoblastoma is rare, occurring in approximately one in every 18,000 live births, the pathogenetic insights gleaned from retinoblastoma have profoundly affected our understanding of common cancers arising from lung, breast, prostate, and virtually every other site. This unique place of retinoblastoma in oncology derives from its very distinct pattern of inheritance and from the fact that the *RB1* gene was not only the first human cancer gene to be cloned but was the first of a whole class of identified human cancer “suppressor” genes.

About 60% of all patients with retinoblastoma have a nonheritable form of the disease with a normal life expectancy if they are cured of the eye cancer. In this group the average age at diagnosis is about 24 months, the eye tumor is always unilateral, and the risk of other cancers is virtually indistinguishable from the normal population.<sup>13</sup> In contrast, the other 40% of patients carry the *RB1* germline mutation and have a heritable cancer predisposition syndrome. The inheritance of a single mutated, inactive allele of the *RB1* gene confers the predisposition to cancer (a dominant trait), but a second inactivating mutation must occur in at least one retinoblast for retinoblastoma to develop. Genetically, because the tumor requires inactivation of both copies of the *RB1* gene, it is considered a recessive trait. However, in pedigrees, the mutation has a dominant phenotype because the chances of at least one retinoblast acquiring the second “hit” is very high. Therefore, a person with the cancer predisposing syndrome genotype (*RB1*<sup>+/-</sup>) will develop retinoblastoma with a 90–95% probability. Only 7–10% of retinoblastoma patients have a positive family history (someone else in the family with retinoblastoma). Hence, the other patients who carry the *RB1* gene defect, about 30% of patients with retinoblastoma overall, have a new germinal mutation. The average age at diagnosis for germinal retinoblastoma is younger than the nonheritable form – ranging from newborn to 12 months – and they are predisposed to a variety of cancers throughout life.<sup>14</sup> About 85% of germinal retinoblastoma patients develop bilateral eye tumors and the unilateral patients who carry the gene defect tend to

develop multifocal tumors in the one eye. Within the age range of birth to 5 years (typically before age 3), about 5–6% of germinal retinoblastoma patients will develop a midline intracranial tumor usually involving the pineal or suprasellar region, that histologically resembles retinoblastoma and has variably been referred to as a pinealoma, primitive neuroectodermal tumor (PNET). These patients are referred to as having trilateral retinoblastoma, whether the midline intracranial tumor occurs in the sella region or pineal gland. Despite the histologic similarity, it is important to recognize that the intracranial tumor is a primary cancer and not a metastasis from the eye tumor. The intracranial tumor is usually diagnosed before, together with, or within 2 years of the retinoblastoma diagnosis. Germinal retinoblastoma patients also have an elevated risk of osteosarcomas, soft tissue sarcomas, and other mesenchymal tumors through their teenage years; melanomas and brain tumors through middle age; and epithelial malignancies such as lung and bladder cancer into later life.<sup>15,16</sup> This elevated risk is much greater in patients who have received external beam radiotherapy (EBR), particularly in the field of radiation treatment (e.g., head and neck).<sup>14,17</sup>

## Genetic Terminology

The genetic terminology used in the retinoblastoma field can be confusing. Clinicians erroneously may use the term unilateral to refer to the nonheritable form of retinoblastoma. However, this nomenclature is inappropriate, since about 12–15% of unilateral cases carry the *RB1* mutation just like bilateral cases.<sup>18</sup> Any patient who carries the *RB1* mutation in cells outside the eye is considered a germinal or heritable case. Patients who have unilateral tumors and no *RB1* mutation outside the eye are considered somatic cases. Epidemiologic studies on second cancers that provide no information about the *RB1* gene status probably overestimate the risk in unilateral, somatic patients. The term sporadic is also commonly misused. Sporadic refers to a lack of family history but is not equivalent to somatic disease since the majority of germinal cases are new mutations. About 90–93% of all retinoblastomas are sporadic with no family history, meaning that they are the result of new mutations that developed either in the sperm or egg. In

contradistinction, virtually all cases in a single family are hereditary.

The term hereditary is often used to indicate the presence of germline *RB1* mutations (i.e., present in virtually all cells in the body, both somatic and germ line), which also includes sporadic, nonfamilial cases. Therefore, a new mutation that develops in the sperm of the father and causes bilateral retinoblastoma would be germinal, hereditary, sporadic, and nonfamilial. The term mosaic refers to the presence of the *RB1* mutation in a subpopulation of cells (somatic, germinal, or both), and is thought to occur from an *RB1* mutation in the developing embryo after conception. The clinical manifestations of a mosaic *RB1* mutation are uncertain in any given patient, but are typically managed clinically like other germinal or hereditary patients. However, the state of *RB1* mosaicism is never inherited and therefore the parents can be ruled out as carriers. However, patients with *RB1* mosaicism can have children with retinoblastoma, although the risk in any individual patient is difficult to predict.

## Molecular Genetics of Retinoblastoma

Because of the seemingly autosomal dominant inheritance pattern for retinoblastoma in the clinical setting, the *RB1* gene was assumed for many years to act in a dominant fashion.<sup>13</sup> A major paradigm shift in the genetic understanding of retinoblastoma, and cancer in general, began with the seminal paper published in 1971 by Alfred Knudson, who proposed that retinoblastoma was caused by two mutational events: “In the dominantly inherited form of the disease, one mutation is inherited via the germ line and the second occurs in somatic cells. In the nonhereditary form, both mutations occur in somatic cells.”<sup>18</sup> The major implication of this “two-hit theory” was that the *RB1* gene functions in a recessive manner at the cellular level – an unprecedented suggestion at the time. Today, it is known that many cancer-causing mutations are recessive or affect tumor suppressor genes.

The Knudson hypothesis languished for another decade due to a lack of scientific methods for identifying the *RB1* gene. An early clue to the location of the *RB1* gene was the recognition in the 1960s

that a portion of the Group D chromosomes (13, 14, and 15) was occasionally deleted in retinoblastoma. Shortly after the Knudson paper, new chromosome banding techniques allowed chromosome 13 to be identified as the target of these deletions.<sup>19</sup> The smallest deleted region was later mapped to chromosome 13q14.1 to q14.3.<sup>20</sup> An enzyme with a measurable activity, esterase D, had been mapped to chromosome 13 and proved to be critical for linkage analysis in the era before recombinant DNA technology was readily available. Using classic deletion mapping, Sparkes and coworkers studied five patients with retinoblastoma and found that, in all five, esterase D activity was only 50% of normal. These data suggested that the loci for retinoblastoma and esterase D genes were both within the deleted segment of chromosome 13q.<sup>21</sup> Based on the fact that the chromosome 13 deletion and the esterase D locus were tightly linked to retinoblastoma in multiple families with clinically and pathologically indistinguishable disease, Murphree and Benedict argued that there was probably a single *RB1* locus.<sup>22</sup> Further, retinoblastoma tissue from a nonhereditary unilateral patient was also found to contain a 13q14 deletion, suggesting that all forms of retinoblastoma involve the same gene on chromosome 13 at locus 13q14.<sup>23</sup> These investigations led to the consensus that a single retinoblastoma locus, *RB1 at 13q14.2*, is mutated in all forms of retinoblastoma.

Meanwhile, a body of scientific work was accumulating to support the notion that *RB1* is a recessive gene that is lost during tumorigenesis. Benedict and coworkers examined a familial retinoblastoma patient and found a 50% reduction of esterase D in normal cells and a complete absence of the enzyme activity in retinoblastoma cells.<sup>24</sup> Dryja and colleagues used DNA fragments from 13q14 to show that homozygous deletions could occasionally be identified in retinoblastoma tissue.<sup>25</sup> In a landmark paper, Cavenee et al. proved beyond doubt the recessive nature of the *RB1* gene and popularized the use of loss of heterozygosity analysis.<sup>26</sup> By comparing DNA from normal and tumor tissue, they found that the region around the *RB1* gene was frequently “reduced to homozygosity” in retinoblastoma tissue. In other words, one copy of the region around *RB1* was lost during tumorigenesis. Cavenee et al. also showed that in heritable cases, the germline copy of 13q

(carrying the mutant *RB1*) that was passed among affected family members was always the one that was retained in the tumor.<sup>26</sup> The chromosomal mechanisms involved in reduction to homozygosity on 13q14 are shown in Fig. 132.1.

**FIG. 132.1** Chromosomal mechanisms for loss of heterozygosity (LOH) that represents the second “hit” and loss of the second *RB1* gene allele in retinoblastoma.

Another breakthrough in the hunt for *RB1* was the cloning of the esterase D gene.<sup>27,28</sup> In the early days of recombinant DNA technology, cloning a gene usually required an activity that could be assayed, and esterase D provided such an activity. Once the esterase D gene was cloned, its DNA sequence was harnessed and could be used to probe adjacent stretches of chromosomal DNA to identify nearby genes. An intensive search ensued for the *RB1* gene, and the esterase D gene proved to be located very nearby to the *RB1* gene. A few short months following the cloning of esterase D, the

search culminated in the discovery of a large gene that contained deletions in many retinoblastomas.<sup>29,30</sup> By the early 1990s, there was a basic molecular understanding of how retinoblastoma is inherited. Transmission of an inactive copy of *RB1* imparts the predisposition to retinoblastoma. Because of the random background mutation rate in the developing retina, inactivation of the second copy then leads to tumor development.

## The *RB1* Gene

The *RB1* gene (Fig. 132.2) contains 27 exons spanning over 200 kilobases of DNA. The 5' end of the gene is oriented toward the centromere of chromosome 13. The promoter region lacks a typical TATA box but contains a CpG-rich region, or CpG island. Germline mutations in the *RB1* gene are distributed throughout the gene with mutational hotspots at CpG dinucleotides.<sup>31,32</sup> Less than 10% of retinoblastoma patients have a constitutional chromosome 13q abnormality (usually a deletion) that can be detected by karyotyping.<sup>33,34</sup> Deletions that are more extensive can be associated with the 13q-syndrome, with features such as growth and mental retardation, facial dysmorphism, microcephaly, skeletal anomalies, and genitourinary abnormalities. About 15–20% of germinal mutations are too small to detect by cytogenetics but can be detected with techniques for analyzing gross DNA rearrangements (e.g., Southern blot). The remainder of *RB1* gene mutations are small alterations involving one or a few nucleotides that can only be detected by high resolution methods and direct sequencing.<sup>35</sup> At our center in 2015, *RB1* gene testing is now performed with next generation sequencing techniques, with results being obtained in 4–6 weeks. The majority of these mutations are frameshift and nonsense mutations, inframe and missense mutations, splicing mutations, and mutations in noncoding regions that result in a truncated, unstable protein product (Table 132.1).<sup>36</sup> A recent review of *RB1* mutations found the following ratios: 37% nonsense, 21% splice, 20% frameshift, 9% large indel, 5% missense, 7% chromosomal deletions, and 1% promoter mutations.<sup>37</sup> The possibility of using truncated pRb protein mutants as the basis for genetic testing to detect germline *RB1* mutations was proposed

several years ago,<sup>31</sup> and recently shown to be feasible.<sup>38</sup> Interestingly, most new germline *RB1* mutations are of paternal origin, suggesting that the gene is more susceptible to mutation during spermatogenesis rather than oogenesis.<sup>39</sup>

**FIG. 132.2** *RB1* gene, mRNA transcript, and protein.

**TABLE 132.1**

## Tumor Regression Patterns Following Primary Chemotherapy

Type	Description	Needs Consolidation
0	Small intraretinal lesion that disappears completely without RPE changes	No
I	Entire lesion calcifies into a mass that looks like "rock-salt." RPE changes at base	Yes (minimal)
II	Homogenous semitranslucent, gray "fish-flesh" lesion	Yes
III	A combination of type I and type II. This is the most common regression pattern	Yes
IV	An entirely flat chorioretinal scar with significant RPE changes, most commonly seen after laser consolidation	Yes
Early retinoma retinocytoma	Looks like type II regression prior to treatment with chemotherapy or radiotherapy and shows no change during or following treatment. May contain cystic or cavitory spaces	Variable

RPE, retinal pigmented epithelium.

Mutation of the second *RB1* allele is typically due to chromosomal aberrations, usually recognized as loss of heterozygosity (LOH) by polymorphism analysis.<sup>40</sup> These mutations occur at a much higher rate than the first, germline mutation ( $10^{-3}$  as compared with  $10^{-7}$  for the first mutation).<sup>41</sup> The most common mechanism leading to LOH is mitotic recombination (50%), followed by nondisjunction with or without subsequent reduplication (~40%).<sup>42</sup> Other mechanisms include small deletions and gene conversions. Therapeutic exposure to ionizing radiation induces DNA damage and increases the risk of LOH, and hence tumorigenesis (i.e., second cancers), within the field of radiation.

Advances in rapid genetic testing have allowed for preimplantation genetic diagnosis (PGD) for retinoblastoma.<sup>43</sup> This procedure allows a couple in which one parent has a known germline mutation to undergo in vitro fertilization; prior to implantation, the embryos are tested for the mutation using single cell polymerase chain reaction and rapid DNA sequencing of the exon in question. Only those embryos that are mutation-free are implanted back into the mother. Although expertise and cutting-edge technology are required, PGD for retinoblastoma is currently offered at multiple centers throughout the United States.

## Low Penetrance Retinoblastoma

The term penetrance refers to the frequency that a heritable disease

is manifest in the offspring of affected individuals. The word expressivity refers to the variability of clinical manifestations in affected individuals. For example, patients with heritable retinoblastoma who develop only unilateral eye disease manifest reduced expressivity. In general, reduced penetrance and expressivity tend to segregate in the same families. Overall, the penetrance of retinoblastoma is about 80–90%, but this represents a heterogeneous group of high-penetrance and low-penetrance families.<sup>44</sup> The diseased-eye ratio (the ratio of the number of eyes containing tumors to the number of mutation carriers in a family) was devised to quantitatively identify low penetrance retinoblastoma families by taking into account both penetrance and expressivity.<sup>36</sup> Most low penetrance families have diseased-eye ratios <1.5, whereas families with complete penetrance typically have diseased-eye ratios of ≥1.5. Initially, investigators postulated that low penetrance retinoblastoma may be due to immunologic factors, DNA methylation, epigenetic mechanisms, delayed mutation, host resistance factors, a second retinoblastoma locus, or modulator genes.<sup>45,46</sup> However, recent research has shown that most low-penetrance retinoblastoma results from mutations at the *RB1* gene locus that result in an pRb protein with reduced activity.<sup>47–50</sup> One of the most common low penetrance mutations is a missense alteration at codon 661 (exon 20).<sup>47,50</sup> Other reported low penetrance mutations include 3-bp deletion in exon 16 that results in the deletion of Asn480,<sup>50</sup> a 4-kb deletion involving exons 24 and 25,<sup>54</sup> and a splicing mutation at the last base of exon 21.<sup>49</sup> Insights gained from these low penetrant *RB1* mutants have added much to our understanding of how the retinoblastoma protein works.

## ***RB1* Gene Mutations in Other Tumors**

Not surprisingly, *RB1* gene mutations occur frequently in tumors linked to retinoblastoma, such as osteosarcomas, soft tissue sarcomas, and other mesenchymal tumors.<sup>51,52</sup> However, investigators were surprised to find that the *RB1* gene is also mutated frequently in some common adult malignancies such as breast, lung, and prostate cancer.<sup>53–55</sup> As our understanding of the *RB1* gene and its protein product have progressed, it has become

clear that *RB1* is disrupted in most human cancers, either by mutation of the gene or, more commonly, by functional inactivation of the protein.<sup>56</sup>

## Retinoblastoma Without the *RB1* Mutation

In 2013 Gallie and colleagues published a landmark paper documenting a small population of unilateral nonhereditary cases with no detectable *RB1* mutations.<sup>57</sup> They analyzed tumor samples from 1068 unilateral tumors, and found no *RB1* mutation in 2.7% of the samples (29 cases). Approximately half of the 29 cases had evidence of MYCN oncogene amplification, ranging from 28 to 121 copies, whereas none of the tested samples with *RB1* mutations had additional copies of MYCN. The authors postulated that in rare cases, retinoblastoma or a tumor resembling retinoblastoma can develop unilaterally in young children without any mutations of *RB1* via the amplification of the MYC oncogene. The clinical profile of these 29 cases revealed a younger age group at presentation than sporadic unilateral retinoblastoma, averaging 4.5 months.<sup>57</sup> Tumors caused by MYCN amplification also demonstrated aggressive histopathologic features, including optic nerve invasion, absence of calcification, and poorly differentiated cells with prominent nucleoli. However, none of the 29 cases developed metastatic disease and the other eye remained normal. Although this is preliminary data, centers should routinely test enucleated globes with unilateral retinoblastoma patients for MYCN amplification. As with all unilateral cases, gene testing should be performed both on the tumor and serum to confirm the nonhereditary status of these patients.

## The Role of the Retinoblastoma Protein in Tumor Suppression

### The Retinoblastoma Protein

The *RB1* gene encodes a 4.7-kilobase messenger RNA transcript that produces a protein of 110 kD (kilodaltons) and 928 amino acids (Fig. 132.2). The pRb protein is phosphorylated in a cell cycle-dependent manner and localizes to the nucleus.<sup>58-60</sup> The

hypophosphorylated form predominates in quiescent and differentiating cells, whereas the hyperphosphorylated species accumulates in cycling cells as they enter DNA synthesis (S) phase (Fig. 132.3).<sup>61–65</sup> The hypophosphorylated form of pRb binds several viral oncoproteins, including SV40 large T antigen, adenoviral E1a, and human papillomavirus (HPV) E7.<sup>66–68</sup> When bound to pRb, these oncoproteins stimulate cell division. Taken together, these findings provide evidence that hypophosphorylated pRb is important in negatively regulating the cell cycle, and that this inhibitory activity can be thwarted either by phosphorylation or viral oncoprotein binding. Further work has shown that the major cell cycle function of pRb is to inhibit the transition of cells out of gap 1 (G1) phase into S phase.<sup>69</sup>

**FIG. 132.3** Role of the Rb protein in the cell cycle and apoptosis.

A major breakthrough in understanding how pRb regulates the cell cycle was the observation that pRb binds to members of the E2F transcription factor family (referred to here as E2F).<sup>70–72</sup> Further work has shown that pRb function is largely dependent on interactions with E2F.<sup>73</sup> E2F sites are found in the promoters of many genes that are important for cell cycle progression, and pRb represses transcription of these genes through its interaction with E2F.<sup>74–77</sup> Since E2F (but not pRb) has a DNA binding domain, the pRb-E2F association would explain how pRb is brought to specific DNA elements to exert its effect. Most E2Fs have a transactivation domain that stimulates expression of genes containing E2F binding

sites in their promoters. pRb binds E2F within the transactivation domain, thereby masking its activity.<sup>71,78</sup> Since E2F activates genes involved in cell division, inhibition of E2F provided a mechanistic explanation for how pRb inhibited cell division.<sup>74,79</sup> However, the picture became more complicated with the recognition that pRb has intrinsic or “active” transcriptional repressor activity and is able to block the expression of genes when artificially brought to promoters by proteins other than E2F.<sup>80</sup> These findings suggest a complex relationship between pRb and E2F. In some situations pRb inhibits genes by simply masking the E2F transactivation domain, whereas in other situations E2F serves as a “courier” to deliver pRb to specific genes for active repression.

The importance of active repression by pRb was pointed out in several studies that showed that this activity is required for pRb to inhibit the G1-to-S phase transition of the cell cycle.<sup>81,82</sup> But how does pRb actively represses transcription? In a series of landmark papers several groups showed that pRb binds to and recruits promoters to proteins that alter chromatin structure, such as histone deacetylases,<sup>82-84</sup> SWI-SNF ATPases, DNA methyltransferases, polycomb complexes, and histone methylases.<sup>85-90</sup> Alteration of local chromatin structure into a restricted conformation prevents access by the transcriptional machinery, thereby inhibiting expression, whereas dynamic reorganization of chromatin into an open configuration allows gene transcription. Depending on the nature of the chromatin-remodeling complex that pRb recruits, the cell cycle inhibition can be temporary, as occurs during the quiescent period between cell divisions, or permanent, as occurs during cell differentiation and senescence.<sup>91</sup>

Studies of the tertiary (three-dimensional) structure of the pRb protein have provided insights into how the protein performs these complex functions. The central region of the pRb protein contains the A box and B box, which are highly conserved from human to plants. These regions interact with each other along an extended interdomain interface to form the A–B pocket. The pocket is critical for the tumor suppressor function of pRb, and is disrupted by most germline mutations in hereditary retinoblastoma patients and somatic mutations in tumors.<sup>31,92</sup> The pocket is required for binding to E2F, chromatin remodeling enzymes, viral oncoproteins, and

other molecules. Many pRb-binding proteins contain an LxCxE (leucine – variable amino acid – cysteine – variable amino acid – glutamic acid) binding motif, which has been shown by crystallographic studies to be located in the B box. The B box does not assume an active conformation unless bound to the A box, thereby providing an explanation for why both boxes of the pocket domain are required for pRb activity. Interestingly, E2F does not contain the LxCxE motif and binds pRb at a distinct site. Recent crystallographic studies confirmed that the E2F binding site, located at the interface between the A and B boxes, is distinct from the LxCxE site.<sup>93</sup> These findings provide a structural explanation for how pRb simultaneously binds E2F and chromatin remodeling proteins, many of which interact with pRb through the LxCxE site.<sup>87</sup> The current molecular view is that pRb orchestrates the assembly of multiprotein complexes, which are then recruited to specific promoters by E2F, where they control access of the transcriptional machinery. Thus, pRb regulates in a dynamic and integrated manner the expression of specific genes involved in cell division, differentiation, and apoptosis.<sup>94</sup>

The carboxy-terminal end of the pRb protein is also critical for its function. This region is required, along with the pocket, for binding to E2F.<sup>95</sup> In addition, most of the phosphorylation sites that seem to be critical for regulating pRb activity are located in the carboxy-terminus.<sup>96</sup> In fact, recent work has shown that phosphorylation of pRb on the C-terminus initiates a novel intramolecular interaction that progressively strips pRb of activity as the cell moves through the cell cycle.<sup>97</sup> The carboxy-terminal region also contains binding sites for the oncoproteins c-abl and MDM2.<sup>98,99</sup> The tyrosine kinase activity of c-abl is blocked when it is complexed with pRb, and this interaction appears to be important for Rb-mediated growth suppression.<sup>100,101</sup> Besides directly blocking c-abl, the C-terminal region also appears to participate in the assembly of multimeric complexes containing pRb, E2F, c-abl, and potentially other proteins.<sup>98</sup> The importance of the pRb-MDM2 interaction is less clear. MDM2 interacts with the p53 tumor suppressor protein and opposes its proapoptotic activity by repressing p53 transcriptional activation and by mediating its degradation.<sup>102,103</sup> While initial results demonstrated that MDM2 blocks pRb function, more recent

studies have shown that pRb can form a trimeric complex with MDM2 and p53 and thereby block the antiapoptotic activity of MDM2 by preventing the degradation of p53.<sup>104</sup>

The function of the amino-terminal end of the pRb protein remains less clear. This region contains phosphorylation sites that may regulate pRb activity. Additionally, this region interacts with several proteins, including a replication-licensing factor (MCM7),<sup>105</sup> a novel G2/M cycle-regulated kinase, and other proteins.<sup>105-107</sup> However, the function of these interactions has not been established. *RB1*<sup>+/-</sup> mice that develop pituitary tumors due to loss of Rb failed to be “rescued” by expression of a mutant form of pRb that lacked the amino-terminus, although the onset of tumors was delayed.<sup>108</sup> In other experiments tumor suppression by pRb was actually enhanced when the amino-terminal region was removed.<sup>109-111</sup> Thus, the amino-terminus appears to contribute only weakly to the overall tumor suppressor activity of pRb.

Not only was the *RB1* gene the first identified tumor suppressor gene, but the Rb pathway was the first, and still one of the most important, tumor suppressor pathways to be elucidated in human cancer.<sup>56</sup> As described above, the pRb protein is critical for regulation of the cell cycle, as well as senescence, differentiation, and apoptosis, all of which are deregulated during cancer formation.<sup>112-116</sup> While the pRb pathway is deregulated in virtually all cancers, the *RB1* gene is mutated in only a limited spectrum of cancers. In these other cancers the pRb protein is inactivated by maintaining it in a hyperphosphorylated state. This occurs by deregulating the pRb pathway, which controls the phosphorylation state of pRb through kinases and kinase inhibitors.

## **The *RB1* Tumor Suppressor Pathway**

Cell cycle progression normally occurs when pRb is inactivated by phosphorylation that is catalyzed by cyclin-dependent kinases (CDKs) in complex with their cyclin partners.<sup>117,118</sup> pRb contains 16 potential sites for CDK phosphorylation, and it oscillates between hypophosphorylated and hyperphosphorylated forms in cycling cells. At least three different cyclin/CDK complexes phosphorylate pRb during the cell cycle.. Cyclin D-ck4/6 phosphorylates pRb early in G1, cyclin E-CDK2 phosphorylates the protein near the end of

G1, and cyclin A-CDK2 is thought to maintain phosphorylation of pRb during S phase.<sup>56</sup> Phosphorylation of specific sites appears to regulate distinct pRb functions, suggesting complex regulation of pRb by these phosphorylation events. For example, binding of E2F, LxCxE proteins, and c-abl are regulated by distinct sets of phosphorylation sites in the carboxy-terminus.<sup>119,120</sup>

pRb is phosphorylated sequentially by different CDKs during the cell cycle. In fact, successive phosphorylation of pRb by cyclin D-CDK4/6 and cyclin E-CDK2 appears to be necessary to completely hyperphosphorylate pRb.<sup>118</sup> Recently, a mechanistic explanation was suggested for how cyclin D-CDK4/6 and cyclin E-CDK2 may regulate distinct pRb functions.<sup>97</sup> Cyclin D-CDK4/6 appears to phosphorylate specific sites in the carboxy-terminal region of pRb, and this phosphorylation triggers an intramolecular interaction between the phosphorylated C-terminal region and a positively charged “lysine patch” encircling the LxCxE binding site in the B box of the pocket. This interaction displaces LxCxE proteins such as histone deacetylase from the pocket, thereby blocking the ability of pRb to arrest the cell cycle.<sup>81,97</sup> However, pRb can still bind to E2F in this partially phosphorylated state. Under hyperproliferative conditions, the intramolecular interaction between the carboxy-terminal region of pRb and the pocket also can recruit cyclin E/CDK2 to the pocket, where it phosphorylates serine-567, an otherwise inaccessible site buried within the pocket.<sup>106</sup> Ser-567 makes critical contacts between domain A and B,4 and this phosphorylation disrupts the A–B interface and disrupts pRb binding to E2F. The sensitive location of Ser-567 is further illustrated by the fact that it is the only CDK phosphoacceptor site in pRb that is a target of naturally occurring missense mutations in tumors.<sup>121</sup> The more complete inactivation of pRb, indicated by phosphorylation of serine-567, leads to release of E2F and increased apoptosis.<sup>115</sup> Taken together, these findings suggest that the normal cell cycle may be regulated by partial phosphorylation of pRb that is catalyzed by cyclin D-CDK4/6, whereas the more complete phosphorylation that requires cyclin E-CDK2 may serve as a checkpoint for an abnormal hyperproliferative state that would trigger cell death.

Proteins called cyclin dependent kinase inhibitors (CDKIs), which

inhibit the kinases that phosphorylate Rb, represent another layer of complexity in the regulation of pRb. The p16INK4a protein is a CDKI that specifically inhibits CDK4, which catalyzes the early phosphorylation of pRb.<sup>122</sup> A tumor suppressor protein in its own right, p16INK4a is mutated or inactivated in many types of cancer, including cutaneous and uveal melanoma.<sup>123</sup> Loss of p16INK4a allows cyclin D-CDK4 to act unopposed in phosphorylating pRb, which results in constitutive functional inactivation of pRb. Since pRb and p16INK4a act in the same pathway, and mutation of either gene results in a similar deregulation of the cell cycle, both genes are rarely mutated in the same tumor.<sup>124</sup> Other CDKIs, such as p21 and p27 have more broad roles in regulating the cell cycle.<sup>125</sup>

## Molecular Pathogenesis of Retinoblastoma

There is now overwhelming evidence that supports the hypothesis that mutational inactivation of the *RB1* gene is the initiating event in retinoblastoma. However, there remain many unanswered questions about the molecular pathogenesis of this tumor. Since pRb is important for regulating normal cell growth and differentiation throughout the body, why does germline mutation of the *RB1* gene predispose primarily to the rare eye tumor? This question was once quite enigmatic but is now becoming clearer. Indeed, carriers of *RB1* mutations are predisposed to a whole range of tumors, but the age of susceptibility is different for each tumor type. Whereas retinoblastomas occur mostly from birth to 5 years of age, mesenchymal tumors tend to occur in the teenage years, and melanomas peak in a slightly older age group. A recent report clearly shows that common epithelial tumors also occur at increased frequency in retinoblastoma survivors, but this effect is only seen in individuals beyond 40 years old.<sup>126</sup> Thus, it seems likely that loss of *RB1* predisposes to a broad range of neoplasms, each requiring different numbers and types of “hits” for tumorigenesis to become manifest; the fewer “hits” required, the earlier in life the tumor begins to appear in patients.

While mutation of the *RB1* gene is clearly necessary for retinoblastoma formation, is inactivation of retinoblastoma alone sufficient for tumorigenesis? Some investigators have argued

additional mutations in other genes must be required based on the following observations. First, deletion of the *RB1* gene in normal cells leads to apoptosis, rather than tumor formation, because loss of pRb triggers a p53-mediated apoptotic response.<sup>127</sup> This presumably explains why most cancers contain mutations in both the pRb and p53 pathways.<sup>91,128</sup> Second, retinoblastomas cannot be produced in mice unless both pRb and p53 are inactivated.<sup>129</sup> This led to a search for mutations in p53 or other proapoptotic genes. Interestingly, however, p53 is rarely mutated in human retinoblastoma, and no other apoptotic genes have been convincingly linked to retinoblastoma.<sup>130</sup> Finally, cytogenetic alterations on other chromosomes (e.g., 6p) are frequently observed in retinoblastomas, potentially suggesting the presence of other retinoblastoma-associated genes located at those chromosomal regions.<sup>131,132</sup>

Recent work has shown that MDM2 and MDMx may play an important role in attenuating the normal apoptotic events that should occur in an *RB1*<sup>-/-</sup> state. MDM2 targets p53 for ubiquitin-mediated proteolysis and is also a downstream target of p53. This creates an autofeedback loop that maintains p53 at a low level. Small molecule inhibition of MDM2 has been shown to lead to increased levels of p53 in retinoblastoma cell lines leading to p53-mediated apoptosis.<sup>133,134</sup>

While the existence of a “second RB gene” cannot be confirmed or refuted at this time, the strong autosomal dominant inheritance pattern of retinoblastoma indicates that the *RB1* gene mutations are clearly rate-limiting, so any other necessary events must occur at such a high spontaneous rate that they do not affect the clinical inheritance pattern. The emphasis on mouse models to understand human retinoblastoma may have limitations. Naturally occurring retinoblastomas are virtually nonexistent in mice and other animals, suggesting that the developing human retina may contain molecular, cellular, and anatomic features that make it uniquely susceptible to this tumor.

An alternative explanation for retinoblastoma pathogenesis is simply that retinal progenitor cells pass through a window of susceptibility prior to terminal differentiation in which loss of pRb leads to a differentiation defect, rather than an apoptotic response,

which leads to an accumulation of proliferating embryonic retinal cells. This hypothesis does not require the conjectural existence of additional “retinoblastoma genes” and satisfactorily accounts for developmental and clinical observations. pRb is indeed required in a cell-autonomous manner for appropriate cell cycle exit and differentiation of retinal progenitor cells.<sup>135</sup> Further, the topographic distribution of retinal tumors parallels the pattern of retinal differentiation. The retina differentiates in a posterior-to-anterior wave from the posterior pole to the ora serrata.<sup>136,137</sup> Interestingly, the chronologic development of retinoblastomas follows this same pattern, with earlier tumors occurring posteriorly and later tumors occurring more peripherally.<sup>137</sup> Retinal progenitor cells that retain the capacity to differentiate into photoreceptors, neurons, and glia can be identified in the retina until after birth, suggesting a window of susceptibility from fetal week 12 until 4–5 years of age for the bi-allelic loss of the *RB1* gene to have the possibility of producing retinoblastoma.<sup>138</sup>

Another controversy regards the cell of origin of retinoblastoma. Retinoblastomas derive from cells of the immature neuroepithelial inner layer of the optic cup that have the potential to differentiate into rod and cone photoreceptors and Müller cells.<sup>139</sup> Several studies have documented the presence of cone-specific markers, such as transducin, cone photopigments (red and green opsin), and cone phosphodiesterase in retinoblastoma.<sup>140</sup> However, since cone differentiation may represent a “default” pathway in the absence of normal signaling,<sup>141</sup> it is unclear whether retinoblastomas arise from neuroblasts that are already committed to the cone lineage, or whether retinoblasts that lose pRb are unable to differentiate along their appropriate lineage and are subsequently directed into the cone pathway. Cone cell precursors, but not mature cone cells, express pRb. In addition, cone cell precursors also express MDM2, which is a transcriptional target of Trβ2 that is also transiently expressed in cone cell precursors. Taken together, loss of pRb in a cone cell precursor that is already expressing MDM2 as part of its developmental program could plausibly lead to transformation and would be consistent with this being a potential cell of origin. More specifically, recent work shows that postmitotic human cone precursors possess cell-type circuitry which is uniquely susceptible

to pRB depletion.<sup>142</sup>

## Retinoblastoma: the Disease

### Terminology

Retinoblastoma can seem like a complicated subject for both medical professionals and affected families. To avoid unnecessary confusion, it is important to use precise terminology when discussing retinoblastoma.

The term “bilateral retinoblastoma” should be used only to describe a phenotype, i.e., a patient who has the clinical disease in both eyes. When the intent is to define a genotype – the whole group or class of patients with a germline mutation, a much clearer term is germinal (or heritable) retinoblastoma. All patients with bilateral disease carry the *RB1* germline mutation but not all people who carry the *RB1* mutation have bilateral disease. The phenotype (clinical presentation of the disease), will depend upon whether the second tumorigenic *RB1* mutation occurs and cancer is initiated in both eyes (bilateral), only one eye (unilateral), or neither eye (unaffected gene carrier).

The term “familial” is correctly used to describe a patient or family in which the germline mutation was passed down from a previous generation. A new sporadic bilateral case of retinoblastoma when neither parent has the *RB1* mutation is more precisely referred to as germinal or “heritable” rather than “hereditary,” although many do not make this distinction. A unilaterally affected child who has one parent with a known *RB1* mutation is clearly both heritable and familial but obviously not “bilateral.” We consider the terms “heritable” and “germinal” to be interchangeable.

### Clinical Overview of Retinoblastoma

Retinoblastoma typically presents between birth and 5 years of age, so the disease predominantly affects young children. The clinical signs that lead to the diagnosis of retinoblastoma are typically noted by one or both parents. In dim light when the pupil dilates

naturally, parents may see light reflected by the tumor causing a “cat's eye” reflection in the pupil (i.e., leukocoria). This whitish pupil reflex may also be noted on pictures, which contrasts with the expected “red eye” on flash photographs (Fig. 132.4). Less commonly, more advanced intraocular retinoblastoma may manifest as the lack of a red pupillary reflex and may appear dark, due to either a vitreous hemorrhage, tumor necrosis, or a complete retinal detachment. When the tumor destroys central vision early in the course of the disease, and binocularity is lost, the presenting sign may be strabismus. Since almost all nonfamilial cases are diagnosed late, patients often have a combination of leukocoria and strabismus at presentation.

**FIG. 132.4** (A) Patient with leukocoria in the right eye and a white mass filling the pupil. (B) “Cat's eye” reflection in the right pupil, noticeable in a flash photograph.

The younger the age of the patient, the more likely the tumors will start in the posterior pole. Early tumors appear as discrete, whitish retinal masses without intrinsic vascularity. As the tumors grow, they increase in both basal diameter and apical height while acquiring more vascularity, eventually fragmenting to cause vitreous or subretinal seeding. Eventually, the expanding mass can cause retinal detachment, neovascular glaucoma and/or intraocular hemorrhage before it spreads beyond the eye, either by contiguous spread through the optic nerve or hematogenously through the choroidal circulation. Very rarely, tumors may spontaneously involute, activating a process that will result in ocular phthisis. If

left untreated, most intraocular retinoblastomas will expand directly into the optic nerve then seed the central nervous system (CNS), or spread via hematogenous dissemination to bone marrow, bone, and other organs. Enucleation was the recommended treatment in James Wardrop's original clinical description of retinoblastoma in 1809 and remains a superb treatment option today, especially for advanced unilateral disease.

## Epidemiology

In the United States, retinoblastoma represents approximately 6% of all childhood cancers under age 5, with stable incidence rates over the past 30 years.<sup>143</sup> In developing tropical and subtropical regions of the world, including Central Africa, Southern Asia, and Central America, retinoblastoma is one of the most common solid tumors of childhood.<sup>144-160</sup> While the worldwide incidence of the heritable form of the disease has been relatively constant, this may not be the case for unilateral sporadic nonheritable retinoblastoma. The possibility of an increasing incidence of unilateral nonheritable disease in underdeveloped countries has come to wide attention in part due to the important work of Ian McGrath and colleagues at the International Network of Cancer Treatment and Research (INCTR website at: <http://www.inctr.org/>). Orjuela and her colleagues at Columbia University in New York and at the Instituto Nacional de Pediatría in Mexico City have suggested deficiencies in maternal diet during pregnancy may increase the risk of sporadic retinoblastoma.<sup>161</sup> Perinatal infection with HPV was suggested as a possible mechanism for increasing the incidence of nonheritable retinoblastoma,<sup>162,163</sup> but this association has not been corroborated by other groups.<sup>164,165</sup>

There are various methods of determining the incidence and prevalence of retinoblastoma in a given population. The overall incidence (heritable and nonheritable cases combined) of retinoblastoma in developed countries is most commonly reported as the number of cases diagnosed in a selected period per live births for that period. Although this index does not reflect the entire population at risk, since children continue to be at risk until 5 years of age and beyond, it does present some uniformity for comparison

of the frequency of the disease across populations. The incidence can also be expressed as the number of cases diagnosed per year for a given population of children in a specified age group.<sup>166</sup>

After 1970, the prevalence of retinoblastoma in the United States (number of cases per number of persons in the at-risk age group) is consistently reported at around 11 cases per million children under 5 years of age, or equivalent to an incidence of 1/18, 000 live births.<sup>167,168</sup> Because there is no complete retinoblastoma registry in North America, the exact incidence is unknown, but it is estimated that there are about 300 new cases per year. These incidence estimates fit closely with studies reported from New Zealand, Sweden, and Australia, which all show incidence rates of 1/17, 000–1/18, 000 live births.<sup>169–171</sup>

As previously mentioned, authors have hypothesized that preconception environmental exposure increases the risk of heritable retinoblastoma and postconception exposure increases the risk of nonheritable retinoblastoma.<sup>172</sup> Bunin and colleagues have demonstrated that some environmental factors, such as gonadal radiation exposure prior to conception and paternal employment in the military or metal industry, were associated with an increased risk of sporadic, heritable retinoblastoma.<sup>33,172</sup> However, the incidence of heritable retinoblastoma among the various populations of the world is remarkably constant, providing evidence that environmental influences likely play an insignificant role in the etiology of the hereditary form of this tumor.<sup>171,173</sup> Buckley also provided evidence that environmental factors probably play a very minor role in the hereditary form of cancer in very young children.<sup>174</sup>

One of the few identified risk factors for retinoblastoma is advanced paternal age, which has been unequivocally associated with new sporadic germline mutations and heritable retinoblastoma.<sup>39,175–180</sup> Excess cancer in relatives is also a common finding in solid childhood tumors, particularly retinoblastoma.<sup>181</sup> Some 80–85% of new heritable tumors preferentially retained the paternal allele (i.e., the mutated allele) and lost the normal maternal allele as the result of a chromosomal error at mitosis.<sup>182,183</sup> These data suggest that new germline *RB1* mutations arise more frequently during spermatogenesis than during oogenesis.

## Natural History of Intraocular Retinoblastoma

There are many characteristic features of retinoblastoma, but also wide variability in its clinical presentation. In general, patients with bilateral retinoblastoma (heritable disease) present at an earlier age (average 12 months) than patients with unilateral disease (average 24 months). However, it is not uncommon for patients with nonheritable unilateral disease to present before 6 months of age. Approximately 90% of children with retinoblastoma present between birth and 5 years of age,<sup>166</sup> but it is not unusual for retinoblastoma to be diagnosed in utero, or as late as 8 years of age. If it can be assumed that retinoblastoma tumors become ophthalmoscopically apparent in the retina within a short time after the second “hit” at the *RB1* locus, then retinoblastoma may have its initiating genetic event in the retina as late as the 5th birthday. If deficiency of maternal diet can affect the incidence of unilateral nonheritable retinoblastoma, then evidence supports the view that the earliest somatic gene mutations can occur during fetal life. Although more is known about the genetic events that cause retinoblastoma than any other cancer, other unknown factors may be at play that contribute to the variable clinical presentations for retinoblastoma.

Regardless of when the cellular events take place that lead to the formation of retinoblastoma, the earliest physical appearance of the tumor is fixed by the fact that all cells in the tiny tumor focus are identical, i.e., they are daughter cells of the original “founder” cell with the same genes and the same growth rate. A new tumor will expand symmetrically as a round or hemispherical lesion that is homogenous (Fig. 132.5). In its earliest manifestation retinoblastoma resembles bacterial colonies on an agar plate. Because tumor growth begins with a single immortalized retinoblast, all intraocular retinoblastomas are initially confined to the retina. Early tumor formation occurs rapidly, with an estimated tumor doubling time of 15 days.<sup>184</sup> Evidence from optic coherence tomography suggests that the early tumor formation occurs predominantly in the outer retina,<sup>185,186</sup> with eventual full-thickness involvement. Our preliminary experience with optical coherence

tomography (OCT) on small tumors suggests the outer nuclear layer as the site of origin for retinoblastoma, which would support the theory of a cone-precursor origin for the tumor.

**FIG. 132.5** Solitary retinoblastoma that is symmetrically round and homogeneous due to a clone of “founder” cells with identical genes and growth rate.

Tumor angiogenesis is essential if tumors are to expand, and conversely, avascularity severely restricts the potential growth of tumors.<sup>187</sup> Intraretinal retinoblastoma with a diameter less than 2 mm are dependent on diffusion of nutrients and oxygen from the choroid, and this may explain the clinical observation that early small tumors in infants don't respond very well to systemic chemotherapy.<sup>188</sup> Enlarging tumors begin to acquire new blood vessels in response to growth factors generated from upregulated growth factor genes and downregulated angiogenesis inhibitory genes. These new blood vessels can be demonstrated on fluorescein angiography as reticular pattern of fine capillaries in small tumors and large neovascular vessels with bizarre branching patterns and associated hypoperfusion and leakage in larger tumors.<sup>189,190</sup> With the recruitment of new blood vessels, tumors continue to grow toward the vitreous cavity (endophytic growth pattern), or into the subretinal space (exophytic growth pattern). Retinoblastoma tumors remain confined to the retina until new mutations occur,

perhaps due to loss of the suppressor gene PTEN,<sup>191</sup> that allow them to grow without extracellular matrix anchorage dependence. Loss of cell adhesion is likely to be the major cellular event required to enable the emergence of vitreous and subretinal seeding.

Tumor cells that invade the vitreous or subretinal space now enter a low-oxygen, low-nutrient microenvironment. The shape and structure of early vitreous seeds are limited to a thickness of two tumor cells surrounding an inner core of necrotic oxygen-starved tumor. However, large avascular vitreous and subretinal masses eventually form, and represent the continued “progression” of an intraocular malignancy (Fig. 132.6). Tumor cells in these masses can survive and even thrive in this new low-oxygen environment. In advanced group D and E eyes it is common to find large avascular masses either in the vitreous or subretinal space (see discussion of retinoblastoma classification, below).

**FIG. 132.6** Vitreous (A) and subretinal (B) seeding from the primary tumor. With enough cell divisions and spontaneous mutations there is loss of cellular adhesion.

Continued growth of the tumor leads to total destruction and even replacement of the retina with tumor cells. Angle closure glaucoma is a common endstage manifestation of massive tumor growth, either from pressure of the tumor pushing the iris lens diaphragm forward, from direct occlusion of the chamber angle by tumor cells or red blood cells, or by proliferation of iris neovascularization to involve the anterior chamber angle. Tumor cells will invade the optic nerve and spread into the chiasm and

brain, either by direct contiguous growth or through seeding of the leptomeninges. Less commonly, the tumor will follow vessels and nerves that penetrate the sclera and expand as a mass lesion in the orbit. Retinoblastoma cells that reach the choroid can spread hematogenously to the lung, bone marrow, and other organs.

The ability to metastasize requires the acquisition of a number of cell capabilities that are not present in early descendants of the original “founder” cell. Interruption of the function of the eye and alteration of its normal anatomy are two of the main reasons that most retinoblastomas are diagnosed and treated before they metastasize. Most retinoblastomas attract attention and are treated, long before they have acquired all of the enabling mutations required for metastasis. Simple access to the bloodstream is required but not sufficient for metastasis. To gain access to distant sites via the bloodstream, a tumor cell must have the ability to digest and move through extracellular matrix,<sup>192</sup> and to digest and penetrate the basement membrane, adventitia, and endothelium of the vessel wall. In order to escape the high-flow vascular channels, a tumor cell must be able to adhere to the vascular endothelium at a location outside the eye, digest its way through all layers of the vessel wall, survive in the extravascular environment, recruit a blood supply, and establish its own microenvironment. Because all these abilities are achieved only through a series of spontaneous mutations that require many tumor cell doublings, most patients who develop metastatic disease have had the continued presence of viable tumor cells for an extended period, often with multiple recurrences before the eye was eventually enucleated. For this reason, efforts to salvage an eye that has had multiple episodes of tumor regrowth over a period of more than 6–12 months should raise increasing concerns about the escalating risk of metastatic disease in that child.

## **Classification of Intraocular Retinoblastoma**

The Reese–Ellsworth group classification system specifically predicts the likelihood of ocular salvage following treatment with EBR. It does not function as well in predicting likelihood of salvaging eyes treated with primary chemotherapy and/or focal

consolidation. The introduction of systemic chemotherapy as the main primary modality to salvage intraocular retinoblastoma in most retinoblastoma centers during the 1990s propelled the creation of a new group classification for intraocular retinoblastoma.

## **Reese–Ellsworth Classification**

The Reese–Ellsworth classification system, originally published in 1964, was a major advance in our collective understanding of retinoblastoma.<sup>193,194</sup> It is a group classification system and as such, only deals with organ-confined intraocular disease. In a staging system evaluating the whole child, a group classification would fit entirely within stage I disease. The Reese–Ellsworth classification was developed just as the indirect ophthalmoscope was being introduced into clinical practice. Anterior tumors, which typically occur in the setting of more advanced disease, also cause the eye to be classified in a more advanced group when using the Reese–Ellsworth classification. The classification does not take into account retinal detachment, subretinal tumor seeding, or other ocular findings such as neovascular glaucoma. Also, vitreous seeding of any amount places the eye in group Vb (the last of 10 subgroups), with the poorest prognosis. Today local vitreous seeding can be successfully treated with intravitreal melphalan injections.

## **International Classification for Intraocular Retinoblastoma**

In 1989 Kingston and colleagues began employing the systemic chemotherapy regimen currently in use in most centers (carboplatin, etoposide, vincristine – known as CEV or VEC in North American centers, and JOE in Britain) in combination with EBR as the primary treatment of retinoblastoma for Reese–Ellsworth group Vb eyes.<sup>195</sup> In January 1990 Murphree was the first to use chemotherapy plus local consolidation without EBR for all Reese–Ellsworth groups.<sup>196</sup> Initially the early stage Reese–Ellsworth eyes in Los Angeles were treated with carboplatin alone combined with transpupillary diode laser hyperthermia (chemothermotherapy). Over the next 5 years at many centers,

advanced intraocular disease was treated with CEV systemic chemotherapy combined with sequential aggressive local therapy.<sup>197,198</sup> Authors introduced the term “chemoreduction” to describe the concept of reducing the volume of the tumor with systemic chemotherapy followed by local consolidation.

Efforts at developing a revised classification that reflected the move away from EBR to primary chemotherapy for intraocular retinoblastoma began as early as 1994, when Murphree and Hungerford co-chaired a meeting of retinoblastoma specialists from around the world for a full day of discussions on the development of a new classification system at the International Congress of Ophthalmology in Toronto. The system that grew out of those discussions took into account zone of disease similar to retinopathy of prematurity. Eventually, the ABC classification system was described at the European Congress of Ophthalmology meeting in Istanbul in 2001 and the case for a new group classification was subsequently published.<sup>199</sup>

The International Classification System ([Box 132.1](#)) is based both on the natural history of retinoblastoma and on the likelihood of salvaging the eye when systemic chemotherapy is used as the primary treatment. Letters “A” through “E” instead of numbers were chosen to designate each classification group to avoid confusion with the Reese–Ellsworth system. The risk of loss of the eye due to retinoblastoma is graduated from “very low” for group [Box 132.1](#) “very high” for group E.

## International Classification for Intraocular Retinoblastoma<sup>195</sup>

### Group A – Very Low Risk

Small discrete intraretinal tumors away from the fovea and optic disc

- All tumors are  $\leq 3$  mm in greatest dimension, confined to the retina
- All tumors are located further than 3 mm from the fovea and 1.5 mm from the optic disc

## **Group B – Low Risk**

All remaining discrete retinal tumors without seeding

- All tumors confined to the retina not in group A
- Any tumor size and location with no vitreous or subretinal seeding
- Small cuff of subretinal fluid allowed (3 mm from tumor border)

## **Group C – Moderate Risk**

Discrete local disease with minimal focal subretinal or vitreous seeding

- Tumor(s) must be discrete
- Subretinal fluid involving up to one quadrant of the fundus
- Local subretinal or vitreous seeding, less than 3 mm from the tumor

## **Group D – High Risk**

Diffuse disease with significant vitreous and/or subretinal seeding

- Tumor(s) are massive or diffuse
- Subretinal fluid, one quadrant of the fundus to total retinal detachment
- Diffuse subretinal seeding, may include subretinal plaques or tumor nodules
- Diffuse or massive vitreous disease may include “greasy” seeds or avascular tumor masses

## **Group E – Very High Risk**

Presence of any one or more of these poor prognosis features

- Neovascular glaucoma and/or buphthalmos

- Tumor anterior to anterior vitreous face involving ciliary body or anterior segment on clinical exam or ultrasound biomicroscopy (i.e., tumor touching the lens)
- Diffuse infiltrating retinoblastoma
- Opaque media from hemorrhage
- Tumor necrosis with aseptic orbital cellulitis
- Phthisis bulbi

In this classification, the letter “A” is assigned to those eyes for which both the likelihood of curing the tumor and retaining excellent vision are both high. In intraocular group A eyes the lesions are small and are away from critical visual structures (fovea and optic nerve). Groups A and B contain all eyes in which the tumor remains confined to the retina. In groups C and D eyes, the tumor has spread into the vitreous and subretinal space. In the case of group C eyes the spread is local. In the case of group D eyes the seeding is diffuse (Fig. 132.7). The definition of local seeding has been further defined as 3 mm or less from the margin of the tumor, whereas subretinal or vitreous seeding more than 3 mm has been defined as being diffuse. Group E eyes have been destroyed by the tumor and are rarely salvageable; these eyes demonstrate neovascular glaucoma, buphthalmos, vitreous hemorrhage, ocular phthisis, or tumor extending anterior to the anterior vitreous face. In this system the morbidity of the treatment increases from group A to group E, and the probability of salvaging the eye and useful vision decreases from A to E. Within limits, when chemotherapy is the primary treatment of retinoblastoma, absolute volume of the tumor is relatively less important than whether the tumor has become dispersed within the eye to either the vitreous or the subretinal fluid or both.

**FIG. 132.7** Photographs depicting groups A–E; intraocular retinoblastoma as described in the new group classification (for details see text).

## Disease Prognosis

### Retinoblastoma Survival Rates

The overall survival rate from retinoblastoma in developed countries is very high, and the deaths in these patients occur from a mixture of causes. In the first 4 years of life mortality is typically from metastatic retinoblastoma or trilateral disease. Later deaths are

increasingly likely to be the result of genetically predisposed second primary tumors such as osteosarcoma or fibrosarcoma, often induced by radiation treatment given during the first two years of life. Thus, the overall survival rate will differ depending upon the time period examined. The survival rate in 1980 from one major retinoblastoma center in the United States was 92%.<sup>200</sup> The similar overall 5-year cumulative survival rate was 91% in SEER (Surveillance, Epidemiology, and End Results) data from 1974 to 1985.<sup>168</sup> However, Abramson and colleagues reported that 86% of bilateral retinoblastoma patients survive 15 years.<sup>200</sup> Five years after diagnosis, more children die of second malignant neoplasms than from retinoblastoma. In the Netherlands the presence of a National Registry shows the striking difference in overall survival between the subgroup of genetically predisposed patients and those who have no genetic predisposition.<sup>201</sup> A major controversy has arisen concerning the percentage of patients who will eventually succumb to second malignant neoplasms (SMNs). Abramson and colleagues had previously reported that as many as 90% of patients carrying the retinoblastoma predisposition allele develop a SMN within 30 years of diagnosis of the original retinoblastoma.<sup>202</sup> In a more recent report of a large number of patients with nearly complete ascertainment from the New York and Boston groups, 6% of bilateral patients had died of SMNs by 40 years after diagnosis if they had not been treated with EBR.<sup>203</sup> In contrast, 35% died of SMNs if EBR had been used in their treatment.

In any given country, the overall survival rate depends upon whether or not there was a delay in receiving medical attention. These delays are likely to be cultural, e.g., if there is no tradition of seeking medical help until a process is far advanced. For example, in a report from Malaysia in 1980, only 6 of 20 patients survived retinoblastoma; all were initially seen with advanced disease and were older children at initial diagnosis.<sup>204</sup> In comparison, in Great Britain where there is a tradition of early access to medical care, only 26 of 317 patients managed at Moorfield's and St Bartholomew's Hospitals in London between 1970 and 1984 developed orbital extension.<sup>205</sup> In Argentina delayed diagnosis was related to lack of access to medical care and initial consultation with a pediatrician instead of an ophthalmologist.<sup>206</sup> In the 1960s Nigeria

had an extremely high mortality rate because of late medical attention and lack of treatment facilities.<sup>207</sup> In Japan 50 years ago, only 50% of patients with unilateral disease and 17% of patients with bilateral disease survived more than 5 years.<sup>208</sup>

## Factors Affecting Survival

Traditionally there have been histologic features in enucleated eyes that have seemed to correlate with increased risk of metastatic disease.<sup>209</sup> There are three main histologic findings that are considered to be “high-risk” features when an enucleated globe with retinoblastoma is examined: (1) retrolaminar optic nerve invasion; (2) massive choroidal invasion; (3) scleral invasion.<sup>210</sup> Invasion by the tumor into the optic nerve posterior to the lamina cribrosa either alone or combined with massive invasion of the choroid is considered to be an indication for adjuvant chemotherapy (Fig. 132.8). Patients with isolated massive choroidal invasion represent a controversial group when considering adjuvant therapy, but most centers treat these patients with adjuvant chemotherapy. Patients with scleral invasion always require aggressive adjuvant chemotherapy, sometimes combined with orbital radiation. A review of the estimated risk for each high-risk histopathologic feature in the literature and the current recommendations for adjuvant treatment was published by our group in 2015.<sup>210</sup>

**FIG. 132.8** (A) Histopathology showing invasion of the tumor into the optic nerve posterior to the lamina cribrosa. (B) Massive tumor invasion of the choroid.

There appear to be no inherent differences in the risk for metastatic disease between patients that are genetically predisposed to retinoblastoma and those without genetic predisposition, nor for patients with unilateral or bilateral disease.<sup>40</sup> Delay in diagnosis is a major factor adversely affecting survival of both heritable and nonheritable disease.<sup>211</sup>

Multiple episodes of recurrent disease in an eye is a bad prognostic sign for the survival of the eye and perhaps for the overall survival of the child, particularly if the fundus view is lost and enucleation is delayed. The more cell divisions a tumor cell goes through, the more likely it is that one of the progeny cells will achieve the enabling mutations that allow this clone of cells to survive outside the eye. With each visible recurrence inside the eye, more of those abilities may have been acquired through spontaneous mutations.

## **Factors Affecting Salvage of Eye and Vision**

As suggested by Knudson in 1976, early detection of retinoblastoma when the tumors are small is perhaps the most important factor that increases the likelihood of salvage of the eye.<sup>2</sup> A significant delay in initial diagnosis is associated with a decreased likelihood of retaining the eye. Haik and his colleagues evaluated the cause of the delay in diagnosis.<sup>212</sup> According to these authors, the first delay in diagnosis occurs before the observation of the first symptom by the child's parents or other observer. A second delay occurs between the observation of the first symptom and the visit to the primary care physician. These authors maintain that educating parents on the clinical significance of these signs could possibly reduce this second source of delay. Approximately 50% of the patients without a positive family history and 25% of patients with a positive family history had a delay averaging 4–5 months before the primary care physicians referred them to an ophthalmologist.<sup>212</sup>

When patients are treated with a chemoreduction strategy, there is a direct correlation between prognosis and group classification. In group A, eyes are virtually all preserved with excellent visual acuity with focal modalities alone. Group B eyes have nearly as good a prognosis (90–95%) with the combination of systemic chemotherapy and focal modalities, but the visual outcome varies

from 20/20 to 20/200 depending on whether or not the fovea is destroyed by the tumor. Group C eyes are salvaged at a rate approximating 70–80% with chemoreduction. In contrast, group D eyes with diffuse dissemination and more advanced disease have no greater than a 50% chance of survival without the use of other modalities such as EBR or intravitreal melphalan injections. Only an occasional group E eye is salvaged with chemoreduction, and enucleation is generally recommended.

For patients with macular tumors, posttreatment vision is often 20/200 or worse, but occasionally can be better. In a series of 17 patients with large macular tumors, post-EBR treatment vision ranged from 5/200 to 20/50.<sup>213</sup> The authors pointed out that the ophthalmoscopic appearance and size of the tumors gave little reliable guidelines to visual outcome. In another series of 11 patients following treatment of macular retinoblastomas, two patients eventually recovered 20/20 vision.<sup>214</sup> We have had experience with a patient who had a macular lesion completely filling the space within the vascular arcades. After treatment this tumor mass shrunk away from the disc and the fovea to a site 4 disc diameters temporal to the fovea. Vision returned with excellent central fixation. In this case, and in some other cases, the tumor obviously had mushroomed over the surface of the retina and did not destroy the foveal cones.

## Diagnosis of Retinoblastoma

### Signs and Symptoms

Leukocoria is the phenomenon created when light entering the eye is reflected back out through the pupil by the yellow or yellow–white tumor. The observer sees this reflex or reflected light diffusely filling the pupil, giving rise to the term “leukocoria” or white pupil. Retinoblastomas in the posterior pole of the globe that have reached 3 mm in basal diameter are sufficiently large to generate a leukocoric reflex. In the United States more than half of all retinoblastomas are diagnosed after observation of leukocoria, in the affected eye, usually by a close family member.

In a retrospective review of 1265 patients with retinoblastoma

from New York Hospital, leukocoria was the presenting sign in 56% of all cases.<sup>215</sup> It is informative to note that in the New York series observation of leukocoria correlated with the presence of advanced (Reese–Ellsworth group Va or Vb) disease. The red-reflex test, as used in a standard manner by pediatricians, will only be positive in the presence of undilated pupils only when advanced or large retinoblastoma is present.

The likelihood of observing leukocoria relates directly to the diameter of the pupil at the time of observation. Family members often see leukocoria in the early evening or in dim light when the pupil dilates naturally. Because their observation is intermittent and due to the variations in pupil size, parents or family members often question their own observation. This tendency to be uncertain about the observation can be reinforced if the pediatrician or primary care physician does not dilate the pupil, does not observe the leukocoria, and assures the family that there is no abnormality.

Flash photography can easily document the presence of leukocoria; however, the camera must be either a model that lacks the “eliminate red eye” feature or have that feature turned off. The flash illuminates the interior of the eye, and the film records the reflected glow from the tumor (leukocoria), before the pupil has a chance to constrict to the bright flash. If an abnormality in the normal red reflex is observed, the parent or family member should immediately take the child and photograph to their pediatrician demonstrating the leukocoria and insist on a referral to an ophthalmologist, preferably one who specializes in pediatrics (for websites where information is available for parents see [www.retinoblastoma.net](http://www.retinoblastoma.net)).

Brightly lit rooms and high light intensity on the direct ophthalmoscope are two of the factors that most commonly prevent pediatricians and other primary care physicians from making an early diagnosis of retinoblastoma. The sensitivity of this clinical test for pediatricians can be increased by performing the red reflex examination in a darkened room, and with repeated practice during well-child examinations. Any child who presents with descriptions of leukocoria or any observed abnormality on the red reflex test should be referred to a pediatric ophthalmologist.

The American Academy of Pediatrics (AAP) has published a

policy statement regarding how their members should perform the red reflex test. (Their recommendations can be found on the AAP website at [www.aap.org](http://www.aap.org), under Policy Statements; red reflex testing.) This policy statement is a step forward in the effort to assure early detection for all infants and toddlers with intraocular retinoblastoma. However, it should be noted that pupillary dilation is not a part of the general recommendation and is probably underutilized due to concerns regarding side effects of the dilation drops.<sup>216</sup>

Decreased visual acuity caused by destruction of the fovea eventually causes strabismus in young children with retinoblastoma. Strabismus is the initial sign in one of every five patients with retinoblastoma and results from direct infiltration of the macula by the tumor or a serous retinal detachment.<sup>215</sup> Acquired strabismus in any child always requires an immediate dilated fundus examination to rule out the possibility of retinoblastoma.

Other less common signs and symptoms of retinoblastoma include a red, painful eye from neovascular glaucoma, buphthalmos, uveitis, poor visual behavior if bilateral, failed vision screening in older kids, and an aseptic orbital cellulitis in advanced cases (Fig. 132.9). In five cases of retinoblastoma presenting with the clinical picture of aseptic orbital cellulitis, the imaging studies were misinterpreted as showing extraocular extension of the tumor into the optic nerve.<sup>217</sup> We have had similar experiences in patients with advanced intraocular retinoblastoma presenting as orbital cellulitis. Systemic treatment with 3 days of oral corticosteroids will often lead to dramatic reduction of the swelling, leading to a resolution of the orbital findings on MRI scans.

**FIG. 132.9** (A) Aseptic orbital cellulitis in a patient with advanced intraocular retinoblastoma. (B) Corneal clouding and conjunctival chemosis in an eye with neovascular glaucoma secondary to advanced intraocular retinoblastoma.

### **Diseases Simulating Retinoblastoma (Pseudoretinoblastoma)**

In 500 consecutive referrals for retinoblastoma, simulating lesions were found in 212 of the 500 patients.<sup>218</sup> There was a total of 23 different conditions that referring pediatricians or ophthalmologists were unable to distinguish from retinoblastoma. The three most common causes of pseudoretinoblastoma were persistent hyperplastic primary vitreous or persistent fetal vasculature (28%), Coats disease (16%), and presumed ocular toxocariasis (16%) (Fig. 132.10). Congenital cataract and retinopathy of prematurity were less frequently mistaken for possible retinoblastoma in this series than in other, earlier reports. Our experience in Los Angeles is similar, in that persistent fetal vasculature is the most common condition referred for leukocoria in infants, while older children referred for leukocoria are often diagnosed with Coats disease or toxocariasis. Other diagnoses that we have seen simulate retinoblastoma include familial exudative vitreoretinopathy (FEVR), Norrie disease, idiopathic vitreous hemorrhage, and congenital retinal folds.

**FIG. 132.10** (A) Unusual presentation of Coats disease in a 4-year-old child simulating retinoblastoma. Foveal nodule is the result of chronic lipid from telangiectatic vessels in the periphery seen here by fluorescein angiography (B).

In 1996, de Potter and colleagues evaluated the role of magnetic resonance imaging (MRI) in differentiating solid intraocular tumors from intraocular lesions with primary retinal detachment. They reported that solid intraocular tumors appeared hyperintense on T1-weighted images and hypointense on T2-weighted images.<sup>219</sup> Also, these lesions showed abnormal enhancement on contrast-enhanced T1-weighted images with fat suppression techniques. In secondary serous or exudative retinal detachment from intraocular lesions (Coats disease, persistent hyperplastic primary vitreous, phthisis bulbi, and retinopathy of prematurity), MRI showed hyperintensity of the subretinal space on both T1- and T2-weighted images and no enhancement in the subretinal space on contrast-enhanced sequences.

## Meeting the Family and Making a Diagnosis

We, the authors, have developed our own approach to diagnosis and care over a number of years. Obviously, different physicians in different practice settings will develop systems and approaches that work best for their patients. Below, we share our own recommendations.

The first meeting between the ocular oncologist and the family should generally occur in the office as soon as possible after the family's pediatrician or ophthalmologist has seen something in the

child's eye that arouses the suspicion of retinoblastoma. The two major advantages of performing the examination on the same day are that the child's pupils are already dilated and the anxiety and stress level of the family is high. Often the family has been told there is a "mass" or "tumor" in the eye. In our experience, more than 90% have not heard the word "cancer."

Introduce yourself to the family members and do not approach the child until you have had a discussion with the family. Be reassuring in your mannerisms. The first question to ask the parents is: "What brought you to the pediatrician in the first place?" followed by: "Then what happened when you saw an ophthalmologist?" It is important to ascertain what the family has been told or not told and what their understanding of the information is at the start of the examination. After the discussion with the parents, proceed with the examination of the child. As mentioned earlier, even if the child is an infant in the arms of one of the parents, it is important to explain to the parents what you will do before you do it to lessen anxiety.

After you have determined that you suspect the child may have retinoblastoma and you have fully explained how and why you are leaning toward this diagnosis, you can explain the rest of the diagnostic process, most importantly the need for (1) orbit and brain MRI with and without contrast, and (2) examination of both eyes under anesthesia. If the suspicion for retinoblastoma is low but cannot be ruled out on office examination, the child can delay the MRI until the examination under anesthesia (EUA) has been done. Parents must understand that their child will receive sedation or anesthesia for the next two procedures. Explain that both examinations are part of the protocol used around the world to form a definitive diagnosis for retinoblastoma. Many parents assume, either because they have been on the internet or been in a chat room, that having an MRI means that you suspect that the tumor has progressed to the brain. This is why it is so important to reassure every family you have contact with that this is the accepted protocol and it is the best way to finalize a diagnosis. It is very useful to let the family know that they are in partnership with you and the team of other physicians regarding the diagnosis and treatment plan for the child.

You must tell the family that you will inform them of the results of every examination as soon as you have them. You must also follow through and when you have the results of the MRI you must telephone them with the findings, rather than have them wait until your next appointment to see them. Parents experience so much stress during this process that it can affect their health and ability to care for their family. Provide answers as soon as possible, even if it confirms a diagnosis of retinoblastoma. Parental anxiety will be reduced by the knowledge that you now know what you are dealing with and that they will be an active part of the treatment planning.

The office examination allows the physician to determine the likelihood of this child having retinoblastoma. Another purpose of the office examination is to evaluate the level of visual acuity in each eye. Almost invariably, the parents are not aware of unilateral vision loss. They think that because both eyes move together, that both are seeing normally. Fixation and following behavior on a small toy or other object of interest to the child should be determined for each eye tested separately in a way that the family sees and acknowledges the outcome (often that one eye sees much better than the other). Demonstration of the lack of visual behavior in one eye may go a long way toward helping the parents accept the need for enucleation, should that become a treatment recommendation.

After dilation, the light on the indirect ophthalmoscope should be turned down to a very low level and a very brief 5–10-second view should be sufficient to establish whether or not the mass is typical for retinoblastoma, and whether the involvement is unilateral or bilateral. It may be possible to be certain that the mass in the eye is retinoblastoma. There is usually no need to restrain the child, nor to determine with certainty whether the tumor is unilateral or bilateral at this point. In occasional situations, it may be necessary to examine the child in the office with an eyelid speculum if they are not cooperative or the need for the exam under anesthesia cannot be ascertained any other way.

## Diagnostic Workup

At the initial office visit, a B-scan ultrasound examination is also necessary. If the office B-scan examination shows the classic shadowing of intralesional calcium, an eyelid speculum examination is not necessary. Even if the initial indirect ophthalmoscope examination reveals evidence of retinoblastoma, it is still recommended to perform the office ultrasound examination to augment the clinical examination and determine whether one or both eyes are involved.

Regardless of whether calcium can be demonstrated by ocular ultrasound on the child in the office, we routinely order an MRI scan of the brain and orbits (with gadolinium enhancement and fat suppression) for two reasons. First, to evaluate whether there is extraocular extension and optic nerve invasion by the tumor ideally before the staging examination under anesthesia, and second, the MRI of the brain should have specific cuts directed through the region of the pineal gland to eliminate the possibility of the “trilateral” retinoblastoma syndrome first described in 1983,<sup>218,219</sup> and discussed later in this chapter. The MRI scan can demonstrate infiltrative spread into the optic nerve, subarachnoid seeding, and involvement of the brain. MRI and computed tomography (CT) are both useful in determining the extent of recurrent disease, extraocular spread, and defining second primary tumors.<sup>220</sup>

It is preferable to have the results of the MRI before the staging examination in the majority of cases although the EUA can proceed even if the MRI results are not yet available. If the ophthalmologist can confirm that the patient does not have optic nerve tumor extension or trilateral disease, then enucleation can occasionally be performed immediately after the EUA if the eye is particularly advanced and the parents and clinicians are ready to proceed.

Unlike MRI, CT scanning involves exposing the child to a low dose of radiation. This exposure should be avoided if at all possible in cases of heritable retinoblastoma because of the generalized cancer predisposition syndrome. At CHLA, we *never* perform CT scan in any child with confirmed or suspected retinoblastoma. Sometimes a CT scan has already been performed by the emergency department or referring medical center, and it may provide useful information. Exophytic retinoblastoma tends to demonstrate calcification, either in a solid mass or in multifocal locations.<sup>220</sup> Soft

tissue components of retinoblastoma will demonstrate enhancement with contrast material in all cases. It should be kept in mind that calcification can also occur in any of the retinoblastoma-simulating lesions where significant ocular disruption or phthisis is evident, but this dystrophic calcification usually is deposited along the lines of normal structures. We have also seen numerous cases of retinoblastoma without calcification on CT or ultrasound examination, although it is helpful in making the diagnosis if present. It is important to note that ultrasonography performed by a skilled technician is superior to CT scan in detecting intraocular calcification, and CT should never be done after the staging EUA as it adds no useful information.

## Metastatic Workup

At centers where retinoblastoma is a relatively rare diagnosis there is often confusion between the workup for intraocular retinoblastoma and metastatic retinoblastoma. There is no place for routine body scans, PET scans, or total body CT scans in patients during the initial workup and treatment of intraocular retinoblastoma. A metastatic work-up can be considered if there is evidence from neuroimaging or pathology of an enucleated eye that the child in question has extraocular (i.e., orbital extension) or metastatic disease.

Until the late 1980s, it was routine for all newly diagnosed retinoblastoma patients in ocular oncology centers to have a bone marrow aspiration and biopsy, as well as a lumbar puncture with analysis of the cerebrospinal fluid (CSF) to look for evidence of CNS spread. Almost uniformly, these tests were normal unless there was evidence clinically or on imaging studies that extraocular spread of the tumor was likely to be present.

Among centers treating retinoblastoma in developed countries, routine bone marrow aspiration and biopsy, as well as lumbar puncture, are not considered necessary in new patients with retinoblastoma when imaging studies show no evidence that tumor has spread outside the eye. These tests add considerable time and expense to the workup and contribute to discomfort for the child, and experience has shown that they are unnecessary in the typical

case of intraocular retinoblastoma. On the other hand, they are essential if the treating physician suspects extraocular or metastatic retinoblastoma when the clinical history or neuroimaging studies suggest a complicated case.

When retinoblastoma presents as aseptic orbital cellulitis as a result of massive intraocular tumor necrosis and hemorrhage, radiologists may diagnose optic nerve invasion on MRI because of the perineural edema. A metastatic workup should be delayed for 2–3 days, while the affected child is treated with a relatively high dose of systemic corticosteroids. This decreases the edema and allows, within 2 or 3 days, a more accurate assessment of the optic nerve signal on the imaging study.

In cases in which there is clear evidence of tumor outside the eye, the full metastatic workup should be pursued. Studies should include a bone scan in addition to a search for tumor cells in the CSF and bone marrow. Aspiration from more than one site may be of value because bone marrow involvement can be uneven. The aspirates are typically taken from the iliac crest in young children under general anesthesia.

## Staging Examination Under Anesthesia

Before any treatment for retinoblastoma can be initiated, a staging EUA has to be performed.

During the staging EUA, a complete evaluation and documentation of every feature of the eyes should be undertaken with careful attention given to the examination of the anterior segment, iris, and vitreous cavity. A handheld slit-lamp evaluation of the anterior segment and vitreous should be part of this examination, looking for the presence of vitreous seeding. A Tonopen eye pressure should be taken as soon as the child is under anesthesia and before the speculum is inserted. A measurement of the corneal diameter and an ultrasonic measurement of the length of the eye are also helpful to rule out buphthalmos and assess for nanophthalmia, respectively.

The EUA is a good time to carefully examine the child for low-set and posteriorly rotated ears, simian crease in the palms, broad thumbs, hypertelorism, telecanthus, and other minor congenital

anomalies. Systemic findings can suggest other diagnoses that can be helpful in making the diagnosis, such as the 13q deletion retinoblastoma syndrome. A careful retinal drawing with colored pencils should be made of both eyes, with the location of each lesion noted.

Typically, enucleation should be combined with a staging examination only if the MRI has been completed and it shows no extraocular disease and the parents are ready mentally and emotionally to proceed. Parents typically need time to acknowledge and accept the need for enucleation. The affected child, especially if older than 2 years of age, should have a simplified explanation of what will happen during enucleation surgery. Waiting a few days will not significantly increase the risk for metastatic disease, but a long delay before enucleation is not recommended. Our practice is to schedule the enucleation within 7–10 days once a decision has been made. However, there are unique situations when the involved eye is advanced (i.e., buphthalmic), when immediate enucleation at the time of the staging EUA is the best option.

Wide-angle retinal photography or RetCam digital imaging is extremely useful in documenting the size and location of the tumors and confirming the features that allow group classification of the eye. Printed images of the tumor also help the family accept the reality of the diagnosis. Comparison of Retcam images are useful during follow-up examinations under anesthesia to demonstrate to the family the response or lack of response to treatment. In addition, the RetCam also allows the use of fluorescein angiography in the diagnosis and management of retinoblastoma.<sup>190</sup> A fluorescein angiogram is especially useful in confirming the presence of neovascularization of the iris in retinoblastoma eyes with glaucoma and/or chronic retinal detachment (Fig. 132.11). We also find fluorescein angiogram of value if there is a questionable area of recurrent retinoblastoma in a previously treated lesion or scar. In this case an actively growing recurrent lesion will leak, stain with fluorescein, and accumulate dye. Inactive lesions do not stain. The diagnosis of an early “presumed” retinoma may be facilitated by fluorescein angiography. A newly diagnosed, untreated eye that contains a lesion that appears to be type II or type III regression and does not

leak or stain on fluorescein angiography may well be a retinoma (see a more thorough discussion of retinoma later in the chapter).

**FIG. 132.11** (A) RetCam fluorescein angiography showing normal iris appearance at 51 seconds, compared to (B) abnormal eye with significant rubeosis iridis due to advanced retinoblastoma.

B-scan ultrasonography is useful to measure the height of each discrete tumor in millimeters. Ultrasonography is superior to CT in its ability to detect the presence of calcium within retinoblastoma tumors (Fig. 132.12). In 1973 Coleman described the reliability of ultrasound in retinoblastoma diagnosis.<sup>221,222</sup> In 1975 Sterns et al. reported two configurations, solid and cystic.<sup>223</sup> However, these authors were not always able to differentiate between vitreous hemorrhage and retinoblastoma. In one series of 38 eyes retinoblastoma was the ultrasound diagnosis in 25 and pseudoglioma in 11, and all diagnoses were correct.<sup>224</sup> Ultrasound should be able to detect a tumor as small as 2 mm in diameter.<sup>225</sup>

**FIG. 132.12** B-scan ultrasonography in retinoblastoma shows an intraocular mass with calcification and shadowing.

Fine-needle aspiration biopsy has been described as a diagnostic tool,<sup>226</sup> but its use is strongly discouraged in any patient suspected to have intraocular retinoblastoma. In 2002 Karcioğlu published a survey of major ocular oncology centers that had treated 3651 patients since 1986.<sup>227</sup> During those 17 years, fine-needle biopsy was performed only eight times (once in every 456 patients with retinoblastoma). The biopsy was usually done in older children with a diagnosis of uveitis in which retinoblastoma could not be ruled out. Six of the eight patients were 4 years of age or older. The use of fine-needle biopsy should be limited to those exceptional cases in which a diagnosis cannot be arrived at by any other means, the eye has visual potential, and the procedure is performed by an experienced ocular oncologist. With clinical experience, atypical cases can almost always be diagnosed correctly without the need for introducing a needle into the posterior segment of an eye with possible retinoblastoma.

## The Approach to the Child With Cancer

In this section, we discuss some of the less obvious issues involved

in the successful treatment of a child with cancer. The overall treatment approach should consider the child first, rather than focus on the salvage of the eye. Focusing on the eye with retinoblastoma instead of the child may mean the eye is retained (perhaps with little or no vision) but the child/teen/adult has been affected by the morbidity of the treatment and perhaps permanently scarred psychologically. Attempting to salvage an eye with advanced retinoblastoma often means more than 20 EUAs during the treatment course. Children who have undergone treatment for intraocular retinoblastoma may become terrified of medical settings and filled with foreboding and anxiety. In addition, the treatment process becomes very stressful for the parents and siblings as well. If the treating physician understands parental grief behavior, the process becomes easier for everyone involved.

In discussions with the family it is important to stress that preservation of the child's life must be the top priority, with salvage of the eye a secondary goal. In cases with unilateral retinoblastoma, when group D or E disease is present, some parents will insist that enucleation be avoided and treatment with chemotherapy be initiated. That emotional response of not wanting their child to lose an eye is normal. Parents seem to have the most difficulty with their concept of how deforming the removal of an eye will be. The parent's perception is that their previously "perfect child" will never have a social life, never get married or have children because of a disfiguring enucleation as a child.

The management team must patiently counsel the family about the reality of treatment consequences and side-effects. Showing the family photographs of other children with prosthetic eyes may be helpful. Cosmetic outcome is an important concern. The parents may have an image in their mind of an older person who lost an eye and has a less-than-optimal prosthesis.

The parents may think loss of one eye makes the child completely blind. Point out that this eye is not useful to the child now and that any vision he or she has now is due to the remaining eye. In unilateral disease, current vision in the good eye will not be impaired. Finally, be aware of the cultural background of the parents. It is often helpful to have a counselor with the same

cultural background.

# Treatment Methods and Techniques

## Developing a Customized Treatment Plan

This section discusses the treatment modalities that are available to the retinoblastoma management team in developing an initial customized treatment plan. Potential benefits and complications are discussed in this section because they must be taken into consideration in developing and presenting any treatment plan to the family for consent.

### Unilateral Nonheritable Retinoblastoma

The ABC classification of intraocular retinoblastoma helps clinicians decide when to treat unilateral retinoblastoma conservatively. Nearly all centers will attempt to salvage unilateral group A, B, and C eyes. Unilateral group E eyes should always be enucleated.

For group A disease, often detected in newborn members of a pedigree of retinoblastoma, or the contralateral eye of a patient with sporadic, advanced disease in the other eye, photocoagulation or cryotherapy should be employed. Photocoagulation is typically repeated to reduce the risk of recurrence while cryotherapy is only repeated if regrowth is noted during follow-up.

We have found that the majority of unilateral group B disease eyes can be successfully treated with three cycles of three-drug chemotherapy combined with focal consolidation. Many centers use the standard six-cycle three-drug chemotherapy regimen for all group B, C, and D eyes. The exact chemotherapeutic regime varies from center to center with some experts preferring to exclude etoposide (due to its leukemogenic potential) while others use single-agent carboplatin and others use a four-drug regimen using cyclosporin.<sup>228</sup> For group B eyes with a solitary lesion in the periphery, aggressive cryotherapy and/or laser therapy can sometimes be used, or perhaps even a radioactive plaque. However, it should be kept in mind that the vast majority of group B eyes cannot be treated with focal modalities alone and that chemoreduction will produce the best outcomes.

Unilateral group C retinoblastoma, which has local dissemination of tumor into the vitreous or subretinal space, has a high success rate with chemoreduction. Systemic chemotherapy with CEV is the most common regimen administered over six cycles for group C disease.

Unilateral group D eyes represent a very controversial category of patients, given that the rate of salvage for chemoreduction alone is 47%.<sup>229</sup> The success rate can be increased to 78% when failures after chemoreduction are salvaged with EBR, but this may not be advisable in unilateral patients. Therefore, the parents and the clinicians face a difficult decision in giving 6 cycles of 3 drug systemic chemotherapy when the rate of saving the eye is approximately 50%. Factors predictive of a poor visual outcome have been identified in group D eyes, and they include a complete retinal detachment, vitreous seeding of at least three quadrants and tumor involvement of more than half the macula. These eyes have been subclassified as being group D2, and they have a worse visual outcome.<sup>230</sup> Unilateral group D2 eyes may be better served by undergoing primary enucleation. The success rate of treating unilateral group D eyes with intraarterial chemotherapy is being assessed with an ongoing Children's Oncology Group (COG) trial, but retrospective studies from the Memorial Sloan Kettering Cancer Center (MSKCC) group suggest that the success rate with intraarterial chemotherapy alone for advanced disease may be as high as 70–80%.<sup>8</sup> In addition, salvage of active vitreous seeding after chemoreduction with intravitreal melphalan injections can be as high as 87%.<sup>8</sup> The optimal treatment approach for unilateral group D disease will evolve over the next 5–10 years, but it should be kept in mind that enucleation remains an excellent option for those eyes with poor visual potential.

### **Bilateral Retinoblastoma: Symmetrical and Asymmetric Disease**

Bilateral group A disease can follow the treatment strategy stated above: focal modalities only, using laser treatment and/or cryotherapy. For bilateral patients with any combination of group B–D disease, systemic chemoreduction is generally recommended, using the standard six cycles of the three-drug chemotherapy

consisting of carboplatin, etoposide, and vincristine. For patients with group A in one eye and group D or E in the other eye, the treatment approach is tailored to the clinical situation. A successful treatment approach is to enucleate the more advanced eye and treat the other eye with focal modalities (laser and/or cryotherapy). This option avoids systemic chemotherapy and is particularly advantageous for children less than 6 months of age to avoid the potential ototoxicity from carboplatin. The other approach is to treat the patient with six cycles of chemoreduction, with plans to enucleate the more advanced eye after two cycles if there is a suboptimal treatment response.

### **Advanced Intraocular Disease (Groups D and E)**

For group E disease, enucleation is generally recommended. In some centers, if systemic chemotherapy is initiated for the contralateral eye, salvage of a group E is considered. There have been rare case reports of successful salvage of group E eyes with chemoreduction.<sup>231</sup> However, enthusiasm for this approach should be tempered by the finding that up to 39% of group E eyes harbor high-risk histopathologic features.<sup>232,233</sup> There is also evidence that if a group E eye is removed after two cycles of systemic chemotherapy, there is no increased risk of death.<sup>234</sup> However, pre-enucleation chemotherapy can mask high-risk pathology and increase the risk of metastatic disease if enucleation is performed more than 3 months after diagnosis.<sup>234</sup> Therefore, if an attempt is made to salvage a group E eye, enucleation should be strongly considered after two cycles if there is not a dramatic response and the fundus findings cannot be monitored on indirect ophthalmoscopy. As mentioned, pre-enucleation chemotherapy can mask high-risk histopathologic features. Therefore, this approach should only be undertaken if the child is scheduled to receive the full six cycles of chemotherapy (for the other eye) because the regimens for intraocular disease and adjuvant chemotherapy after enucleation are similar.

If the neuroimaging study at diagnosis suggests invasion of the tumor into the optic nerve, there are two approaches. In those cases that have optic nerve enhancement of less than 5 mm, we recommend immediate enucleation of the group E eye, allowing the

socket to heal for 2 weeks, then starting systemic chemotherapy for the contralateral eye or adjuvant therapy if the case is unilateral once pathology confirms the presence of postlaminar optic nerve invasion. For bilateral cases, if the fovea is threatened in the contralateral eye, then systemic chemotherapy can be started immediately, with plans to enucleate the eye with the optic nerve enhancement after 1–2 cycles. Typically the enucleation is scheduled approximately 2 weeks after the cycle of chemotherapy so that the socket can heal for 2 weeks prior to the next cycle of chemotherapy. However, clinicians should be aware that the nadir for thrombocytopenia is about 2 weeks after chemotherapy. If there is optic nerve enhancement of more than 5 mm, there is concern regarding a positive optic nerve margin with upfront enucleation. Therefore, the child will require institution of a more aggressive protocol requiring a full course of high-dose multiagent chemotherapy before enucleation is performed (i.e., neoadjuvant chemotherapy).

## Systemic Intravenous Chemotherapy

The introduction of systemic intravenous chemotherapy for the primary treatment of intraocular retinoblastoma by Kingston et al. in 1996 set off a dramatic shift in the management of intraocular retinoblastoma.<sup>195</sup> Although the outcome from the first 14 eyes with Reese–Ellsworth group Vb retinoblastoma treated in London were disappointing, variations on their protocol are widely used today as the most common primary globe-sparing treatment for retinoblastoma throughout the world.

### Terminology

The term “chemoreduction” refers to the use of systemic chemotherapy for intraocular retinoblastoma combined with focal modalities such as laser therapy, cryotherapy, and/or brachytherapy. Systemic chemotherapy given to patients with high-risk pathology after enucleation is referred to as “adjuvant” chemotherapy in that it provides prophylactic treatment to patients without any clinical or radiographic evidence of metastatic disease.<sup>210</sup> The term “neoadjuvant” chemotherapy is used to denote

chemotherapy given to patients before a scheduled enucleation, typically for patients with more than 5 mm of optic nerve enhancement on the staging MRI scan. A detailed discussion of the treatment of extraocular disease is beyond the scope of this book and is the domain of the treating ophthalmologist. The usual agents employed for extraocular retinoblastoma include cisplatin, cyclophosphamide, vincristine, and doxorubicin. Pratt et al. described the St. Jude experience with chemotherapy for extraocular retinoblastoma between 1962 and 1984.<sup>235</sup> A total of 11 children received chemotherapy for measurable extraocular disease that had been present at diagnosis (7/11 patients) or developed later (4/11 patients). In this series from 1985, only 2 patients demonstrated complete responses and achieved long-term disease-free survival. In the modern era, the success rate for treating systemic relapse not involving the CNS is approximately 67% with aggressive multimodal therapy and stem cell rescue.<sup>210</sup> For patients with CNS relapse, the survival rate remains dismal despite all measures.

## **Chemoreduction Regimens**

In the majority of centers, systemic chemotherapy remains the most commonly used primary treatment for intraocular retinoblastoma. The chemotherapy agents may vary slightly but most protocols consist of the systemic administration of carboplatin, etoposide, and vincristine, given over a 2-day period every 3 or 4 weeks. The administration of the drugs and the time required for the suppressed bone marrow to recover is considered one cycle. In Los Angeles, we use six cycles of CEV for intraocular group C and D disease and three cycles for intraocular group B disease (Fig. 132.13). The dose of carboplatin used at our center is slightly higher (13 mg/kg per day for 2 consecutive days) versus the dose used at other centers (18.6 mg/kg for 1 day). With this regimen, six cycles of CEV has been well tolerated in our patient population. Almost all children will receive transfusions at some point during the course, and the rate of Grade III neutropenia can range between 10% and 30%.

**FIG. 132.13** Group B retinoblastoma, before (A) and after (B) primary chemotherapy.

Admittedly, primary intravenous chemotherapy for intraocular retinoblastoma administers a large volume of medication to the entire body to treat a relatively small organ. There is also concern about the possible association of etoposide and secondary acute myelogenous leukemia (AML), which has been reported in a small cohort of children treated for retinoblastoma.<sup>236,237</sup> For this reason, some centers have dropped etoposide from the regimen for less advanced disease (groups A and B). The drug is known to be leukemogenic at higher doses and there has been concern that exposing patients with the *RB1* mutation would increase their risk for secondary AML. Most experts agree that if etoposide poses a risk for second tumors, it remains a small one. Perhaps a bigger concern is the potential risk of hearing loss following carboplatin use. Wilson and colleagues have reported an increase in carboplatin-related ototoxicity at St. Jude.<sup>238</sup> Similar results have not been duplicated elsewhere, although it remains a concern particularly in children less than 6 months of age. The risk of ototoxicity is significant in this patient population when one considers that many retinoblastoma patients are visually disabled relying on other sensory input such as hearing. As with other intravenous forms of chemotherapy, risks of bone marrow suppression, alopecia, and central line infection exist; in rare cases these complications can be severe and life-threatening.

Infants <6 months of age at diagnosis receive a modified dosing regimen with a 50% decrease in all agents for the first cycle. At our institution, vincristine is routinely omitted for patients <2 months of age due to concerns regarding paralytic ileus and irritability. After

the first cycle at 50% dose CEV (or CE), patients are then monitored for intraocular tumor response and Grade III neutropenia (i.e., absolute neutrophil count <1000). If there is adequate tumor response or evidence of systemic toxicity, patients are kept at the 50% dose for the next cycle. If there is inadequate tumor response and no Grade III neutropenia, then the dose is increased to 75%. Patients in this age group can be increased to 100% dose of CEV if all factors are present: (1) older than 3 months of age; (2) no Grade III neutropenia to 75% dose; and (3) inadequate tumor response to 75% dose.

### **Sub-Tenon Carboplatin**

The addition of sub-Tenon carboplatin to augment penetration of systemic carboplatin has been advocated by a number of groups over the past 10 years.<sup>239</sup> However, following sub-Tenon or subconjunctival injections a number of complications have been described including lid swelling, orbital soft tissue scarring and atrophy, and secondary optic neuropathy<sup>240-242</sup>. In particular, severe orbital scarring can lead to strabismus and make subsequent enucleations challenging, and orbital fat atrophy can lead to permanent soft tissue socket deformities. For these reasons, most centers have abandoned the use of sub-Tenon carboplatin injections. For patients with persistent vitreous seeding following chemoreduction, intravitreal melphalan injections have become the treatment of choice (see section on Intravitreal chemotherapy).

### **Intraarterial Chemotherapy**

As far back as 1953, Kupfer described a case of retinoblastoma treated with nitrogen mustard injected directly into the carotid artery.<sup>243</sup> Later, in the 1960s and 1970s, Reese and Ellsworth combined EBR with intracarotid chemotherapeutic agents.<sup>244-246</sup> They later abandoned this approach, not having detected significant benefits of the combined approach over radiotherapy alone. In the 1980s, Kaneko at the National Cancer Institute in Tokyo, Japan developed a new method to administer ocular chemotherapy – he described it as selective ophthalmic arterial infusion (SOAI).<sup>3,247-249</sup> With this approach, developed in a culture

that abhors enucleation, a balloon catheter was inserted in the femoral artery, past the internal carotid and guided just past the origin of the ophthalmic artery. The balloon was then inflated and melphalan injected into the arterial vasculature, allowing it to “backflow” into the ophthalmic artery. Often adjuvant treatments were also administered but more than half of treated eyes were preserved.<sup>4</sup>

In 2008 Abramson and colleagues modified this technique with direct insertion of the cannula into the ophthalmic artery.<sup>6</sup> A phase I/II trial of nine treated patients with group V retinoblastoma salvaged seven eyes that would have otherwise been enucleated; the two enucleated eyes showed no evidence of active disease. While the initial series used melphalan, additional follow-up reports have infused other agents, including carboplatin and topotecan, with promising results. The technique has been used successfully in unilateral and bilateral cases, and as both a primary and salvage approach.<sup>6-8,250-252</sup> Currently, intraarterial chemotherapy (IAC) is the primary modality used to treat unilateral group D retinoblastoma in some centers, rather than chemoreduction. Follow-up electroretinogram (ERG) data suggests improved ERG findings in some very advanced cases as the retina reattaches, but also a small cumulative degradation in eyes receiving multiple treatments.<sup>253,254</sup> Defining an event as “enucleation or need for radiotherapy,” cumulative 4-year data from this group demonstrated a 81.7% event-free survival for eyes that received intraarterial chemotherapy as primary treatment, and 58.4% for eyes that had previous treatment failure with intravenous chemotherapy and/or EBR.<sup>8</sup> Although a meaningful comparison with chemoreduction is currently not possible in the literature, there is a general consensus that IAC offers somewhat higher salvage rates for group D eyes, albeit with a higher risk of local and regional side-effects (Fig. 132.14). The Shields group recently published a globe salvage rate of 94% for group D eyes in a small group of patients treated with intraarterial chemotherapy (17 patients).<sup>255</sup> A large-scale retrospective study evaluating the long-term results of group D eyes treated with IA chemo at MSKCC will be published soon. The results of an ongoing COG trial on unilateral group D tumors treated with primary IAC will likely

determine whether this technique will be widely adopted by the ocular oncology community and whether it will replace primary systemic intravenous chemotherapy.

**FIG. 132.14** (A) Advanced group D retinoblastoma before and (B) after intraarterial chemotherapy showing dramatic tumor regression.

The technique is technically challenging, requiring significant expertise and experience in pediatric artery catheterization by the neurointerventionalist.<sup>255</sup> The procedure is performed under general anesthesia in the neuroangiography or interventional suite, using a microcatheter inserted into the femoral artery (Fig. 132.15). The microcatheter (500  $\mu\text{m}$  in diameter) is then guided into the internal carotid artery, and fluoroscopy is performed to confirm its placement at the ostium of the ophthalmic artery. Many practitioners have raised concerns regarding the potential for systemic and CNS risks with this approach, including death and stroke, especially in the context of unilateral disease, where enucleation is generally curative. We are aware of one unpublished case of an asymptomatic stroke following IAC, and there are several reports of third nerve palsy, as well as retinal and choroidal vascular occlusion.<sup>5,256,257</sup> Transient side-effects are fairly common following IAC, such as eyelash loss, periorbital edema, and cutaneous hyperemia.<sup>258</sup> One recent study found a reduction in subfoveal choroidal thickness after IAC, suggesting the possibility of permanent choroidal vascular toxicity.<sup>259-261</sup> Concerns have also been raised regarding the small dose of radiation hereditary retinoblastoma patients receive during the fluoroscopy portion of

the procedure, which is necessary to confirm the correct placement of the catheter at the ostium of the ophthalmic artery.<sup>262,263</sup>

**FIG. 132.15** (A) Child undergoing intraarterial chemotherapy in the angiography suite with the catheter inserted into the femoral artery. (B) Cerebral angiogram confirming perfusion of the ophthalmic artery. (C) Angiogram showing vasculature of the globe and orbit with the microcatheter positioned at the ostium of the ophthalmic artery.

The primary drug used in IAC is melphalan, which was identified as the most effective drug against retinoblastoma in vitro.<sup>3</sup> Recommended doses of melphalan per infusion have ranged between 2.5 and 5 mg per infusion, based on weight and age, with an average 3-year-old receiving 5 mg of melphalan.<sup>8</sup> Systemic neutropenia is also observed after IAC, with 29% of cycles being associated with Grade 3 or 4 neutropenia.<sup>264</sup> The risk of neutropenia appears to be the highest when the dose exceeds 0.4 mg/kg of melphalan.<sup>262</sup> The procedure is also technically difficult in children below 6 months of age due to the small size of the ophthalmic artery. The group at MSKCC has reported successful treatment in

children who are at least 3 months of age and 6 kg in weight.<sup>265</sup> In patients who have failed primary therapy and IAC is being used for a recurrence, multiple drugs are often used, using melphalan, carboplatin, and topotecan in combination.<sup>252,266,267</sup>

## Intravitreal Chemotherapy Injection

Despite the success of using systemic chemotherapy regimens for the treatment of intraocular retinoblastoma, eye preservation rates for eyes with diffuse vitreous seeding (i.e., group D) have been disappointing, with approximately 50% of eyes avoiding radiation or enucleation.<sup>229</sup> In fact, vitreous seeding is the most common reason for failure with systemic chemoreduction. Using salvage radiotherapy for recurrent vitreous seeding, success rates range between 50% and 70%,<sup>229,268,269</sup> but with the expected short-term and long-term side-effects. The use of intravitreal chemotherapy injections was first reported in Japan, but with some reports of failure, including extraocular spread.<sup>3</sup> Munier modified the protocol to increase its safety, using small needles, paracentesis, and cryotherapy to the injection site.<sup>10,11</sup>

In 2012 intravitreal chemotherapy injection (IVC) emerged as a potential new therapy to treat resistant vitreous seeding in eyes with advanced retinoblastoma, as two clinical series were published in the literature.<sup>10,270</sup> Since then, intravitreal injections of chemotherapeutic drugs have been performed in Europe and the United States as a salvage therapy for eyes with recurrent vitreous seeding from retinoblastoma. In several large series, authors have reported excellent globe salvage rates of 83–100%.<sup>9,10,271,272</sup> The injections have been shown to be safe with no cases of extraocular spread in Europe or the United States.<sup>11,273</sup> In the largest series to date, Munier and colleagues reported on 122 injections in 25 group D eyes with a median follow-up of 22 months (range 9–31 months). They reported an ocular salvage rate of 87% (20 of 23 eyes) for those eyes with resistant vitreous seeding.<sup>9,10</sup> In this series, the eyes developed a “salt and pepper retinopathy” at the injection site in the peripheral retina in 10 cases, but there were no other significant ocular complications and no signs of tumor spread outside the eye.<sup>10</sup> Abramson and colleagues have published clinical data on 16

patients who received weekly intravitreal melphalan injections and found no evidence of systemic spread of the drug.<sup>272</sup> However, there was a small but permanent (and cumulative) degradation of the overall ERG signal in eyes that received intravitreal melphalan injections at a dose of 30 µg.<sup>272</sup> Smith et al. performed a review of 1287 intravitreal chemotherapy injections in 306 eyes with retinoblastoma, and calculated a 3% risk of significant ocular side-effects.<sup>273</sup> There were also no cases of extraocular spread in the United States or Europe in this review.<sup>273</sup> At our center, we are aware of two cases of severe retinal toxicity which presented with a clinical picture resembling a combined retinal artery and retinal vein occlusion. Although parents should be aware of the small risk of significant ocular side-effects with intravitreal melphalan injections, the overall risk is lower than with other modalities such as radiation therapy or intraarterial chemotherapy infusion.

The current protocol for IVC utilized by clinicians was established by Munier in 2012, utilizing small needles, anterior chamber paracentesis, and cryotherapy at the injection site.<sup>10</sup> The schedule used by most centers is 4–6 weekly injections until the vitreous seeding is resolved clinically, with an average of 4.5–6.5 injections per eye.<sup>10,272</sup> An alternative schedule is to use a short course of three injections one week apart, and then waiting 4 weeks and documented clinical relapse before giving an additional injections. Our early results suggest that approximately half the eyes can be cured with the initial three injections. Doses of melphalan used by clinicians have ranged between 10 and 50 µg.<sup>270,272</sup> Currently, most centers use between 20 and 30 µg, keeping in mind that permanent but small ERG changes have been observed at 30 µg.<sup>272</sup> Melphalan is very unstable once reconstituted and injection should be performed within 2 hours to avoid loss of potency.<sup>274</sup> There have also been recent reports combining intravitreal melphalan and topotecan for refractory cases.<sup>270,275</sup> Munier has classified active vitreous seeding into the categories of dust, spheres, and the more extensive cloud (of seeds).<sup>276</sup> Francis and colleagues analyzed the number of injections needed to eradicate each category of seeding, and found eyes with dust required a median of three injections while eyes with clouds with seeding required a median of eight injections and almost 8 months

for complete resolution (Fig. 132.16).<sup>277</sup>

**FIG. 132.16** (A) Cloud of active vitreous seeding, both with a large central fragment and diffuse seeding in the inferior vitreous. (B) Resolution of vitreous seeding after seven intravitreal melphalan injections. Note the peripheral retinal atrophy that can be seen after melphalan injections.

Clinicians should keep in mind that intravitreal melphalan should be reserved for eyes with recurrent vitreous seeding after primary therapy has failed. Our clinical experience has demonstrated that intravitreal melphalan injections have no effect on retinal or subretinal tumors. The clinical protocol originally described by Munier should be carefully followed to avoid complications.<sup>10</sup> Although there is the potential for ocular toxicity, the risk of extraocular spread is negligible and the safety profile appears to be better than with other modalities used to treat vitreous seeding.

## Laser Treatment

In conjunction with systemic chemotherapy for intraocular retinoblastoma, tumor consolidation with laser therapy is an important component of the chemoreduction protocol. Laser therapy is also commonly used as the sole, primary modality for group A tumors that are less than 2 mm in diameter and thickness.

Two main laser wavelengths are used for retinoblastoma, the green 532-nm argon and the 810-nm diode infrared lasers. The energy of a laser is converted to heat only when it is absorbed, typically by the retinal pigment epithelium (RPE). Therefore, laser treatment is more effective for smaller and flatter tumors. It can be challenging to treat elevated tumors that are more than 2–3 mm away from the RPE and those tumors with an underlying calcium base. In comparing the two lasers, the shorter-wavelength green 532-nm argon is more effective for creating very focal scars, while the diode laser should have deeper penetration into bigger tumors. In addition, the green argon laser is better absorbed by the relatively nonpigmented retinoblastoma, and is typically the choice when treating tumors with a calcified base. The longer wave length 810-nm diode infrared laser provides deeper penetration and probably has a lower risk of causing a hemorrhage.

The technique we find useful with the argon 532 nm is essentially the same for both primary treatment of group A lesions and focal consolidation following primary chemotherapy in groups B–D. In general, focal consolidation begins after the first or second cycle of systemic chemotherapy after the tumor volume has been reduced. The initiation of laser treatment for tumors in the macula is usually delayed until a minimum of 2–3 cycles to allow for more tumor reduction and maximal visual recovery. The goal of the therapy is to completely cover each lesion with 50% overlap during at least three different sessions. We choose initial power setting of 250–300 mW, with a duration of 300 msec. The power and time settings are kept low to prevent tumor disruption, retinal contraction, and possible hemorrhage that may be associated with excessive energy delivery. In general, the first burns are placed at the edge of the lesion with the spot half on and half off the tumor. The power and/or duration can be adjusted to achieve gentle whitening of the tumor. We do not recommend exceeding 600 mW of power with the 532 nm laser. Once the lesion is outlined, then the entire lesion including any type I regression-associated calcium is covered with overlapping rows of burns (Fig. 132.17). A small to moderate-sized lesion may require 200–400 burns for good coverage. The burns over the thicker areas of the tumor may be virtually invisible compared with those placed at the edge of the lesion. Typically, the

power is kept at low levels around the periphery of a larger tumor and increased over the apex of the tumor if a color change is not observed. Repeat the laser coverage at 2–4-week intervals during and/or after the administration of systemic chemotherapy until the entire lesion has been covered on at least three different occasions. It is important that the tumor be reduced to type I regression (calcified) or type IV scars (flat) by the time the last cycle of chemotherapy has been given (Fig. 132.18). If the tumor has a large amount of type II regression (“fish flesh”) or active tumor after the last cycle of chemotherapy, regrowth of the tumors off chemotherapy is extremely difficult to control with focal modalities alone.

**FIG. 132.17** Technique for laser focal consolidation. 1. First burns are placed at the edge of the lesion with the spot half on and half off the tumor. 2. The lesion is then outlined with 50% overlap of the previous spot. 3. The lesion is then covered completely with 50% overlap.

**FIG. 132.18** (A) Group B tumor prior to treatment with systemic chemotherapy and focal laser consolidation. (B) After treatment there is significant reduction in tumor volume and appropriate flattening.

Because the infrared 810-nm diode laser has a longer wavelength than the argon laser, it penetrates further and is absorbed mainly by the retinal pigment epithelium. It is useful primarily if RPE is intact under the lesion to be treated. One major advantage of the infrared laser is its larger spot size allowing more rapid coverage of the lesion and offering less opportunity to deliver excessive concentrated energy that might cause bleeding or tumor disruption. The end point of energy application is, like that for the argon laser, a gentle whitening of a spot placed half on and half off the tumor. Because of the larger spot size, the power is generally set initially at 300, and can be adjusted upward to 700–800 mW if required. Typically the diode laser is used in continuous mode with the duration set at 9000 msec and the interval at 50 msec, with the total time of each laser spot controlled by the surgeon with the pedal. The appearance of punctate hemorrhages within the treated area indicates maximum energy is being delivered.

Complications of focal laser consolidation include burns of the iris at the pupillary margin and focal lens opacities, both of which are very rare in experienced hands. Other complications that are associated with excessive energy delivered to the tumor include subhyaloid and vitreous hemorrhage. We are also aware of several cases in which repeated laser photocoagulation delivered to multiple recurrences of a lesion in the macula was associated with the appearance of an extrascleral nodule of retinoblastoma in the orbit. It is likely that extraocular disease in these rare cases was a

complication of repeated laser applications causing scleral thinning and the creation of a portal of exit for tumor cells into the orbit. Although laser treatment is the safest modality used for intraocular retinoblastoma, any treatment given in excess of what is required to achieve tumor control can lead to significant complications.

Clinicians should also recognize that focal consolidation may lead to decreased vision from RPE scar migration or “creep” in lesions near the foveola. Care must be taken when applying laser on the foveal side of a tumor near fixation. Lee and colleagues demonstrated an increase in the size of laser scars following red diode laser application.<sup>278</sup> It is reasonable to consider close observation after sufficient primary chemotherapy of a small tumor located near the fovea or in the papillomacular bundle that demonstrates complete regression, until documented regrowth is observed. In these rare cases, central vision can be spared by withholding laser treatment if regrowth does not occur.

## Cryotherapy

Destruction of the tumor by cryotherapy results from disruption of cellular membranes following the freeze–thaw cycle. It can also have a local vaso-occlusive effect on the tumor and nearby retina/choroid. Cryotherapy is useful for larger peripheral tumors and up to 3.0 mm in diameter and 3.0 mm in thickness.<sup>279–281</sup> The bigger tumors may require more than one treatment although we typically wait to see the effects of the first cryotherapy application before retreating. Cryotherapy can also be used for posterior pole tumors that are not responding to laser treatment, although a limited conjunctival peritomy is necessary so that accurate placement of the probe can be obtained. In addition, because the probe tip position cannot be easily confirmed while the freezing is taking place, it is possible to unintentionally injure the macular or the optic nerve. An important consideration is that cryotherapy routinely destroys a great deal of normal retina surrounding the lesion, thereby increasing the visual deficit from the resulting chorioretinal scar.

After confirming that the cryotherapy unit is working properly, the tip of the probe is used to indent the sclera under the tumor

with indirect ophthalmoscopy. Once the probe is directly beneath the tumor, freezing is initiated, and the ice ball is maintained until it encompasses the entire tumor mass with some overlap over the apex for 1–2 mm. Then the ice ball is allowed to thaw while not moving the tip, and this freeze–thaw cycle is repeated for a total of three applications.

Complications of cryotherapy include vitreous hemorrhage, subretinal fluid, and retinal holes. Rhegmatogenous retinal detachment can result from a combination of atrophic retina and vitreous traction, as cryotherapy results in strong adhesions at the margins of scars.<sup>282,283</sup> We have observed the creation of retinal breaks and rhegmatogenous retinal detachment when the calcium portions of type I regression is included in the ice ball. The presence of subretinal fluid in the region of proposed cryotherapy is a relative contraindication. Extensive cryotherapy can also cause atrophy of the sclera, with formation of a pseudocoloboma of the sclera.

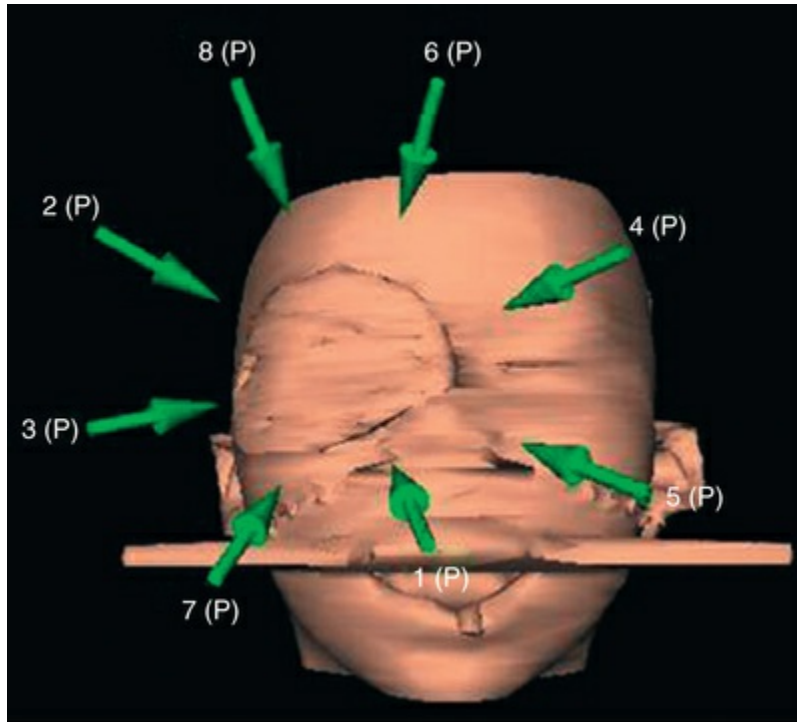

## Radiation Therapy

### External Beam Radiotherapy (Teletherapy)

EBR was the treatment of choice as primary therapy of intraocular retinoblastoma for much of the 20th century. Verhoeff and Reese pioneered the method in the early 1900s. Retinoblastoma is considered a radiosensitive tumor because a high percentage of tumors respond at doses that the retina and optic nerve will tolerate. For Reese–Ellsworth groups I–IV, tumor control rates and ocular salvage rates are relatively high.<sup>284–286</sup> However, the main limiting factor of EBR is the high risk of SMNs in patients with heritable or germinal retinoblastoma. As a result most centers now use EBR as a salvage technique as a last resort if other treatment options such as intraarterial chemotherapy or intravitreal injections have failed. At our center, we use EBR only if there is a large retinal recurrence which has failed every other therapy and it is the only remaining eye with visual potential. EBR is also still used in cases where extraocular spread is strongly suspected or has developed in the orbit. This group includes patients with a positive cut end of the optic nerve after enucleation.

Newer techniques such as intensity modulated radiotherapy (IMRT) allow for a more focal, conformal treatment to the globe and decreased dose to the orbit. IMRT uses computer-controlled tungsten blades selectively to block areas of the treatment volume for a prescribed fraction of each beam's treatment time to make a radiation field with varying intensities. [Fig. 132.19](#) is a three-dimensional reconstruction of a CT scan done on a retinoblastoma patient with his head positioned using a custom-molded headrest and a custom dental impression and custom bolus material over his retinoblastoma-containing right globe. The green arrows represent the central rays of the eight incident IMRT radiation beams converging on the patient's right retina. [Fig. 132.20](#) compares the radiation dose distributions produced by irradiating the entire globe using the eight-beam IMRT arrangement (A) and a single 20 million volt electron beam (B). The IMRT substantially reduces the dose to the frontal lobe posterior to the orbit. [Fig. 132.21](#) compares the radiation dose distributions produced by irradiating the retina using the eight-beam IMRT arrangement (A) and a single lateral 6 million volt photon beam. Both methods limit the radiation dose to the lens of the eye. The lateral photon beam, however, gives a substantially higher dose to the sphenoid sinus and contralateral orbit.

**FIG. 132.19** Three-dimensional reconstruction of a computed tomography scan. The *green arrows* represent the central rays of the eight incident intensity-modulated radiation therapy beams converging on the patient's right retina.

**FIG. 132.20** Radiation dose distributions produced by irradiating the entire globe using the eight-beam intensity-modulated radiation therapy (IMRT) arrangement (A) and a single 20-million-volt electron beam (B). The IMRT substantially reduces the dose to

the frontal lobe posterior to the orbit. (Courtesy of Arthur Olch, PhD, FAAPM.)

**FIG. 132.21** Radiation dose distributions produced by irradiating the retina using (A) the eight-beam intensity-modulated radiation therapy arrangement and (B) a single lateral 6-million-volt photon beam. Both methods limit the radiation dose to the lens of the eye.

The widespread use of IMRT at most centers may reduce the rate of second malignancies long term as well as cataract formation and orbital hypoplasia when compared to standard lateral port EBR. Long-term studies on the use of IMRT for retinoblastoma are not yet available, but it is expected that the side-effect profile will be more favorable than with standard EBR. Total doses to the tumor range between 36 and 42 Gy with IMRT with daily fractions of 200 cGy. Sedation of the patient is necessary to ensure immobilization of the child's head during the daily delivery of radiotherapy. A custom-made head immobilization device is also required to reproduce the position of the patient's head throughout the course of approximately 20 daily treatments. With any EBR technique, the anterior retina (especially the anterior nasal retina) receives a lower total dose due to efforts to spare the lens. For this reason, EBR is much more effective at treating smaller, posterior tumors than larger, anterior tumors. At these doses, the retina and optic nerve typically do not develop late visual complications.

Despite efforts to spare the lens, a significant percentage of patients develop visually significant cataracts following IMRT. In the series reported by Schipper et al., 18 of 54 radiated eyes developed clinically detectable cataract, but only five of the 18 eyes

so affected required cataract surgery.<sup>287</sup> Lens opacity developed only in lenses in which a posterior portion of >1 mm had to be included in the treatment field. The minimum cataractogenic dose in that series was 8 Gy to the lens. Hungerford et al. noted that, by using the Utrecht device (the contact lens) for fixating the eye, the lens and anterior segment can be effectively spared while the whole retina is treated with a full dose of radiation.<sup>288</sup> Our experience at CHLA is that the rate of visually significant cataract is higher than what has been reported in the literature and that the majority of these patients require cataract surgery after IMRT at some point during childhood. We recommend waiting 2 years between the last treatment for retinoblastoma before performing cataract surgery and using a clear cornea approach.

## **Proton Beam Radiotherapy**

Proton beam is a unique type of radiotherapy which utilizes heavy charged particles with a very sharp Bragg peak curve. This results in dosimetric plans that are more focal with less scatter to critical adjacent structures, including the orbital bones, CNS, and pineal region. In particular, the Bragg peak property of protons allows for a reduced dose of radiation to structures behind the tumor, such as the orbit, brain, and skull base. Recent studies have demonstrated the dosimetric superiority of protons over more traditional EBR and even IMRT.<sup>289,290</sup> Furthermore, the Boston group has published preliminary data showing a significant difference in the 10-year rates of second cancers in retinoblastoma patients between protons and photons (0% vs. 14%).<sup>291</sup> Proton beam radiotherapy is also potentially a shorter course of treatment when compared to IMRT, which typically takes at least a month. However, the entrance dose to the cornea is typically higher with proton beam radiotherapy compared to IMRT. A report from Boston described using an oblique or lateral beam to reduce the exposure to the cornea and orbital bones.<sup>292</sup> The same group published a globe salvage rate of 75% for group C and D eyes,<sup>292</sup> but overall globe salvage rates with proton beam appear to be similar to IMRT.<sup>289</sup> The challenge when considering proton beam treatment for retinoblastoma remains the high cost of such equipment and the relatively few centers capable of administering fractionated proton beam treatments under

anesthesia to the pediatric population. Despite the theoretical advantages of proton beam radiotherapy for retinoblastoma, there are not enough documented clinical advantages to recommend this modality over IMRT.

## **Brachytherapy**

The use of brachytherapy in the treatment of retinoblastoma was originally pioneered by Moore and Scott in 1929. Ophthalmic applications were designed using radium and, later, cobalt 60. In 1977, Rosengren and Tengroth reported on the reasonably successful results of such treatment in 20 patients.<sup>293</sup>

Currently, there are two main isotopes in use for intraocular retinoblastoma: iodine-125 in the United States, and ruthenium-106 in Europe. Iodine-125 isotope secured in a gold carrier became a common radiation source used in brachytherapy when cobalt was abandoned decades ago. The gold carrier for the iodine was later modified with deeper wells for the seeds creating a conformal treatment plan (Fig. 132.22).<sup>294</sup> In primary brachytherapy, the calculated dose to the apex of the tumor is generally in the range of 40–45 Gy. These doses are significantly less than what is used for uveal melanoma, but the retina within 3 mm of the plaque margin will still develop significant radiation retinopathy. The isotope ruthenium-106 (a  $\beta$ -emitter), is commonly used in Europe due to the unavailability of iodine sources. The advantage of ruthenium is that the half-life is much longer than iodine so that a single plaque may be reused for up to 1 year. However, with a  $\beta$ -emitter the scleral dose of a ruthenium plaque is higher than a similar plan with iodine-125; as a result, retinoblastoma lesions higher than 5 mm cannot be treated. Also, in ruthenium plaques, the plaque itself contains the radiation sources. Therefore, it is not possible to custom design the location of the radiation seeds in the plaque to conform to the shape of the tumor. However, ruthenium plaques are available in numerous shapes and sizes to address this issue.

**FIG. 132.22** (A) Gold carrier for the iodine was modified with deeper wells for the seeds creating a conformal treatment. The seeds can be loaded specifically depending on location of tumor. (B) The ruthenium plaque itself contains the radiation source. Therefore the possibility of differentially loading radiation seeds in the plaque to conform to the shape of the tumor is avoided with ruthenium.

Primary brachytherapy is an option for some group B patients if the tumor is located away from the posterior pole. Similarly, some group C patients can also be treated with brachytherapy if the tumor is peripheral and there is only a cuff of subretinal fluid. Unlike EBR, brachytherapy does not appear to increase the risk of second cancers in heritable cases, although there are significant ocular side-effects. Shields et al. reported their results of plaque therapy in 103 eyes, used both as primary therapy and for salvage after failure of other modalities.<sup>295</sup> With a mean follow-up of 38 months, 87% of eyes were successfully treated and 13% showed tumor recurrence. Tumor control rates for ruthenium brachytherapy has been reported to be 73%, although similar to iodine-125, its use as salvage therapy is often less successful than primary therapy.<sup>296</sup> The main limiting factor with plaque therapy for posterior pole tumors is the likelihood of permanent visual loss associated with high doses of radiation to the retina and other vital structures. Another limiting factor is the appearance of vitreous seeds after brachytherapy, but intravitreal melphalan injections can now be used to treat residuals seeds which appear during follow-up.

The technique of localizing the plaque when treating retinoblastoma differs somewhat from the localization technique for choroidal melanoma, primarily because of absence of pigment in retinoblastomas. Transillumination techniques used with melanomas are not helpful in localizing retinoblastoma. Surgeons rely on localizing the margins of the tumor with scleral depression and indirect ophthalmoscopy when using COMS plaques, or preoperative computer modeling using Eye Physics plaques.<sup>297,298</sup> With the Bebig Corp. Software, the radiation physicist can tell the surgeon the position in clock-hours for the center of the anterior edge of the plaque, the location of the eyelets, and how many millimeters those points are located posterior to the limbus (Fig. 132.23).<sup>298</sup> When suturing a radioactive plaque in a young child with retinoblastoma, extreme care must be taken not to perforate the thin sclera with the spatulated needle. In general, children are admitted postoperatively to ensure that they can be monitored during brachytherapy. If there is concern regarding the child disrupting the plaque position, sedation may be required. The duration of plaque treatment is generally shorter for retinoblastoma than for melanoma due to the lower total dose, and in most patients the admission time is 2–3 days.

**FIG. 132.23** Dosimetry planning is carried out with the help of sophisticated software, such as that available from Bebig Corporation. The position in clock-hours for the center of the anterior edge of the plaque, the location of the eyelets, and how many millimeters those points are located posterior to the limbus are shown.

A child should never receive both brachytherapy and EBR to the same eye due to the very high risk of radiation-related ocular side-effects.<sup>286</sup> Use of brachytherapy for consolidation immediately following primary systemic chemotherapy is also associated with an extremely high risk of aggressive radiation retinopathy. We have observed rapid radiation retinopathy in several eyes when 40 Gy was given to the eye with brachytherapy immediately following completion of CEV chemotherapy. In that situation, other modalities may be used to temporize for several months or a lower total dose to the tumor should be considered.

## Enucleation

Enucleation is not only the oldest surgical procedure used to treat intraocular retinoblastoma but often the best option for advanced disease that has compromised the visual potential of the eye.

Despite the progress of various conservative modalities, enucleation remains the most commonly employed technique for treating retinoblastoma worldwide. This chapter will focus on specific technical issues related to performing enucleation for retinoblastoma, including some “surgical pearls” which have been very effective in the authors' experience.

## Indications

There are several categories of patients who are considered excellent candidates for enucleation: (1) unilateral advanced tumors (particularly with extensive seeding) with negligible visual potential (group D or E); (2) a blind eye with recurrent disease following chemotherapy and/or radiation; (3) bilateral retinoblastoma with advanced disease and dismal visual potential in one eye and the other eye which can be treated otherwise; and (4) any patients with suspected optic nerve, anterior segment, choroidal, scleral, or extraocular tumor involvement. Finally, patients are also considered candidates for enucleation if they have suspected active tumor in the eye and cannot be followed due to obscured media (e.g., vitreous hemorrhage or phthisis).

If a bilateral patient has advanced disease, which is symmetrical or almost so, then it is reasonable to delay enucleation until response to primary chemotherapy has been evaluated in both eyes. This is because it may not be possible to predict how the tumor(s) in any particular eye will respond to systemic chemotherapy. This approach has been criticized because important pathologic risk factors (e.g., invasion into the optic nerve) might be obscured by systemic chemotherapy. However, this is not a major concern if the child undergoes enucleation of the worse eye and receives the full six cycles of systemic chemotherapy for the contralateral eye. In most centers the adjuvant protocol that would be given if an enucleated eye contained high-risk pathologic features is similar to the traditional three-drug six-cycle primary chemotherapy protocol for intraocular disease (carboplatin, etoposide, and vincristine). When the decision has been made to proceed with enucleation for any patient with retinoblastoma, surgery should ideally be scheduled within 7–10 days. Waiting any longer exposes the child unnecessarily to the risk of metastatic disease (particularly in

untreated patients and any group D), and possibly ocular discomfort if glaucoma or periocular inflammation is present. Prior to enucleation, all patients should be evaluated with a brain and orbit MRI scan to ensure that there is no radiographic evidence of optic nerve or extraocular extension that may require neoadjuvant chemotherapy prior to enucleation to minimize the chances for local and systemic relapse.

## **Preoperative Counseling**

Before performing an enucleation on any child with retinoblastoma, regardless of age, a member of the retinoblastoma management team should thoroughly prepare the child and the extended family. It is also important to discuss with the parents the technical aspects of the surgery and the expected postoperative course. It may be helpful to share with the parents the perspective that enucleating an eye with advanced disease is a reason to celebrate, as it is likely that a relatively simple operation will cure their child with cancer. Greater than 96% of patients who present with intraocular retinoblastoma are cured by enucleation.<sup>299,300</sup> It should also be emphasized to the parents that the involved eye has not had useful vision for a prolonged period and that the child will not experience any functional limitations from enucleation. The adults in the extended family need to see photographs of other children who have had enucleations; if possible they should be able to hold and feel the implant and ocular prosthesis. Finally, it should be explained that the operation is not overly painful and can usually be performed on an outpatient basis. A child as young as 12 months old may be able to understand that his/her eye is sick, and certainly an 18- to 24-month-old child will be able to understand this concept. Therefore, it is very important that the parents be honest with their child about what is about to happen. It is also critical to involve siblings of whatever age in the preoperative discussions. Siblings in the 2- to 6-year-old group may engage in “magical thinking,” believing that a previous push or shove of their affected sibling may have caused this problem.

One of the most important considerations when enucleation is part of the treatment plan is the experience of the surgeon with the procedure. Any ophthalmologist without significant experience

doing enucleations for retinoblastoma and harvesting fresh tumor in a manner acceptable to ocular pathology should not assume that these procedures are routine. The implications of technical failures during the surgery may be catastrophic in this subgroup of children. For example, inadvertently opening the globe releases tumor cells into the orbit, greatly increases the risk for metastatic disease. Improper tumor harvesting can compromise *RB1* gene testing, which may have future implications on the child's overall medical care. Finally, a less than ideal cosmetic outcome may have far-reaching social and emotional repercussions for the family and the child. There are also special pediatric anesthesia considerations for children who are undergoing enucleations for retinoblastoma. Presurgical anxiety can be significant, especially in older children, and experienced pediatric anesthesiologists typically use oral Versed (midazolam) in the preoperative holding area. It is often helpful for one of the parents to don a "bunny suit" over their street clothes and carry the child into the operating room. There, while the child is being held in the arms of the parent, mask anesthesia is given until the child can be gently positioned on the operating room table.

## **Surgical Procedure**

Before prepping for surgery, both pupils should be dilated prior to the procedure, so that the presence of the tumor can be confirmed by indirect ophthalmoscopy and the other eye taped and shielded. This step is critical to avoid a tragic error in enucleating the wrong eye. Once the presence of the tumor in the correct eye has been confirmed, the correct eye is prepped and draped. Surgery begins by placing an eyelid speculum for exposure; in general, the widest exposure is preferred, although the tension on the lids may need to be reduced once the globe is removed to allow for closure over the implant. The conjunctiva at the limbus is desiccated with cotton-tipped applicators and outlined with a marking pen to allow for easy identification of the conjunctival edges during final closure. A conjunctival peritomy is started at either the 3 or 9 o'clock positions, and care is taken to preserve as much conjunctiva as possible by "hugging" the limbus with the Westcott scissors. Gentle bipolar cautery may be used on focal points of bleeding from the episclera.

It should be emphasized that meticulous hemostasis maintained from the beginning of the procedure allows the surgery to be precise, and also assures control of postoperative ecchymosis and orbital edema. In addition, care should be taken to avoid undue manipulation and pressure on the globe, and to avoid any maneuvers that may increase the risk of sclera perforation or injury.

Once the conjunctival peritomy has been completed, the Tenon layer is separated from the sclera in the four oblique quadrants, using gentle blunt dissection with the tips of the curved Stevens scissors held parallel with the sclera. Be mindful that vortex veins exit the sclera about 16–18 mm posterior to the limbus. A blunt 20-gauge cannula is then used to infuse local anesthetic (3–4 ml of 1% lidocaine with epinephrine mixed with 0.5% marcaine with epinephrine and Wydase [hyaluronidase]) into the retrobulbar space (typically inferonasally). This maneuver may prevent sudden bradycardia during the rest of the procedure, greatly reduces the amount of bleeding when the optic nerve is transected, and provides postoperative pain control.

The four rectus muscles are then sequentially isolated with muscle hooks, imbricated with a double armed 5-0 Vicryl suture, and transected from the globe at their insertion sites. A suggested sequence of muscle disinsertion follows: (1) inferior rectus, (2) lateral rectus, (3) medial rectus, (4) superior rectus. When passing needles through muscle tissue, the angle of passage should always be parallel or away from the sclera to avoid inadvertent globe perforation. A longer muscle insertion (about 5 mm) is left at the insertion of either the medial rectus or lateral rectus muscles (surgeon's preference) to allow for some traction on the globe (with an Adair clamp) during transection of the optic nerve. As each muscle is disinserted, the ends of the Vicryl suture are secured to the drape with a labeled Steri-Strip to prevent tangling during the rest of the procedure. The superior oblique muscle is then isolated with a muscle hook using a sweeping motion behind the superior rectus insertion, and transected from the globe. The inferior oblique muscle is located in the inferolateral, anterior orbit by sweeping the muscle hook away from the globe toward the orbital rim; this muscle is highly vascular and should be cauterized with bipolar cautery before transection. A visual inspection is then performed of

the anterior and equatorial sclera surfaces to ensure that there are no adhesions remaining between the orbit and sclera (other than the optic nerve).

The scissors chosen to transect the optic nerve varies with the preference of the surgeon. In general, we prefer a pair of slim-profile scissors with long tips that are slightly curved (e.g., long Metz or Metzenbaum scissors). It is our impression that the exaggerated 15-degree curve on the enucleation scissors increases the risk of sclera perforation and reduces the ability to extend the tips into the posterior orbit. Some surgeons utilize an enucleation snare to cut the optic nerve although we do not have a great deal of experience with this instrument because of the induced crush artifact. For similar reasons, we also do not recommend clamping of the optic nerve prior to transection. Another option is to sever the optic nerve under direct visualization through a superior orbital approach, utilizing a small upper lid incision.<sup>301</sup>

### **Long Optic Nerve Stump.**

Certain surgical steps can facilitate obtaining the minimum 15 mm of optic nerve stump recommended in all enucleation cases for retinoblastoma. An Allis Adair artery clamp (same width as the rectus muscle insertion) can be used to exert gentle traction on the globe during this critical step. Our personal experience is that gentle traction applied to the 5 mm of rectus stump will serve to “lengthen” the nerve in the orbit exposed to the scissors. An initial spreading movement adjacent to the optic nerve with the scissors will open the posterior Tenon layer and allow the tips to enter the retrobulbar space. While maintaining tension on the Allis clamp, the scissors tips are mobilized along the medial orbital wall and moved in a vertical motion to palpate the optic nerve. If the surgeon cannot feel the optic nerve with this motion, the nerve may be either below or above the scissors tips due to globe rotation. The surgeon should then find the medial rectus insertion and rotate the globe so that it is located in the correct anatomic position. It should also be kept in mind that the optic nerve follows a temporal to nasal route as it plunges toward the orbital apex. Once the optic nerve is palpated, the tips are opened slightly (with the optic nerve between the tips) and pushed nasally/posterior toward the medial wall. With

the scissors tips pushing toward the posterior belly of the medial rectus muscle, posterior pressure is maintained and the scissors are closed around the optic nerve, transecting the nerve in one decisive motion. The tension on the globe should release at this point, confirming that the optic nerve has been successfully transected. The globe will now move forward and you will note some attachments of orbital fat and soft tissues holding the globe within the orbit. The scissors are then used to gently lyse these attachments fairly close to the globe to avoid cutting any motor nerves within the muscle cone.

After the globe has been removed from the orbit, it is placed on a separate Mayo stand which has been set up with several instruments, including a corneal trephine, small Castro Viejo forceps, and Westcott scissors. Hemostasis within the orbit is obtained with a tonsil ball (i.e., spherical gauze pad) soaked in epinephrine (1 : 1000 concentration) and activated thrombin. An assistant gently holds the tonsil ball within the muscle cone while the globe is prepared for pathologic examination. Another option for hemostasis is to use a test-tube filled with a frozen-slush saline solution to tamponade the orbit. Using the epinephrine soaked tonsil ball (or ice-filled test tube) as a tamponade for approximately 10 minutes results in little postoperative swelling or bruising. There is typically no need for a pressure patch and the dressing can be removed the following day after outpatient surgery.

### **Harvest of Fresh Tumor for *RB1* Testing or Other Research Uses.**

On the Mayo stand, the optic nerve stump should be measured and inspected for any gross pathologic changes. A posterior optic nerve margin is obtained prior to opening the globe to avoid any tumor contamination by artifactual clumps of tumor cells. The posterior stump of optic nerve is prepared by marking the surgical margin with ink, and then transecting the optic nerve with a razor blade 4 mm behind the sclera. This posterior optic nerve margin should be placed into a jar of 10% buffered formaldehyde and submitted separately. The globe is then inspected for any evidence of extraocular tumor extension and the location of the inferior oblique muscle is used to aid in orientation of normal globe landmarks (e.g.,

macula). The location of the base of the tumor is outlined with a marking pen on the sclera, determined either with transillumination or from preoperative fundus drawings. Then, a small sclero-choroidal window is created, adjacent to the tumor base near the equator with a 6- to 8-mm corneal trephine. Once the opening into the vitreous chamber is established, tumor tissue should be gently removed with forceps and scissors. For genetic testing, the sample is sent fresh in saline in a petri dish. Samples of the tumor for research purposes are placed into the appropriate vials and transported immediately to the lab. It is best to leave a hinge on one side of the scleral flap so that it can be closed with one or two suture(s) following the removal of tumor sample. The globe should be placed in a second jar of formalin (separate from the optic nerve stump) and be allowed to fix for at least 24–48 hours before sectioning.

Once the surgeon has completed the handling of the tumor specimen, his/her surgical gloves should be changed before returning to the operating table for the closure. Instruments used to handle the tumor or to open the globe should never be returned to the operative field.

### **Insertion of Orbital Implant.**

A variety of porous and nonporous orbital implants are available to re-establish the orbital volume, including silicone, hydroxyapatite, Medpor, and dermis fat graft. The type of implant chosen depends mainly on the preferences of the surgeon, although there are some important considerations in retinoblastoma patients. Nonporous implants (e.g., silicone spheres) have a lower exposure and extrusion rate, but also have a higher rate of migration in young children than porous implants (e.g., hydroxyapatite, Medpor). Performing an implant exchange later in life is difficult with a porous implant due to the presence of implant ingrowth and therefore a nonporous implant may be a better choice when placing an implant smaller than 18 mm. On the other hand, porous implants such as hydroxyapatite and porous polyethylene (Medpor) offer the potential for better motility, particularly if the implant is pegged later in life to allow coupling with the prosthesis. However, it should be kept in mind that there is no proven motility

advantage for nonpegged porous implants (hydroxyapatite, Medpor) when compared to nonporous implants (silicone). In addition, porous orbital implants have higher rates of implant exposure and infection compared to silicone spheres, as well as higher costs.<sup>302</sup>

We routinely use coated hydroxyapatite implants in our patients as it is easy to work with, has a low rate of migration, and allows the attachment of the extraocular muscles to the anterior surface of the implant. In any child undergoing enucleation, the largest implant that can be reasonably fitted into the orbit should be selected, both to encourage orbital growth and to obviate the need to place a secondary implant when the child grows. In general, an adult-sized 20-mm implant can be placed safely in children older than 2 years of age, while children between 12 and 24 months can be fitted with an 18-mm implant. Children less than 12 months of age may require an 18-mm or 17-mm implant. The implant is soaked in bacitracin solution prior to implantation. The goal is to place the implant as deep into the muscle cone as possible, to minimize postoperative enophthalmos and the risk of anterior implant exposure. This is accomplished by sliding the implant into the muscle cone with the introducer, while applying steady pressure on the surface of the implant.

### **Attention to Surgical Closure and Prevention of Implant Extrusion.**

Once the implant is positioned within the muscle cone and the rectus muscles are attached, the Tenon layer is mobilized over the surface of the implant to ensure that closure can be achieved without undue tension. If the Tenon layer cannot be closed without tension, then the implant is repositioned deeper into the orbit or a smaller implant is chosen. The anterior Tenon capsule is then closed over the implant using buried 5-0 Vicryl sutures (P-3 needle); typically five or six sutures are placed to accomplish a right closure without gaps, which will prevent any postoperative dehiscences of this fascial layer. The conjunctival edges are carefully identified and closed with a running 6-0 plain gut suture. Antibiotic ointment is applied over the socket and a small or medium conformer is then placed to maintain the fornices in the postoperative period. With

the conformer in place, the lids should be able to close. If not, a smaller conformer should be fitted for the patient to prevent discomfort or possible loss of the conformer during the early postoperative period. A double gauze eye patch is adequate as a dressing and we have not found it necessary to place a pressure patch.

### **Postoperative Care.**

Careful attention must be paid to the prevention of nausea, vomiting, and the possibility of an orbital hemorrhage, which will lead to unnecessary discomfort as well as a delay in the healing process. We typically administer intravenous antibiotics, steroids, and a dose of ondansetron (Zofran) or similar agent during surgery. Postoperative pain is controlled for approximately 4 hours by the long-acting local anesthetic infused into the posterior orbit prior to cutting the optic nerve. In addition, appropriate doses of liquid hydrocodone (Lortab) or similar analgesic should be given every 4–6 hours for the first 24–48 hours. We generally discharge the patient after the surgery and see the patient on the first postoperative day for a clinical assessment and dressing change. We instruct the parents to change the patch daily for 7–10 days combined with the application of antibiotic ointment or drops several times per day. We have not found oral postoperative antibiotics to be routinely necessary but some centers advocate their use. Once the postoperative edema has completely resolved 4–6 weeks following enucleation, the patient can be fitted with a prosthesis by the ocularist.

As stated previously, extreme care should be taken to avoid accidental perforation of the globe as this may require additional treatment with associated morbidity. What should the surgeon do if scleral perforation occurs during enucleation of an eye with active retinoblastoma? Surgery should be completed to ensure that the entire globe has been removed, using extreme care to avoid further spillage of the intraocular contents. If the area of tumor exposure is localized, the surgeon should debulk that area of the orbit and send it to pathology as a separate specimen. The socket should then be irrigated with sterile water to encourage hydrolysis of any remaining tumor cells. We would suggest placing a nonporous

implant (e.g., silicone sphere) in case any further socket surgery becomes necessary, although some experts recommend not placing an implant in this situation.<sup>4</sup> The decision to treat the area with local or systemic modalities must be made on a case-by-case basis by the oncology team. If the enucleated globe has high-risk pathology, then systemic adjuvant chemotherapy will be necessary. If the globe does not contain high-risk pathology, the oncology team may still decide to give postoperative chemotherapy to treat any viable cells which may have seeded the orbit. The decision to treat the socket with radiotherapy is controversial and should be considered for those cases with a high risk for orbital recurrence.<sup>303</sup> For example, a patient with a positive optic nerve margin would be expected to have clinically viable disease remaining in the orbit and adjuvant radiotherapy would be indicated. However, surgeons should be aware that orbital radiation given in the first 6 weeks following enucleation will lead to severe socket contracture in all patients and noticeable orbital bone hypoplasia in children less than 18 months of age. There is also concern regarding the association between radiation and second cancers in very young children (<1 year of age) with the germinal form of retinoblastoma. Regardless of the management approach, all of these patients with possible orbital exposure should be carefully monitored with serial MRI scans every 3 months for the first year after enucleation.

Outpatient postoperative care is critical for all children who have undergone enucleation for retinoblastoma, particularly during the first year after surgery. During the first month after surgery, the patient and parents should meet with the oncologist, to discuss the histopathologic findings and their implications. The decision to treat children after enucleation for high-risk pathologic features with adjuvant chemotherapy is controversial. At most centers, 6 months of systemic chemotherapy with a three-drug regimen is recommended for post-laminar optic nerve invasion, massive choroidal invasion, scleral invasion, and anterior segment invasion. The ophthalmologist should be aware that the risk of orbital tumor recurrence is highest during the initial 12 months after enucleation and therefore the prosthesis should be removed and the socket checked for any abnormalities during postoperative visits.<sup>205,299</sup>

Orbital growth following enucleation will be normal if a large

orbital implant is placed in the orbit at the time of surgery and no orbital radiation from an external source is given.<sup>304</sup> However, failure to replace the eye with an orbital implant and failure to maintain the presence of an ocular prosthesis will result in orbital growth deficiency.<sup>305</sup> Imhof and colleagues demonstrated that the growth of irradiated orbits was significantly impaired ( $p < .001$ ) when compared with nonirradiated orbits, and that secondary enucleation did not add to the bony growth retardation triggered by EBR.<sup>306</sup> Not surprisingly, these authors observed the growth-impairing effect of EBR to be most profound when the child is irradiated before 6 months of age ( $p < .01$ ). Orbital growth studies in rabbits show a decrease in orbital growth following enucleation, that was mitigated by an expandable but not static orbital implant.<sup>307</sup> Based on the findings of Fountain et al., growth in enucleated human orbits may be normal if a large but nonexpandable orbital implant is used.<sup>304</sup>

## Regression Patterns Following Treatment

The regression patterns following primary chemotherapy are typically formed after two to three cycles of chemoreduction. They are described in [Table 132.1](#) and guidelines about the need for focal consolidation for each type are also given. The patterns of tumor regression following primary chemotherapy are similar to those that result from treatment with EBR, and the nomenclature used by clinicians is identical. Some tumors develop complete calcification with rapid reduction to type I regression. This favorable response can occur in some tumors by the end of the first cycle of systemic chemotherapy, while others may not develop much calcification by the end of the sixth cycle. Pure type II regression (“fish flesh”, translucent mass) is an uncommon response following primary chemotherapy in our experience. Type III regression (combination of types I and II) is the most common ([Fig. 132.24](#)). Type IV regression is a flat scar, with either atrophic changes, increased pigmentation or a combination of the two. The least common type of regression pattern is type 0 (no visible lesion), but we have observed it in small foveal lesions that were not lasered. As previously mentioned, any active tumor is lasered, with minimum

of three sessions to achieve either a type I or type IV scar. Some type II or III regression patterns may require 15–20 laser sessions to achieve this goal.

**FIG. 132.24** (A–D) Regression patterns I–IV after treatment of retinoblastoma.

Most of the information related to regression patterns in treated retinoblastoma has been reported in eyes treated with EBR. In 1993, Singh and colleagues reported their evaluation of 180 individual tumors in 105 eyes of 83 patients treated at St Bartholomew's Hospital in London with EBR, and found that recurrence of tumor growth was seen in 13/180 tumors (7%), all by 40 months following the end of treatment and none after 4 years.<sup>308</sup> In 1991, the New York experience with 89 tumors in 57 eyes treated only with EBR showed that type II was the most common regression pattern throughout the period of follow-up.<sup>309</sup> The largest tumors showed type I regression and the smallest lesions (1 DD or less) completely disappeared. In 1983, Buys and colleagues from New York reported the regression patterns following cobalt plaque radiotherapy.<sup>310</sup>

They found that type IV regression (a flat scar or bare sclera) in nine of 31 eyes with no recurrence from type IV regression by 6.5 years following treatment. Type I was the most common regression pattern, with fewer type II and III.

Following chemoreduction, Shields et al. reported that type I regression was more common with larger tumors and those closer to the fovea.<sup>311</sup> In our practice, we have not noted a consistent correlation between preoperative factors and the final regression patterns. Shields et al. also noted no differences in recurrence rates between different regression patterns.<sup>312</sup> However, we have noted that the amount of type II regression is a strong predictive factor for future tumor recurrence. Therefore, we perform focal consolidation aggressively to reduce type II or type III regression to type I or type IV; this process should ideally be completed by the end of the six cycles of chemoreduction, but if not, laser treatment is typically continued on a monthly basis until this goal has been achieved.

## New Tumors or Tumor Recurrences During Posttreatment Follow-Up

For ophthalmologists following patients with heritable retinoblastoma, the concern always is whether new tumors may appear, either during or after chemotherapy. In a review of 165 tumors in 57 eyes of 34 patients with heritable bilateral retinoblastoma treated with single agent carboplatin and focal consolidation, 63 new tumors appeared in 27 eyes.<sup>313</sup> The mean age of the patient at the time of tumor presentation was 9 months and the mean time to tumor appearance following carboplatin therapy was 4.4 months. Shields et al. reported that in 162 eyes of 106 affected patients, new tumors occurred in 24% of eyes.<sup>314</sup> Most commonly these new tumors appeared in the eyes of children diagnosed at a very young age or who were members of a pedigree with retinoblastoma. Because these newly appearing tumors have no blood supply, the systemically administered chemotherapy should not be expected to prevent their appearance. There is a recent report suggesting that new tumor formation is almost never encountered following intraarterial chemotherapy, possibly due to higher intraocular drug levels after selective arterial infusion.<sup>315</sup>

Another type of new tumor formation is recurrence following initial response, and this can be classified as edge scar recurrence, main tumor recurrence, or new preretinal tumor formation from vitreous seeding. In our experience, focal regrowth or edge scar recurrence is usually seen within 2–6 months following the completion of chemoreduction (Fig. 132.25). Fortunately, most scar recurrences can be treated successfully with aggressive focal consolidation using laser therapy or cryotherapy, if detected early enough. Serial RetCam images are helpful in determining if a suspicious area is regrowth or persistent type II regression. Early focal regrowth usually appears as a slight elevation that will have a pink blush of fine vascularization, and fluorescein angiography can demonstrate the early lacy hyperfluorescence and late leakage. After the last cycle of chemotherapy, we follow children with EUAs at monthly intervals until laser treatment has been completed. Then we follow patients at 6-week intervals for approximately 6 months given that this is the period of time at highest risk for tumor recurrence. After the 6 month monitoring period, children can be followed according to the screening schedule for new tumors: every 1 month below age 1, every 2 months between ages 1 and 2, and every 3 months between ages 2 and 3. After the child has reached age 3–4 years *and* it has been at least 2 years since the last active tumor was observed, follow-up can be transitioned to the office setting. In the office, we examine these children with indirect ophthalmoscopy of the fundus (without a speculum) as well as ultrasound B scan of the peripheral retina. It is unlikely that you will see small tumors in the periphery that are small enough to treat with focal modalities without EUA, but the risk of new tumors is extremely remote when these recommendations are followed.

**FIG. 132.25** (A) Type IV regression after primary chemotherapy and focal laser consolidation. (B) Edge recurrence seen 3 months later.

## Late Effects of Treatment

The late effects of treatment are of major concern to parents and to affected children, as well as to the ophthalmologist who follows these children as they become teenagers and young adults. There are several major studies examining these late effects, which we will summarize. In 1991, 99 German patients treated for retinoblastoma between 1965 and 1982 were reviewed to determine the late effects of treatment.<sup>316</sup> The median age of these 99 patients was 16 years (range 6–27 years) and the median length of follow-up was 15 years (range 6–27 years). In 2001, a series of 21 Israeli retinoblastoma patients treated in Haifa between 1976 and 1994 were described.<sup>317</sup> In this series, the median age of follow-up was 12 years; 13 of the 21 patients were treated with EBR and eight with chemotherapy. In 1996, Imhof and colleagues reported the late orbital effects of radiation in their Dutch series of 68 patients treated with EBR.<sup>306</sup> Radiation alone was given to 77 orbits and both radiation and enucleation to 43. Mean follow-up in the Dutch patients was 5 years 5 months (range 1–20 years). In 2003, an Australian series from Melbourne described 47 eyes treated with EBR between 1965 and 1997, with at least 2 years follow-up.<sup>284</sup>

### Bony Hypoplasia of the Midface (Orbit)

The late effects of enucleation combined with EBR, either before or after surgery, create the most significant cosmetic deformities in

retinoblastoma patients, manifesting as deficient growth of the orbital bones and atrophy of the conjunctiva and soft tissues of the socket. The difference in the anatomy as teenagers and adults is striking when growth of irradiated orbits is compared with the growth of nonirradiated orbits.<sup>306</sup> The age of the child when radiation is given influences the extent of the growth retardation, and for this reason any EBR should be avoided if possible in a child less than 12 months of age. Enucleation by itself does not appear to have an additive growth retarding effect on the orbital bones, despite the concern regarding small orbital implants in young children undergoing enucleation. In the German patients, 72 eyes were enucleated without radiation; the cosmetic outcome was significantly better in those eyes than in 28 patients who received EBR plus enucleation.<sup>316</sup> In the Israeli series, 12 of 13 patients treated with EBR had significant hypoplasia of the bony orbit.<sup>317</sup> In the Australian series, growth arrest of the orbital bones was a significant late effect.<sup>284</sup> Orbital reconstruction is difficult in these patients because of the deficiency of a blood supply in the orbital region following radiation. In a report from China, reasonably good results were reported with a hydroxyapatite onlay bone graft substitute covered with a vascularized pedicle flap.<sup>318</sup> Other approaches have been used including free grafts transfer with microvascular anastomoses but with varying success.<sup>319</sup>

## **Radiation Cataract**

Tolerance levels of ocular structures vary greatly. The lacrimal gland, cornea, and conjunctiva can each tolerate up to 50 Gy (5000 rad) of radiation, while the retina tolerates 45 Gy or less. The sclera is the most resistant, tolerating >500 Gy. The most sensitive ocular structure is the lens. Radiation cataract following EBR was discussed in detail by Schipper.<sup>320</sup> The minimum cataractogenic dose was 5.5 Gy and the maximum noncataractogenic dose was 11 Gy in Verhoeff's early treatment using orthovoltage.

A 1996 study compared two different EBR techniques: an anterior lens-sparing electron beam technique and a modified lateral beam technique.<sup>321</sup> The authors reported an overall incidence of cataracts of 22% and no difference in cataract development between the two groups. The system of stabilizing the eye with a vacuum contact

lens developed by Schipper and colleagues reduced the number of eyes that develop surgical radiation cataracts.<sup>287,322</sup> In a series reported from Jerusalem, 20% of irradiated eyes developed cataract.<sup>323</sup> This was similar to the rate of 3/13 eyes (23%) in the Haifa series that developed radiation cataract.<sup>317</sup>

In December 1990 the Wills Eye Hospital experience with the treatment of cataracts and retinoblastoma was reported.<sup>324</sup> A total of 42 eyes in 38 patients had cataract surgery. One eye developed retinal detachment, four had amblyopia, and three developed tumor recurrence, one with extension of retinoblastoma into the subconjunctival space through the sclerotomy. Appropriate timing for cataract removal in retinoblastoma patients has not been documented or verified in the literature. Most centers wait at least 2 years after the eye demonstrates inactive disease to prevent tumor spreading outside the eye as a result of surgery.

## **Radiation Retinopathy**

Radiation retinopathy is a dose-related complication and can present as both retinal and choroidal infarcts.<sup>325</sup> In a series reported from Israel, 12% of radiated eyes developed radiation retinopathy that was first detected 11–72 months (mean 37 months) following treatment.<sup>323</sup> The total dose required to control retinoblastoma is believed to be between 36 and 42 Gy, which is close to the threshold for radiation retinopathy. Other clinical factors may predispose the patient for retinal toxicity, including young age (age <1 year) and concomitant treatment. Although actual data is scarce, the risk of radiation retinopathy is probably increased if brachytherapy or EBR is given immediately following systemic or intraarterial chemotherapy. In a 1996 report from London, 28 eyes were treated with two cycles of CEV chemotherapy followed by 40–44 Gy EBR followed by two additional cycles of triple-drug chemotherapy. There does not seem to have been significant radiation retinopathy in this series.<sup>195</sup> However, we continue to recommend temporizing patients for 2–3 months following chemotherapy before starting EBR to reduce the risk of radiation retinopathy.

Radiation retinopathy has also been described following primary brachytherapy, but tends to occur in proximity to the location of the primary tumor.<sup>326</sup> However, we have also seen widespread

exudative retinopathy causing a complete serous retinal detachment several years following brachytherapy of a macular tumor. Given the extensive treatment that these eyes receive, clinicians should expect a high rate of ocular side-effects with both brachytherapy and EBR in the retinoblastoma population. Management options for radiation retinopathy remain very limited, as anti-VEGF therapy for macular edema is an unproven treatment in this setting, and only an option for those eyes that have been quiescent for a minimum of 2 years.

## **Second Malignant Neoplasms (SMN)**

Long-term studies demonstrate a consistent association between high-dose EBR used to treat intraocular retinoblastoma and the appearance of SMNs in the field of radiation.<sup>202,203</sup> Patients who have bilateral retinoblastoma treated with EBR also develop second malignancies outside the radiation field, such as breast cancer and uterine cancer. Therefore, the single most important factor in determining a patient's lifetime risk of developing a second cancer is a history of radiation treatment in the setting of heritable disease. Another important factor is age of treatment, with the highest risk for those patients who were treated in the first 12 months of life.<sup>327</sup> A third factor is the dose of radiation used, with the highest risk of SMN for those patients who received EBR before the era of dose reduction. There was one report suggesting that the use of older alkylating agents may contribute to the risk for certain SMNs, independent of the history of radiation treatment.<sup>328</sup>

The tissue specificity and relatively short time to radiation-induced solid tumor in hereditary retinoblastoma survivors are, according to Strong and colleagues, consistent with the radiation effect in a predisposed cell.<sup>181,329</sup> François cites more than 300 cases of sarcomas arising in radiated bones, with a latent period of between 3 and 30 years.<sup>330</sup> The tumor types seen in SMNs vary greatly, but up to 80% are osteogenic sarcomas, leiomyosarcoma, and malignant fibrous histiocytoma.<sup>202,203,331</sup> The tumors appearing out of the field include osteosarcomas, breast carcinoma, cutaneous melanoma, and uterine cancers. Other tumor types include renal cell carcinoma, Ewing's sarcoma, carcinoma of the tongue, and medulloblastoma.

All these cases fit the criteria of Cade as radiogenic neoplasms.<sup>332</sup> Approximately 75% of all SMNs in retinoblastoma patients occur in radiated areas. In the July 1993 issue of the *Journal of the National Cancer Institute*, Eng and colleagues provided follow-up on 1000 patients with retinoblastoma treated in New York and Boston.<sup>16</sup> A total of 35% of bilaterally affected retinoblastoma patients treated with EBR will have died of a second malignant neoplasm by 40 years after diagnosis. Only 6% of the bilaterally affected patients not treated with EBR met the same fate. In a review of 215 patients with bilateral retinoblastoma from the Armed Forces Institute of Pathology (AFIP), the 30-year cumulative incidence of SMNs for 137 patients receiving radiotherapy was 35% compared with a cumulative incidence of approximately 6% for 78 patients (5/78) who did not receive radiation.<sup>333</sup> Among those patients who did receive radiation, the incidence rate was 29% inside the radiated field and 8% outside the field. In this study, the incidence rate outside the radiated field was not significantly different from the rate reported for patients who did not receive radiation.

Appropriate surveillance for second primary tumors involves the parents performing weekly examinations of their at-risk children searching for foci of pain, tenderness, or swelling. It has been suggested that susceptible patients have body scans every year. However, bone scans deliver radiation to the patient, and yearly full body MRI scans are costly over a child's lifetime. We have the experience of a child having a completely normal MRI scan only 4 months prior to first symptoms of a SMN. Given the lack of convincing data, routine surveillance scanning for SMN is probably not indicated.

Among patients who eventually develop SMNs, the common finding was that symptoms were present for several months before the diagnosis was suspected. We believe in the importance of educating parents to be aware of nodules, pain in the joints or skull, lumps on the skull, or pain in the extremities that does not resolve in 5–7 days. Such signs or symptoms should prompt a visit to the pediatrician or primary care specialist with an accompanying statement that the child is at high risk for bone cancer and should be examined. Early diagnosis of SMNs can be associated with a good outcome. We have one patient who has survived 17 years

after diagnosis of an osteosarcoma of the greater wing of the sphenoid.

The risk for death from SMNs in patients who are genetically predisposed at 40 years after diagnosis of retinoblastoma has been reported 6% if their retinoblastoma was not treated with EBR and 35% if EBR was used.<sup>16</sup> Data from the Utrecht registry of all cases in the Netherlands from 1945 to 1977 demonstrated that the cumulative risk at 25 years was 22% compared with the 50% risk published by Abramson. Because high doses of EBR were used in earlier studies the incidence of SMN among patients treated in the last 15 years may be smaller.<sup>201</sup>

## Metastatic Retinoblastoma

### Risk Factors

The risk of extraocular disease after enucleation or globe-conserving treatment is very low in developed countries, ranging between 0% and 4%.<sup>299,334</sup> As previously reviewed, group E eyes have the highest rate of metastatic spread and therefore enucleation is recommended to minimize this risk. Specific clinical features that have been shown to increase the risk of metastasis include the presence of a group E tumor, rubeosis iridis, neovascular glaucoma, and clinical symptoms for greater than 6 months prior to diagnosis.<sup>232</sup> As previously mentioned, there are histopathologic features that have been classified as “high risk” features, and published rates of metastasis have been estimated from the literature.<sup>210</sup> There is consensus that patients with a positive optic nerve margin and scleral invasion require aggressive postenucleation treatment to reduce the risk of metastatic disease. The vast majority of centers also treat patients with tumor invasion of the optic nerve posterior to the lamina cribrosa, although some centers follow these patients and treat the approximately 10% of patients who relapse with aggressive multimodal chemotherapy.<sup>335</sup> Patients with isolated massive choroidal invasion (>3 mm in thickness) represent a very controversial group for adjuvant treatment, as only 6% of patients with this feature will relapse.<sup>210</sup> Patients with massive choroidal invasion combined with any degree of optic nerve invasion should receive adjuvant treatment as

their risk or relapse is greater than 10%.<sup>210</sup>

The onset of metastatic disease is variable, but most cases have been diagnosed by 3 years of age.<sup>336</sup> Metastases are most commonly seen in the bones or bone marrow, paranasal sinuses, salivary glands, lymph nodes, subcutaneous tissue, liver, spleen, lungs, testes, and CNS.<sup>337-340</sup> The prognosis of patients with metastatic disease depends a great deal on whether or not the CNS is involved with metastatic spread.<sup>341</sup> There have been few, if any, survivors once metastatic retinoblastoma involves the CNS. In contrast, if only bone marrow and bone are involved recent reports provide some measure of hope with myeloablative therapy, bone marrow transplant together with focal radiation to bulky disease.<sup>341</sup> Before the introduction of bone marrow rescue techniques, the length of survival after diagnosis of metastatic retinoblastoma varied from 6 to 12 months. However, there have been encouraging reports that high-dose multimodal chemotherapy combined with bone marrow rescue have been associated with long-term survival.<sup>341-345</sup>

## **Orbital Retinoblastoma**

Extraocular disease at presentation is extremely rare in developed countries. When the diagnosis of intraocular retinoblastoma is delayed, the natural history of intraocular retinoblastoma involves eventual extension through the eye wall into the orbit then to regional lymph nodes with eventual metastatic spread. These patients will present with evidence of orbital retinoblastoma at diagnosis, with proptosis, orbital inflammation, and evidence of an orbital mass on imaging studies. We have also seen rare cases of direct CNS extension and CNS metastatic disease at presentation. The risk for extraocular disease strongly depends on the delay in diagnosis in the setting of advanced intraocular disease. In developing countries where primary medical care is not universally available, many retinoblastoma cases present with extraocular disease.<sup>335</sup>

It is important to understand that the majority of patients who present with orbital retinoblastoma have regional or distant metastatic disease, and therefore require a systemic approach as well as aggressive treatment of the orbital component. Chantada and his colleagues from Argentina reported 84% had 5-year event-

free survival when orbital retinoblastoma was treated with primary chemotherapy, limited excision, and orbital radiation.<sup>335,346</sup> We agree with these authors that orbital exenteration is not necessary for these patients, and surgical management has a limited role. We recommend systemic chemotherapy and orbital radiotherapy after an incisional biopsy to confirm the diagnosis. Debulking of large tumors in the orbit may lessen the tumor burden, but often there is dramatic regression with the institution of systemic chemotherapy and orbital radiation.

### **Retinoma (Retinocytoma)**

A benign form of retinoblastoma, initially described by Gallie et al. as a “retinoma,” presents as a translucent lesion with some calcification and underlying pigmentary changes.<sup>347,348</sup> The “retinocytoma” has been introduced by other authors.<sup>349,350</sup> Histologic studies have shown that this is a benign variant of retinoblastoma and not a regressed retinoblastoma. Retinomas are typically diagnosed on routine fundus evaluations of healthy patients, or on screening examinations of family members of a patient with retinoblastoma. The typical fundus appearance is a gray translucent mass containing calcified nodules and surrounded by retinal pigment clumping and atrophy. We have seen patients with retinomas and benign vitreous “seeding” that do not change on follow-up exams, and other authors have had similar observations. Lueder and colleagues have described two patients with retinomas and vitreous seeding that were followed for 8 and 33 years, respectively, without evidence of disease progression or transformation.<sup>351</sup> Histopathologic examination shows benign-appearing round blue cells in a bed of well-vascularized ground substance with calcific foci. There are no mitoses, cellular pleomorphism, nuclear atypia, rosettes, or other characteristics of malignancy.

The retinoma or retinocytoma has benign histopathologic features but may rarely retain the ability to undergo malignant transformation into a rapidly growing retinoblastoma.<sup>352</sup> Histologic description of a malignant transformation event was described in a 24-year-old woman from Lausanne.<sup>353</sup> Eagle and colleagues reported a case of a 7-year-old child from Philadelphia who was

seen at age 4 years and found to have a typical retinoma. Three years later the tumor suddenly grew rapidly and seeded the vitreous, leading to loss of the eye.<sup>352</sup> The possibility for malignant transformation underscores the need for close follow-up of these patients. If the retinoma is peripheral, we consider performing careful laser treatment to flatten the lesion, which should reduce the risk of malignant transformation.

There are occasional retinoblastomas which regress into tumors that resemble retinomas, both clinically and histopathologically. In addition, there may be areas of retinoma formation in patients who present with untreated retinoblastoma. These “presumed” retinomas appear gray and translucent, much like the lesion described by Aaby and colleagues.<sup>349</sup> The lesions we have seen resemble type II or III regression, and have translucent portions and cystic spaces (Fig. 132.26). Sequential direct laser photocoagulation can be used to knock the lesions down to a flat scar (type IV regression), but we would recommend documenting progressive growth of these lesions before considering enucleation or radiotherapy.

**FIG. 132.26** (A) Presumed retinoma. Appearance is similar to type II regression prior to any treatment. (B) After focal laser consolidation it begins to regress. (C) Several laser treatments later the tumor is nearly flat.

## Diffuse Infiltrating Retinoblastoma

In the rare and atypical form of retinoblastoma called diffuse infiltrating retinoblastoma, no mass forms in the eye (Fig. 132.27). Instead, the tumor expands by diffusely infiltrating the retina, causing irregular thickening. In this form of atypical retinoblastoma, calcification is not commonly seen. In one review, only four of 28 diffusely infiltrating retinoblastomas demonstrated the presence of intraocular calcium.<sup>354</sup> As a result, neither ocular ultrasound nor CT scanning may be helpful in making this diagnosis as both imaging methods reveal diffusely thickened retina.<sup>355</sup> MRI may provide useful information in some cases.<sup>356</sup>

**FIG. 132.27** Diffuse infiltrating retinoblastoma. (A) Unusual tractional and exudative retinal detachment in a 4-year-old. (B) B-scan ultrasonography showed no calcium. (C) Fluorescein angiogram resembles Coats disease. (D) Histopathology revealed retinoblastoma involving the entire retina. Subretinal fluid and exudate was present.

Although rare, the diffusely infiltrating retinoblastoma is a frequent cause of misdiagnosis. The classic presentation is unilateral uveitis or retinal detachment in an older child without any previous history, although authors from Taiwan reported one hereditary case.<sup>357</sup> The eye is often red and may present with a pseudohypopyon, nodules on the surface of the iris or in the anterior chamber, and/or endothelial tumor nodules resembling keratic precipitates. The vitreous is frequently hazy, and exudates may cover the peripheral retina. The retina may appear gray, infiltrated, and thickened. This type of retinoblastoma can also

present with a hyphema.<sup>355,357,358</sup> Grossniklaus et al. reported an anterior variant where the only tumor focus was in the anterior retina.<sup>359</sup> Because of the late diagnosis in most of these cases, enucleation is the treatment of choice in the management. Since the lesion grows within and destroys the sensory retina, little is gained by attempts to salvage the eye. Systemic prognosis after enucleation is generally excellent.<sup>360,361</sup>

## Retinoblastoma in Older Children

Almost 90% of all cases of retinoblastoma in the United States are diagnosed before the patient is 5 years old.<sup>362</sup> However, newly diagnosed cases have been reported at ages 7–15 years, and in adults.<sup>363–365</sup> In our experience, it is not uncommon for children to be diagnosed with advanced unilateral retinoblastoma between 7 and 8 years of age. The persistence of a rare embryonal retinal cell has been proposed as one explanation for this rare onset of retinoblastoma at an advanced age.<sup>365</sup> An alternative explanation is that a retinoma or retinocytoma that occurs early in life may be unrecognized until it undergoes malignant transformation.<sup>350,352,366</sup> In 400 consecutive retinoblastoma patients, 26 were found to be 5 years of age or older at the time of initial diagnosis.<sup>367</sup> In that series, all of the older children had sporadic, unilateral retinoblastoma.

The clinically important aspect of retinoblastoma presenting in older children is that misdiagnosis is common. Five of the 26 children had vitrectomy prior to the diagnosis of retinoblastoma.<sup>367</sup> The authors suggest that clinicians should consider the possibility of retinoblastoma in children who have unexplained vitreous hemorrhage or atypical endophthalmitis or uveitis. Because of the advanced nature of the unilateral disease in these older children, almost all the cases have group E disease and therefore require enucleation.

## Trilateral Retinoblastoma (Primitive Neural Ectodermal Tumors, Pinealoma)

The term trilateral retinoblastoma (TRB) classically refers to the association of bilateral intraocular retinoblastoma with a pineoblastoma, a primitive neuroectodermal tumor that arises in

the pineal gland. The link between intraocular retinoblastoma and an ectopic, intracranial malignancy was first recognized in 1977 by Jakobiec and colleagues.<sup>368</sup> In 1980, Bader et al. reported a series of 10 children with bilateral RB who developed another primary malignancy in the pineal gland, and the term trilateral retinoblastoma was associated with this diagnosis.<sup>369</sup> Histopathologically, the intracranial tumor in TRB resembles PNET, with varying degrees of neuronal and photoreceptor differentiation. One explanation for the development of TRB is that the retina and the pineal gland have a common embryologic origin, and there may be vestigial photoreceptor elements in the pineal gland. In lower animals the pineal gland functions as a photoreceptor organ and is sometimes referred to as the “third eye.” In the literature there is some dispute regarding the cell of origin for TRB, and more recent studies suggest that the tumor may arise from the germinal layer of primitive cells (subependymal plate) rather than the pineal gland.<sup>370,371</sup> For that reason, some authors refer to the intracranial tumor in retinoblastoma patients as a pineal neuroblastic tumor (PNT) rather than a pineoblastoma.<sup>372</sup>

Although TRB was classically defined as a patient with bilateral retinoblastoma who develops a tumor in the pineal region, in a minority of TRB cases the intracranial tumors are in suprasellar or parasellar locations. These ectopic tumors at the skull base are referred to as ectopic intracranial neuroblastic tumors (or EINT).<sup>372</sup> When comparing the age of presentation, EINT patients appear to develop earlier than those children with PNT.<sup>372</sup> There are also reports of patients with heritable, unilateral retinoblastoma who have developed midline intracranial tumors. These TRB patients with heritable, unilateral RB appear to be more likely to develop EINT than PNT.<sup>370</sup> There are also rare cases of siblings of patients with retinoblastoma who developed TRB without having clinical evidence of an intraocular tumor.<sup>370</sup> In all cases of TRB, the midline intracranial malignancy appears to represent a focus of multicentric tumorigenesis in patients with the *RB1* cancer predisposition syndrome. There does not appear to be a specific genetic mutation in the retinoblastoma gene that predisposes to the development of TRB. Based on the clinical spectrum of TRB in the literature, it is probably appropriate to refer to TRB as the association of a midline

intracranial malignancy and the heritable form of retinoblastoma.<sup>371</sup>

## Incidence

The overall incidence of TRB has been estimated to be 3% of all patients with retinoblastoma, up to 5–6% for patients with bilateral RB, and as high as 10–15% of patients with familial RB.<sup>370,373</sup> TRB used to be a major cause of death from retinoblastoma during the first 5 years of life.<sup>374</sup> In recent years, with the more widespread use of chemoreduction and decreased utilization of external beam radiation for patients with bilateral RB, the incidence of TRB appears to be decreasing. A series of 99 patients with bilateral or familial RB treated with systemic chemotherapy at the Will's Eye Hospital did not develop TRB, with at least 4 years of follow-up.<sup>374</sup> Based on this series, the authors postulated that patients with the genetic form of retinoblastoma who receive systemic chemotherapy for their intraocular disease are protected against the future development of TRB. An alternative explanation is that the reduced use of EBR and its related oncogenic effects in patients with the *RB1* mutation correlates with the decreased incidence of TRB. The majority of TRB patients in the literature prior to 1995 received EBR to one or both eyes,<sup>371,375</sup> while essentially the same patient population with bilateral RB was treated with systemic chemotherapy after the mid-1990s.

## Clinical Presentation

The mean age at diagnosis of TRB is between 26 and 40 months, with a range of 1–142 months.<sup>371,372,376</sup> Overall, 89% of TRB patients have bilateral RB, and 11% have unilateral, heritable RB.<sup>371</sup> Among all cases of TRB, 43–68% have a positive family history of retinoblastoma.<sup>372,376</sup> Patients with TRB are usually diagnosed with intraocular retinoblastoma by 5–8 months,<sup>372,373,376</sup> which is earlier than the average age of diagnosis for bilateral RB (i.e., 1 year of age). This may indicate a more clinically and biologically aggressive disease in these patients with TRB, or perhaps indicate a greater percentage of familial cases in the group of patients who develop TRB. Typically, the intracranial tumor is diagnosed asynchronously with the intraocular tumor, with the interval between the diagnosis of bilateral RB and the diagnosis of the brain tumor being an

average of 20–33 months.<sup>371–373,376</sup>

At diagnosis, a minority of TRB patients are asymptomatic, discovered on routine neuroimaging studies,<sup>371</sup> but most have signs of elevated intracranial pressure (ICP). Presenting signs and symptoms of increased ICP include headache, nausea, vomiting, anorexia, lethargy, somnolence, gait disturbances, increased head circumference, and of course papilledema.<sup>371,376</sup> When retinoblastoma patients are diagnosed with an intracranial malignancy, it can occasionally be difficult to distinguish TRB from intracranial metastatic disease, although the latter tends to present with leptomeningeal disease. The critical factor is whether the optic nerve in the most involved eye has evidence of postlaminar infiltration on pathology; if not, then the intracranial lesion is most likely TRB. If a biopsy is performed, there may be certain histopathologic features that may be helpful in identifying TRB. For example, in about one-third of cases of TRB, there can be evidence of tumor differentiation such as Flexner–Wintersteiner or Homer Wright rosettes, which is extremely unusual for metastatic disease.<sup>368</sup> However, CNS metastases and TRB are treated with a similar approach so a diagnostic biopsy is not an absolute necessity if the determination cannot be made on clinical grounds.

## Screening

Screening recommendations for TRB are somewhat controversial, mainly because of the low incidence of TRB and the need for anesthesia for performing MRI in this population. Approximately one-quarter of TRB patients are diagnosed on routine screening, typically within the first 3 years after diagnosis of retinoblastoma. Meta-analysis of published TRB cases has found that tumors diagnosed on routine screening tend to be smaller than those found in symptomatic patients.<sup>372,377</sup> Patients diagnosed with TRB on routine screening also tend to survive longer,<sup>370–372,377</sup> although age of death appears to be the same for both symptomatic TRB patients and those found on screening.<sup>372</sup> It has been suggested that this advantage in survival may be due to lead time bias.<sup>378</sup> Given the relatively short interval between the diagnosis of retinoblastoma and the occurrence of TRB, routine screening would likely detect the majority of cases within several years. One review study found

that 89% of TRB patients developed the intracranial tumor within 4 years of the intraocular tumor diagnosis.<sup>370</sup> On the other hand, the clinician has to consider the costs of screening, the necessity of general anesthesia for performing neuroimaging in these young children, and the occasional unnecessary intracranial biopsies performed on benign lesions found on routine neuroimaging.<sup>378</sup> Not infrequently, asymptomatic children with retinoblastoma will have a cystic lesion in the region of the pineal gland identified on routine neuroimaging studies. Neuroradiology expertise is required in assessing the risk of malignancy for these patients with pineal cysts, and neurosurgical consultation should be requested. If the lesion is predominantly cystic and less than 1.5 cm in diameter, neurosurgical biopsy can be avoided in the vast majority of cases and the patient followed carefully with repeat imaging.

In modern retinoblastoma centers, MRI is generally performed at diagnosis to rule out the concurrent presence of orbital or intracranial disease. There is not universal agreement on how often subsequent neuroimaging should occur and when it should be discontinued. The patients at highest risk for TRB are those children with bilateral disease or a positive family history. Therefore, screening programs should be directed at children with bilateral retinoblastoma and those unilateral patients with a positive family history, during the first 3–4 years after the diagnosis of retinoblastoma. A schedule of neuroimaging every 3 months for 2 years, every 4 months the next 2 years, and every 6 months for the next 5 years has been proposed.<sup>371</sup> Another author has suggested screening every 3 months during the first year after diagnosis of retinoblastoma, and at least two times a year for the next 3 years.<sup>372</sup> At our center, we perform neuroimaging every 6 months in bilateral children and unilateral patients with a positive family history until the child is 3–4 years of age as a routine screening protocol. For all children with the *RB1* mutation, CT scans should be avoided to minimize low-dose radiation exposure.<sup>373</sup>

## Treatment

The overall prognosis for TRB is poor even with aggressive treatment, as patients usually die of disseminated neuroaxis disease within the first year after diagnosis. The average survival time after

diagnosis of TRB is 6–11 months, regardless of the location of the intracranial tumor.<sup>371,373,377</sup> With an aggressive multimodal treatment approach (chemotherapy, surgery, radiation), a minority of patients can be cured. One series found that treatment appears to prolong survival from 1.3 to 9.7 months.<sup>376</sup> There appears to be no difference in survival time between patients with tumors in the pineal region versus the sella region.<sup>370</sup> Although the location of the intracranial tumor does not affect survival, tumor size greater than 15 mm appears to be a critical size for tumor dissemination. In 1999 Kivela published a meta-analysis of 106 cases of TRB published in the medical literature from 1966 to 1998. Only five patients were event-free survivors at 10–168 months and all of the survivors had tumors less than 15 mm detected via screening.<sup>372</sup>

The mainstay of therapy for TRB is intensive cisplatin-based therapy (with other agents) and autologous stem cell rescue. Aggressive chemotherapy used to be followed by craniospinal irradiation (e.g., 36 Gy with boost to pineal gland to 59 Gy) in many TRB patients.<sup>379</sup> Spinal metastases are very common in TRB, being present in 69–89% of cases at autopsy.<sup>371</sup> However, there are serious long-term toxicities of craniospinal radiation in the very young child. Therefore, current strategies are directed toward avoiding irradiation and using intensive chemotherapy followed by autologous stem cell rescue. In 2010 Dunkel and colleagues published a multicenter series of 13 patients treated with high-dose chemotherapy and autologous hematopoietic stem cell rescue, at a median time from diagnosis of TRB of 5 months (range from 4 to 9 months). In this series, five patients achieved event-free survival with a median follow-up time of 77 months from diagnosis TRB (range 36–104 months). Interestingly, four of the five patients who have achieved event-free survival had tumors that were at least 2 cm in diameter, and none of the event-free survivors received EBR. Surgical resection may play a role in certain cases if the intracranial disease is not disseminated<sup>380</sup> (Fig. 132.28).

**FIG. 132.28** Gadolinium-enhanced magnetic resonance imaging of a 3-year-old boy with trilateral retinoblastoma. (A) Before treatment, showing tumor in pineal region. (B) After tumor excision.

**Natural History**

**Treatment**

**Pathology**

**Systemic and Familial Involvement**

**Genetics**

## Introduction

Cavernous hemangioma of the retina is a rare vascular hamartoma. The tumor is composed of clumps of dark intraretinal aneurysms that demonstrate a characteristic “cluster-of-grapes” appearance. It is usually unilateral and rarely increases in size. The hemangioma is almost always asymptomatic, although mild visual disturbance as a result of macular involvement or vitreous hemorrhage has been

reported occasionally. Patients with this hamartoma may also have hemangiomas involving the skin and central nervous system. Several pedigrees with varying manifestations of the retinal and systemic characteristics have been reported consistent with an autosomal dominant pattern of inheritance.

## Clinical Findings

Retinal cavernous hemangiomas are composed of clusters of saccular aneurysms filled with dark blood. There is no intervening retinal tissue between the aneurysms. The aneurysms range in size from microaneurysms to a half-disc diameter (DD).<sup>1</sup> The typical tumor is isolated, 1–2 DD in size, and resembles an intraretinal cluster of grapes ([Fig. 133.1](#), see also [Fig. 133.2](#)).<sup>2,3</sup> However, the clinical appearance can be quite variable, ranging from a single aneurysm to a wide distribution over the entire fundus or following the course of a major vein (see [Fig. 133.3](#)). Commonly, layering of the red blood cells within the aneurysms causes a plasma–erythrocytic separation that has been called a “pseudohypopyon.” Often a white or gray fibroglial membrane covers the surface of the tumor (see [Fig. 133.3A](#)). The adjacent retinal blood vessels appear unaffected by the tumor, with no evidence of feeder vessels. Although a mild lipid exudate has been reported adjacent to the hemangioma in one case,<sup>4</sup> exudation from the tumor is extremely rare either at presentation or with long-term follow-up. The slow circulation through the aneurysms is responsible for the lack of exudation of lipid or fluid.

**FIG. 133.1** Cavernous hemangioma of the retina. Note the layering of blood within the large aneurysm. Visual acuity is 20/20, and the patient is asymptomatic.

**FIG 133.2** Cavernous hemangioma of the optic nerve head. Note the characteristic cluster of grapes appearance. Visual acuity was 20/15.

**FIG. 133.3** (A) Involvement of the veins in addition to the capillaries. (B) Note extensive empty shells of the cavernomas in the vicinity of the veins that do not fill with fluorescein. (Courtesy of Stephen J. Kim, MD, reproduced with permission from Agarwal A, editor. Gass' atlas of macular diseases, 5th edition.

Elsevier Inc. 2012.)

Retinal cavernous hemangiomas are symptomatic when they are located in or adjacent to the macula which has been reported in approximately 10% of the cases in the literature.<sup>1,5,6</sup> In these cases, visual acuity can be decreased on the basis of both tumor location and amblyopia. Visual disturbance can also result from vitreous hemorrhage. Cavernous hemangioma can cause simultaneous subretinal, intraretinal, and preretinal hemorrhage (Fig. 133.4). Although vitreous hemorrhage has been reported in 10% of retinal cavernous hemangiomas, it is usually minimal and unassociated with long-term loss of visual acuity.<sup>1</sup> However, vitreous hemorrhage, if it occurs in a child, may cause amblyopia.<sup>7</sup> One patient who presented at birth with hyphema and vitreous hemorrhage suffered recurrences over 52 years eventually requiring enucleation for glaucoma and pain.<sup>8</sup> The tumor extension into the ciliary body in this case was the cause of the recurrent hyphemas.

**FIG. 133.4** (A) Patient with a combined preretinal, intraretinal, and subretinal hemorrhage. (B) When the blood cleared, a typical cavernous hemangioma of the retina could be seen. (Courtesy of Lawrence Yannuzzi, MD.)

Cavernous hemangiomas have also been reported to be located on the optic nerve head.<sup>9-11</sup> These tumors have a clinical appearance similar to the retinal lesions (Fig. 133.2). An enlarged blind spot may be demonstrated on the visual field, but visual acuity is normal. Gündüz et al.<sup>12</sup> described a patient with a cavernous hemangioma in the superonasal quadrant of the fundus and unilateral decreased visual acuity, with associated red–green color defect. Cone response and 30-Hz flicker responses were nearly absent. More recently, a 22-month-old child with unilateral macular cavernous hemangioma was noted to also have peripheral nonperfusion in both eyes on wide-field angiography. Whether this is a true association or a coincidence was not able to be determined.<sup>13</sup> The present understanding is that cavernous hemangiomas are isolated ocular lesions except in familial cases where they are associated with cavernomas in the brain, and very occasionally in the spinal cord.

## Differential Diagnosis

The characteristic appearance of a retinal cavernous hemangioma is rarely confused with other conditions. Retinal telangiectasis can have a similar appearance, and several authors have suggested that

older cases of cavernous hemangioma were mistakenly called Coats' disease or Leber's military aneurysms.<sup>3,9,14</sup> The lack of intraretinal exudate distinguishes this tumor from Coats' disease, but the differentiation from Leber's can be more difficult. Gass points out that the retinal telangiectasis of Leber's military aneurysms is a progressive condition affecting the integrity and structure of the "intrinsic" vasculature, whereas the cavernous hemangioma is a sessile tumor projecting from and partly isolated from the retinal blood vessels.<sup>8</sup> On the other hand, Giuffre<sup>15</sup> reported a case with a cavernous hemangioma and retinal telangiectasis closely located in the same eye, suggesting a relation between these two developmental conditions. Telangiectatic or microaneurysmal vascular dilation can also be seen as late sequelae in branch vein occlusions and diabetic retinopathy but should be easily differentiated from retinal cavernous hemangioma by the associated features.

Cavernous hemangioma can be distinguished from retinal capillary hemangioma (von Hippel disease) relatively easily. The capillary hemangioma is a discrete tumor with characteristic feeder and draining vessels. It is often accompanied by adjacent lipid exudate or exudative retinal detachment.

Racemose hemangioma (Wyburn Mason syndrome) is another retinal vascular anomaly where dilation of the larger retinal vessels with direct arteriovenous anastomosis is seen, and this lesion should not be confused with cavernous hemangioma.

## Ancillary Studies

Fluorescein angiography may show autofluorescence of the gray-white epiretinal membrane overlying the tumor. The aneurysms will fill slowly and often incompletely up to 30 minutes after dye injection. Dye will rarely extravasate from the tumor in the late phase of the angiogram. In addition, the plasma-erythrocytic separation often seen on clinical examination is dramatically demonstrated in the later phases of the angiogram. The fluorescein collects in the superior portion of the aneurysm, with the gravitated blood cells blocking its accumulation in the inferior area (Fig. 133.5 and see Fig. 133.3B). While optical coherence tomography (OCT) is

not typically required to make the diagnosis, which tends to be a clinical one, it may demonstrate associated features such as an epiretinal membrane.<sup>16</sup>

**FIG. 133.5** Fluorescein angiography of cavernous hemangioma of the retina. (A) Slow and often incomplete filling of the aneurysms. (B) Plasma-erythrocytic separation in the late phases. (Courtesy of J. Donald M. Gass, MD, reproduced with permission from Agarwal A, editor. Gass' atlas of macular diseases, 5th edition. Elsevier Inc. 2012.)

Although performing echography is rarely necessary, the ultrasonographic features have been described by Shields<sup>3</sup> in cases in which diagnosis was rendered difficult by vitreous hemorrhage. A-scan shows a high initial spike and high internal reflectivity. B-scan shows an irregular surface, large internal acoustic density, and absence of choroidal excavation. Many cavernous hemangiomas are too small to exhibit a characteristic echographic pattern.

## Natural History

Growth of a retinal cavernous hemangioma is exceedingly rare. Klein et al.<sup>4</sup> reported the only case of enlargement, and this developed after photocoagulation. Messmer et al.<sup>1</sup> noted enlargement of the fibroglial component, which may represent progressive thrombosis of some of the aneurysms. In a later report,

Kushner et al.<sup>17</sup> monitored two patients over 5–10 years and reported definitive growth.

Visual loss can occur from growth of an associated epiretinal membrane.<sup>18</sup> In addition, macular pucker has been reported separate from the membrane overlying the hemangioma; the membrane and the tumor in this case were probably unrelated.<sup>1</sup> Vitreoretinal or vitreopapillary traction may occur occasionally.<sup>19</sup>

Vitreous hemorrhage is the most common cause of progressive visual disturbance in patients with cavernous hemangioma. Although usually mild due to slow blood flow through the hemangioma, isolated cases of severe hemorrhage have been reported.<sup>20–22</sup> Impairment of visual acuity from vitreous hemorrhage is a very uncommon event.

## Treatment

Because cavernous hemangiomas rarely increase in size or cause lipid exudation or severe vitreous hemorrhage, these tumors generally do not require treatment. Photocoagulation or cryotherapy has been advocated if vitreous hemorrhage occurs. However, Gass<sup>9</sup> has reported one case of vitreous hemorrhage following xenon photocoagulation, and Klein et al.<sup>4</sup> described a patient in whom the hemangioma enlarged greatly after xenon treatment. The value of laser treatment or cryopexy remains unproven and periodic observation is standard care. However, for rare cases of nonclearing vitreous hemorrhage, vitrectomy has proved to be effective. Haller and Knox<sup>22</sup> reported a case of dense, nonclearing vitreous hemorrhage due to persistent vitreous traction to a cavernous hemangioma of the optic disc. During vitrectomy, the vitreopapillary traction was relieved and the preretinal portion of the hamartoma was excised. Minimal bleeding occurred and was easily controlled with intraocular diathermy. Vision improved from light perception to 20/40.

## Pathology

Histopathologic study of retinal cavernous hemangioma demonstrates a tumor arising from the inner half of the retina (Fig.

133.6).<sup>23</sup> The tumor comprises of multiple endothelial-lined, thin-walled aneurysms. These aneurysms are separated by thin, fibrous septa. There is no evidence of intraretinal or subretinal exudate.

**FIG. 133.6** Histologic examination of a cavernous hemangioma of the retina shows multiple endothelial-lined vascular saccules (*arrow*). (Courtesy of J. Donald M. Gass, MD. Reproduced with permission from Agarwal A, editor. Gass' atlas of macular diseases, 5th edition. Elsevier Inc. 2012.)

The cavernous hemangioma is a localized vascular hamartoma arising from the capillaries and is partly isolated from the normal vascular tree as seen on fluorescein angiography.<sup>24</sup> Electron microscopy performed on an eye enucleated for leukocoria in a 6-month-old infant showed the aneurysms to be lined by nonfenestrated, flat endothelial cells with terminal bars on the luminal side and a thin basement membrane.<sup>25</sup> Pericytes were also present. The vessels were surrounded by processes of fibrous astrocytes invested by a basal lamina. These features of normal retinal vessels in association with the slow flow through the vascular abnormality probably account for the lack of exudates and hemorrhage.<sup>24</sup>

A preretinal membrane can overlie the tumor and contains processes of fibrous astrocytes with cytoplasmic filaments. The membrane is attached to the internal limiting membrane (ILM) but is also directly connected to the inner retina through breaks in the

ILM. Immunohistochemistry shows the presence of glial fibrillary acidic protein (GFAP) both intraretinally and in the preretinal membrane. These characteristics support a glial origin for the preretinal membrane.

## Systemic and Familial Involvement

Reports of several individuals and pedigrees with retinal cavernous hemangiomas, as well as cutaneous and central nervous system angiomatous lesions, led to the concept that this entity is part of a neuro-oculocutaneous syndrome. Weskamp and Cotlier<sup>26</sup> first reported such a patient with occipital cutaneous angiomas, intracranial calcifications, and seizures who turned out to have a cavernous hemangioma in the pre-Rolandic area of the cerebral cortex diagnosed at the time of craniotomy. Subsequently, several familial cases have been seen, and it is now established that the incidence is higher in Hispanic Americans than non-Hispanic Americans.<sup>6</sup>

A variety of cutaneous lesions have been reported in association with this tumor.<sup>27-30</sup> Most commonly patients have cutaneous capillary malformations on the back of the neck. However, Schwartz et al.<sup>29</sup> reported a patient with cutaneous angiomas on the abdomen, and Mildner discussed a 14-year-old with a cavernous hemangioma of the chest.<sup>28</sup> In addition, Gautier-Smith et al.<sup>27</sup> have reported an association with angioma serpiginosum, a progressive condition with widespread dilation of subpapillary venous plexuses. These cutaneous lesions are associated with motor and sensory loss and have peripheral nerve involvement.<sup>27-30</sup>

Angiomas of the central nervous system are the more consistent association with retinal cavernous hemangiomas. In fact, cerebrocavernous malformations (CCMs) are far more common than retinal cavernomas. The overall incidence of cerebrocavernous hemangioma is between 0.1% and 0.5% in the general population. Only 5% of these patients have an associated retinal hemangioma. Among those with CCMs, the proportion of familial cases has been estimated to be as high as 50% in Hispanic American patients and 10-40% in other populations. In addition to the patient reported by Weskamp and Cotlier,<sup>26</sup> Gass<sup>9</sup> has reported one patient with a

retinal cavernous hemangioma and seizures whose father had cavernous hemangiomas of the midbrain, pons, and cerebellum. He reported another patient with a retinal cavernous hemangioma, a cutaneous angioma, and seizures who had a child who died after excision of the cavernous hemangioma of the third and lateral ventricles.<sup>24</sup> Schwartz et al.<sup>29</sup> reported a patient with a retinal cavernous hemangioma, cutaneous angiomas, and a cerebrovascular lesion consistent with cavernous hemangioma on computed tomography (CT) scan and magnetic resonance imaging (MRI). Subsequently, Pancurak et al.<sup>5</sup> reported a family with two members having CT scans consistent with cavernous hemangioma of the brain. Bell et al.<sup>31</sup> reported a case of bilateral cavernous hemangioma associated with a cavernous hemangioma in the left parietal lobe. Most recent is the report by Sarraf et al.<sup>32</sup> of a family of 12 affected members spanning three generations. The proband had multiple CCMs and a choroidal hemangioma; her son had a retinal cavernous hemangioma; her daughter had CCMs; a sister manifested cutaneous hemangiomas, CCMs, and a choroidal hemangioma; and her father had multiple cutaneous hemangiomas. This is the first association with choroidal hemangioma.<sup>32</sup>

CCMs occur predominantly in the cerebrum and pons, rarely in the spinal cord, and about 60% are symptomatic (Fig. 133.7).<sup>33</sup> They can present with focal or generalized seizures (45%), cerebral hemorrhages (41%), focal neurologic deficits, or headaches.<sup>34</sup> Some 40% of patients with cavernous hemangioma of the brain have calcifications apparent on skull radiographs,<sup>35</sup> but CT is currently the best diagnostic procedure to demonstrate calcium. MRI is most sensitive of all imaging modalities. Gradient echo sequences can identify three times more lesions than turbo spin echo on MRI and is recommended. Four specific MRI patterns have been identified based on the hemangioma characteristics, presence of old or fresh blood, and calcium.<sup>5,36</sup> A perilesional dark halo appearance on MRI is one characteristic feature of CCMs due to hemosiderin laden macrophages around the malformations.<sup>37</sup>

**FIG. 133.7** Discrete and confluent cavernous angiomas are present in the cortex and subcortical white matter. The lesions were found incidentally at autopsy. (Reproduced with permission from Rubenstein LJ. Tumors of the central nervous system. Washington, DC: Armed Forces Institute of Pathology; 1972.)

Patients have also been reported with extraocular muscle paresis. Although this may be related to a cavernous hemangioma of the midbrain, Yen and Wu<sup>38</sup> have reported a patient with agenesis of the internal carotid artery associated with retinal cavernous hemangioma and bilateral oculomotor palsies.

## Genetics

Several pedigrees have been reported with cavernous hemangioma of the retina in which various family members had retinal, cutaneous, or neurologic lesions. The most extensive pedigree, reported by Goldberg et al.,<sup>19</sup> spanned four generations. One daughter had a retinal cavernous hemangioma, another daughter had seizures and cutaneous lesions, six relatives had seizures, and 14 other relatives had cutaneous vascular lesions. In a family reported by Pancurak et al.<sup>5</sup> the proband had a retinal cavernous hemangioma, his sister had cavernous hemangiomas of both retina and brain, his mother had a cavernous hemangioma of the brain, and a niece had a retinal cavernous hemangioma.

Three separate genes have been identified in association with

familial CCMs: *CCM1/KRIT1*, *CCM2/MGC4607*, and *CCM3/PDCD10*.<sup>34,39-42</sup> *CCM1* is located at chromosome locus 7q11-q22 and was the first one identified with the familial form of CCMs. Linkage studies have shown that a *CCM1* mutation is involved in 40–53% of familial CCMs and nearly half of these patients have neurologic manifestations before 25 years of age.<sup>43,44</sup> The product of *CCM1*, named Krev interaction trapped 1 or KRIT1, is an ankyrin repeat-containing protein that interacts with RAP-1A (Krev-1), which is a member of the RAS family of GTPases.<sup>43,44</sup> *CCM2* is located at 7p15–13; mutations in this gene are involved in up to 25–40% of familial CCMs. Patients with *CCM2*-associated disease have a lower number of gradient-echo sequence lesions than those with *CCM1* or *CCM3* disease, and the number of lesions increases less rapidly with age than in patients with *CCM1* disease. *CCM3*, localized at 3q25.2-q27, encodes programmed cell death protein 10 (*PDCD10*) and is the most recently discovered gene involved in familial CCMs.<sup>45</sup>

*CCM3* mutation carriers are less common (10%) than *CCM1* or *CCM2* carriers, but they have near 100% penetrance and these patients are more likely to present with hemorrhage and have symptoms before 15 years of age.

## Introduction

Retinal hemangioblastoma (RH), also called retinal capillary hemangioma, retinal capillary hemangioblastoma, or retinal angioma, is a benign neoplasm with vascular features originating in the neurosensory retina or optic disc. RHs typically occur in the setting of von Hippel–Lindau (VHL) disease, an autosomal dominantly inherited condition in which mutations in the Von Hippel–Lindau tumor suppressor gene, *VHL*, lead to development of characteristic benign and malignant neoplasms or cysts in the central nervous system and viscera. Solitary RH can arise sporadically in the absence of VHL disease. Diagnosis of VHL disease in affected individuals is critically important, given the life-threatening nature of some of its manifestations and the benefits of surveillance and timely intervention, and can be made based on clinical criteria and/or genetic testing for mutations in the *VHL* gene.

## Von Hippel–Lindau Disease

VHL disease (Online Mendelian Inheritance in Man (OMIM) #193300) is an autosomal dominantly inherited multisystem neoplasia disorder arising from mutations in the *VHL* gene. Cardinal manifestations include RH, brain and spinal cord hemangioblastoma, renal cell carcinoma, pheochromocytoma, endolymphatic sac tumor, epididymal and broad ligament cystadenomas, pancreatic neuroendocrine tumors, and renal and pancreatic cysts.<sup>1</sup> VHL disease has an approximate incidence of 1 in 36,000 live births, and a penetrance of over 90% by 65 years of age.<sup>2</sup>

Improvements in early diagnosis, surveillance, and treatment have led to a better prognosis, and a multispecialty team is helpful for optimal management of this complex condition.

## History

Over a century ago, von Hippel described RHs in several generations of a small number of families.<sup>3</sup> In 1926, the Swedish pathologist Lindau observed the link between retinal and cerebellar hemangioblastomas and the association with cysts in the kidney, pancreas, and epididymis as features of a familial syndrome.<sup>4</sup> Melmon and Rosen established the first clinical diagnostic criteria for VHL disease in a landmark paper in 1965.<sup>5</sup> Seizinger and colleagues discovered the linkage of the VHL gene to the short arm of chromosome 3 in 1988,<sup>6</sup> and Latif and colleagues identified the VHL tumor suppressor gene shortly thereafter in 1993.<sup>7</sup>

## The VHL Gene and Protein

Von Hippel-Lindau disease is caused by mutation in the VHL tumor suppressor gene, *VHL*, located on chromosome 3 (3p25-26).<sup>7</sup> The product of the gene, the VHL protein (pVHL), has been found to play a key role in cellular oxygen-sensing, and an understanding of its function has not only provided insight into the molecular pathology of VHL disease but also a better understanding of cell signaling and function under normoxic and hypoxic conditions.<sup>8</sup> *VHL* is ubiquitously expressed and encodes 213 amino acid and 160 amino acid isoforms of pVHL, which are both thought to exhibit similar tumor suppressor activity.<sup>9</sup> pVHL serves as the substrate-recognition subunit of a ubiquitin ligase complex that assigns proteins for proteasomal degradation. Among the targets of this ubiquitin ligase are the transcription factor subunits hypoxia-inducible factor 1 $\alpha$  (HIF-1 $\alpha$ ) and hypoxia-inducible factor-2 $\alpha$  (HIF-2 $\alpha$ ), which undergo prolyl hydroxylation under normoxic conditions, allowing for binding to pVHL and attachment of ubiquitin peptides that result in their proteasomal degradation.<sup>10,11</sup> Under hypoxic conditions, or in the absence of normal pVHL, HIF-1 $\alpha$  and HIF-2 $\alpha$  are not degraded, form heterodimers with hypoxia-

inducible factor 1 $\beta$  (HIF-1 $\beta$ ), and act as transcription factors for a wide array of target genes. Over 800 known genes regulated directly by HIFs play a variety of roles in orchestrating the cell's response to hypoxia.<sup>8</sup> Among the proteins upregulated by HIF signaling are a number promoting cell proliferation and survival, such as transforming growth factor- $\alpha$  and epidermal growth factor receptor, and others promoting angiogenesis, such as vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF), which have been hypothesized to play a role in development of neoplasms in VHL disease, including RH.<sup>12-16</sup> pVHL has other actions independent of HIF signaling, but the significance of these for development of VHL disease is unknown.<sup>8</sup>

The majority of individuals with VHL disease inherit a mutant copy of the VHL tumor suppressor gene from an affected parent, and a wild-type (normal) copy of the gene from the other parent. Knudson's two-hit model for tumorigenesis states that neoplasia results from the somatic inactivation of the normal allele in one or more cells of an individual with a germline mutation in the other allele.<sup>17</sup> In a large study evaluating 181 kindreds with VHL disease, 42 cases (23%) presented absent any suggestive family history, indicating a putative first-generation diagnosis.<sup>18</sup> Mosaicism, in which somatic mutation occurs during embryogenesis and leads to affected and nonaffected tissues within a single individual, explains occasional germline transmission from an apparently unaffected parent in which only certain tissues are affected, and also explains occasional cases in which VHL disease manifests clinically but initial genetic testing is negative for mutation.<sup>19,20</sup> Stolle and colleagues published a report in 1998 on genetic testing methods that allowed for identification of germline mutations in 93/93 (100%) of families with VHL disease, establishing the value of *VHL* gene testing for diagnosis of this condition.<sup>21</sup>

Mutations of *VHL* resulting in VHL disease are highly varied, and range from basepair substitution in a single amino acid codon to the complete deletion of the gene.<sup>22,23</sup> Although many of these mutations are thought to impair pVHL regulation of HIF signaling, the pleomorphic manifestations of VHL disease suggest that distinct mutations may affect pVHL function in different ways, and possibly even confer novel functions.<sup>24</sup> Early work on correlation of

genotype and phenotype suggests that different types of *VHL* mutation may result in particular disease manifestations. For example, the location of a missense mutation in *VHL* correlates significantly with the presence and phenotype of ocular *VHL* disease, which influences visual acuity loss in different subgroups of patients.<sup>25</sup>

## Clinical Features of Ocular Von Hippel-Lindau Disease

RHs are among the most common manifestations of *VHL* disease, but accurate prevalence of ocular involvement has been difficult to ascertain from case series. In a large cohort in which patients and affected family members were identified based on a diagnosis of *VHL* disease, and not on the basis of visual symptoms, 335/890 (38%) patients of 220 unrelated pedigrees were found to have ocular involvement.<sup>26</sup> Forty-two percent of those with ocular *VHL* disease had unilateral involvement, and 58% had bilateral involvement. Eighty-five percent of affected eyes manifested RHs exclusively in peripheral (extrapapillary) retina, 8% had RHs exclusively in proximity to the optic disc, and 7% had RHs in both the peripheral retina and juxtapapillary regions. Among the 421 eyes with peripheral RHs, the tumor count ranged from 1 to 11 (mean  $2.5 \pm 1.8$ ). Those affected were from 7 to 84 years old (mean 36 years old, standard deviation  $\pm 15$  years), and 151/335 (45%) were male. Interestingly, although passage of time results in new tumor formation in some individuals, in this cohort age was not significantly associated with the number of peripheral RHs ( $p=.61$ ).

The initial clinical appearance of an extrapapillary RH is that of a subtle red or grayish dot no larger than a few hundred micrometers, with an ophthalmoscopic appearance similar to that of a dilated capillary, microaneurysm, or small intraretinal hemorrhage (Fig. 134.1). Small tumors are sessile, but with growth they often become more nodular (Fig. 134.2). Feeding and draining blood vessels characteristically appear as the tumor grows larger and become progressively tortuous and enlarged (Fig. 134.3). At this stage, extrapapillary tumors become variably exudative, with

development of retinal edema and hard exudates around the tumor and/or in the macula (Fig. 134.3). Without treatment, large or multiple RHs can grow and displace the normal structures of the retina, and occasionally cause exudative retinal detachment (Fig. 134.4). The epiretinal fibrous proliferation and posterior hyaloid contraction that can accompany large RHs can cause macular epiretinal membrane and macular thickening, vitreomacular traction, or traction retinal detachment. Preretinal or vitreous hemorrhage is unusual in untreated tumors, but can occur. Neovascularization of the iris, neovascular glaucoma, and phthisis bulbi can occur in eyes with large or multiple tumors. A significant majority of RHs exhibit growth over time, but occasionally untreated tumors will remain static for considerable periods, and rarely they regress spontaneously.<sup>27</sup>

**FIG. 134.1** Small retinal hemangioblastomas. Five small retinal hemangioblastomas at various stages of early development are visible in temporal retina posterior to the equator. The smallest three lesions (*arrows*) are subtle and can easily be overlooked. The largest two lesions (*arrowheads*) remain sessile (flat) and show easily visible early afferent and efferent

vessels. The most superior lesion shows some early associated epiretinal proliferation. (National Eye Institute, Bethesda, MD.)

**FIG. 134.2** Fully developed retinal hemangioblastomas. Two nodular hemangioblastomas manifest well-developed afferent and efferent vessels, without any associated exudation. The larger lesion is approximately 1.5 mm in diameter and shows epiretinal proliferation on its surface. (National Eye Institute, Bethesda, MD.)

**FIG. 134.3** Peripheral retinal hemangioblastoma with macular exudation. Visual acuity is decreased in the setting of severe hard exudates involving the macula. Note the dilated, tortuous afferent and efferent tumor vessels. A second tumor along the inferotemporal vascular arcade appears more fibrotic and does not contribute to the exudation.

**FIG. 134.5** Small juxtapapillary retinal hemangioblastoma. No exudation is present, visual acuity is not affected, and the lesion remains asymptomatic. (National Eye Institute, Bethesda, MD.)

RHs arising in proximity to the optic disc have a different clinical appearance and may be difficult to discern ophthalmoscopically when small and sessile. Small tumors may exhibit little more than localized fullness of the neural rim or retina at the disc margin, but with further growth, a distinct whitish-pink thickening becomes visible, sometimes with associated fine, lacy vessels (Fig. 134.5). Feeder vessels are typically not visible. These tumors sometimes exhibit minimal growth over years, but often evolve exudation eventually. Intraretinal edema, with or without hard exudates, may progress to involve the central macula (Fig. 134.6).

**FIG. 134.6** Juxtapapillary retinal hemangioblastoma with macular exudation. (A) A prominent retinal hemangioblastoma is visible on the temporal optic disc rim. Note the central macular cysts and superotemporal punctate hard lipid deposits. (B) An optical coherence tomography line scan of the central macula shows marked cystoid macular edema nasally and centrally. The tumor resides in the inner retina nasally. (National Eye Institute, Bethesda, MD.)

**FIG. 134.4** Multiple retinal hemangioblastomas with exudative retinal detachment. Retinal

hemangioblastomas of various sizes, dilated and tortuous afferent and efferent vessels, hard exudates, and foci of epiretinal fibrosis are visible in this severely affected eye. Prognosis in such cases is very guarded.

The ophthalmoscopic appearance of RHs is characteristic and is often sufficient to make the diagnosis. Very small lesions, as mentioned earlier, may be hard to distinguish from other focal microvascular abnormalities when other conditions are being considered. The lesion that most closely resembles larger tumors, and may be difficult to differentiate in some cases, is a vasoproliferative tumor of the ocular fundus.<sup>28</sup> Fundus photography, especially with use of montage techniques or a wide-angle camera to capture the location and size of extrapapillary RHs, may be helpful for monitoring for growth or regression of lesions. For identifying small tumors or evaluating atypical lesions or features, ancillary testing can be helpful. Fluorescein angiography shows prominent early hyperfluorescence of RHs that typically persists and often progresses to leakage in the late phase of the study. It is a sensitive test for detection of extrapapillary and juxtapapillary RHs, and can be helpful to rule out other conditions. In cases of macular exudation originating from an extrapapillary RH, macular vessel leakage is typically absent. Associated peripheral microvascular abnormalities or capillary nonperfusion are not typical, but we have seen occasional cases in which the retina evolves a more widespread vasculopathy, usually in the setting of multiple or large RHs and significant tumor exudation. Optical coherence tomography can be useful to document the features of juxtapapillary RHs and is especially helpful for characterizing any macular edema or epiretinal macular traction. Ultrasonography shows an acoustically solid retinal mass with a smooth anterior border with variable but mostly medium reflectivity (Fig. 134.7), but it is not often used for follow-up of most tumors. Orbital shadowing and choroidal excavation are not seen.

**FIG. 134.7** B-scan and standardized A-scan echogram of a retinal hemangioblastoma, thickness 3.3 mm, reflectivity variable but predominantly medium.

RHs are typically asymptomatic at the early stages of development. Vision loss is generally caused by exudation affecting the macula, glial proliferation or posterior hyaloid contraction related to the tumor with resultant retinal striae and thickening, or in advanced cases, traction and/or exudative retinal detachment. While number of tumors did not increase significantly with age in the aforementioned cohort study,<sup>26</sup> the risk of vision loss was found to increase with age in another cross-sectional case series.<sup>29</sup> The risk of severe vision loss also increased with presence of juxtapapillary lesions, increasing peripheral tumor number, and the extent of retinal involvement.<sup>26</sup> In the cohort studied at the National Eye Institute, approximately 77% of eyes had vision of 20/20 or better, and the prevalence of legal blindness from ocular VHL disease was low: 6% of patients manifested vision less than 20/160 in the better-seeing eye. However, approximately 20% of all patients with ocular VHL disease had at least some degree of unilateral visual impairment, indicating a substantial burden of disease.

Retinal vascular proliferation is a less common manifestation of

ocular VHL disease. Approximately 8% of patients with ocular VHL disease in the National Eye Institute cohort manifested these lesions, which bear some resemblance to the retinal neovascularization seen in ischemic retinopathies, but occur in the absence of significant retinal capillary nonperfusion (Fig. 134.8).<sup>30</sup> Another case series describing such lesions divided them into “vascularized glial veils” arising in proximity to the optic disc, and “retinal vascular hamartomas” with a sessile, saccular, nest-like appearance in extrapapillary retina.<sup>31</sup> These lesions are variably vascular or fibrotic, tend to occur at the posterior pole, and exhibit a variable natural history, with regression or stasis in some cases and progressive growth in others. Patients with retinal vascular proliferation are often young and may manifest these lesions in the absence of any RH in the affected eye. We have seen occasional cases of indeterminate lesions that share characteristics of RHs and vascular proliferation, but the distinction is important, when possible, for treatment (see below, [Treatment of ocular von Hippel–Lindau disease](#)).

**FIG. 134.8** Retinal vascular proliferation. Lacy epiretinal vessels (*arrow*) are present on the nasal optic disc rim. Cellophane maculopathy in the setting of thickened posterior hyaloid and/or early epiretinal

membrane formation is visible temporally. (National Eye  
Institute, Bethesda, MD.)

There are a number of other manifestations of VHL disease that may affect vision and come to the attention of the ophthalmologist. Expanding cerebellar hemangioblastomas may cause intracranial hypertension, papilledema, and eventual optic atrophy if not treated in a timely fashion. Central nervous system hemangioblastomas rarely occur in the optic nerve, optic chiasm, or optic tract.<sup>32-37</sup> Pheochromocytomas may cause hypertension and consequent hypertensive retinopathy.

## Pathology of Ocular Lesions

Histopathologic evaluation of RH demonstrates capillary-like fenestrated vascular channels surrounded by vacuolated, “foamy” stromal cells, with presence of occasional tumorlet cells, and a variable amount of reactive gliosis (Fig. 134.9).<sup>38-42</sup> Microdissection of specimens with analysis of DNA has shown a loss of heterozygosity at the VHL gene locus in stromal cells, but not in areas of the tumor with predominance of vascular channels or glial cells.<sup>42,43</sup> On this basis, RH has been classified as a neoplasm, in which proliferation of vacuolated stromal cells (Fig. 134.10) occurs after loss or inactivation of both *VHL* alleles. Similar loss of heterozygosity has been demonstrated in VHL disease-related central nervous system hemangioblastomas,<sup>44</sup> which are histopathologically similar to RH. Genetic analysis of other prototypical VHL disease tumors, including renal cell carcinoma, pheochromocytoma, pancreatic adenoma, and endolymphatic sac tumor, supports the Knudson two-hit model for tumorigenesis in this disorder.<sup>45-51</sup> The identity of vacuolated stromal cells in RH remains uncertain. Older ultrastructural and immunohistochemical studies suggested that these cells might represent lipidized fibrous astrocytes or glial cells.<sup>40,52</sup> Other investigators hypothesized that these might evolve from “vasoformative stem cells.”<sup>53</sup> A study of cerebellar hemangioblastomas showed that analogous stromal cells in these tumors may originate from developmentally arrested angioblasts.<sup>54</sup> Immunohistochemical analysis of RH demonstrated

that stromal cells express CD133, a stem cell marker expressed by hematopoietic, endothelial, and neural progenitors.<sup>55</sup> Evaluation of extrapapillary RH successfully treated by xenon photocoagulation, argon laser, and cryotherapy has demonstrated occlusion of vascular channels, gliosis, and fibrous metaplasia of retinal pigment epithelium.<sup>56-58</sup> Histopathologic evaluation of retinal vascular proliferation has been limited, but a single case reporting analysis of surgically excised tissue described a fibrovascular membrane composed of loose connective tissue and small blood vessels.<sup>30</sup>

## Diagnosis and Surveillance of Von Hippel–Lindau Disease

The diagnosis of von Hippel–Lindau disease has traditionally been based on the following clinical criteria: (1) A positive family history AND presence of a central nervous system hemangioblastoma, RH, pheochromocytoma, OR clear cell renal carcinoma; OR, (2) in the absence of a family history, presence of two or more central nervous system hemangioblastomas or RHs, OR one central nervous system hemangioblastoma or RH, AND a visceral tumor (with the exception of epididymal and renal cysts, which are frequent in the general population).<sup>5,59</sup> Genetic testing has become standard to confirm the diagnosis and can be especially useful in challenging cases, such as when a patient presents with one or more central nervous system hemangioblastomas or RHs in the absence of a family history or visceral lesions. Genetic testing is also important to establish the diagnosis in at-risk family members of a patient with VHL disease, given the latency and heterogeneity of clinical manifestations but a penetrance of over 90% by age 65.<sup>1,59</sup>

Median survival of those with VHL disease, for whom

complications of renal cell carcinoma and central nervous system hemangioblastoma remain principal causes of death, has improved in recent years, thanks to earlier diagnosis, standardized disease surveillance programs, and advances in treatment.<sup>1,59</sup> Because of the complexity of this condition, optimal management involves care by an integrated multispecialty team with expertise in neurosurgery, neuroradiology, urologic and endocrine surgical oncology, ophthalmology, otolaryngology, pathology, genetics, and rehabilitation medicine, when feasible. Various groups have published recommendations for age of initial screening and frequency of follow-up testing for cardinal disease features (Table 134.1).<sup>60</sup> Consensus recommendations do not presently exist, but those by Choyke and colleagues presented in Table 134.1 provide an example of the general guidelines used in management of these patients.

**TABLE 134.1**

**Recommended Intervals for Screening Individuals at Risk for Von Hippel–Lindau Disease**

Exam or Procedure	Age of Screening (Frequency)
Ophthalmoscopy	Infancy (yearly)
Plasma or 24-hour urinary catecholamines and metanephrines	~2 years (yearly and when blood pressure is elevated)
MRI of brain and spine	~11 years of age (yearly)
CT and MRI of internal auditory canals	Onset of symptoms, hearing loss, tinnitus, vertigo
Ultrasound of abdomen	~8 years (MRI as indicated)
CT of abdomen	~18 years or earlier if clinically indicated (yearly)
Audiology testing	When clinically indicated

CT, computed tomography; MRI, magnetic resonance imaging.

## Treatment of Ocular Von Hippel–Lindau Disease

The goal of treatment for an extrapapillary RH is generally destruction of the lesion, to render it incapable of further growth or

exudation. Small tumors with features suggesting inactivity or partial regression can occasionally be observed, but in such cases, close surveillance is imperative, and the threshold for offering ablative treatment for any sign of growth or activity should be low. Small tumors can be destroyed quite readily, before vision loss has occurred and with minimal risks of treatment; in contrast, larger lesions can be much more difficult to ablate, and damage induced by treatment frequently leads to a variable and occasionally significant acute exudative response that can cause retinal detachment and threaten vision. Accordingly, a core principle of management is to identify RHs as early in their development as possible, and to offer timely therapy or referral to an ophthalmologist proficient in managing ocular VHL disease. Given the advantages of early ablative therapy and the asymptomatic nature of small tumors, optimal management begins with adequate surveillance for appearance of RHs, so that timely treatment can be performed.

Ophthalmic evaluation, with indirect ophthalmoscopic and biomicroscopic examination of the retina, and use of ancillary imaging when possible in order to optimize the detection rate for small lesions is indicated annually for individuals with VHL disease, starting in early childhood. Identification of any ocular lesions requires prompt intervention and close subsequent surveillance, with follow-up tailored to the circumstances. Treated tumors are followed closely after any attempted ablation, to assess for expected regression or any sign of regrowth or recurrent exudation. Occasional eyes manifest new tumors frequently, and must be watched very closely.

Other treatments, such as surgical excision of large RHs, and pharmacotherapy to mitigate tumor exudation (such as intravitreal administration of VEGF antagonists), have been employed in select circumstances and are further discussed below. Compared to treatment options for extrapapillary RHs, those for juxtapapillary RHs are very limited, because of the greater potential for harm to vision by any ablative therapy. Management of this subset of tumors is discussed separately below.

## **Ablative Treatment of Extrapapillary Retinal**

## Hemangioblastomas

A number of ablative modalities have been employed for treatment of extrapapillary RHs, including thermal laser photocoagulation, cryotherapy, radiation (including brachytherapy, external beam radiation, and proton beam radiation), photodynamic therapy, and transpupillary thermotherapy. The feasibility and efficacy of therapy depend on a number of factors, such as tumor size, tumor location, degree of exudation, presence of retinal detachment, associated epiretinal fibrosis or hemorrhage, associated chorioretinal scarring (as from previous ablative treatment), position relative to location of any scleral buckling materials in previously operated eyes, the number and characteristics of other viable tumors inside the eye, associated retinal vascular changes or vascular proliferation, and response to previous treatment.

Extrapapillary RHs up to 1.5 mm in diameter can be effectively destroyed using thermal laser photocoagulation under most circumstances, and various laser types, including argon green, diode, yellow dye, and krypton, have all shown efficacy.<sup>57,61–65</sup> We typically use yellow or green wavelengths, with longer burn duration (0.2–0.4 seconds) than would be typical for panretinal photocoagulation or laser retinopexy, and power sufficient to create whitening in the area of the burn. It has been theorized that vascular lesions such as RHs may absorb yellow light more efficiently than other laser wavelengths based on the absorption spectrum of oxyhemoglobin,<sup>66</sup> but no randomized comparison of ablative laser type or technique has been performed. Feeder vessels at this tumor size are small, when visible at all, and we do not treat them. Some have advocated laser photocoagulation of the retina around the tumor, but we usually confine burns to an area sufficient to blanch the entire tumor surface. RHs anterior to the equator can be challenging to treat using slit-lamp laser delivery, and occasionally we use indirect laser photocoagulation to treat these lesions. The appearance of scant intraretinal or preretinal hemorrhage on the tumor surface immediately following laser photocoagulation is common, but vitreous hemorrhage is rare and usually only seen with treatment of larger lesions (see below). At this size, it is unusual for RHs to elaborate significant exudation or to be associated with significant epiretinal fibrosis, but coexisting

tumors may be responsible for presence of such features, and can make it difficult to apply sufficient burn intensity to a RH. When effective, laser treatment of small RHs results in a chorioretinal scar, sometimes associated with a shrunken, variably whitened vestige of the lesion, and other times with disappearance of the RH. A regressed but visible lesion corresponding to the original RH is compatible with destruction sufficient to prevent further growth or exudation, but treated areas must be followed over time for any sign of a still-viable RH. Retreatment is sometimes necessary, especially for larger tumors (see below), and the technique for retreatment is the same.

Extrapapillary RHs between 1.5 and 4.5 mm in diameter are more difficult to destroy using thermal laser photocoagulation. Success presumably depends on whether sufficiently intense photocoagulation can be applied throughout the thickness of the tumor. The treatment technique is similar to the one described above for small lesions, but frequently involves applying long-duration burns (often more than 0.4 seconds), using a power setting typically lower than that needed for a typical panretinal photocoagulation or laser retinopexy spot, designed to cause progressive grey-whitening over the course of the burn. Feeder vessels are often visible, and some have included photocoagulation of the feeding arteriole in treatment,<sup>67,68</sup> but in our hands this has not appreciably increased chances of success or lowered risks of the procedure, and we do not typically treat them. Sessile tumors are more easily treated than very nodular ones, and any associated exudation, epiretinal fibrosis, or preexisting hemorrhage can significantly hamper ability to apply adequate treatment. Appearance of scant intraretinal or preretinal hemorrhage on the tumor is common with treatment, as for smaller lesions, and vitreous hemorrhage is uncommon. Reasonable success rates have been reported with use of laser endophotocoagulation at vitrectomy in cases in which ablative therapy is applied adjunctive to vitreoretinal surgery.<sup>69</sup> In our experience, a significant number of RHs in this size range are not destroyed even following multiple sessions of laser photocoagulation. However, transscleral cryotherapy is frequently effective for destruction of these tumors, even in the setting of associated exudation, hemorrhage, or fibrosis.

Treatment can be applied transconjunctivally in the office setting for anterior tumors, or applied transsclerally in the surgical suite after conjunctival incision to allow for appropriate probe placement for postequatorial tumors. In either case, we typically use a double freeze–thaw technique as advocated by Singh and colleagues.<sup>65</sup> In our hands, use of cryotherapy seems to be associated with a greater posttreatment exudative response than use of laser photocoagulation (see below). Photodynamic therapy with verteporfin infusion has been attempted for ablation of tumors this size with mixed success,<sup>70,71</sup> and we have not found it effective enough to use routinely. Whether following laser photocoagulation or cryotherapy, complete disappearance of a treated tumor this size is uncommon, and assessment of whether adequate destruction has been achieved can be challenging. Encouraging signs include a decrease in tumor size, decrease in redness or vascularity, resolution of any subretinal fluid and hard exudates, normalization of the caliber and decrease in the tortuosity of any feeding and draining vessels, and an underlying chorioretinal scar. However, the only definitive measure for success is documentation of no regrowth or recurrent exudation over long-term follow-up, and we have seen quiescent and regressed-appearing tumors manifest new signs of viability and activity years following ablative therapy.

Extrapapillary RHs greater than 4.5 mm in diameter can be difficult to destroy, with decreasing success rates and increasing risks of treatment with increasing tumor size. Thermal laser photocoagulation and photodynamic therapy are almost always ineffective for large tumors. Cryotherapy can sometimes be effective for lesions this size, but becomes less so for very large tumors. For RHs more than 4.5 mm in diameter, we will often try cryotherapy, if it can be applied with adequately low risks, but consider use of brachytherapy (plaque radiotherapy) for higher-risk cases or following unsuccessful cryotherapy. Kreusel and colleagues reported use of ruthenium-106 brachytherapy for treatment of 25 eyes (24 patients).<sup>72</sup> Mean diameter of treated RH was 3.8 mm, and the authors reported destruction of 23 of 25 tumors with a single treatment session. However, they reported poor outcomes in nine eyes, in which the postoperative course was characterized by decrease in visual acuity and increasing exudative

or traction retinal detachment. Application of external beam radiation has been described in advanced cases, but has not resulted in long-term outcomes favorable enough to result in common use.

Ablative treatment of RHs larger than approximately 1.5 mm in diameter may prompt a rapid and sometimes significant increase in exudation as a response to acute injury. In our experience, the magnitude of this response is variable, and can be difficult to predict, but correlates with increasing tumor size, amount of baseline exudation, prominence of feeding and draining vessels, use of cryotherapy (compared to thermal laser photocoagulation or photodynamic therapy), and presence of vitreous cell and flare (implying preexisting breakdown of the blood–ocular barrier). Subretinal fluid often accumulates within hours following treatment (Fig. 134.11). In mild cases, such fluid may remain confined to the region around the treated RH until resolution weeks later; in more severe cases, frank exudative retinal detachment occurs, with dependent migration of subretinal fluid in the days following treatment and slow resolution weeks to months later. Peripheral exudative retinal detachment frequently causes scotomas, and migration of subretinal fluid into the macula can impair visual acuity. In our experience, visual acuity does often recover with resolution of subretinal fluid in cases of macular involvement. Risk of posttreatment exudation should not deter necessary ablative therapy in most cases, because eyes with such RHs are at high risk of vision loss without treatment, but a patient must be counseled about the risks undertaken and the need to follow the eye closely after treatment. Although we are not aware of any controlled clinical trials testing this approach, we routinely give a short course of systemic corticosteroids with a goal of minimizing posttreatment exudation. We tailor dosing to the risks of such exudation, and in high-risk cases often give prednisone (1 mg/kg per day) or equivalent for 1–3 days, starting on the day of treatment, and taper quickly to discontinuation within 4–7 days. In our experience, longer courses of corticosteroids do not hasten resolution of subretinal fluid, so we avoid administration for more than a week. The safety of corticosteroid use should be assessed in the context of systemic manifestations of VHL disease and any

comorbid conditions.

**FIG. 134.11** Retinal hemangioblastomas manifesting posttreatment exudation after cryotherapy. (A) Two hemangioblastomas, both greater than 1.5 mm in diameter, are visible. Two small hemangioblastomas are present inferiorly but are difficult to visualize in this photograph. Visual acuity measured 20/16. Double freeze–thaw cryotherapy (with conjunctival incision for optimal probe positioning) was recommended for the two superior lesions, and laser photocoagulation was recommended for the two inferior lesions. Intravenous methylprednisolone was administered intraoperatively to blunt expected exudation. (B) One day following treatment, acute peripheral exudative retinal detachment is present superiorly and temporally. Prominent cryotherapy effect is visible around the temporal lesion. View of the superior lesion is obscured by a fibrin membrane that has congealed on the tumor surface. Laser effect is visible at the site of the two small lesions inferiorly. Oral prednisone and topical prednisolone acetate were given for 1 week. (C) Three years later, the two large tumors appear regressed, with reduction in the dilation and tortuosity of feeding and draining vessels and disappearance of superotemporal lipid. Chorioretinal scarring is present at the two sites of laser treatment inferiorly, where small tumors are no longer visible. Visual acuity remains 20/16. Note subtle perivascular lipid just inferior to the regressed but still visible superior tumor. This lipid was not present initially, or a year after cryotherapy, and this tumor is being observed closely for possible viability and need for further treatment.

(National Eye Institute, Bethesda, MD.)

## Surgical Excision of Extrapapillary Retinal Hemangioblastomas

Given the poor success and significant risks of ablative therapy in very large RHs, surgical excision of RHs at vitrectomy is occasionally employed.<sup>69,73</sup> Gaudric and colleagues reported a case series of 23 eyes (21 patients) that underwent vitreoretinal surgery for severe ocular VHL disease, in which 14 eyes received ablative therapy (laser endophotocoagulation or cryotherapy) as adjunct to vitrectomy and the other nine eyes had surgical excision and removal of RHs. For the nine eyes undergoing RH excision, an average of two operations was necessary, and eight of nine eyes had an attached retina 6 months following surgery. However, neovascular glaucoma and new RH growth occurred in four eyes between 4 and 8 years after the initial surgery, and visual acuity in remaining eyes was poor (20/320 or worse). In our experience, a number of factors contribute to a high rate of postoperative proliferative vitreoretinopathy and retinal detachment in such eyes, and these complications, combined with high rates of new RH appearance, have limited the success of this approach.

## Treatment of Juxtapapillary Retinal Hemangioblastomas

Management of juxtapapillary RHs is constrained by the adverse effects on vision that can result from ablative therapies used for treatment of extrapapillary RHs. Decrease in visual acuity, altitudinal visual field loss, and development of central scotomas have been associated with treatment of such tumors with thermal laser photocoagulation.<sup>74</sup> Photodynamic therapy with verteporfin has been attempted and seems to exhibit a better safety profile than laser photocoagulation, but has demonstrated limited success and somewhat mixed results.<sup>70,75</sup> Given these considerations, we observe juxtapapillary RHs when possible. As mentioned previously, the natural history is variable, and some lesions remain relatively static for long periods of time. Exudation may wax and wane and can remain compatible with good vision until the central macula

becomes chronically involved. In the absence of safe ablative options, treatment is typically confined to attempting to mitigate exudation affecting central vision. Photodynamic therapy, proton beam therapy, or pharmacotherapy using VEGF antagonists or corticosteroids may decrease exudation in some cases, but risks of therapy must be carefully weighed, and success is often limited.<sup>70,75-78</sup>

## Treatment of Retinal Vascular Proliferation

Small foci of retinal vascular proliferation, whether juxtapapillary or extrapapillary, can often be observed. They do not seem to carry the same risk of vitreous hemorrhage or traction retinal detachment as does neovascularization in ischemic retinopathies, and they occasionally regress spontaneously.<sup>30</sup> When they grow large or become more fibrotic and contractile in proximity to the fovea, they can decrease visual acuity, and vitrectomy can be performed to remove the membranes.<sup>30</sup> In some cases, surgery is definitive; in others, retinal vascular proliferation may regrow after successful peeling. It is important to distinguish these lesions from RHs. Retinal vascular proliferation does not typically produce exudation and does not regress readily in response to laser photocoagulation (probably in part because of its epiretinal location). RHs may induce epiretinal proliferation or retinal vascular proliferation on their surface, but the tumors themselves reside within the neurosensory retina and cannot be peeled. We have seen occasional lesions that seem to share features of both, with a surface appearance suggesting epiretinal proliferation, but exudation typical for RH, and good regression in response to ablative laser photocoagulation. These hybrid lesions probably represent small RHs with overlying retinal vascular proliferation.

## Antiangiogenic Pharmacotherapy

An understanding of the inappropriate activation of hypoxia response pathways in cells lacking functional pVHL opens the door for rational design of treatments that might be capable of preventing growth or even inducing regression of RH and other neoplastic lesions in VHL disease. Observation of the highly

vascular nature of tumors in VHL disease led to a hypothesis that VEGF, a HIF-inducible protein and potent mediator of angiogenesis and vascular permeability, might be important in their evolution, and there are several lines of evidence implicating VEGF expression in the pathology of VHL disease. Renal carcinoma cell lines defective for pVHL manifest increased production of VEGF, mRNA, and protein, and show a corresponding decrease when pVHL function is restored.<sup>79</sup> VEGF protein levels are elevated in pathologic specimens from renal carcinomas exhibiting mutations of *VHL*.<sup>80</sup> Neutralizing antibodies to VEGF reduce rates of progression among patients with advanced clear cell renal carcinoma, in which sporadic tumors harbor frequent inactivation of pVHL.<sup>81,82</sup> VEGF messenger RNA is upregulated in the hepatic cavernous hemangiomas seen in mice heterozygous for *VHL* mutation.<sup>83</sup> pVHL-defective cell lines derived from central nervous system hemangioblastomas and RH have not been developed, but analysis of pathologic specimens has revealed increased VEGF production.<sup>43,84,85</sup> Vacuolated stromal cells in VHL-associated RH exhibit high levels of VEGF messenger RNA and protein.<sup>43</sup>

Administration of VEGF antagonists in ocular VHL disease has been reported in case series and small, uncontrolled clinical trials. In one prospective study, Dahr and colleagues evaluated intravitreal pegaptanib sodium (3 mg) in five patients with VHL disease manifesting juxtapapillary or large extrapapillary RH.<sup>77</sup> Pegaptanib sodium, a pegylated aptamer antagonizing the VEGF<sub>165</sub> isoform, was administered every 6 weeks for at least six injections, and two of five patients completed the course of treatment and 1 year of follow-up. These two patients experienced a decrease in RH-associated exudation, but no change in size of the tumors. The other three patients demonstrated progression of ocular disease and did not complete the course of treatment. In another prospective trial, Wong and colleagues tested intravitreal ranibizumab in five patients with RH not amenable or responsive to standard treatments.<sup>78</sup> Ranibizumab (0.5 mg), a humanized monoclonal antibody fragment binding all VEGF-A isoforms, was given every 4 weeks for 6 months, with additional treatment considered through 12 months. Participants received a mean of 10 injections over an average of 47 weeks. Visual acuity decreased by 9 ( $\pm$  20) letters and

there was no consistent improvement in RH exudation or tumor size.

The complexity of the cellular response to hypoxia is underscored by the hundreds of genes known so far to be regulated by the HIFs that signal inappropriately in the absence of functional VHL protein.<sup>8</sup> Given the pleiotropic effects of HIF signaling, and the possibility that some of pVHL's tumor suppressor function may involve HIF-independent mechanisms,<sup>85</sup> it is perhaps not surprising that initial efforts antagonizing angiogenic pathways for control or regression of RH have met with little success, but hope remains that broader targeting of this and other pathways may provide an eventual alternative to ablative therapy for these tumors.

## Conclusion

RH is a benign neoplasm of the neurosensory retina or optic disc that occasionally manifests as a solitary, sporadic lesion, but typically appears as one or more tumors in the setting of VHL disease, an autosomal dominantly inherited condition involving benign and malignant neoplasms or cysts in the central nervous system or viscera. Referral of a patient with RH for clinical and/or genetic testing for VHL disease can be life-saving, given the potentially lethal nature of manifestations such as central nervous system hemangioblastoma and renal cell carcinoma, and given the benefits of surveillance and early intervention in affected individuals. Other critical components of ophthalmologic management include appropriate surveillance of patients with VHL disease for appearance or growth of RHs, retinal vascular proliferation, or other manifestations of ocular VHL disease, and timely application of ablative treatment for extrapapillary RHs, in order to minimize vision loss resulting from complications of progressive growth. RHs arising in proximity to the optic disc present a particular challenge, because they are frequently not safe to destroy using traditional ablative techniques. Improved understanding of the molecular pathology of VHL disease offers potential for development of nonablative therapies to arrest growth or induce regression of RH and other neoplasms in this condition.

## **Introduction**

### **History, Diagnosis, and Genetic Basis**

Tuberous sclerosis complex (TSC) is a rare multisystem genetic disorder, characterized by hamartomatous tumors of the brain, skin, viscera, and eye. It is inherited in an autosomal dominant fashion,<sup>1</sup> with a high degree of penetrance<sup>2</sup> albeit with variable phenotypic expression. The first publication of a color plate by Rayner of a patient with an apparent facial angiofibroma took place in 1835.<sup>3</sup> In 1880 D.M. Bourneville, from a neuropathologic study of a young patient with seizures, hemiplegia, mental subnormality, who also had renal tumors, coined the term tuberous sclerosis.<sup>4</sup> Von Recklinghausen had, in 1862, published a description of what turned out to be TSC.<sup>5</sup> However, the eponym Bourneville disease was commonly used to describe this condition until only recently. In 1908 Vogt<sup>6</sup> first proposed epilepsy, mental retardation, and the skin lesions of adenoma sebaceum as a diagnostic triad. In 1920 Van der Hoeve<sup>7</sup> first recognized retinal involvement in tuberous sclerosis. Ophthalmologists now recognize astrocytic hamartomas of both the retina and the optic nerve as common features of this condition.

The diagnostic criteria are based on the premise now that there are no truly pathognomonic features or clinical criteria for the diagnosis of tuberous sclerosis or TSC.<sup>6</sup> Signs that were once regarded as sufficiently specific are now known to occur as isolated findings in normal individuals without TSC.<sup>8</sup> In theory, the perfect disease classification scheme should have both a high sensitivity (low rate of missing the diagnosis of tuberous sclerosis) and a high specificity (low rate of incorrectly labeling a patient with tuberous sclerosis). The 2012 Tuberous Sclerosis Complex Consensus Group classified patients into two diagnostic groups: possible and definite, reduced from three groups in the 1998 classification: possible, probable, and definite.<sup>5,9</sup> Patients can be classified into one of three

categories based on the presence of clinical features of varying specificity (primary features: high specificity; secondary features: moderate specificity; tertiary features: lower degree of specificity).<sup>9</sup> The classic triad included seizures, mental retardation, and cutaneous angiofibromas, which, however, only occurs in 29% of cases.<sup>10</sup> Mental retardation and seizures were also left out of the revised criteria by the 1998 expert consensus panel.<sup>11</sup> The addition of DNA testing complements the clinical diagnosis and helps with genetic counseling, especially in concert with prenatal testing.<sup>12</sup> A definite diagnosis now depends on two major features (lymphangiomyomatosis and angiomyolipomas) or one major feature with two or more minor features or the presence of a *TSC1* or *TSC2* mutation of confirmed pathogenicity.<sup>13</sup>

## Genetic Diagnostic Criteria

A pathogenic mutation in *TSC1* or *TSC2* is an independent diagnostic criterion, sufficient for the diagnosis of TSC regardless of the clinical findings. A pathogenic mutation was defined as a mutation that prevents protein synthesis or inactivates the function of *TSC1* or *TSC2* proteins, hamartin, and tuberin respectively. However, a significant fraction (10–25%) of TSC patients have no mutation identified by conventional testing. Therefore a normal result does not exclude TSC.<sup>5</sup>

## Systemic Manifestations

### Neurologic

#### Seizures

Children with tuberous sclerosis often have seizures that are referred to as “infantile spasms” or “salaam attacks.”<sup>8</sup> These seizures are characterized by repetitive myoclonic spasms of the head, neck, and limbs. Originally described by West,<sup>14</sup> an English general medical practitioner, through the experience of his own son in 1841, the seizures last for seconds but may occur in bouts of 10–50. Hoyt<sup>15</sup> described infantile spasms as “lightning fast nodding of the head, often with extension or flexion of the trunk and frequently

also of the arms.” According to Pampliglione and Pugh,<sup>16</sup> 25% of children affected by “infantile spasms” develop other stigmata of tuberous sclerosis within 4 years of diagnosis. Infantile seizures, the most common feature of the disease, tend to evolve into grand mal seizures at a later time and are seen in 93% of patients.<sup>12,17</sup> Presently, the treatment of epilepsy in TSC (which occurs in 75–90% of cases) remains a major challenge, even with new anticonvulsant medications.<sup>18,19</sup> Vigabratin has shown promise with about 30% of patients with infantile spasms responding. However, retinal toxicity to vigabratin and MRI detectable cerebral lesions have been described in children receiving the medication. Even after neurosurgery, seizures recur in approximately 30% of cases.<sup>20</sup> The advent of mTORC1 inhibitors has led to a paradigm shift in treatment possibilities. Currently in addition to FDA approval for renal angioliomas and subependymal astrocytomas that cannot be resected, mTORC inhibitors (like rapamycin or everolimus) are in clinical trials for TSC-related refractory epilepsy, neurocognitive manifestations, and facial angiofibromas.<sup>13</sup>

## Cognitive and Behavioral Disability

Children with tuberous sclerosis may have normal or above-average intelligence.<sup>17</sup> However, Lagos and Gomez<sup>17</sup> reported that 44 (62%) of 71 tuberous sclerosis patients were labeled as mentally retarded. Subsequent reports confirm that neurocognitive manifestations ranging from profound cognitive disabilities to mild learning impairment occur in around 45% of patients.<sup>21</sup> While the majority of individuals with TSC have normal intelligence, they may still be prone to specific cognitive memory, attentional, and executive skills deficits.<sup>22</sup> It should be noted that early reports emphasizing the prevalence of mental retardation in tuberous sclerosis suffered from selection bias because they were based on patients who were institutionalized.<sup>12</sup> In the Lagos and Gomez series<sup>17</sup> intracranial calcifications were more commonly seen in patients with normal intelligence. The cause of both seizures and mental retardation may be related to the presence of cortical tubers (Fig. 135.1) and subependymal hamartomas (Fig. 135.2). These tumor masses represent benign astrocytic hamartomas, which

characteristically involve the basal ganglia, lateral and third ventricles, and the posterior fossa. Histopathologically, they consist of well-differentiated large astrocytes in an admixture of fibrillary astrocytes and calcospherules.<sup>23</sup> They frequently undergo cystic degeneration and dystrophic calcification, accounting for their typical radiologic features (Fig. 135.3) and for the name tuberous sclerosis.<sup>24</sup> Most significant variables associated with a poor cognitive outcome include a history of refractory seizures, *TSC2* mutations, and cortical tubers in specific locations of the brain.<sup>25</sup>

**FIG. 135.1** Cortical tuber (dimpled gyrus in center of illustration) destroying the normal cortical architecture.

**FIG. 135.2** Subependymal astrocytic hamartoma adjacent to the basal ganglia protruding into the lateral ventricle. (Courtesy of S. Ludwin.)

**FIG. 135.3** Axial flair reformat magnetic resonance imaging of tuberosus sclerosis lesions. (Courtesy of Dr. Angelica Oviedo, Dalhousie University/Capital Health, Halifax NS Canada.)

Brain tumors are associated with tuberosus sclerosis. These well-circumscribed lesions are classified as subependymal giant-cell astrocytomas and should not be confused with the giant-cell variant

of glioblastoma multiforme, a malignant astrocytoma.<sup>26</sup>

A case of giant cerebral aneurysm with visual loss as a result of optic nerve compression in a patient with tuberous sclerosis has been reported.<sup>27</sup>

## Skin Features

Facial angiofibromas, formerly referred to as adenoma sebaceum, occur as a reddish-brown papular rash found characteristically in a “butterfly” distribution over the face. This rash has often been considered to be a pathognomonic hallmark of tuberous sclerosis and is very sensitive, occurring in over 85% of patients.<sup>17</sup>

Histopathologically, “adenoma sebaceum” consists of multiple smooth papules that are benign angiofibromas.<sup>28</sup> The rash is generally not apparent at birth but appears in childhood, generally before the age of 9 years, and tends to intensify with time.<sup>23</sup> It is most prominent in the nasolabial folds and over the malar areas.

The skin lesion formerly believed to be pathognomonic for tuberous sclerosis is the hypopigmented macule or patch (Fig. 135.4). These lesions are variable in shape, with only an occasional one justifying the term ash-leaf sign. Often present at birth, this is the first clinical sign of disease. Its occurrence is highly variable, being present in up to 75% of affected children.<sup>29</sup> Pathologically, the ash-leaf lesion is an achromic nevus,<sup>30</sup> as opposed to vitiligo, in which the melanocytes are actually missing. Ultraviolet light (classically a Wood's lamp) may be used effectively in a darkened room to screen for the ash-leaf sign.<sup>31</sup> The importance of this clinical sign in the workup of a child with infantile spasms of unknown cause cannot be overemphasized.<sup>29</sup>

**FIG. 135.4** Hypopigmented skin macule or patch (achromic nevus), sometimes referred to as an ash-leaf sign. (Courtesy of P. McLeod.)

Shagreen patches represent areas of skin affected by fibromatous infiltration. This sign is seen in approximately 20% of cases, often in the lower back.<sup>32</sup> This flesh-colored, leathery plaque on the lumbosacral area is highly characteristic of the tuberous sclerosis complex.<sup>31</sup> Subungual fibromas may be seen on the hands and feet.<sup>17,31</sup>

## Visceral Features

Although Vogt's classic triad of mental deficiency, epilepsy, and facial angiofibromas implies central nervous system and skin involvement, it is important to be cognizant of the possible presence of visceral tumors. Renal angioliipomas are hamartomas that occur singularly or in multiples, in unilateral or bilateral fashion. They are present in 80% of patients with tuberous sclerosis.<sup>23</sup> They are benign tumors that are not known to metastasize to distant sites,<sup>33</sup> although extension to the renal vein has been noted.<sup>34</sup> Cardiac hamartomas also occur. They are rhabdomyomas that are single or multiple whitish nodules that characteristically protrude into the ventricles.<sup>23</sup> Slowly, progressive subpleural cysts may form and can rupture, causing a spontaneous pneumothorax.<sup>35</sup> Hamartomas of the liver, thyroid, pancreas, and testis have been reported.<sup>23</sup>

## Skeletal Features

The skeletal system is affected in 40% of cases.<sup>8</sup> Sclerotic calcified areas are seen in the skull and spine. Skull radiographs may show opacities over the calvaria that represent intraosseous sclerotic areas of intracranial calcified astrocytic hamartomas. Computed tomography (CT) scans are particularly helpful in the investigation of tuberous sclerosis.<sup>36</sup> Phalangeal cysts affect the hands and feet.<sup>8</sup>

## Ocular Manifestations

### Retinal Manifestations

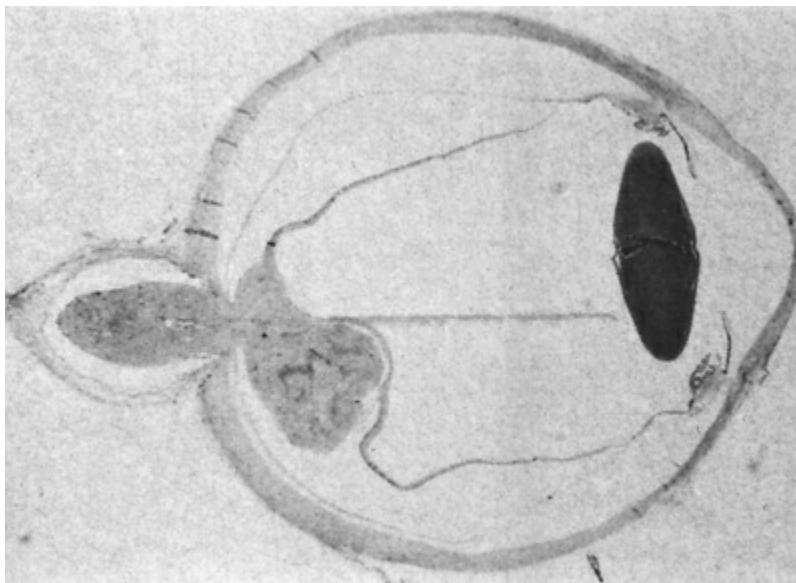

The retinal phakomas of tuberous sclerosis are astrocytic hamartomas of the retina, seen in an estimated 53% of patients, according to Lagos and Gomez<sup>17</sup> in their Mayo Clinic series of 71 cases. Shelton<sup>37</sup> found evidence of retinal hamartomatous lesions in all seven patients examined. Solitary astrocytic hamartomas may be seen in otherwise healthy patients, but in patients with tuberous sclerosis they may be multifocal or bilateral. Although most frequently seen in the setting of tuberous sclerosis, these hamartomas may also be noted in patients with neurofibromatosis.<sup>38,39</sup> Although astrocytic hamartomas of the retina are the principal ocular manifestation of the tuberous sclerosis complex, two patients have been reported in whom stromal depigmentation of the iris and atypical colobomas were correlated on histopathologic examination with hamartomas of the iris pigment epithelium and ciliary body epithelium.<sup>40</sup>

Typically, astrocytic hamartomas can be classified morphologically as one of two types: (1) large, whitish (calcified) nodular masses or (2) flat, translucent (noncalcified) smooth tumors.<sup>41</sup> Nyboer et al.<sup>42</sup> have described an intermediate type of retinal hamartoma having features of both types. These lesions typically occur at or near the optic disc. More peripheral lesions may occur, and these may be more easily confused with retinoblastoma. Although almost all astrocytic hamartomas of the retina in tuberous sclerosis are endophytic in nature, an exophytic case has been described (Figs. 135.5 and 135.6 illustrate a different case).<sup>34</sup> This case consisted of the pathologic examination of an eye

enucleated for neovascular glaucoma from a 10-year-old boy with tuberous sclerosis and seizures. The retina was totally detached and was associated with a large multinodular mulberry-like astrocytic tumor in the subretinal space.

**FIG. 135.5** Exophytic (subretinal) peripapillary astrocytic hamartoma appearing with an exudative retinal detachment. (Courtesy of J. Augsburger.)

**FIG. 135.6** Pathologic correlate (low-power

photograph) of the eye containing the lesion illustrated in Fig. 135.5. (Courtesy of J. Augsburger.)

The exophytic tumors are astrocytic tumors in the subretinal space.<sup>43</sup> The endophytic tumors are astrocytic hamartomas of the nerve fiber layer of the retina (Figs. 135.7 and 135.8).<sup>14</sup> These retinal tumors are benign and non-neoplastic,<sup>23</sup> generally showing minimal or slow evidence of growth,<sup>15</sup> although progressive enlargement associated with the development of calcification has been reported.<sup>42</sup> Retinal astrocytomas can, therefore, occasionally show progressive enlargement, retinal detachment, and vitreous seeding – findings that can “mislead the clinician towards a diagnosis of retinoblastoma.”<sup>44</sup> The reverse, however, has also been reported, since spontaneous regression of retinal astrocytic hamartoma has been described.<sup>45</sup>

**FIG. 135.7** Endophytic astrocytic hamartoma of the retina. (Courtesy of P. McLeod.)

**FIG. 135.8** Pathologic correlate of an endophytic astrocytic hamartoma of the retina. (Courtesy of R. Bell.)

Most astrocytic (glial) hamartomas of the retina are composed of elongated fibrous astrocytes with small oval nuclei and cytoplasmic processes.<sup>39</sup> Larger tumors, particularly those located on or near the optic nerve, may have large round and moderately pleomorphic astrocytes.<sup>46</sup> Foci of calcification may be seen. Clinically, Gass<sup>38</sup> has noted that these lesions may show varying degrees of tumor vascularization, which is more evident angiographically than ophthalmoscopically. Fluorescein angiography of retinal astrocytomas characteristically shows late-phase relative hyperfluorescence with leakage of dye into the vitreous cavity.<sup>38</sup> Fluorescein angiography, however, has not been considered helpful in differentiating astrocytic hamartomas from solitary retinoblastoma.<sup>47</sup>

Ocular complications related to the presence of retinal hamartomas have been reported as rare complications of tuberous sclerosis. These include vitreous hemorrhage, retinal vascular abnormalities (including telangiectasia, neovascularization, and exudation), and vitreous seeding, which is characteristically described in association with optic nerve head or epipapillary astrocytic hamartomas. Vitreous hemorrhage may arise from the substance of retinal or optic nerve astrocytomas, according to a clinicopathologic report in which the vitreous hemorrhage was thought to be arising from the surface of an epipapillary astrocytic hamartoma.<sup>48</sup> The hemorrhage was observed intraoperatively

during pars plana vitrectomy surgery to remove old vitreous hemorrhage. Attempts to use endodiathermy to cauterize an apparent surface bleeding site exposed cystic spaces within the tumor that were filled with hemorrhagic material and actively bled. A myriad of small vascular channels were confirmed pathologically.<sup>39</sup> Blood-filling intratumor cystic spaces in a large epipapillary tumor, resulting in vitreous hemorrhage, were first reported by Van der Hoeve in 1921.<sup>49</sup> Atkinson et al.<sup>50</sup> reported vitreous hemorrhage in two cases of optic disc astrocytomas. Koch and Walsh<sup>51</sup> also reported vitreous hemorrhage in a case associated with increased intracranial pressure and papilledema. Vitreous hemorrhage may also arise from retinal neovascularization associated with a retinal astrocytoma.<sup>52</sup> The angiogliomatous nature of retinal astrocytic hamartomas has been stressed in a pathologic report by Barsky and Wolter,<sup>41</sup> giving rise to speculation regarding the possible angioblastic and astroblastic origin of these lesions. Retinal telangiectasis with surrounding intraretinal lipid exudation in the parafoveal region and serous retinal detachment affecting the macula have been reported to occur in association with multiple astrocytic hamartomas.<sup>43</sup> A single case of a peripapillary lesion that hemorrhaged into the vitreous, increased in size, and underwent spontaneous necrosis has been reported.<sup>53</sup>

## Optic Nerve Phakomas

As reported by Lagos and Gomez,<sup>17</sup> retinal and optic nerve astrocytomas occur in 53% of cases. These lesions “protrude above or overlie the optic disc” (Fig. 135.9) and, according to Miller,<sup>54</sup> “may initially have a grayish or grayish pink appearance, but later develop a glistening, yellow, mulberry appearance.” Optic nerve astrocytomas have long been known to be capable of vitreous seeding and vitreous hemorrhage, as noted earlier, since Van der Hoeve's 1921 report.<sup>49,51</sup> In 1984, vitreous seeding associated with an intense vitritis in a patient with tuberous sclerosis was reported by De Juan et al.<sup>55</sup> These authors speculated that the development of a posterior vitreous detachment with associated traction at the optic disc may have resulted in vitreous seeding.

**FIG. 135.9** Glistening, mulberry-like optic nerve astrocytic hamartoma protruding above and overlying the optic disc. (Courtesy of J. Shakin.)

## Ocular Adnexal Lesions

Angiofibromas (adenoma sebaceum) of the skin of the lids occur in tuberous sclerosis, giving rise to a typical salmon-colored lid.<sup>56</sup> Isolated white eyelashes (poliosis) located among normally pigmented ones have been reported in a patient in whom the fundus of one eye was remarkable, not only for an astrocytic hamartoma of the retina, but also for a leaf-shaped area of hypopigmentation in the retinal periphery,<sup>57</sup> similar in appearance to the hypopigmented skin lesions (ash-leaf spots). Hypopigmented iris spots have also been reported as an early sign of disease.<sup>58</sup> Other isolated associations with tuberous sclerosis have been summarized by Williams and Taylor.<sup>12</sup>

## Differential Diagnosis

The differential diagnosis of astrocytic hamartomas of the retina and optic nerve depends to a great extent on whether the diagnosis of tuberous sclerosis can be established. This diagnosis is based on various primary, secondary, and tertiary features, most of which were initially put forth by Gomez<sup>59</sup> and recently revised in 2012 by the Tuberous Sclerosis Complex Consensus Group<sup>5</sup>:

Definite diagnosis: Two major features or one major feature with  $\geq 2$  minor features

Possible diagnosis: Either one major feature or  $\geq 2$  minor features (see Table 135.1).

**TABLE 135.1**

**Updated Diagnostic Criteria for Tuberous Sclerosis Complex, 2012**

<b>A. GENETIC DIAGNOSTIC CRITERIA</b>
The identification of either a <i>TSC1</i> or <i>TSC2</i> pathogenic mutation in DNA from normal tissue is sufficient to make a definite diagnosis of tuberous sclerosis complex (TSC). A pathogenic mutation is defined as a mutation that clearly inactivates the function of the <i>TSC1</i> or <i>TSC2</i> proteins (e.g., out-of-frame indel or nonsense mutation), prevents protein synthesis (e.g., large genomic deletion), or is a missense mutation whose effect on protein function has been established by functional assessment ( <a href="http://www.lovd.nl/TSC1">www.lovd.nl/TSC1</a> ; <a href="http://www.lovd.nl/TSC2">www.lovd.nl/TSC2</a> ; Hoogeveen-Westerveld et al. <sup>60,61</sup> ). Other <i>TSC1</i> or <i>TSC2</i> variants whose effect on function is less certain do not meet these criteria, and are not sufficient to make a definite diagnosis of TSC. Note that 10% to 25% of TSC patients have no mutation identified by conventional genetic testing, and a normal result does not exclude TSC, or have any effect on the use of clinical diagnostic criteria to diagnose TSC.
<b>B. CLINICAL DIAGNOSTIC CRITERIA</b>
<b>Major Features</b>
<ol style="list-style-type: none"> <li>1. Hypomelanotic macules (<math>\geq 3</math>, at least 5-mm diameter)</li> <li>2. Angiofibromas (<math>\geq 3</math>) or fibrous cephalic plaque</li> <li>3. Ungual fibromas (<math>\geq 2</math>)</li> <li>4. Shagreen patch</li> <li>5. Multiple retinal hamartomas</li> <li>6. Cortical dysplasias<sup>a</sup></li> <li>7. Subependymal nodules</li> <li>8. Subependymal giant cell astrocytoma</li> <li>9. Cardiac rhabdomyoma</li> <li>10. Lymphangi leiomyomatosis (LAM)<sup>b</sup></li> <li>11. Angiomyolipomas (<math>\geq 2</math>)<sup>b</sup></li> </ol>
<b>Minor Features</b>
<ol style="list-style-type: none"> <li>1. "Confetti" skin lesions</li> <li>2. Dental enamel pits (<math>&gt;3</math>)</li> <li>3. Intraoral fibromas (<math>\geq 2</math>)</li> <li>4. Retinal achromic patch</li> <li>5. Multiple renal cysts</li> <li>6. Nonrenal hamartomas</li> </ol>
<b>Definite Diagnosis</b>
Two major features or one major feature with $\geq 2$ minor features
<b>Possible Diagnosis</b>
Either one major feature or $\geq 2$ minor features

<sup>a</sup>Includes tubers and cerebral white matter radial migration lines.

<sup>b</sup>A combination of the two major clinical features (LAM and angiomyolipomas) without other features does not meet criteria for a definite diagnosis.

Therefore, in the presence of a single retinal (or optic nerve) hamartoma, only one additional major feature, or two or more minor features, are required to make the diagnosis of tuberous sclerosis complex. The first step for the ophthalmologist should be

carefully to reexamine both eyes for signs of one or more retinal or optic nerve hamartomas. Retinal and optic nerve astrocytic hamartomas can also be present in patients with neurofibromatosis.<sup>38</sup>

If the diagnosis of tuberous sclerosis or neurofibromatosis cannot be clearly established, the appearance of the retinal or optic nerve hamartoma may provide clinical clues related to the associated systemic condition. Shields and Shields<sup>24</sup> state that a tumor that consists of a mulberry-like calcification is pathognomonic of tuberous sclerosis. However, when the only retinal tumor seen is a small, translucent, and whitish noncalcified thickening of the nerve fiber layer, it may be difficult, if not impossible, to distinguish it from myelinated nerve fibers or retinoblastoma.<sup>24</sup> This difficulty in differentiating between small astrocytic hamartomas of the retina and retinoblastoma has also been stressed by others.<sup>62</sup> Gass<sup>47</sup> has reported that fluorescein angiography, although helpful in outlining the rich capillary network in these tumors, is not helpful in differentiating astrocytoma from retinoblastoma. However, despite this potential source of major diagnostic error, case series that examine cases of possible retinoblastoma rarely include a single case of astrocytic hamartoma of the retina.<sup>15,63</sup> In Howard and Ellsworth's series of 500 cases of suspected retinoblastoma in 1965,<sup>63</sup> not a single case of astrocytic hamartoma was mentioned, although there were 265 cases without retinoblastoma. Shields and Shields,<sup>24</sup> who list astrocytic hamartoma in the differential diagnosis of retinoblastoma, confirm the rarity of a mistaken diagnosis in their own series. Of the 136 patients sent to their clinic with the diagnosis of possible retinoblastoma, only one patient had an astrocytic hamartoma. Shields et al.<sup>39</sup> reported the use of fine-needle biopsy to help differentiate an astrocytic hamartoma from a retinoblastoma.

Other disorders that can mimic astrocytic hamartoma include myelinated nerve fibers and inflammatory lesions.<sup>8</sup> Furthermore, given the angiomatous component of these lesions, Coats disease and other causes of retinal telangectasis<sup>39,52,53,62,64</sup> should be included in the differential diagnosis. A more thorough list of clinical

**Box 135.1** of astrocytic hamartoma is provided in [Box 135.1](#).

## Differential Diagnosis of Astrocytic

## Hamartomas

- Retinal astrocytoma
- Retinoblastoma
- Myelinated nerve fibers
- Coats disease
- Other causes of retinal telangiectasis
- Retinal capillary angioma
- *Toxocara canis*, toxoplasmosis
- Other causes of choroiditis and scleritis
- Other causes of exudative retinal detachment with underlying mass lesion
- Optic disc astrocytic hamartoma
- Optic disc drusen
- Retinitis pigmentosa associated with optic disc excrescences (hyaline bodies) versus astrocytic hamartomas
- Optic disc glioma (variant of optic nerve glioma)
- Other primary optic disc tumor
- Other causes of unilateral optic disc swelling or papillitis

Optic disc hamartomas, after they have developed the yellow, glistening, mulberry appearance so characteristic of these lesions,<sup>54</sup> may be confused with optic disc drusen. However, optic disc drusen lie within the disc, whereas astrocytic hamartomas protrude above it<sup>54</sup> and obscure both the optic nerve and retinal blood vessels.<sup>65</sup> Heckenlively<sup>66</sup> reviewed the controversy of the origin of

the “globular excrescences or hyaline bodies of the optic nerve head.” These hyaline bodies are suspected of being drusen based on the pathologic studies of Spencer,<sup>46,67</sup> Puck et al.,<sup>68</sup> and Novak and Foos.<sup>69</sup> Heckenlively's interpretation is that these studies do not put to rest the issues raised by Robertson,<sup>70</sup> namely, that vitreal epipapillary excrescences in patients with retinitis pigmentosa represent astrocytic hamartomas.<sup>66</sup> Optic disc glioma may also be confused with astrocytic hamartomas. Gliomas of the optic disc may initially appear with disc swelling or obscuration of the disc by a whitish, protuberant mass. These lesions can be easily confused with astrocytic hamartomas, especially in the case of a noncalcified hamartoma. Although more commonly described in neurofibromatosis, Shields and Shields<sup>24</sup> note that optic disc glioma can also appear in patients with tuberous sclerosis. Other neoplastic lesions of the optic disc should be considered in the differential diagnosis, including capillary and cavernous hemangioma.<sup>54</sup>

## Genetics and Pathophysiology as a Guide to Treatment

Tuberous sclerosis complex is a systemic disorder that is inherited in an autosomal dominant fashion in which mutations in the tumor suppressor genes *TSC1* or *TSC2* lead to the development of benign hamartomas throughout the body as described, with incomplete penetrance and variable expressivity. However, approximately 70–75% of cases are said to arise from new mutations.<sup>13,71</sup> The prevalence of disease in an Oxford, UK study has been approximated at 1 in 15, 000.<sup>72</sup> More recently, prevalence has been estimated at 1 in 6000 to 1 in 9000 people. Worldwide there are at least 2 million people affected.<sup>13</sup> Linkage studies have demonstrated the genetic heterogeneity of this condition, with two separate mutations accounting for the vast majority of cases.<sup>73–75</sup> The two genes responsible for most cases of tuberous sclerosis are located on chromosome 9 at q34 (*TSC1*) and on chromosome 16 at p13.3 (*TSC2*).<sup>76</sup> No phenotypic differences are noted in patients with the two different mutations, although mutations in *TSC1* appear to be associated with a milder clinical phenotype.<sup>74,77</sup> The *TSC2* gene

accounts for as many as 90% of the clinical cases.<sup>13</sup> Tuberin, the product of *TSC2*, has partial homology to Rap 1-GTPase-activating protein, which supports the theory that tuberin plays a role in cell growth regulation.<sup>73</sup> The product of *TSC1* has been identified as hamartin.<sup>78</sup> These proteins are widely expressed in the brain and form a heterodimer that functions as a suppressor of the mammalian target of rapamycin (mTOR), the mTOR Complex 1, mTORC1, by inhibiting the mTOR, a serine/threonine kinase cascade,<sup>79</sup> part of a cascade modulating cellular growth and differentiation, tumor suppression, and intracellular signaling.<sup>13,78</sup>

More severe clinical manifestations tend to occur in individuals with *TSC2* mutations. They tend to present with more hypomelanotic skin macules and learning disabilities with more frequent neurologic and ophthalmologic signs, renal cysts, and ungual fibromas.<sup>13</sup> Genetic counseling and a three-generation genetic history is essential because patients with the tuberous sclerosis gene have a 50% chance of transmitting the gene to their offspring.<sup>73</sup> Parents of patients with tuberous sclerosis should be made aware of the possibility of germ-line mosaicism. It is important that these individuals have a thorough systemic evaluation, which should include CT/MRI scanning of the head and renal ultrasonography to rule out tuberous sclerosis.<sup>73</sup> If the results of these examinations are normal in the parents, the child likely suffers from a new mutation, and the subsequent risk of another child having tuberous sclerosis has been estimated at 1%.<sup>63</sup>

## Novel Treatment Approaches – Summary

Updated recommendations for surveillance and management of TSC manifestations have been published.<sup>80</sup> A better understanding of the molecular biology of TSC has led to a paradigm shift with respect to treatment possibilities in recent years. The activity of mTORC1 is very sensitive to rapamycin and related compounds such as everolimus; these agents have already undergone successful clinical trials for TSC-related subependymal astrocytomas and renal angiomyolipomas, leading to regulatory approval in many

countries including the United States, Canada, and Europe. Currently mTORC1 inhibitors are undergoing clinical trials for TSC-related refractory epilepsy, neurocognitive manifestations, and facial angiofibromas.<sup>13</sup>

**Phacomatosis Pigmentovascularis**

**Oculodermal Melanocytosis**

**Other Phakomatoses**

**Combined Systemic Hamartomas**

**Conclusion**

## **Introduction**

The phakomatoses are a group of syndromes characterized by systemic hamartomas of the eye, brain, skin, and sometimes the viscera and bones.<sup>1-4</sup> As a result of the multisystem involvement, the phakomatoses are also known as oculoneurocutaneous syndromes. Variable clinical manifestations of these syndromes are

recognized, and comprehensive care of the patient often involves coordination of several specialists, including neurologists, dermatologists, ophthalmologists, and oncologists.

The term “phakoma” was first used by Van der Hoeve in 1932 to indicate a mother spot, or birthmark, a characteristic finding in many of these entities.<sup>4</sup> At that time, retinal and cerebellar hemangiomas (von Hippel–Lindau syndrome), neurofibromatosis (von Recklinghausen syndrome), and tuberous sclerosis complex (Bourneville syndrome) were all classified as phakomatoses. Later, encephalofacial hemangiomas (Sturge–Weber syndrome), racemose angiomas (Wyburn–Mason syndrome), and cavernous hemangioma of the retina with cutaneous and central nervous system involvement were included with these conditions. More recently, other entities such as organoid nevus syndrome, oculodermal melanocytosis, and phacomatosis pigmentovascularis have been categorized with these classic oculoneurocutaneous syndromes.

## **Definition of Hamartia, Hamartoma, Chorista, Choristoma**

To better understand the phakomatoses, certain terms such as hamartia, hamartoma, chorista, and choristoma should be defined.<sup>1</sup> Hamartia and hamartoma are terms that refer to a malformation that is composed of tissues normally present at the location where it develops. A hamartia is a nontumorous anomaly, and a hamartoma is a tumorous malformation. The term systemic hamartomatosis is used to designate multiple organ involvement. Examples of hamartomas include the retinal hemangioblastoma (capillary hemangioma) that occurs from already present vascular tissue in the retina in von Hippel–Lindau syndrome, or the cutaneous peripheral nerve tumors that occur from the already present neural tissue within the skin in patients with neurofibromatosis.

Chorista and choristoma are terms that refer to a malformation composed of elements that are not normally present at the site where they develop. A chorista is a nontumorous anomaly and a choristoma is a tumorous malformation. The classic example of a

choristoma is the limbal dermoid, a tumor composed of dermal elements that are not normally present in the bulbar conjunctiva or cornea. Most of the phakomatoses are comprised of hamartomas rather than choristomas.

Most phakomatoses display an autosomal dominant mode of inheritance, often with incomplete penetrance. Notable exceptions are encephalofacial hemangiomas (Sturge–Weber) and racemose hemangiomas (Wyburn-Mason) in which germline heredity does not appear to play a role.

Most of the tumors that develop with the phakomatoses are benign. They are usually stationary or slowly progressive lesions that generally lack the capacity for limitless proliferation found with cancers.<sup>1</sup> Some phakomatoses can be associated with malignant neoplasms. For example, there is an increased incidence of malignant schwannomas of the peripheral nerves in patients with neurofibromatosis. Renal cell carcinoma occurs with greater frequency in patients with von Hippel–Lindau disease.

Patients with the phakomatoses might only manifest some of the clinical features of a particular syndrome and this is referred to as a “forme fruste.” Furthermore, patients can occasionally exhibit lesions characteristic of one entity and other lesions characteristic of another and this is referred to as the crossover phenomenon. For example, the café-au-lait spots seen in patients with neurofibromatosis can occasionally be seen in patients with tuberous sclerosis complex or encephalofacial hemangiomas.

In other chapters in the book, the conditions of tuberous sclerosis complex (Bourneville syndrome) and retinocerebellar hemangiomas (von Hippel–Lindau syndrome) have been described. In this chapter, we elaborate on other phakomatoses. These phakomatoses include neurofibromatosis (von Recklinghausen syndrome), encephalofacial hemangiomas (Sturge–Weber syndrome), retinal racemose hemangiomas (Wyburn-Mason syndrome), retinal cavernous hemangiomas, organoid nevus syndrome (Solomon syndrome), phacomatosis pigmentovascularis (*Cesioflammea* type), and oculodermal melanocytosis (nevus of Ota). Because this book covers primarily diseases of the ocular fundus, most emphasis is placed on retinal and choroidal manifestations.

# Neurofibromatosis (Von Recklinghausen Syndrome)

Neurofibromatosis is an oculoneurocutaneous syndrome characterized by multisystem involvement.<sup>5,6</sup> It is transmitted by an autosomal dominant mode of inheritance with about 80% penetrance. About one-half of the cases occur initially as spontaneous mutations with a negative family history.

Neurofibromatosis is subcategorized into types 1 and 2. Type 1 is called peripheral neurofibromatosis or von Recklinghausen syndrome, whereas type 2 is called central or bilateral acoustic neurofibromatosis. Type 1 neurofibromatosis is characterized by peripheral and cutaneous manifestations and is related to an abnormality on chromosome 17. Type 2 is characterized by central nervous system (CNS) tumors and early onset of posterior subcapsular cataract. Type 2 neurofibromatosis is related to an abnormality on chromosome 22.

## Neurofibromatosis Type 1

### General Considerations

Neurofibromatosis type 1 occurs at a rate of 1 in 3000 persons, but it is estimated that the frequency could be higher, as some individuals manifest only mild features. Approximately one-half of affected patients represent a new mutation. This condition is caused by an autosomal dominant mutation in the *NF1* gene that leads to decreased production of the protein neurofibromin, which has a tumor suppressor function. Only one deleted is necessary to manifest this condition. The *NF1* gene is on long arm of chromosome 17. There have been more than 250 mutations identified. Complete gene deletion leads to severe phenotype. This highly penetrant phenotype has a wide variety of manifestations and can vary within families. Another locus, the *SPRED1* gene, has been found in patients with “mild neurofibromatosis” and this represents Legius syndrome.<sup>7</sup>

The criteria for diagnosis of neurofibromatosis type 1 are listed in [Table 136.1](#).<sup>8,9</sup> This condition more often affects patients of the white

race and equally in boys and girls. Scoliosis can be a prominent feature.

**TABLE 136.1**

**Diagnostic Criteria for Neurofibromatosis Type 1 (NF1): At Least Two of the Following Seven Criteria Should be Present for Diagnosis<sup>a</sup>**

1. Café-au-lait	≥6 café-au-lait spots larger than 5 mm diameter in prepubertal children (<10 years)
	<i>or</i>
	≥6 café-au-lait spots larger than 15 mm in diameter in postpubertal individuals (adults)
2. Freckles in axilla or inguinal region	Crowe sign
3. Skin neurofibroma	≥2 typical neurofibroma
	<i>or</i>
	≥1 plexiform neurofibroma
4. Optic nerve glioma	
5. Iris Lisch nodules	≥2 lesions
6. Osseous lesion	Sphenoid dysplasia
	<i>or</i>
	Long bone abnormalities (cortex thinning or pseudoarthrosis)
7. Relative (1st degree) with NF1 by above criteria	Parent, sibling or offspring

<sup>a</sup>Some manifestations do not appear until later life, delaying diagnosis.

Adapted from Stumpf DA, Alksne JF, Annegers JF. Neurofibromatosis. Conference statement. National Institute of Health Consensus Development Conference. Arch Neurol 1988;45:575–8; and Gutmann DH, Aylsworth A, Carey JC, et al. The diagnostic evaluation and multidisciplinary management of neurofibromatosis 1 and neurofibromatosis 2. JAMA 1997;278:51–7.

## Ophthalmologic Features

Neurofibromatosis has the most diversified ocular findings among the phakomatoses.<sup>10–17</sup> This condition can involve the eyelid, conjunctiva, aqueous outflow channels, uveal tract, retina, orbit, and optic nerve (Fig. 136.1).

**FIG. 136.1** Neurofibromatosis type 1. (A) Iris Lisch nodules. (B) Multifocal choroidal freckling. (C) Axillary freckling. (D) Multiple cutaneous neurofibromatosis. (E) Vasoproliferative tumor with exudative retinopathy.

Eyelid involvement is characterized by nodular or plexiform neurofibroma. Nodular neurofibroma appears as a solitary or multifocal painless, smooth-surfaced, and well-defined mass, often the size of a pea, and without color change. Plexiform neurofibroma presents as a diffuse thickening of the eyelid that can produce the typical S-shaped curvature to the eyelid, a finding highly characteristic of neurofibromatosis. The conjunctiva can be involved by diffuse or localized neurofibromas. Patients with neurofibromatosis have an increased incidence of congenital glaucoma, which can be secondary to several mechanisms. There is a high association of neurofibromatosis type 1 with optic nerve glioma.<sup>12</sup>

A variety of ocular fundus lesions can occur in patients with

neurofibromatosis. Multiple iris hamartomas, known as Lisch nodules, are the most common uveal abnormality of neurofibromatosis type 1.<sup>11</sup> These characteristically orange–tan nodules appear in early childhood (usually by age 6 years) as discrete, multiple, bilateral tumors of the anterior border layer of the iris, classically measuring less than 1 mm diameter and best detected by slit-lamp biomicroscopy. Histopathologically, iris Lisch nodules are hamartomas composed of aggregates of melanocytes on the anterior border layer of the iris.

The choroidal findings in patients with neurofibromatosis type 1 include unifocal or multifocal choroidal nevus, diffuse plexiform neurofibroma, neurilemoma, and melanoma. Multiple bilateral, choroidal nevi are highly suggestive of neurofibromatosis type 1.<sup>10</sup> They are usually small, ill-defined, and randomly distributed. They might be best seen with near-infrared reflectance imaging or multispectral imaging with long wavelength.<sup>10</sup> Choroidal neurofibroma usually appears as a diffuse thickening of the uveal tract from an increased number of neurofibromatous and melanocytic elements. Choroidal neurilemoma (schwannoma) is a rare finding and manifests as a circumscribed, amelanotic elevated tumor.<sup>14</sup> Most solitary choroidal neurilemmomas, however, are not associated with neurofibromatosis. There appears to be a higher incidence of uveal melanoma in patients with neurofibromatosis.<sup>15</sup>

Several retinal and optic disc lesions can occur with neurofibromatosis. Retinal astrocytic hamartoma is a manifestation of neurofibromatosis, but is more common with tuberous sclerosis complex. Retinal vasoproliferative tumor can occur with neurofibromatosis, leading to exudative retinopathy and risk for blindness.<sup>16,17</sup> Fundus changes can occur secondary to optic nerve glioma, including optic disc edema, optic atrophy, opticociliary shunt vessels and, rarely, central retinal vein obstruction.

## **Dermatologic Features**

The most important cutaneous manifestations of neurofibromatosis include café-au-lait spots (pigmented macules), freckles in the axillary or inguinal region, and urticarial pigmentosa. Café-au-lait spots are found in 95% of patients with neurofibromatosis type 1, but they can be seen in patients with other conditions, such as

McCune–Albright syndrome, tuberous sclerosis complex, and Fanconi anemia. Café-au-lait spots can be found in persons without neurofibromatosis type 1. They represent the earliest manifestation of neurofibromatosis type 1 and can be found in infancy as a very light hyperpigmented macule that becomes more noticeable over time or with sun exposure.

Subcutaneous or cutaneous benign neurofibromas are an important finding but are rare in young children and typically appear in older children or later. Deep neurofibromas might not be visible and are detected only by palpation. Puberty and pregnancy can increase number and growth of neurofibromas. Plexiform neurofibromas can be invasive and ill-defined, occasionally associated with pain. Rapid growth of neurofibroma is suggestive of malignant degeneration.

## **Central Nervous System Features**

The most important central nervous system feature of neurofibromatosis type 1 is the optic nerve glioma (juvenile pilocytic astrocytoma). Optic nerve glioma can present with obvious features of painless proptosis or subtle features of color or visual acuity abnormalities. Magnetic resonance imaging shows enlargement of the optic nerve, often so large that it develops a fold (kink) within its substance to accommodate the orbit, leading to down-and-out proptosis. This mass shows enhancement on T1-weighted, gadolinium contrast images, particularly notable in the axial and coronal views. It is important to differentiate this tumor from optic nerve sheath meningioma as the systemic implications and therapy differ. This is best determined using gadolinium-enhanced, orbital fat suppressed, T1-weighted coronal views. With glioma, the central substance of the nerve enhances whereas with meningioma, the peripheral encircling arachnoid sheath enhances. Glioma is more often associated with neurofibromatosis type 1, whereas meningioma is more associated with neurofibromatosis type 2.

## **Other Features**

There are numerous orthopedic problems in patients with neurofibromatosis type 1. Sphenoid wing dysplasia, congenital

pseudoarthrosis with tibial or forearm bowing, thoracic cage asymmetry with inferior rib prominence, and scoliosis/kyphosis. Scoliosis at a young age (under 10 years) can progress. Other findings include macrocephaly and hypertension.

A number of other benign and malignant systemic tumors have been associated with neurofibromatosis. Sarcomas can arise from the peripheral nerve sheath, either de novo or from preexisting benign cutaneous nerve sheath tumors. Malignant peripheral nerve sheath tumors can occur in over 20% of patients. There seems to be an increased incidence of breast, genitourinary, and gastrointestinal tumors, as well as cutaneous melanoma. Patients with neurofibromatosis probably have a slightly higher incidence of pheochromocytoma.

## **Management**

The management of neurofibromatosis varies with the location and the extent of the disease. Most fundus lesions require no treatment. Choroidal melanoma and neurilemoma are often clinically indistinguishable, and have usually required plaque radiotherapy, resection, or enucleation. Iris Lisch nodules, congenital hypertrophy of the retinal pigment epithelium, and retinal astrocytic hamartoma are observed. Retinal vasoproliferative tumors often require cryotherapy, laser photocoagulation, photodynamic therapy, or plaque radiotherapy to control exudative findings.<sup>16,17</sup>

Neurofibromatosis type 1 is caused by mutation in the protein neurofibromin that inhibits the RAS pathway, which regulates cellular proliferation and differentiation. Systemic targeted biologic agents have been explored to halt growth of tumors such as sirolimus, an mTOR inhibitor.<sup>18</sup>

## **Neurofibromatosis Type 2**

### **General Considerations**

Neurofibromatosis type 2 is a multisystem disorder with prominent features of central nervous system tumors, including bilateral vestibular schwannomas (acoustic neuromas), spinal cord schwannomas, meningiomas, gliomas, and juvenile posterior subcapsular cataract. This condition is also referred to as MISME

syndrome, a mnemonic referring to related tumors of MIS (multiple inherited schwannomas), M-meningiomas, and E-ependymomas.<sup>19</sup> Cutaneous features are uncommon with this form of neurofibromatosis. The criteria for diagnosis of neurofibromatosis type 2 are listed in [Table 136.2](#).

**TABLE 136.2**

**Diagnostic Criteria for Neurofibromatosis Type 2 (NF2). Diagnosis Is Established With at Least One of the Three Items Listed Below**

Feature
1. Bilateral eighth cranial nerve tumors confirmed on magnetic resonance imaging or computed tomography
2. Unilateral eighth cranial nerve tumor <i>plus</i> Relative (1st degree) with NF2
3. Two of the following: Meningioma Glioma Schwannoma Juvenile posterior subcapsular lens opacity  <i>plus</i> Relative (1st degree) with NF2

Adapted from Stumpf DA, Alksne JF, Annegers JF. Neurofibromatosis. Conference statement. National Institute of Health Consensus Development Conference. Arch Neurol 1988;45:575–8; and Gutmann DH, Aylsworth A, Carey JC, et al. The diagnostic evaluation and multidisciplinary management of neurofibromatosis 1 and neurofibromatosis 2. JAMA 1997;278:51–7.

Neurofibromatosis type 2 can be associated with reduced lifespan secondary to central nervous system tumors, particularly if they are present at a young age and are multiple. The average age at symptom onset is approximately 20 years but can be delayed. Early age at symptom onset and the presence of intracranial meningioma at diagnosis are two signs of higher risk for disease severity and mortality. In an analysis of 150 affected patients, more than 40% were expected to die by 50 years.<sup>20</sup> Recent advances in treatment have extended life prognosis.

The incidence of neurofibromatosis type 2 is 1 in 25,000 live births and has nearly 100% penetrance by 60 years of age.<sup>21</sup> It is estimated that this condition has a diagnostic prevalence of 1 in 100,000 people. Neurofibromatosis type 2 is related to a mutation in the *NF2* gene at chromosome 22q12.2. This gene produces merlin (also

called neurofibromin-2), a tumor suppressor. When mutated, decreased function of merlin leads to the uncontrolled development of tumors, particularly in the central nervous system. One-half of affected patients have a de novo mutation.

## Ophthalmologic Features

Neurofibromatosis type 2 displays three important ophthalmologic findings, notably posterior subcapsular cataract in childhood, combined hamartoma of the retina and retinal pigment epithelium, and epiretinal membranes (Fig. 136.2) (Table 136.3). The juvenile posterior subcapsular cataract (<50 years) is a criterion for diagnosis of this condition. Other lens opacity in the capsular or cortical region of young patients are believed related to neurofibromatosis type 2. Lisch nodules are not a feature of neurofibromatosis type 2.

**FIG. 136.2** Neurofibromatosis type 2. (A) Right eye with retinal pigment epithelial (RPE) hyperplasia and nearly invisible inner retinal mass (*arrow*) classified as

combined hamartoma. (B) Left eye with more obvious combined hamartoma and retinal traction and RPE hyperplasia. (C) Magnetic resonance imaging (MRI) showing schwannomas of spine (*arrows*). (D) MRI showing bilateral acoustic neuroma (*arrows*).

**TABLE 136.3**

**Frequency of Clinical Features in Patients With Neurofibromatosis Type 2**

Feature	Frequency Associated With Neurofibromatosis Type 2 (%)
<b>OPHTHALMOLOGIC FEATURES</b>	
Juvenile posterior subcapsular cataracts	60–81%
Epiretinal membranes	12–40%
Retinal hamartomas	6–22%
<b>CUTANEOUS FEATURES</b>	
Cutaneous tumors	59–68%
Cutaneous plaques	41–48%
Subcutaneous tumors	43–48%
Intradermal tumors	Rare
<b>CENTRAL NERVOUS SYSTEM FEATURES</b>	
Bilateral vestibular (cranial nerve VIII) schwannomas	90–95%
Other cranial nerve schwannomas	24–51%
Intracranial meningiomas	45–58%
Spinal tumors	63–90%
Extramedullary	55–90%
Intramedullary	18–53%
Peripheral neuropathy	66%

Adapted from Asthagiri AR, Butman JA, Kim HJ, et al. Neurofibromatosis type 2. *Lancet* 2009;373:1974–86.

Epiretinal membranes and combined hamartoma of the retina and retinal pigment epithelium can have overlapping clinical phenotype and can be multifocal ([Fig 136.2](#)). Of those with severe clinical features of neurofibromatosis type 2, 80% display epiretinal membranes.<sup>21</sup> By enhanced depth imaging optical coherence tomography (OCT), this lesion shows a sawtooth, folded, or combination features from vitreoretinal traction.<sup>22</sup> The hamartomas are along the inner retina but lead to prominent retinal dragging, corkscrew retinal vessels, gray–green appearance, and tumor formation.<sup>22,23</sup>

## **Dermatologic Features**

The cutaneous features of neurofibromatosis type 2 are slightly different than those in type 1. Occasionally, overlap of the two conditions can be seen. Café-au-lait spots are occasionally found. Axillary or inguinal freckling is not often found with neurofibromatosis type 2. Subcutaneous schwannomas or neurofibromas can be found, and malignant transformation is extremely rare. Neurofibromatosis type 2 displays skin plaques, represented by well-circumscribed, roughened areas less than 2 cm and often with slight hyperpigmentation and hypertrichosis.

## **Central Nervous System Features**

Neurofibromatosis type 2 is also called central nervous system neurofibromatosis because of the importance of these related tumors. The central nervous system tumors represent the majority of findings in neurofibromatosis type 2 and vary with the size and extent of the associated tumors. Acoustic neuromas (vestibular schwannomas) are the most common and well-recognized feature. If bilateral, they are considered pathognomonic of type 2 neurofibromatosis. Patients present with symptoms of tinnitus, gradual hearing loss, and later growth produces brainstem compression, hydrocephalus, and facial palsy.

Spinal cord schwannomas, particularly dumbbell-shaped, are common. Spinal cord ependymomas, astrocytomas, and meningiomas can occur less frequently. Intracranial meningiomas are frequent and can manifest with or without symptoms. Nonvestibular schwannomas, particularly of cranial nerves III and V, are diagnosed at a fairly early age, but can be indolent and slow-growing.

## **Other Features**

Sensory motor polyneuropathy can be found, particularly in those with schwannomas.

## **Management**

Patients with neurofibromatosis type 2 should have annual ophthalmic, neurologic, dermatologic, and auditory examinations.

This requires a multidisciplinary team. Surgical resection of symptomatic neurologic tumors is performed, but radiotherapy or chemotherapy can be used, particularly for ependymomas. Erlotinib and lapatinib (epidermal growth factor inhibitors) for unresectable progressive schwannomas is under trial.<sup>24</sup> Additionally, bevacizumab and Gleevec have been investigated for treatment of schwannomas. Regarding ophthalmic care, cataract surgery can be beneficial. Additionally, monitoring of epiretinal membrane with clinical examination and OCT, with surgical removal if progressive, can be considered.<sup>23</sup>

## Encephalofacial Hemangiomatosis (Sturge–Weber Syndrome)

### General Considerations

The Sturge–Weber syndrome is characterized by congenital hamartomas of the eye, skin, and brain that manifest at different times during life, mostly in childhood. These include choroidal hemangioma, facial nevus flammeus (port wine stain), and brain hemangioma with intracranial calcification.<sup>25–37</sup> Some patients display a forme fruste, or partial expression, rather than the entire syndrome. In contrast to the other systemic hamartomatosis, there is no recognizable hereditary pattern associated with Sturge–Weber syndrome. There is no predisposition for sex or race.

This condition affects 1 per 50,000 persons. Roach has designed a classification for Sturge–Weber syndrome (Table 136.4).<sup>25,26,31</sup> In 1987, Happle proposed that Sturge–Weber syndrome was an example of somatic mosaicism of a genetic trait.<sup>32</sup> In 2003, Comi and associates supported this theory by demonstrating abnormality in the gene expression of fibronectin in fibroblasts from the region of the port wine stain compared with normal skin.<sup>33</sup> Recent study has found activating somatic *GNAQ* gene mutation in the port wine stain.<sup>30</sup> A variable but progressive course can occur in the lesions in the brain, eye, and skin as well as those related to otolaryngological, endocrine, emotional, and behavioral aspects.

**TABLE 136.4****Roach Diagnostic Scale for Classification of Encephalotrigeminal Angiomatosis (Sturge–Weber Syndrome)**

Type	Title	Involvement of Skin, Eye, and Brain
Type I	Classic Sturge–Weber syndrome	Leptomeningeal angioma present
		Cutaneous facial angioma present
		Glaucoma likely present
Type II	Sturge–Weber syndrome	Leptomeningeal angioma absent
		Cutaneous facial angioma present
		Glaucoma possibly present
Type III	Sturge–Weber syndrome forme fruste	Leptomeningeal angioma present
		Cutaneous facial angioma absent
		Glaucoma absent

Adapted from Roach ES. Neurocutaneous syndromes. *Pediatr Clin North Am* 1992;39:591–620.

## Ophthalmologic Features

The ocular findings associated with Sturge–Weber syndrome include eyelid involvement with the nevus flammeus, prominent epibulbar blood vessels, glaucoma, retinal vascular tortuosity, and diffuse choroidal hemangioma (Fig. 136.3). Glaucoma is more common in patients with Sturge–Weber syndrome than it is in the other systemic hamartomas. In a study of 50 patients with nevus flammeus, there was an 8% overall incidence of glaucoma.<sup>27</sup> If the facial hemangioma involved both the first and second division of the trigeminal nerve, the incidence was 15%.<sup>27</sup> The glaucoma occurs unilaterally on the side of the facial hemangioma and it can gradually lead to extensive optic disc cupping and blindness. The associated glaucoma can be either congenital or juvenile. Sullivan and associates reviewed eye findings in 51 patients with Sturge–Weber syndrome and found 71% with glaucoma (onset before 2 years of age in most cases), 69% with conjunctival or episcleral prominent vessels, and 55% with diffuse choroidal hemangioma.<sup>34</sup>

**FIG. 136.3** Sturge–Weber syndrome. (A) Facial nevus flammeus. (B) Diffuse choroidal hemangioma with serous retinal detachment, retinal pigment epithelial hyperplasia, and visual loss, confirmed on ultrasonography (C) and optical coherence tomography (OCT) (D). Following plaque radiotherapy (E), complete resolution of retinal detachment (F), tumor on ultrasonography (G) and subretinal fluid on

## OCT (H).

The main abnormality of the uveal tract in patients with Sturge–Weber syndrome is diffuse choroidal hemangioma.<sup>35,36</sup> Patients with this tumor display bright red pupillary reflex in the involved eye compared with the contralateral eye. This phenomenon, which is due to the light reflex from the highly vascularized tumor in the posterior pole, has been called the “tomato catsup” fundus.<sup>28</sup> B-scan ultrasonography typically demonstrates a diffuse, highly echogenic thickening of the choroid. The tumor is usually unilateral but bilateral cases associated with bilateral facial nevus flammeus have been recognized. Choroidal hemangioma is usually diagnosed when the affected patient is young (median age 8 years), either because the associated facial hemangioma prompts a fundus examination or because visual impairment occurs from hyperopic amblyopia or from secondary retinal detachment. Diffuse choroidal hemangioma can lead to a total retinal detachment and secondary neovascular glaucoma.

Other fundus changes seen with Sturge–Weber syndrome include congenital retinal vascular tortuosity and pigmentary alterations from a longstanding nonrhegmatogenous retinal detachment, sometimes causing a “pseudoretinitis pigmentosa” appearance.

## **Dermatologic Features**

The classic skin lesion of Sturge–Weber syndrome is the facial nevus flammeus or port wine stain. Although it typically occurs in the cutaneous distribution of the fifth cranial nerve, it can have many variations, ranging from minor involvement of the first division of the nerve to massive involvement of all three divisions.

The port wine stain has been found to harbor *GNAQ* mutation.<sup>30</sup> Of 192 children with port wine stains, the most valuable predictor of adverse outcomes was stain involving the forehead with its inferior border at the outer canthus of the eye to the top of the ear and involving upper eyelid – a feature that involves all three divisions of the trigeminal nerve.<sup>29</sup> Bilateral involvement did not worsen outcome. All children with a forehead stain should have an ophthalmic examination and brain MRI.<sup>29</sup>

## Central Nervous System Features

The typical CNS feature associated with Sturge–Weber syndrome is a diffuse leptomeningeal hemangioma that is ipsilateral to the facial hemangioma.<sup>30</sup> This lesion can show secondary calcification that appears radiographically as a radiopaque double line which has been called the “railroad track” sign. The calcification often increases during the first 20 years of life and usually becomes stable in adulthood. Seizures, stroke, headache, learning disorders, and developmental delay can occur as a result of the leptomeningeal hemangioma (Table 136.5).

**TABLE 136.5**  
**Clinical Findings in the Sturge–Weber Syndrome**

Feature	Percentage
Cutaneous facial nevus flammeus	87%
Bilateral cerebral involvement	15%
Seizures	72–93%
Hemiparesis	25–93%
Hemianopia	44%
Headache	44–62%
Developmental delay or mental retardation	50–75%
Glaucoma	30–71%
Choroidal hemangioma	40%

Of all patients with facial port wine stain, only 8% show complete features of Sturge–Weber syndrome.

## Management

The management of diffuse choroidal hemangioma varies with the extent of the tumor and secondary retinal detachment. If the tumor is minimally elevated and without subretinal fluid, observation is advised and correction of the induced hyperopic change and related amblyopia should be considered. Thicker tumors with secondary retinal detachment are treated with oral propranolol, photodynamic therapy, plaque radiotherapy, or external beam radiotherapy.<sup>34,37</sup> Oral propranolol is an alternative that may or may not be efficacious. Multispot photodynamic therapy often resolves the fluid, but this procedure requires patient cooperation during delivery. Plaque radiotherapy and external beam radiotherapy with a total dose of 20–40 Gy has been reliably successful in achieving

resolution of subretinal fluid and return of some visual acuity, depending on the chronicity.<sup>37</sup> The treatment of related glaucoma can be complex.

The cutaneous lesions seen with Sturge–Weber syndrome can be managed by repetitive laser photocoagulation in infancy and later cosmetic creams to cover the defect. Both of these methods can improve the cosmetic appearance.

## Racemose Hemangiomas (Wyburn-Mason Syndrome)

### General Considerations

Racemose hemangioma of the midbrain and ipsilateral retina is called the Wyburn-Mason syndrome.<sup>38</sup> In contrast to the other oculoneurocutaneous syndromes, it has few skin changes except for occasional small hemangiomas. The ocular and central nervous system changes, however, can be quite striking. Like Sturge–Weber syndrome, this congenital condition does not appear to be familial and does not exhibit a hereditary pattern. The characteristic arteriovenous communications can range from subtle asymptomatic lesions to more extensive lesions that form tumor-like vascular masses, often referred to as racemose or cirroid hemangiomas.

The exact association of the retinal and central nervous system hemangiomas is not clear, but it is estimated that 30% of patients with the retinal findings have brain findings.<sup>38</sup> On the other hand, it is estimated that 8% of patients with brain findings have retinal findings.

### Ophthalmologic Features

The classic ocular finding is the racemose hemangioma of the retina (Fig. 136.4).<sup>38–44</sup> Similar vascular malformations can occur in the orbit and adjacent structures. These retinal arteriovenous communications have been divided into three groups according to the Archer classification (Table 136.6).<sup>41</sup> Group I is characterized by interposition of an abnormal capillary plexus between the major

vessels. It is not a true tumor and the affected patient is often asymptomatic. Group II is typified by a direct arteriovenous communication without interposition of capillary or arteriolar elements. The dilated blood vessels in this group can superficially resemble a retinal capillary hemangioma, but no tumor, exudation, or retinal detachment is present. In general, these patients have few visual symptoms, but they can have associated cerebral arteriovenous malformations. Group III is characterized by a more extensive, complex arteriovenous communication, which is often associated with visual loss. In this group, the most striking feature is one or more dilated arteries that emerge from the optic disc, pass for a variable distance into the retina, form distinct arteriovenous communications, and then pass back to the optic disc as large veins. There is characteristically no exudation or retinal detachment and the vessels do not leak fluorescein. Although these lesions are believed to remain stationary indefinitely, we have observed changes in the distribution of the blood vessels over several years. Branch retinal vein obstruction can occur.<sup>42,43</sup> Iris racemose hemangioma has not been associated with retinal racemose hemangioma or the Wyburn-Mason syndrome.<sup>44</sup>

**FIG. 136.4** Wyburn-Mason syndrome. (A) Archer type III retinal vascular malformation seen clinically and on (B) fluorescein angiography.

**TABLE 136.6****Archer Classification for Wyburn-Mason Syndrome**

Group	Feature	Comments
I	Abnormal capillary plexus between the major vessels of the arteriovenous malformations	Such lesions tend to be small, patients asymptomatic, and intracranial involvement uncommon
II	Arteriovenous malformations lack any intervening capillary bed between the artery and vein	Risk of retinal decompensation resulting in retina edema, hemorrhage, and vision loss. Low risk for intracranial arteriovenous malformations
III	Extensive arteriovenous malformations with dilated and tortuous vessels and no distinction between artery and vein	High risk for visual loss due to retinal decompensation or retinal compression of nerve fiber layer, optic nerve, or other vessels. High risk for intracranial arteriovenous malformations

Adapted from Archer DM, Deutman A, Ernest JT, et al. Arteriovenous communications of the retina. *Am J Ophthalmol* 1973;75:224–41.

## Dermatologic Features

There are no significant cutaneous changes associated with racemose hemangiomatosis, except for the rare occurrence of small facial angiomas.

## Central Nervous System Features

The racemose hemangioma of the central nervous system is most often found in the midbrain. Spontaneous intracranial hemorrhage from the malformation can lead to a variety of neurologic symptoms, most notably stroke and focal neurologic defects. Intracranial hemorrhage occurs far more frequently than intraocular hemorrhage. These malformations typically become symptomatic in the second or third decade of life and present with headache, vomiting, or meningismus. Hydrocephalus can ensue. In one analysis of the differential diagnosis of strokes in children, the leading causes included familial cavernous malformations, hereditary hemorrhagic telangiectasia, and moyamoya disease, as well as Wyburn-Mason syndrome and others.<sup>39</sup>

## Other Features

The bones of the skull can frequently be involved with the vascular malformation. When the mandible or maxilla is affected, prolonged

bleeding can occur during invasive dental work.

## Management

In general, no dermatologic or ophthalmic treatment is necessary in patients with racemose hemangiomas. The retinal vascular lesion is monitored for vein obstruction or hemorrhage. Branch retinal vein obstruction usually resolves without treatment, but intravitreal injection of antivascular endothelial growth factor or panretinal photocoagulation can be considered to prevent ischemic vascular complications and glaucoma. If persistent vitreous hemorrhage is found, then vitrectomy removal is performed.

# Retinal Cavernous Hemangiomas

## General Considerations

There are two types of retinal cavernous hemangioma, including those that occur sporadically and those associated with the syndrome of cutaneous and central nervous system vascular malformations.<sup>45-51</sup> The latter is associated with a highly penetrant autosomal dominant mutation and is considered a phakomatosis. Genetic abnormalities have been found on chromosomes 3q, 7p, and 7q.

## Ophthalmologic Features

The only ocular manifestation of this syndrome is the retinal cavernous hemangioma (Fig. 136.5). Ophthalmoscopically, this lesion appears as a dark grape-like cluster of venous intraretinal aneurysms either at the optic disc, macula, or in the peripheral retina.<sup>45-51</sup> There is no obvious feeding artery and the lesion is typically centered along the course of a vein. This lesion produces no exudation or subretinal fluid, likely due to the fact that the thin-walled channels are lined by nonfenestrated endothelium. Repetitive vitreous hemorrhages (often mild and subclinical) can lead to white fibroglial tissue on the surface.<sup>50</sup> This nonprogressive thin-walled, aneurysmal retinal tumor can remain hidden in the fundus for decades until dilation is performed or the patient

develops vitreous hemorrhage.

**FIG. 136.5** Retinal cavernous hemangioma in a patient with brain hemangiomas.

The main complication of retinal cavernous hemangioma is vitreous hemorrhage. Larger tumors can be associated with severe fibroglia and related retinal dragging with displacement of the macula.

The most important diagnostic test for retinal cavernous hemangioma is fluorescein angiography, which produces highly characteristic, if not pathognomonic, features of hypofluorescence persistent into the late frames with slow nonleaking filling of the aneurysms. Fluorescein is contained within the venous aneurysms of the lesion and pools in the plasma in the superior portion of each vascular space, while the blood elements collect in the inferior portion. This produces the typical fluorescein–blood interface in the late angiograms that characterizes retinal cavernous hemangioma. Other rare ophthalmic findings include iris cavernous hemangiomas with repetitive hemorrhages.<sup>48</sup>

### **Dermatologic Features**

The hemangiomas of the skin in this syndrome are variable in their appearance and distribution on the body. The lesions occur most commonly on the back of the neck. Involvement of the eyelids is rare.

## Central Nervous System Features

Cavernous hemangioma can involve any region of the central nervous system but is more common in the supratentorial rather than infratentorial region. Spinal cord involvement can occur. Symptoms include seizures, hemorrhage, and focal neurologic defect most commonly. About 25% of patients display no neurologic symptom despite having a cavernous hemangioma within the brain.<sup>49</sup> Intracranial hemorrhage occurs in 12–48%. Magnetic resonance imaging can provide information to the location and size of the mass.

## Other Features

Various ophthalmic manifestations related to brain injury can occur, such as diplopia due to paresis of extraocular muscles, presumably secondary to bleeding into the oculomotor nuclei. It is likely that many patients have vascular lesions in the central nervous system that remain subclinical throughout life.

## Management

The cutaneous hemangiomas seen with this condition are generally small and asymptomatic and require no treatment. Most cavernous hemangiomas of the retina are also asymptomatic and require no treatment. Vitreous hemorrhage can be an occasional complication of larger tumors and the blood could spontaneously resolve over several months. If not, then pars plana vitrectomy with blood removal is performed. For repetitive vitreous hemorrhages, several techniques have been attempted to control the vascular retinal tumor, including cryotherapy, photocoagulation, photodynamic therapy, and plaque radiotherapy. Plaque radiotherapy induces vascular sclerosis, similar to the gamma knife or CyberKnife radiotherapy used to treat the central nervous system hemangiomas.

# Organoid Nevus Syndrome

## General Considerations

The organoid nevus syndrome (ONS) is an oculoneurocutaneous condition without clear genetic abnormality. The features include the sebaceous nevus of Jadassohn, cerebral atrophy, arachnoidal cyst, epibulbar complex choristoma, eyelid coloboma, posterior calcified scleral cartilage, and occasionally other features.<sup>52-55</sup> The sebaceous nevus of Jadassohn is a well-recognized dermatologic entity, but the complete syndrome of organoid nevus syndrome is relatively uncommon. This sporadic condition displays more choristomas than hamartomas, unlike other phakomatoses. Despite the lack of genetic understanding, there have been exceptionally rare cases of multiple generations affected with organoid nevus syndrome.

This condition was originally described by Jadassohn with the term “organoid nevus” to emphasize the prominence of the cutaneous component. Later, terms such as “nevus sebaceous of Jadassohn” and “Solomon syndrome” were applied to this condition.

## **Ophthalmologic Features**

Although there are several ophthalmic features of the organoid nevus syndrome, two most important ones are the epibulbar complex choristoma and posterior scleral cartilage/bone (Fig. 136.6).<sup>52-54</sup> The epibulbar complex choristoma is a fleshy lesion of the conjunctiva that often extends onto the cornea. It is composed histopathologically of a dermolipoma that contains variable combinations of ectopic lacrimal gland and hyaline cartilage. The posterior scleral cartilage produces a yellow-white discoloration of the fundus near the optic disc, but in some cases there is evidence of bone.<sup>54</sup> With ultrasonography and computed tomography, there is a bone density plaque at the level of the choroid and sclera that corresponds to the intrascleral cartilage/bone.<sup>54</sup>

**FIG. 136.6** Organoid nevus syndrome. (A) Facial nevus sebaceous of Jadassohn. (B) Subtle epibulbar choristoma. (C) Subtle cartilaginous choristoma superior to disc but confirmed on computed tomography as calcified (D).

## Dermatologic Features

The main dermatologic feature of the organoid nevus syndrome is the sebaceous nevus of Jadassohn. It appears as a geographic yellow–brown lesion that often involves the preauricular or brow region and extends onto the scalp where it is associated with alopecia and often down along the neck and nose. This lesion becomes hypertrophied with time. There are three stages of this cutaneous lesion dependent on patient age.<sup>52</sup> The first stage occurs in infancy with underdevelopment of hair, sebaceous glands, and adnexal structures. The second stage occurs at puberty with overdevelopment of adnexal structures. The third stage occurs in adulthood with benign and malignant tumors including basal cell carcinoma, syringocystadenoma papilliferum, sebaceous adenoma, keratoacanthoma, and others. It is estimated that 20% of patients

with sebaceous nevus of Jadassohn will develop basal cell carcinoma arising from the nevus. In one study of 707 patients with sebaceous nevus of Jadassohn the most common benign tumors were trichoblastoma (7%) and syringocystadenoma papilliferum (5%).<sup>55</sup> The malignant tumors were basal cell carcinoma (1%) and squamous cell carcinoma (<1%), all of which occurred in adults.

## **Central Nervous System Features**

Patients with the organoid nevus syndrome can develop seizures, due mainly to enlarging subarachnoid cysts in the central nervous system, and mental retardation. Imaging studies have shown arachnoidal cysts, leptomenigeal hemangiomas, hamartomas, cerebral cortical atrophy, and the MEAN tumor (meningoencephaloangioneuromatosis).

## **Other Features**

Rarely, organoid nevus syndrome can have cardiac and renal abnormalities, including patent ductus arteriosus, ventricular septal defect, coarctation of the aorta, nephroblastomatosis, and horseshoe kidney. Other rare relationships include vitamin D-resistant rickets and liver cysts.

## **Management**

The epibulbar choristoma generally remains stationary and can be safely observed. However, there is a risk for amblyopia, which should be monitored and corrected. Larger or progressive lesions might require surgical excision, but often the lesion is full thickness within the wall of the eye and complete resection is not possible. There is no treatment of the benign cartilaginous/bony fundus lesion. There has been no documentation of enlargement of this lesion. This lesion should be differentiated from choroidal osteoma and retinoblastoma, particularly since it occurs in infancy. The cutaneous sebaceous nevus is usually resected to minimize risk for transformation into basal cell carcinoma or other adnexal tumors. Monitoring of the central nervous system with imaging is advised for arachnoidal cyst and tumor.

# Phacomatosis Pigmentovascularis

## General Considerations

Phacomatosis pigmentovascularis is a rare condition representing the coexistence of cutaneous vascular malformation (usually nevus flammeus) with melanocytic nevus (usually melanocytosis).<sup>56-61</sup> Since the first report on this condition by Ota in 1947, there have been few reports, mostly in the dermatologic literature.<sup>56</sup> In 2005, Tran and Zografos reported three cases, all with uveal melanoma.<sup>57</sup> In 2011, Shields et al. published 7 cases, of which 3 had choroidal melanoma, 1 with optic disc melanocytoma, and 1 with conjunctival melanoma in situ (primary acquired melanosis).<sup>60</sup> Phacomatosis pigmentovascularis is divided into three types: phacomatosis cesioflammea, phacomatosis spilorozea, and phacomatosis cesiomarmorata (Table 136.7).<sup>58,60</sup> Phacomatosis cesioflammea is characterized by coexistence of a dermal melanocytosis (blue spot) and nevus flammeus (port wine stain). “Caesius” is Latin for “bluish gray” and “flammea” for “flame” or “fire.” The other two types have less relationship to the eye.

**TABLE 136.7**

**Classification of Phacomatosis Pigmentovascularis (PPV)**

New Classification	Findings	Old Classification
Phacomatosis cesioflammea	Nevus caesius (blue spot) or melanocytosis with nevus flammeus	PPV II a/b
Phacomatosis spilorozea	Nevus spilus (speckled lentiginous nevus) with pale pink telangiectatic nevus	PPV II a/b
Phacomatosis cesiomarmorata	Nevus caesius (blue spot) with cutis marmorata	PPV V a/b
Phacomatosis pigmentovascularis unclassifiable	Various pigmentary and vascular nevi	PPV IV a/b and no name

Adapted from Happle R. Phacomatosis pigmentovascularis revisited and reclassified. Arch Dermatol 2005;141:385–8.

The association of dermal melanocytosis with cutaneous nevus flammeus is believed to be due to the “twin spotting” phenomenon, which is the association of two genetically different clones of cells within a region of normal cells.<sup>59</sup> This involves sporadic somatic

recombination and a mosaic distribution of lesions. Moutray and associates describe monozygotic twins discordant for phacomatosis cesioflammea, supporting postzygotic twin spotting theory.<sup>59</sup> In that report, twin #1 was normal and twin #2 had cutaneous nevus flammeus of the arm, maxilla, and periocular region in addition to Mongolian spot and bilateral ocular melanocytosis.

## Ophthalmologic Features

The ophthalmologic features of phacomatosis pigmentovascularis include a spectrum of findings with unilateral or bilateral periocular facial nevus flammeus (port wine stain), ocular or oculodermal melanocytosis, secondary glaucoma, and risk for uveal or conjunctival melanoma (Fig. 136.7). There are only few reports in the ophthalmic literature.

**FIG. 136.7** Phacomatosis pigmentovascularis. (A) Newborn baby with facial nevus flammeus, subsequently treated with laser photocoagulation and regressed at a later date (B). (C) Fundus photography demonstrates dark ocular melanocytosis in right eye and normal fundus left eye (D).

## **Dermatologic Features**

Fernandez-Guarino reviewed the published dermatologic literature on 216 cases of phacomatosis pigmentovascularis and classified 77% as cesioflammea, 13% as spilorosea, 1% as cesiomarmorata, and 8% unclassifiable.<sup>61</sup> The cutaneous manifestations included mostly pigmented lesions of nevus of Ota (melanocytosis); Mongolian spot, or café-au-lait spot; nonpigmentation of vitiligo; and vascular lesions of nevus flammeus (port wine stain) or nevus anemicus. These cutaneous findings tended to be patchy without midline separation and scattered over the surface of the body.

## **Central Nervous System Features**

Neurologic features of phacomatosis pigmentovascularis include seizures, cortical atrophy, Arnold Chiari type 1, bilateral deafness, idiopathic facial paralysis, hydrocephalus, diabetes insipidus, plexiform neurofibroma, psychomotor developmental delay, and electroencephalogram alterations.<sup>61</sup>

## **Other Features**

Miscellaneous features include scoliosis, extremity length asymmetry, syndactyly, macrocephaly, renal agenesis, renal angiomas, hepatosplenomegaly, cavernous hemangioma, umbilical hernia, hypoplasia of leg veins, IgA deficit, hyper IgE syndrome, eczema, and premature eruption of teeth.<sup>61</sup>

## **Management**

The cutaneous features should be managed by a dermatologist. Often the port wine stain responds to infantile laser therapy. The ophthalmologist should follow the patient lifelong for the development of glaucoma and melanoma. Monitoring of neurologic status should also be performed.

# **Oculodermal Melanocytosis**

## **General Considerations**

Ocular or oculodermal melanocytosis is a congenital pigmentary

condition that can affect the periocular skin, sclera, uvea, orbit, palate, ear drum, and meninges.<sup>1-3,62-73</sup> This condition predisposes the patient to melanoma, particularly uveal melanoma and occasionally orbital or meningeal melanoma.<sup>62-75</sup> Ocular or oculodermal melanocytosis can occur as a diffuse condition, affecting all quadrants of the eye in a homogeneous fashion, or as a sectoral condition, affecting only a portion of the eye.<sup>71</sup> This is a sporadic condition with no genetic mutation identified.

## **Ophthalmologic Features**

The ophthalmologic features of ocular or oculodermal melanocytosis include dermal periocular pigmentation (flat blue nevus) with occasional pigment in the temporal fossa along the hairline; scleral pigmentation; and uveal pigmentation involving the iris, ciliary body, and choroid (Fig. 136.8). Orbital pigmentation with blue nevus cells is occasionally found. The iris can manifest mammilations, or clumping of tissue into a “polka dot” appearance, related to the dense pigment. Early onset equatorial drusen is often found. The main concern of this excessive pigmentation is the risk for the development of uveal melanoma (1/400 risk for whites),<sup>67</sup> orbital melanoma, and meningeal melanoma. Uveal melanoma arising from melanocytosis carries double the risk for metastatic disease.<sup>74,75</sup> Occasionally, optic disc melanocytoma and ipsilateral headache are a part of this syndrome.

**FIG. 136.8** Oculodermal melanocytosis. (A) Diffuse melanocytosis manifesting with nevus of Ota surrounding right eye and sclera with melanocytosis (B). (C) Sector melanocytosis of iris. (D) Sector melanocytosis of choroid.

Genetic evaluation following enucleation of an eye with melanoma arising from melanocytosis revealed normal disomy chromosome 3 in the melanocytosis and monosomy chromosome 3 in the melanoma.<sup>72</sup>

### **Dermatologic Features**

The dermatologic features include predominantly the flat blue dermal nevus of Ota, classically in the periocular region and often with extension into the temporal region. This rarely leads to cutaneous melanoma.

### **Central Nervous System Features**

The blue nevus can extend to involve the meninges and carries a small risk for the development of meningeal melanoma.<sup>73</sup>

## Other Features

Similar blue nevus pigmentation can involve the ipsilateral palate and tympanic membrane.

## Management

The main concern with this condition is the development of uveal melanoma. Twice-yearly dilated examination is advised. Any patient with the development of unexplained subretinal fluid or lipofuscin orange pigment should be suspected of harboring uveal melanoma. Melanoma develops at a slightly earlier age (approximately 35 years) in those with oculo(dermal) melanocytosis compared to those without (approximately 55 years).<sup>74</sup>

## Other Phakomatoses

Other oculoneurocutaneous conditions sometimes loosely classified with the phakomatoses include ataxia telangiectasia (Louis–Bar syndrome), Klippel–Trenaunay–Weber syndrome, and diffuse neonatal hemangiomatosis. These associations are detailed in the literature, but are beyond the scope of this discussion.

## Combined Systemic Hamartomatoses

The systemic hamartomatoses are derived from primitive neuroectoderm or mesectoderm, and rarely various combinations of these syndromes can occur. The examples of such overlap can be found in the literature, usually as single case reports. For example, features of neurofibromatosis have been seen in association with von Hippel–Lindau syndrome and Sturge–Weber syndrome. Reports of retinal capillary hemangiomas and oculodermal melanocytosis have individually been found in neurofibromatosis. Another example is the overlap of Sturge–Weber syndrome with oculodermal melanocytosis, a condition described above as phacomatosis pigmentovascularis.

## Conclusion

In summary, there are several phakomatoses that involve congenital and acquired features and are represented mostly with benign tumors or hamartomas. Strict criteria are necessary to meet the diagnosis of several of the phakomatoses such as neurofibromatosis types 1 and 2 as well as Sturge–Weber syndrome, whereas others necessitate simple recognition of salient features such as oculo(dermal) melanocytosis. Lifelong, multidisciplinary management of affected patients and family is advised.

Prognosis

## **Conclusion**

## Introduction

Retinal metastases represent a small percentage of intraocular malignancy secondary to systemic cancers, even though 10% of patients who die of cancer have been found to have intraocular metastases.<sup>1-4</sup> While relatively rare, the diagnosis of retinal metastases can be challenging as its presentation can mimic other etiologies. High clinical suspicion and use of appropriate diagnostic techniques are vital in order to successfully diagnose and manage these challenging cases. This chapter provides a review of the literature of this rare clinical entity and management recommendations.

## Metastatic Cascade

Metastases are responsible for most cancer deaths.<sup>5</sup> The understanding of metastases is limited due to the “hidden” nature of this process as it occurs inside the body and is difficult to observe.<sup>5</sup> Although many tumor cells are shed daily into the bloodstream or lymphatic system in those with cancer, the evidence is unclear on the fate of these tumor cells.<sup>6,7</sup> Some models suggest that the majority do not survive in the circulation, while others suggest that most can survive and extravasate.<sup>5,6,8-10</sup> For tumor metastasis to develop, a series of biologic steps must be completed for a tumor cell to grow at a different site.<sup>5,6,10-15</sup>

## Dissociation, Invasion, and Intravasation

For tumor cells to invade the circulation, they must dissociate from the primary tumor.<sup>5,6,10-14</sup> On a molecular level, the dissociation is initiated by an array of motility factors<sup>11-12</sup> and requires modulation of the expression of cadherins and integrins.<sup>5,6,13-16</sup> Degradation of the extracellular matrix by proteolytic enzymes (primarily matrix metalloproteases and the plasminogen activator system), facilitates invasion of the surrounding connective tissue components.<sup>5,6,13,15,17-23</sup> Metalloproteases also modulate cell adhesion in their local environment and help release growth factors from their stores.<sup>18,19,21</sup> Then, tumor cells must penetrate the basement membranes of endothelial cells to enter the blood and lymphatic circulation.<sup>5,6,15</sup>

This step again requires well-coordinated proteolysis, as well as mechanical deformation and locomotion of the tumor cells.<sup>5,6,14,15</sup> If this complex interaction is regulated successfully, certain populations of cells can break through matrix and endothelium to reach the bloodstream.

## Hematogenous Dissemination

Because intraocular structures have no lymphatic supply, metastatic cancer cells can gain access to the eye only by hematogenous routes. From the aorta, tumor cells enter the internal carotid artery directly on the left and indirectly through the innominate artery on the right. After passing through the internal carotid artery, tumor cells reach the eye through the ophthalmic artery. The ophthalmic artery gives rise to 10–20 short posterior ciliary arteries supplying the posterior uvea, two long ciliary arteries supplying the anterior uvea, and the central retinal artery supplying the inner half of the retina and the optic disc.

The destination within the eye of circulating tumor cells may depend on several factors. Tumor size, vascular circulatory patterns, and organ-specific factors that encourage tumor growth (so-called seed and soil factors) all may play a role in the location of metastases.<sup>5,6,15</sup> Reese emphasized that, although tumor emboli are more prominent in the uvea, more than 90% of infectious emboli involve the retina.<sup>24</sup> Because large emboli (e.g., tumor emboli) travel along the vessel wall in the slower-moving part of the bloodstream, they are more likely to enter vessel branches, such as the short ciliary arteries. Small emboli (e.g., bacterial emboli) travel in the central, faster-moving part of the bloodstream toward the terminal vessels, such as the central retinal artery.<sup>25</sup> The marked vascularity of the posterior choroid relative to that of the retina (as noted above) could also contribute to more frequent choroidal involvement as metastatic tumors to the retina and optic disc, supplied by the central retinal artery, are rare.<sup>3,4</sup>

## Extravasation and Angiogenesis

Although circulation patterns and tumor size may play a role in implantation, metastatic growth may require organ-specific factors

that facilitate tumor cell survival.<sup>5,15,16,26–28</sup> Animal models of metastases support the role of both vascular flow patterns and organ compatibility factors in the development of metastases.<sup>5,29–31</sup> Tumor cell anchorage at a target organ site depends on shear-resistant attachment to local endothelium. Various integrins and selectins have been identified which appear to mediate such specialized tumor cell adhesion under dynamic flow conditions.<sup>5,16,32,33</sup>

The delivery of the tumor cell to the site of metastasis depends on mechanical flow, but the growth or survival can depend on organ-specific molecular interactions. These interactions can encourage tumor cell growth via expression of growth factors and altering the gene expression of tumor cells.<sup>5,6,34–37</sup> Expression of specific chemokine receptors by tumor cells may also target tumor cells to specific organs that express the specific ligands for these receptors.<sup>5,15,38–41</sup> This match could lead to chemokine signal activation of genes which would encourage tumor cell growth.<sup>5,15</sup> Specific interactions unique to retinal metastasis to this point have not been identified.

After the colony at the secondary site is established, angiogenesis will again play a key role in the continued growth of the tumor. The onset of angiogenesis involves an alteration in the balance between positive and negative regulators. In vivo experiments with human tumor cell lines have shown that both vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (FGF) have direct roles in tumor-associated angiogenesis.<sup>42,43</sup> VEGF and FGF-2 also are the two major angiogenic factors in the retina and increased expression of both has been identified in retinal tumors.<sup>44–47</sup> VEGF not only regulates tumor-associated angiogenesis in response to local hypoxia and various cytokines, but may regulate breakdown of the blood–ocular barrier in ocular melanoma and other tumors.<sup>47–50</sup> FGF-2 is a potent mitogen of choriocapillary endothelial cells, and FGF acts synergistically with VEGF to stimulate tumor angiogenesis.<sup>44,51–53</sup>

## Review of Case Reports

As noted above, retinal metastasis represents a small percentage of

intraocular metastasis. Until recently, publications in the literature have been limited to case reports.<sup>54-96</sup> The first was published in 1934 and was diagnosed at autopsy.<sup>54</sup> Until 1979, the diagnosis of retinal metastasis was made either by enucleation or at autopsy. Since 1979, diagnosis of retinal metastasis has been made via biopsy, including vitreous, chorioretinal, retinal biopsies; clinical inspection; or surgical removal.<sup>63</sup> Although the case reports reviewed provide detail in presentation and treatment of retinal metastases, follow-up is limited for many of the publications. More recently, the largest single-center series published eight cases diagnosed in a 40-year review.<sup>95</sup> The clinical appearance, symptoms, and outcomes from the published case reports will be reviewed below and are displayed in [Table 137.1](#).

**TABLE 137.1**  
**Retinal Metastases: Case Reports**

Reference	Primary Disease	Age	Sex	Eye	Initial Symptoms	Signs	Diagnosis Pathology
Smoleroff and Agatston (1934) <sup>54</sup>	Gastroesophageal adenocarcinoma	55	M	OD	None	White irregular mass in inferotemporal retina	Autopsy
Uhler (1940) <sup>55</sup>	Cutaneous melanoma	26	M	OD	Diplopia	Papilledema; infiltration of temporal retina	Autopsy
Kennedy et al. (1958) <sup>56</sup>	Rectosigmoid adenocarcinoma	51	M	OD	Blurred vision	Circumscribed grayish-white lesion in macula	Enucleation (enlarging mass)
Duke and Walsh (1959) <sup>57</sup>	Uterine	60	F	OD	Decreased	Vitreous opacities; white elevated mass in macula	Enucleation (secondary glaucoma)
Liddicoat et al. (1959) <sup>58</sup>	Cutaneous melanoma	43	M	OS	None	Perivascular white sheathing with hemorrhage, midperiphery	Autopsy
Riffenburgh (1961) <sup>59</sup>	Cutaneous melanoma	45	M	OS	Decreased visual acuity, floaters	Vitreous cells, irregular gray mass with sharp borders in nasal retina	Enucleation (primary choroid melanoma)
Koenig et al. (1963) <sup>60</sup>	Undifferentiated bronchogenic pulmonary carcinoma	56	M	OD	Sudden	Vitreous floaters; white lesion with neovascularization and exudates in	Enucleation (secondary glaucoma)

						temporal retina	
Flindall and Fleming (1967) <sup>61</sup>	Unknown	68	M	OS	Blurred vision, floaters	Dense vitreous; veil-like exudate	Enucleation (secondary glaucoma)
Klein et al. (1977) <sup>62</sup>	Squamous cell pulmonary carcinoma	52	M	OU	Decreased visual acuity	Yellow-white infiltrate temporal to macula OD; exudative retinal detachment OS	Autopsy
Young et al. (1979) <sup>63</sup>	Pulmonary carcinoma	63	M	OS	Decreased visual acuity	Vitreous cells; white retinal mass at macula; perivascular white patches	Vitreous aspirate, then autopsy
Robertson et al. (1981) <sup>64</sup>	Cutaneous melanoma	43	F	OU	Floaters	Golden-brown vitreous spherules; brown plaque over superior retina	Vitreous aspirate
	Cutaneous melanoma	37	F	OS	Floaters	Golden-brown vitreous spherules	Aqueous aspirate, then enucleation (secondary glaucoma)
Letson and Davidorf (1982) <sup>65</sup>	Cutaneous melanoma	44	M	OU	None	Gray-brown retinal and perivascular infiltrates with feathery edges	None
de Bustros et al. (1985) <sup>66</sup>	Cutaneous melanoma	33	M	OS	Decreased visual acuity	Tan retinal mass with exudates and hemorrhages	Not stated
Takagi et al. (1989) <sup>67</sup>	Pulmonary adenocarcinoma	45	M	OS	Blurred vision	Whitish vitreous granules; white masses on disc and within inferotemporal retina	Enucleation (to prevent CNS spread)
Eagle (1988) <sup>68</sup>	Unknown carcinoma	53	F	OS	Blurred vision	Few vitreous balls; white macular lesion with satellites and vascular sheathing	Vitreous aspirate and eye wall biopsy (including retina and choroid)
Best et al. (1990) <sup>69</sup>	Cutaneous melanoma	71	F	OS	Blurred vision, floaters	Yellow-white globular vitreous opacities	Vitreous aspirate, then enucleation (pain)
Leys et al (1990) <sup>70</sup>	Oat cell pulmonary carcinoma	49	M	OS	No ocular symptoms	Single white retinal plaque temporal to macula	Autopsy
	Breast	42	F	OS	Blurred vision,	Vitreous opacities	Vitreous

	adenocarcinoma				floaters	just anterior to macula	aspirate
Striebel-Gerecke et al. (1992) <sup>71</sup>	Oat cell pulmonary carcinoma	47	F	OD	Floaters	White cone-shaped mass in vitreous; white infiltrate in inferonasal retina	Vitreous aspirate, then autopsy
Tachinami et al. (1992) <sup>72</sup>	Rectal adenocarcinoma	61	M	OD	Blurred vision	Yellow-white mass superior to macula, serous detachment	Autopsy
Balestrazzi et al. (1995) <sup>73</sup>	Cutaneous melanoma	40	F	OD	Blurred vision	Vitreous hemorrhage; yellow-white highly vascularized mass in superonasal retina	Vitrection and surgi resection
Spraul et al. (1995) <sup>74</sup>	Breast and colonic adenocarcinoma	74	F	OD	Decreased visual acuity	Yellow-white mass in superotemporal retina, serous detachment	Enucleati (pain)
Spraul et al. (1996) <sup>75</sup>	Cutaneous melanoma	55	M	OD	Decreased	Vitreous hemorrhage; pigmented mass in temporal retina	Vitreous aspirate, then enucleati (pain)
Cangiarella et al. (1996) <sup>76</sup>	Esophageal adenocarcinoma	51	F	OS	Decreased visual acuity	Vitreous cells; nasal retinal hole and detachment with white retinal infiltrate	Vitreous aspirate
Ganduz et al. (1998) <sup>77</sup>	Cutaneous	81	M	OS	Floaters	Total hypHEMA (no view)	Vitreous aspirate, then enucleati (pain)
Spadea et al. (1999) <sup>78</sup>	Cutaneous melanoma	40	F	OD	None	Vitreous pigment; yellow-white highly vascularized retinal lesion in periphery	Vitrection and surgi resection
Soheilian et al. (2002) <sup>79</sup>	Cutaneous melanoma	49	M	OU	Blurred vision	Vitreous hemorrhage; pigmented mass in superotemporal retina	Vitreous aspirate
Hutchinson et al. (2001) <sup>80</sup>	Large bowel adenocarcinoma	63	F	OS	Decreased vision	Highly vascular lesion; serous retinal detachment	None stati
Truong et al. (2002) <sup>81</sup>	Breast carcinoma	59	F	OS	Decreased vision	Milky white retinal infiltrates	None stati
Zografros et al. (2003) <sup>82,84</sup>	Cutaneous melanoma	48	M		Decreased vision	Beige-colored vitreous	Vitreous aspirate cells; reti

							detachment
	Lung melanoma	57	F		Decreased vision	Greyish retinal mass Intraretinal hemorrhages	None stated
Saornil et al. (2004) <sup>83</sup>	Gastric adenocarcinoma	70	M	OS	Decreased vision	Yellow, white solid retinal mass.; neovascular glaucoma	Enucleation (pain)
Apte et al. (2005) <sup>85</sup>	Adenocarcinoma of cecum	39	M	OS	Visual field defect	Retinal hemorrhage	Vitreotomy surgical
Sirimaharaj et al. (2006) <sup>86</sup>	Breast carcinoma	60	F	OS	Decreased vision	White precipitates within retina. intraretinal hemorrhages; vascular sheathing	Vitreous aspirate
Rundle et al. (2006) <sup>87</sup>	Breast carcinoma	55	F	OD	Metamorphopsia	Discrete white lesion	None stated
Khurana et al. (2007) <sup>88</sup>	Cutaneous melanoma	76	M	OD	Floater, Decreased vision	Pigmented preretinal lesion	Vitreotomy membranar peel
Alegret et al. (2009) <sup>89</sup>	Nasopharyngeal carcinoma	15	M	OD	None	Amelanotic retinal lesion	None
Kim et al. (2010) <sup>90</sup>	Gastric adenocarcinoma	64	F	OU	Decreased vision, macular infiltrates	Multiple vitreous seeds	Vitreous aspirate
Coassin et al. (2011) <sup>91</sup>	Small cell carcinoma, presumed lung in origin	56	F	OD	Floater, decreased vision	White retinal infiltrate; intraretinal hemorrhages	Vitreotomy retinal biopsy
Payne et al. (2012) <sup>92</sup>	Adenocarcinoma of lung	62	M	OS	Decreased vision	Retinal whitening; preretinal hemorrhage	Vitreotomy retinal biopsy
Krema et al. (2013) <sup>93</sup>	Cutaneous melanoma	54	F	OS	Temporal field loss	Diffuse pigmented lesion	Enucleation
Singh et al. (2014) <sup>94</sup>	Small cell lung carcinoma	78	M	OD	Blurred vision	Patchy white infiltrates; retinal hemorrhages	Vitreotomy retinal biopsy
Shields et al. (2014) <sup>95</sup>	Lung carcinoma	64	F		Not recorded	7 mm retinal infiltrate; vitreous seeds; vitreous Hemorrhage	Not recorded
	Cutaneous melanoma	45	M		Not recorded	12 mm retinal infiltrate; vitreous seeds	Enucleation
	Cutaneous melanoma	59	M		Not recorded	11 mm retinal infiltrate; subretinal fluid	Enucleation
	Cutaneous melanoma	85	M		Not recorded	9 mm retinal infiltrate; vitreous seeds; vitreous hemorrhage	Enucleation
	Esophageal carcinoma	56	M		Not recorded	12 mm retinal infiltrate;	Not recorded

						subretinal fluid	
	Breast carcinoma	58	F		Not recorded	1.5 mm retinal infiltrate; subretinal fluid	Not recorded
	Breast carcinoma	75	F		Not recorded	2 mm retinal infiltrate; subretinal fluid	Not recorded
	Cutaneous melanoma	55	M		Not recorded	5 mm retinal infiltrate	Not recorded
Gubbiotti et al. (2015) <sup>96</sup>	Breast carcinoma	52	F	OD	Blurred vision	Retinal lesion	None

CNS, central nervous system; OD, right eye; OS, left eye; OU, both eyes.

## Demographics

A total of 52 cases of isolated retinal metastasis have been reported (with or without vitreous involvement). Of those 52 cases there were 29 females and 23 males. The average age at diagnosis of retinal metastases was 53 years (range 14–85). The primary tumor sites included 19 cases of cutaneous melanoma, 10 cases from the gastrointestinal tract, 11 cases from the lungs, 8 cases of breast carcinoma, 1 case from the genitourinary tract, 1 case from the nasopharynx, and 3 cases of unknown primary malignancy.

## Clinical Findings

### Symptoms

The most common visual complaint among those with retinal metastases is decreased or blurred vision ([Table 137.1](#)). Floaters are also a common complaint. Other symptoms include pain, diplopia, and red eye. Some cases presented without any specific visual symptoms.<sup>54,58,65</sup> The underlying primary source of the metastases did not have a bearing on the type of visual symptom reported by the patient.

### Signs

The clinical appearance of retinal metastases can vary based on the primary tumor and level of invasion of the tumor. Metastatic melanoma typically presents as a pigmented lesion within the retina with irregular borders and flat appearance ([Fig. 137.1](#)). Carcinoma tends to be nonpigmented, white, or yellow in

appearance and variable in size. (Fig. 137.2). Some metastatic carcinomas can appear with significant mass and an elevated appearance with surrounding subretinal fluid.

**FIG. 137.1** Cutaneous melanoma metastatic to the retina. Note the hemorrhages both intraretinal and preretinal that accompany the pigmented lesion with irregular borders.

**FIG. 137.2** Small cell lung carcinoma metastatic to the retina. (A) At the macula, perivascular retina infiltrates are seen. (B) Nasal to the nerve, multiple retinal

lesions are seen of varying size. Scattered intraretinal hemorrhages are also seen. (Courtesy of Daniel F. Martin, Rishi P.

Singh, and Careen Y. Lowder.)

Intraretinal hemorrhage and exudates have been described in association with these lesions (Figs. 137.3 and 137.4). Subretinal hemorrhage has also been described as a presenting feature of metastatic carcinoma.<sup>85</sup> Perivascular infiltrates can also be seen in some cases (Figs. 137.5 and 137.6). Retinal hemorrhages and exudates are thought to occur secondary to damage to the retinal microvasculature. Additionally, subretinal fluid has been described in several cases of retinal metastases. The appearance of subretinal fluid or exudative retinal detachment warrants an evaluation for a choroidal lesion.

**FIG. 137.3** Adenocarcinoma of unknown source metastatic to the retina. A white–yellow retinal lesion with scattered exudates, extending temporally from the macula. (Courtesy of Ralph C. Eagle Jr.)

**FIG. 137.4** Lung adenocarcinoma metastatic to the retina. At the macula, the white retinal mass has dilated vessels and hemorrhages on its surface.

**FIG. 137.5** Metastatic lung cancer to the retina. Note the perivascular sheathing in the inferior-temporal macula.

**FIG. 137.6** Cutaneous melanoma metastatic to the retina and vitreous. Note the extensive pigment on the surface of the retina and within the retina. Pigmented vascular sheathing is noted, which may be preretinal in origin.

Vitreous cells are often seen in association with retinal metastases. These cells are usually pigmented in cases of metastatic melanoma and can be large. Vitreous cells in melanoma cases can be floating throughout the vitreous cavity (described as “brown spherules” or “globular vitreous opacities”).<sup>64,69</sup> In contrast, vitreous cells associated with metastatic carcinoma tend to be white and confined to the area overlying retinal involvement.<sup>68,70</sup>

Other signs include secondary glaucoma from tumor invasion into the ciliary body, iris, or anterior chamber angle.<sup>57</sup>

## Differential Diagnosis

The differential diagnosis of a metastatic retinal lesion is varied based on the initial appearance of the lesion. Choroidal metastasis with overlying retinal metastasis should be excluded initially (Fig. 137.7). For nonpigmented white retinal lesions seen in metastatic carcinoma, the differential includes inflammatory and infectious diseases such as toxoplasmosis chorioretinitis, cytomegalovirus (CMV) retinitis, herpetic-associated retinitis, syphilitic retinitis, endogenous endophthalmitis, sarcoidosis, multifocal choroiditis,

birdshot choroidopathy, acute posterior multifocal placoid pigmentary epitheliopathy (APMPPE), intraocular lymphoma, and other collagen vascular diseases. For pigmented lesions such as seen with metastatic melanoma the differential also includes choroidal tumors including melanoma and metastatic choroidal tumors, neovascular macular degeneration. Given the appearance of exudates and hemorrhages in some cases, retinal microvascular diseases such as hypertensive retinopathy, diabetic retinopathy, and retinopathy secondary to anemia are also possible diseases. Finally, conditions that may simulate the vitreous floaters of retinal metastases include granulomatous uveitides, amyloidosis, asteroid hyalosis, or intraocular lymphoma.<sup>69,70</sup>

**FIG. 137.7** Lung adenocarcinoma metastatic to the retina and choroid. (A) A primarily amelanotic, elevated choroidal mass in the temporal fundus. Note the overlying white retinal lesion, presumably from retinal invasion. (B) Elsewhere in the same eye, a solitary white retinal lesion likely represents a separate retinal metastasis.

In the setting of systemic malignancy and a potentially compromised immune system, the differential of infectious retinitis warrants further discussion. Multiple case reports highlight the initial diagnosis or treatment of infectious retinitis in cases of retinal metastasis.<sup>92,94,95</sup> CMV retinitis typically occurs in patients with CD4 counts less than 50 cells/ $\mu$ L.<sup>97</sup> The appearance of CMV retinitis may begin as a small white retinal infiltrate that can expand to a fluffy white lesion which is perivascular in origin with intraretinal

hemorrhages. CMV retinitis can also appear as a granular lesion with atrophic appearance of retina and a leading edge of retinitis with faint whitening and minimal hemorrhage. There is typically minimal vitreous inflammation, and the disease tends to spread slowly (approximately 250  $\mu\text{m}/\text{week}$ )<sup>97</sup> (Fig. 137.8).

**FIG. 137.8** Fundus photograph of a patient with cytomegalovirus retinitis. Note the posterior leading edge with a granular whitening of the retina. The retina is atrophic just anterior to this lesion indicating progression. Note minimal intraretinal hemorrhage.

In contrast, herpetic retinitis tends to be rapidly spreading with confluent areas of outer retinal whitening which progress to full-thickness retinitis.<sup>97,98</sup> Typically the peripheral retina is affected first with circumferential progression. The lesions do not usually follow the retinal vessels like CMV retinitis, though an occlusive retinal vasculitis is typically seen.<sup>97,98</sup> Significant vitreous inflammation is seen in those with a competent immune system, while those with a compromised immune system can have mild inflammation. Optic disc edema is often seen. The contralateral eye is often also affected (Fig. 137.9).

**FIG. 137.9** Fundus photograph of a patient with herpetic retinitis. There is circumferential retina whitening affecting the deeper layers of the retina. There is minimal inflammation in this patient who is severely immunocompromised from chemotherapy.

Toxoplasmosis retinochoroiditis can also present as a whitish-yellow retinal lesion. Typically a chorioretinal scar will be seen in cases of reactivation with surrounding whitening or other satellite lesions.<sup>97</sup> Vitreous inflammation is usually seen. In some cases, no previous scar is seen and a solitary white chorioretinal lesion with irregular borders will be noted. A multifocal retinitis can be seen in patients who are immune compromised<sup>97</sup> (Fig. 137.10).

**FIG. 137.10** Fundus photograph of a patient with multifocal toxoplasmosis retinochoroiditis. Multiple white lesions at the level of the retina and choroid are

noted in the posterior pole. This patient has been immunocompromised by steroid use.

## Diagnostic Evaluation

A patient presenting with a retinal lesion with a history of systemic malignancy warrants a metastatic workup. In some case reports the retinal metastasis was the presenting system in a previously undiagnosed malignancy.<sup>76</sup> This presentation is rare though and most patients present with a previous history of malignancy. A complete history and physical with review of systems should be performed. Coordination with the patient's oncologist is imperative in evaluating for potential metastases. Given the potential for infectious etiologies including endogenous endophthalmitis, a review of recent illnesses, history of fever, chills, or other signs of infections should be reviewed.

Blood work including serum chemistry, liver function panel, and complete blood count should be ordered.<sup>99</sup> Depending on the appearance of the lesion, serum markers for infectious disease such as syphilis (rapid plasmin regain, [RPR] and fluorescent treponemal antibody absorption [FTA-Abs]), toxoplasmosis (antitoxoplasmosis IgG and IgM antibodies), should be drawn. Blood cultures may also be drawn. Serum markers for malignancy such as carcinoembryonic antigen (CEA) are not clearly associated with intraocular malignancy, thus their use may be limited in this setting.<sup>97</sup>

Diagnostic imaging is usually warranted in these patients. B-scan ultrasonography can assist in determining if there is potential choroidal disease with secondary retinal disease. B-scan ultrasonography has shown intermediate to high internal reflectivity on A-scan and dense thickening of the retina on B-scan.<sup>69,70,74,75,78,79</sup> However, ultrasonographic analysis of retinal metastases is limited by the thin size of most retinal lesions and the lack of established criteria given the rarity of such cases. Although fluorescein angiography is not diagnostic, it is helpful in differentiating metastatic tumors from non-neoplastic conditions.<sup>4</sup> Prominent vascularity is a conspicuous feature of metastatic cancer, and progressive hyperfluorescence in the late phases of the angiogram is characteristic (Fig. 137.11). Optical coherence

tomography can also be used to confirm the involvement of the retina and retinal surface (Figs. 137.12 and 137.13). Several case reports describe a thickened retina with hyperreflectance without any noted changes in the underlying choroid.<sup>81,91,92</sup>

**FIG. 137.11** Fluorescein angiography of cutaneous melanoma metastatic to the retina. (A) In the early frame the retinal vasculature is clearly visible with early hyperfluorescence of the vessels and some early leakage. (B) In a late frame staining of the retinal mass is evident and leakage from the retinal vessels is also present.

**FIG. 137.12** Spectral domain optical coherence tomography of a patient with retinal metastasis displaying retinal thickening and inner retina hyperreflectance with outer retinal shadowing.

**FIG. 137.13** Spectral domain optical coherence tomography of lung cancer metastatic to the retina. The mass has led to significant thickening of the retina, disorganization of the retinal structures, and shadowing of the outer retina and choroid.

Systemic imaging should be performed in patients with suspected metastasis. This again should be coordinated with the patient's oncologist to ensure the proper imaging is ordered for the suspected malignancy. Options include positron emission tomography (PET), computed tomography (CT) scan, combined PET/CT scans, and magnetic resonance imaging (MRI). Given the high incidence of brain metastases in the setting of retinal metastasis, imaging of the brain is warranted to identify potential lesions.

Ultimately, to make the diagnosis of retinal metastasis, a tissue diagnosis needs to be performed. This can be performed in several ways. Prior to obtaining a sample, coordination with an experienced ocular pathologist is recommended in order to identify the correct handling of the specimen and the specific amount of tissue required. A vitreous or aqueous aspirate can be the only sample required to make a diagnosis in those patients with significant vitreous or aqueous cells. Fine-needle aspiration biopsy (FNAB) of intraocular lesions can also be used to establish a diagnosis. Both the reliability and safety of FNABs have been demonstrated with no increase in tumor-related mortality rates.<sup>99,101,102</sup> In some cases however, pars plana vitrectomy with retinal biopsy may be needed. In cases where the diagnosis is

unclear and the differential includes infectious etiologies, vitrectomy offers the ability to obtain a substantial sample. In those particular cases, vitreous specimens could be sent for viral and toxoplasmosis polymerase chain reaction (PCR) identification. Tissue biopsy during a vitrectomy offers the ability to directly visualize the area in question and obtain a significant sample. With any sample, an experienced pathologist is needed to handle and accurately review the biopsy.<sup>99</sup>

## Treatment

Treatment of metastatic retinal disease can vary based on a number of factors. The type of primary tumor, sites of additional metastases, the area of tumor involvement within the eye, vision, and the presence of pain all will determine the treatment for the eye. Eyes with poor vision and which are in severe, intractable pain should be considered for enucleation.<sup>4</sup> External beam irradiation can be effective in controlling intraocular metastatic tumors, thus enucleation is usually only reserved for select cases. In multiple case reports, external beam irradiation has demonstrated effectiveness in controlling tumor size and leading to tumor regression.<sup>63,66,71,80,86,89</sup> In one case, autopsy studies of one eye revealed eradication of the tumor (metastatic pulmonary adenocarcinoma) within the retina, although the retinal architecture had been destroyed by prior tumor invasion.<sup>63</sup>

When patients are asymptomatic and the intraocular tumor is well controlled, systemic chemotherapy alone has been considered, but results in patients with retinal metastases have been discouraging. With systemic chemotherapy, three cases of cutaneous melanoma and one case of rectal adenocarcinoma metastatic to the retina failed to respond.<sup>64,65,71,72</sup> Additionally, one case of adenocarcinoma of the cecum failed to respond to multiple cycles of chemotherapy, but responded after excision and palliative radiation.<sup>85</sup> With systemic and intravitreal chemotherapy, one reported case of breast carcinoma metastatic to the retina displayed partial regression of the vitreous involvement, but retinal detachment with massive vitreous traction occurred.<sup>70</sup> The use of anti-HER2 (human epidermal growth factor receptor 2) therapy in a case of metastatic breast cancer to the brain and retina has been

reported.<sup>96</sup> Shrinkage of the retinal and brain mass was noted after three cycles and treatment was continued for 12 cycles but stopped due to progression in the brain and liver.

Surgical resection has also been described as potential therapy. In one case, as noted above, the lesion was removed via vitrectomy and retinectomy and orbital radiation was performed postoperatively. After 3 months of follow-up, the eye and vision were stable.<sup>85</sup> Two reported cases of isolated retinal metastasis secondary to cutaneous melanoma were treated with vitrectomy and surgical resection.<sup>73,78</sup> In one case, surgical resection of the vascularized mass in the superotemporal retina, with systemic chemotherapy, resulted in resolution of blurred vision with 20/20 visual acuity. However, brain metastases developed within 1 year, and the patient committed suicide 3 months later.<sup>73</sup> In the other case, surgical resection of a peripheral lesion preserved vision for 12 months, until the patient committed suicide.<sup>78</sup> For more peripheral isolated lesions, surgical resection and vitrectomy may offer an alternative to external beam irradiation.

Plaque radiotherapy has proven to be effective in the treatment of well-circumscribed, isolated choroidal metastases.<sup>66,90,100,103,104</sup> However, its use in patients with retinal metastasis has not been described. Photodynamic therapy has been reported as a treatment of a presumed isolated retinal metastasis secondary to breast cancer.<sup>87</sup> However, follow-up was limited to only 8 weeks with tumor regression noted and stable visual acuity.

## Prognosis

The prognosis for patients with retinal metastasis is poor. The survival from diagnosis to death in the review of reported cases ranges from 2 weeks to 5 years. Caution is recommended in interpreting these numbers as many case reports lack long-term follow-up after reporting a few weeks or months of survival. In the largest single-center case series<sup>95</sup> five of eight patients died within 1 month of the diagnosis of retinal metastasis – confirming the relative poor prognosis.

External beam radiation can reduce tumor size and salvage eyes prior to death.<sup>63,66,71,86</sup> Several eyes with intractable pain and/or

glaucoma required enucleation. Visual acuity results vary and depend on the extent of macular involvement. In those eyes with small lesions in the periphery, there is a chance to maintain good visual acuity as opposed to those eyes with large macular involvement. Despite improved diagnostic techniques and new treatment modalities, the prognosis remains poor.

## Conclusion

Retinal metastasis is a rare complication of systemic malignancy. Visual symptoms include blurred vision and floaters, thus any patient with a history of malignancy should have a complete eye examination in the setting of those symptoms. Signs suspicious for retinal metastases include white or gray retinal infiltrates associated with perivascular sheathing with localized vasculopathy. Ancillary testing including ultrasonography, fluorescein angiography, and optical coherence tomography can assist in determining the location of lesion and rule out choroidal disease. Diagnosis should be established by biopsy, either vitreous biopsy or FNAB or retinal biopsy via vitrectomy. Important diseases that can mimic retinal metastasis include infectious retinitis such as CMV retinitis, herpetic retinitis, and toxoplasmosis retinochoroiditis. Choroidal tumors with secondary retinal involvement are other diseases to consider in the differential. Currently, external beam irradiation offers the most effective palliative therapy. Surgical resection and plaque radiotherapy are other potential options in treating this disease. Because of heightened awareness in the medical community, the rising incidence of certain tumor types (e.g., carcinoma of the lung), and the improved survival rates in others, an increasing number of patients with intraocular metastases will be seen in clinical practice. The ophthalmologist's responsibility is to establish the diagnosis with minimal invasion, alert the oncologist, and initiate a therapeutic plan in hopes of preventing further visual loss, pain, and enucleation.

## **Introduction**

**Cancer-Associated Retinopathy (CAR) Syndrome**

**Cutaneous Melanoma-Associated Retinopathy (MAR) Syndrome**

**Paraneoplastic Vitelliform Maculopathy (PVM)**

**Management of Paraneoplastic Retinopathy**

**Bilateral Diffuse Uveal Melanocytic Proliferation (BDUMP)**

**Conclusion**

## **Introduction**

Cancers are capable of producing effects on remote tissues without direct tumorous spread and unrelated to the effects of opportunistic infection or medical therapy. Syndromes not caused directly by cancer cells are referred to as “paraneoplastic,” or “remote,” manifestations of cancer. Paraneoplastic syndromes are known to occur in the absence of systemic tumor spread and may precede a clinically recognized tumor.

Neurologic paraneoplastic syndromes have been estimated to

occur in up to 15% of cancer patients, half of whom have primary carcinoma of the lung.<sup>1</sup>

The prevalence of ophthalmic paraneoplastic syndromes is unknown. Although uncommon, the remote effects of cancer on the eye are important to recognize because they may be the presenting signs of previously undiagnosed malignancy or may suggest recurrence of previously treated disease.<sup>2-4</sup> Furthermore, the recognition of these syndromes in patients with unexplained visual loss may aid the ophthalmologist in palliative management, since the disabling ocular symptoms may be amenable to medical therapy.<sup>3,5</sup>

Paraneoplastic neuro-ophthalmic syndromes include cancer-associated retinopathy (CAR), melanoma-associated retinopathy (MAR), paraneoplastic vitelliform maculopathy (PVM), and bilateral diffuse uveal melanocytic proliferation (BDUMP). BDUMP has been proposed to be the result of tumor induced ectopic peptides, while most other paraneoplastic ophthalmic syndromes are felt to be part of a spectrum of autoimmune disorders that also encompass autoimmune retinopathy ([Chapter 80](#), Autoimmune retinopathies) and paraneoplastic optic neuropathy with vitritis (PON).<sup>5,6</sup>

## Cancer-Associated Retinopathy (CAR) Syndrome

In 1976, Sawyer and coworkers<sup>2</sup> described three patients with sudden onset of vision loss, positive visual phenomena, ring-like scotomas, and nyctalopia who developed light perception vision and were later diagnosed as having bronchogenic carcinoma. Fundus examination demonstrated only nonspecific pigment mottling in the posterior pole, normal optic nerves, and a slight degree of vascular attenuation with variable sheathing. Histopathologic examination in each case demonstrated widespread severe degeneration of the outer nuclear retinal layer and disintegration of photoreceptors, as well as the presence of macrophages containing phagocytosed granules from the retinal pigment epithelium (RPE) ([Fig. 138.1](#)). In contrast with retinitis

pigmentosa, the RPE and choriocapillaris were remarkably preserved in all eyes examined. The authors believed that these features excluded a vascular basis for the observed findings and concluded that these represented a remote effect of bronchogenic carcinoma.<sup>2</sup>

**FIG. 138.1** Paramacular retina from the eye of a 61-year-old woman with cancer-associated retinopathy (CAR) related to uterine carcinoma. Photoreceptors and outer nuclear layers are replaced by glial tissue containing pigment-laden macrophages. Note normal inner retinal layers, retinal pigment epithelium, and choroid. (Courtesy of Alan M. Ross and John L. Keltner.)

Subsequently, Keltner and colleagues<sup>3</sup> described a patient with undifferentiated cervical cancer presenting with progressive blindness, progressive retinal arteriolar narrowing, a few vitreous cells, and a flat electroretinogram (ERG). Antibodies were found in the patient's serum against normal photoreceptors from fresh normal human retinal tissue. A trial of steroids was initiated, which improved vision. Histopathologic examination later disclosed a loss of retinal photoreceptors and the outer nuclear layer. The authors proposed a possible autoimmune mechanism for these findings.

Klinge and coworkers<sup>7</sup> described a similar picture in a patient

with mottled hyperfluorescence on fluorescein angiography, who was later diagnosed with breast carcinoma, and they termed this “paraneoplastic retinopathy.”

The term “cancer-associated retinopathy” (CAR) syndrome has subsequently come to be used to describe the clinical picture of subacute visual loss resulting from circulating antibodies against retinal proteins in the presence of systemic cancerous tumor growth.<sup>1,4,8,9</sup>

There is no gender predisposition in CAR syndrome, and the symptoms of decreased vision, a halo of missing peripheral vision, positive visual phenomena (“sparkles”), photosensitivity, impaired color vision, and night blindness usually antedate the clinical signs and symptoms of systemic malignancy by a mean of 5 months in up to 50% of cases.<sup>10</sup> The longest duration from the onset of CAR syndrome to diagnosis of the carcinoma was 11 years in a patient with a pulmonary carcinoma.<sup>11</sup> Patients with CAR syndrome generally progress from initial stages of visual loss to blindness in 6–18 months.<sup>3,4,9</sup>

ERG findings in patients with CAR syndrome have been reported to show extinguished a and b waves or rod responses larger than cone responses (Fig. 138.2). Occult malignancy should be suspected in patients with acquired night blindness and minimal ocular findings to account for the visual difficulty and abnormal ERG results.<sup>12</sup> The presenting symptoms may be asymmetric, and some patients complain of glare and photosensitivity.<sup>13–16</sup> Cells in the vitreous or anterior chamber are infrequently reported in CAR syndrome.<sup>3,7</sup> Tonic pupils have been reported to be a potential ophthalmic finding in paraneoplastic syndromes.<sup>17</sup> Reduced macular thickness on OCT examination may be observed prior to severe visual loss,<sup>18</sup> and the spectral domain OCT (SD-OCT) demonstrates interruption of the outer retinal layers (inner/outer-segment junction).<sup>19</sup>

**FIG. 138.2** (A,B) Fundus photographs of a 67-year-old woman with small-cell lung cancer and vascular attenuation only. (C,D) Automated perimetry demonstrates severe visual-field constriction of the left eye to a greater extent than the right. (E–G) Optical coherence tomography sections of the macula demonstrate nonspecific and diffuse thinning. (H) Electroretinogram demonstrates decreased and delayed amplitudes of both rods and cones. This patient had negative results for antirecoverin antibodies. (Panel H reprinted with permission from *Ophthalmology Times* 2003;28:14–6. *Ophthalmology Times* is a copyright publication of Advanstar

The most common malignancies related to CAR are carcinomas, and over half of all these patients have a pulmonary malignancy, with the most common being small cell carcinoma of the lung.<sup>2,4,9,13-16,20-29</sup> A chest radiograph should usually be obtained as part of the evaluation of suspect individuals. Other malignancies associated with CAR include those of the colon,<sup>29</sup> endometrium/uterus,<sup>30-32</sup> cervix,<sup>3,26,33</sup> breast,<sup>7,34-36</sup> prostate/bladder,<sup>34,35,37</sup> thorax (rhabdomyosarcoma), abdominal liposarcoma, and systemic lymphoma.<sup>38,39</sup> In rare instances, patients with documented antibodies to the retina and classic symptoms of CAR may not have an associated underlying malignancy. These patients constitute a minority of patients referred to as having autoimmune retinopathy not associated with underlying malignancy and are discussed in greater detail in [Chapter 80, Autoimmune retinopathies \(Fig. 138.3\)](#).<sup>1,14,37,40,41</sup>

**FIG. 138.3** Multifocal electroretinogram of a 33-year-old woman with autoimmune retinopathy, right eye. This patient tested positive for serum antibodies against retinal proteins p37, p40, and p52 while noting loss of central and midperipheral vision. Vitreous cells are noted in both eyes but the fundus exam was otherwise nondescript. Note the diffuse reduction of amplitudes throughout the entire test field observed on both the trace array (and three-dimensional plot; bottom). There are also focal areas of greater reduction noted. The ring averages (right) demonstrate reduction of amplitude with minimal delays in timing. The findings in the fellow eye were symmetrical to this exam. (Courtesy of Kean T. Oh.)

There has been a growing body of evidence supporting an autoimmune basis for CAR syndrome.<sup>42,43</sup> In 1982 Kornguth et al.<sup>23</sup> reported on the presence of 23-kDa serum antiretinal ganglion cell antibodies in patients with visual dysfunction and small cell carcinoma of the lung. Subsequently, Grunwald et al.<sup>13</sup> described

the reaction of such antibodies with specific retinal antigens in the ganglion cells and inner nuclear layers and immunologically related antigens in tumor cells (as well as their absence in patients with tumors but with no visual defects). They proposed that the small cell tumor produces antigens normally associated with retinal tissue. These antigens are recognized as foreign, since the retina is an immunologically privileged site without antiself suppressor mechanisms.<sup>13,43</sup> CAR syndrome can also be associated with uveitis (vitritis and vascular sheathing);<sup>3,44,45</sup> as the concentrations of the predominantly IgG class autoantibodies reach a critical threshold, they cross the abnormally permeable blood–retina barrier. It is postulated that a cross-reaction with retinal tissue occurs, and subsequently a nonspecific immune-mediated common pathway of retinal degeneration with apoptosis ensues.<sup>36</sup>

The 23-kDa antigen to which antibodies have been produced in up to 60% of individuals with CAR syndrome has been shown to be recoverin,<sup>46</sup> a calcium channel photoreceptor protein.<sup>16,21,26,28,41,47–50</sup> No clear role for recoverin in the normal functioning of photoreceptor cells has been demonstrated, but binding to this protein results in cellular death by some unknown mechanism. Antibodies to the CAR antigen (recoverin) were not previously demonstrated in any other form of retinopathy, nor were these antibodies believed to be expressed by tumors without associated retinopathy.<sup>4,16</sup> Recently, however, a clinically distinctive condition has been described resembling CAR with a cellular immune response against recoverin (recoverin-associated retinopathy).<sup>51</sup>

Now available commercially, the Western blot analysis for the CAR antigen-antibody may be negative even in the presence of CAR syndrome.<sup>44</sup> Moreover, the titers of antibody versus recoverin do not necessarily correlate with the severity of the clinical retinopathy. Hence, clinical criteria and a high index of suspicion remains the mainstay of diagnosis.

Thirkill and coworkers<sup>9</sup> reported on isolation of antibodies reacting strongly with a 23-kDa retinal protein in addition to yet another 65-kDa lung cancer antigen.

Adamus and colleagues<sup>49</sup> reported several cases of CAR syndrome in association with antibodies to a 46-kDa antigen identified as human alpha-enolase, a glycolytic enzyme. Further

work by Adamus has led to the hypothesis that antibodies against recoverin, and other retinal proteins such as alpha-enolase, are cytotoxic by triggering apoptosis via a caspase 3-apoptotic pathway.<sup>52-53</sup> Therefore multiple antigens may be capable of inducing retinal damage and clinical autoimmune retinopathy.<sup>5,39,51,54,55</sup> The heterogeneity of tumor types with many distinct antigens may account for the diversity of observed CAR phenotypes. There exists a high degree of correlation between the presence of serum autoantibodies, the development of visual symptoms, and the presence of retinal degeneration.<sup>54</sup>

## Cutaneous Melanoma-Associated Retinopathy (MAR) Syndrome

A paraneoplastic syndrome of acquired night blindness associated with rapidly developing vitiligo of the skin and uveal tract was reported in two patients with metastatic cutaneous melanoma.<sup>56,57</sup> This process was described originally in 1984 by Gass as “an acute Vogt–Koyanagi–Harada-like syndrome.” These patients, like those with CAR syndrome, had ERG abnormalities with a- and b-waves that were markedly reduced in amplitude, indicating widespread photoreceptor cell dysfunction.

“Paraneoplastic acquired night blindness” in patients with cutaneous malignant melanoma is being reported in greater frequency than in those with typical CAR syndrome.<sup>1,12,14,33,57-67</sup> MAR syndrome is thought to be a clinically distinctive subset of cancer-associated retinopathy. Specifically, this form of cancer-associated retinopathy is clinically differentiated from CAR syndrome by being nonprogressive, causing central visual loss (versus ring scotomas), is associated with a sensation of shimmering or sparkling light, and is associated with vitiligo in up to 20%.<sup>57</sup> In contrast to patients with CAR syndrome and the “acute Vogt–Koyanagi–Harada-like syndrome,” patients with MAR syndrome demonstrate a substantial elevation of rod absolute thresholds and selective reductions in the rod and cone ERG b waves, resembling those of patients with congenital stationary night blindness. The photoreceptor function is intact but signal

transmission between the photoreceptors and second-order interneurons appears to be defective. MAR syndrome, unlike CAR syndrome, is more likely to be visually symptomatic in more advanced stages of systemic disease and, in general, does not manifest before the clinical diagnosis of cutaneous malignant melanoma.<sup>1,66,68</sup> Unilateral presentation of MAR has been reported over 18 months of observation but this may represent asymmetric ocular involvement.<sup>69</sup> Subclinical evidence for MAR may be present in earlier stages of cutaneous melanoma and this may portend a worse overall prognosis for the patient. Antibodies to retinal bipolar cells in MAR syndrome have been reported, but not against the 23-kDa CAR antigen.<sup>63,66,67</sup> The nature of the bipolar cell antigen is not yet known but studies have verified that the bipolar cells are the primary site of pathology in this condition.<sup>70-72</sup> Finally, antibodies against transducin, enolase, aldolase A, and aldolase C have also been documented in patients with MAR.<sup>73</sup>

## Paraneoplastic Vitelliform Maculopathy (PVM)

Paraneoplastic vitelliform maculopathy (PVM) is a multifocal exudative fundus disorder with multiple oval yellow–white lesions at the level of the RPE surrounding the disc and in the macular regions of both eyes. (Fig. 138.4). This condition was described in 2001 by Borkowski et al. in patients having cutaneous melanoma, and the term “paraneoplastic vitelliform retinopathy” was coined by Sotodeh et al. in 2005.<sup>74,75</sup> Subsequently PVM has been reported in patients with choroidal melanoma, carcinoma of the lung, and multiple myeloma.<sup>76-79</sup> PVM has no gender predilection and is associated with only mild subjective visual loss (20/40 to 20/100) with mild nyctalopia and photopsias. Minimal visual field changes were reported and variable ERG responses have been described. A pathologically reduced Arden ratio was found in less than half of reported cases, suggesting relatively normal RPE function in most cases. A clinically indistinguishable entity, acute exudative polymorphous vitelliform maculopathy (AEPVM), has been reported with trauma and with various infections (hepatitis C,

coxsackie B virus, syphilis, and Lyme disease). It has been suggested that the infectious agents cause antibody formation in those patients without associated neoplasm.

**FIG. 138.4** (A) Paraneoplastic vitelliform maculopathy in a multiple myeloma patient with discrete yellowish-orange subretinal deposits surrounding the arcade vessels and disc only. (B) Early fluorescein angiographic examination demonstrates hypofluorescence of the subretinal and sub-retinal pigment epithelium (RPE) lesions with late hyperfluorescence (A,C) and the indocyanine green angiographic examination demonstrates persistent hypofluorescence (B). (C) Spectral domain optical coherence tomography demonstrates an absence of subretinal fluid with hyperreflective subretinal and sub-RPE deposits with hyperreflectivity above the photoreceptors. (Courtesy of Randy Dhaliwal MD.)

Retinal autoantibodies against bipolar cells, enolase, rod outer segment proteins, and bestrophin have all been reported. The heterogeneity of responsible antibodies and of the responsible tumor types is reflected in the variable clinical symptoms and the polymorphous phenotypic appearance of these lesions.<sup>79,80</sup>

Clinicopathologic correlation was reported in one patient revealing atrophy of the inner nuclear layer with extension to the outer plexiform layer and outer nuclear layers. Disorganization and apoptosis in the outer plexiform layer without active inflammation or melanoma cells was the most prominent feature. No excessive lipofuscin deposits were found in RPE cells (as seen in Best disease).<sup>80</sup>

Although rare, the findings of PVM can portend a poor prognosis for survival.

## Management of Paraneoplastic Retinopathy

The management of paraneoplastic retinopathy remains difficult because of its rarity, unclear diagnostic criteria, and uncertainty relating to treatment efficacy and safety. This is especially so in a patient who has painless, vague, and asymmetric visual symptoms but no history of known malignancy. Clinical suspicion remains the most important factor in the diagnosis.

An ERG should be considered in any adult patient who has symptoms of central or paracentral positive visual phenomena (“shimmering” or “dancing” lights), photopsias, and minimal retinal findings. If the ERG is abnormal or extinguished, then a chest radiograph is a common “next step,” since over half of patients with CAR syndrome have a bronchogenic tumor. A history of previous cutaneous malignant melanoma should be elicited in patients with nyctalopia. Central and midperipheral visual complaints also may be documented with visual field testing. Baseline SD-OCT and fundus autofluorescence imaging may be helpful in those cases with more severe symptoms. Antibodies to the CAR-antigen may be obtained, but a negative test is not inconsistent with a diagnosis of CAR syndrome. Given the lack of a diagnostic ERG change in any of the paraneoplastic retinopathies, testing for antiretinal antibodies in the patients' sera seems to be crucial for early detection of the disease.<sup>55</sup>

Difficulties remain with a lack of standardization, reproducibility, and validation of testing for circulating antiretinal

antibodies as well as with our understanding of which antibodies are pathogenic.<sup>77,81</sup>

The Ocular Immunology Laboratory at Oregon Health and Science University offers a comprehensive panel of autoantibody tests for CAR, MAR, PVM, autoimmune retinopathy, and paraneoplastic optic neuropathy (<http://www.ohsu.edu/xd/health/services/casey-eye/diagnostic-services/ocular-immunology-lab/index.cfm>).

Paraneoplastic retinopathy remains a diagnosis of exclusion. A retrobulbar optic neuropathy as a result of tumor spread, ischemia, or toxic effects of chemotherapy must be ruled out.<sup>2</sup> If cancer is not detected initially then continued surveillance at regular intervals is necessary.

An immune basis for CAR would suggest a possible role for immunosuppression therapy. Indeed, Keltner, and others<sup>3,7,14,61,82</sup> have reported visual improvement or stabilization following treatment with oral corticosteroids. The optimal dose of prednisone for CAR patients has not been determined.<sup>8</sup> Anecdotal cases managed with local depot or serial intravitreal steroids have been reported to be helpful.<sup>83,84</sup> Immunomodulatory agents to reduce autoreactive memory B cells, like intravenous rituximab, have also been used successfully, and this may become more promising with newer agents becoming available.<sup>85</sup> No standardized protocols have been established for management of the immunosuppression therapies for CAR, MAR, and PVM.<sup>6,10,73</sup> Immunosuppression has been reported to be effective in improving the visual outcomes in up to 100% of patients with CAR, but long-term data concerning the benefits and sustainability of treatment are not available.<sup>10,77,81</sup>

There have been no reports of visual improvement with treatment directed only at the site of primary tumor, and according to one investigator, vision usually worsens with such management alone.<sup>8</sup> The optimal approach to immunosuppressive therapy for this condition is uncertain. Plasmapheresis may have no effect on the cancer antigens and may paradoxically lead to the production of high concentrations of high-affinity antibodies.<sup>9,47</sup> Prednisone and immunomodulation have successfully stabilized the visual function of CAR patients but may exert a negative effect on the patient's own tumor immunosurveillance. All systemic therapies have the

potential to alter survival, for better or worse, despite any potential beneficial effect on vision.

## **Bilateral Diffuse Uveal Melanocytic Proliferation (BDUMP)**

Machemer, in 1966, reported a case of bilateral and simultaneously appearing uveal lesions in a 57-year-old man with aqueous cells and flare, iris nodules, cataracts, and inferior retinal detachments in both eyes. At autopsy the patient was found to have a pancreatic carcinoma. Histopathologic examination of the enucleated eyes demonstrated predominantly benign cytologic characteristics of uveal melanocytic proliferation.<sup>86</sup>

Isolated case reports of similar cases by Curtin,<sup>87</sup> Font,<sup>88</sup> and Ryll<sup>89</sup> were followed by a series of four cases in 1982 by Barr,<sup>90</sup> who defined a syndrome consisting of (1) simultaneous occurrence of bilateral diffuse melanocytic involvement of the uveal tracts, (2) predominant cytologic benignity, (3) absence of metastases from the melanocytic proliferation, and (4) associated histopathologically proven systemic malignant neoplasm. The cellular benignity has been questioned because of the presence of foci of malignant-appearing epithelioid cells in addition to evidence of scleral invasion.<sup>91</sup> However, there has been no evidence of mitotic activity, and no cases of metastases have been reported from these melanocytic proliferations.<sup>92</sup> It is possible that these patients died as a result of the more lethal non-ocular disease before such spread could take place.<sup>91,93</sup> To date, at least 50 cases have been reported.<sup>94</sup>

Other clinical signs that may be present include iridocyclitis, glaucoma,<sup>56,90,95</sup> dilated episcleral vessels,<sup>24,56,90,92</sup> shallow anterior chambers, iris cysts, ciliary body cysts,<sup>95</sup> and rapidly developing cataracts.

Gass coined the term “bilateral diffuse uveal melanocytic proliferation (BDUMP)” to describe this paraneoplastic syndrome, and he identified the following five cardinal ocular signs that accompany visual loss in these patients:

1. Development of multiple, slightly elevated (usually only up to 2

mm), pigmented, and nonpigmented uveal melanocytic tumors, as well as evidence of diffuse thickening of the uveal tract.

2. Multiple, round or oval, subtle, red patches at the level of the RPE in the posterior fundus.

3. A striking pattern of multifocal areas of early hyperfluorescence on fluorescein angiography corresponding with these patches.

4. Exudative retinal detachment.

5. Rapidly progressing cataracts ([Fig. 138.5](#)).

**FIG. 138.5** (A,B) Fundus photographs of a 60-year-old man with retroperitoneal adenocarcinoma and bilateral diffuse uveal melanocytic proliferation (BDUMP). Multiple, slightly elevated, hypopigmented choroidal lesions resembling choroidal nevi developed in both eyes. (C,D) Midtransit phase fluorescein angiography showing a striking pattern of multiple, irregular, round

areas of hyperfluorescence caused by retinal pigment epithelium changes and uveal melanocytic proliferation. (Courtesy of J. Arch McNamara.)

BDUMP has no gender predilection and the mean age of presentation is 68 years (range, 34–89 years).

The findings of BDUMP usually antedate the findings of systemic malignancy by 3–12 months, and death usually ensues from the effects of the systemic malignancy within 8–24 months.<sup>56,96</sup> The focal and diffuse thickening of the uveal tract can antedate the clinical findings of exudative retinal detachment and red patches by several months. The chronic inferior exudative detachments seen in BDUMP may also be associated with peripheral retinal nonperfusion.<sup>97</sup> Gastrointestinal, genitourinary, and pulmonary cancers and non-Hodgkins lymphoma have all been reported to be associated with the clinical findings of BDUMP.

The pathogenesis of BDUMP remains obscure, but possibilities include (1) a common oncogenic stimulus initiating both the ocular and nonocular tumors;<sup>90</sup> (2) a hormonal stimulus (ectopic peptide) for ocular melanocytic proliferation by the nonocular tumor;<sup>90</sup> (3) an individual predisposed to simultaneous development of ocular melanocytic and nonocular visceral carcinomas;<sup>93</sup> and (4) a proliferation of clinically unapparent hypopigmented diffuse bilateral choroidal nevi in response to a peptide stimulus from the visceral carcinoma.<sup>56,95</sup> An autoimmune basis for this condition is not apparent and autoantibody testing is not indicated.

The characteristic multifocal red patches (or dark gray patches in patients with brunette fundi) that are angiographically seen to hyperfluoresce are of importance in the early diagnosis of this syndrome. Gass et al. and Margo et al. demonstrated by clinicopathologic correlation that these patches represent areas of depigmented RPE overlying hypopigmented, diffuse melanocytic proliferation (Fig. 138.6).<sup>56,91</sup> These patches of melanocytic proliferation with overlying RPE changes are thought to enlarge progressively and become confluent, producing a reticular pattern that angiographically appears hypofluorescent against a background of normal choroidal hyperfluorescence.<sup>56,91</sup> Gass proposes that the RPE changes are attributable to a toxic or immune-mediated process as a result of the melanocytic

proliferation itself or to an interaction of the systemic malignancy and the RPE.<sup>56</sup>

**FIG. 138.6** Histopathologic examination of another patient with bilateral diffuse uveal melanocytic proliferation (BDUMP) and a systemic carcinoma. (A) Enlargement of the ciliary body and mild thickening of the uveal tract by nonpigmented benign melanocytes. (B) Focal areas of pigmented choroidal uveal melanocytic proliferation. (C) Sparing of the choriocapillaris and some partly necrotic melanocytes.

(Reproduced with permission from Gass JD. Stereoscopic atlas of macular diseases: diagnosis and treatment. St. Louis: Mosby; 1987.)

No treatment has successfully stabilized or improved the course of visual loss in patients with BDUMP syndrome. Plasmapheresis to remove the presumed circulating ectopic peptides has been reported to be helpful in stabilizing the vision a small number of patients while undergoing systemic treatment for the underlying malignancy.<sup>98</sup> Prompt recognition of this paraneoplastic syndrome may lead to earlier treatment of the visceral carcinoma and conceivably provide the best hope for survival, although slow growth of the uveal melanocytic proliferation may continue unabated, with a poor prognosis for vision.<sup>56</sup> Saito et al. suggested that oral steroid therapy in those individuals with BDUMP who also manifest with antiretinal antibodies may be beneficial.<sup>94</sup> Duong et al. reported a patient with BDUMP associated with ovarian carcinoma who survived the ovarian cancer but later developed metastatic amelanotic malignant melanoma, suggesting that the uveal manifestations of BDUMP may possibly have metastatic implications.<sup>99,100</sup> This suggests the importance of long-term follow-

up of successfully treated individuals.

## Conclusion

Paraneoplastic retinopathy syndromes are a heterogeneous group of disorders involving the visual system and may be the presenting manifestation of systemic malignancy. It is important for ophthalmologists to be aware of these entities so that they can initiate ancillary testing and prompt an early and aggressive search and treatment of visceral cancers. Evidence in support of an autoimmune basis for CAR, MAR, and PVM suggests an early means of detection of non-ocular malignancy, as well as a possible role for immunosuppression in the palliation of the visually disabling symptoms experienced by these unfortunate patients.<sup>77,81</sup> Plasmapheresis may be helpful in stabilizing the visual manifestations of ectopic peptide-induced BDUMP, and early identification of the associated malignancy could theoretically enhance the prognosis for life.

# Melanocytoma of the Optic Disc

*Carol L. Shields, Leonard Joffe, Jerry A. Shields*

**General Considerations**

**Clinical Features**

**Pathology and Pathogenesis**

**Diagnostic Approaches**

**Management**

**Conclusion**

## General Considerations

Melanocytoma of the optic disc is a benign melanocytic tumor, appearing with dark brown or black color and situated at the optic disc, often with extension into the surrounding choroid, retina, and vitreous.<sup>1-37</sup>

The term melanocytoma was originally coined by Zimmerman to describe a tumor with specific clinical and pathologic features that was located partly or completely within the optic nerve head.<sup>1,2</sup> The clinical and histopathologic nature of this optic disc lesion was clarified by Zimmerman and Garron,<sup>1</sup> and, subsequently, similar melanocytomas of the iris, ciliary body, and choroid have been

recognized.<sup>3-5,15</sup> Melanocytoma is now best defined as a specific variant of melanocytic nevus, located in the optic disc or elsewhere in the uveal tract, characterized clinically by a dark brown to black color, and composed histopathologically of deeply pigmented round to oval cells with small, round, uniform nuclei, often termed “magnocellular nevus.”

Historically, melanocytoma was often confused clinically and histopathologically with uveal malignant melanoma.<sup>1,2</sup> An important difference between the two is that melanocytoma appears to have an equal incidence in all races, whereas uveal melanoma is uncommon in nonwhites.<sup>5,7</sup> Furthermore, it is also uncommon for melanoma to be confined to the optic disc or to secondarily invade the optic nerve.

## Clinical Features

Most melanocytomas remain relatively stable and do not cause central visual impairment. However, slight visual loss related to the tumor can occur in about 26%, usually due to mild retinal exudation and subretinal fluid<sup>7</sup> (Table 139.1). More severe visual loss can rarely occur, secondary to central retinal vein obstruction and/or spontaneous tumor necrosis<sup>6,7,17-22</sup> or malignant transformation.<sup>1-7,31-37</sup> In some cases, such visual loss is reversible with time.<sup>22</sup> From 10% to 30% of patients with optic disc melanocytomas have an afferent pupillary defect (Marcus Gunn pupil) in the involved eye.<sup>7,19</sup> This can occur even with excellent visual acuity, due to compression of the optic nerve fibers by the melanocytoma, a factor that also explains the associated visual field defect.

**TABLE 139.1**

**Clinical Features of Optic Nerve Melanocytoma in 116 Eyes of 115 Patients**

Features	Number (%)
Patient age (mean) at detection	50 (1-91) years
Gender	
Male	44 (38%)
Female	71 (62%)

Race	
White	75 (65%)
Black	33 (29%)
Asian, Hispanic, Indian	7 (7%)
Laterality	
Unilateral	114 (99%)
Bilateral	1 (1%)
Tumor color	
Black	112 (97%)
Brown	4 (3%)
Tumor basal dimension (mean, range)	2 (1–10) mm
Tumor thickness (mean, range)	1 (0.5–3) mm
Additional features	
Choroidal invasion	35 (30%)
Retinal invasion	7 (6%)
Both choroidal and retinal invasion	28 (24%)
Optic disc edema	29 (25%)
Optic disc pallor	2 (2%)
Subretinal fluid	16 (14%)
Retinal exudation	14 (12%)
Retinal/choroidal neovascularization	1 (1%)
Retinal vein obstruction	3 (3%)
Vitreous seeding	5 (4%)

Data from Shields JA, Demirci H, Mashayekhi A, et al. Melanocytoma of the optic disc in 115 cases. The 2004 Samuel Johnson Memorial Lecture. *Ophthalmology* 2004;111:1739–1746.

Melanocytoma is usually unilateral. Bilateral cases have been rarely reported, usually in children but these cases may not be true melanocytomas.<sup>10,11</sup> There has been some controversy as to whether they should be called true melanocytomas or disc pigmentation in association with other congenital disc abnormalities.

Ophthalmoscopically, optic nerve melanocytoma has typical features.<sup>1–7</sup> This mass is characteristically a dark brown to black lesion that is located partly in the optic disc (Fig. 139.1). This tumor is relatively small and can be confined to the disc in 15%. More characteristically, melanocytoma extends over the margin of the optic disc to involve the adjacent choroid (54%) or into the adjacent sensory retina (30%) (Figs. 139.2, 139.3 and Table 139.1).<sup>7</sup> In some cases, the choroidal component is more pronounced than the papillary component. Although optic disc melanocytoma is generally believed to have few local complications, a recent study on 116 affected eyes found disc edema (25%) (Fig. 139.4), intraretinal edema (16%), subretinal fluid (14%), yellow intraretinal exudation (12%), focal hemorrhage (5%), vitreous seeds (4%), and retinal vein obstruction (3%).<sup>7</sup> These local complications can

produce visual symptoms or visual loss in 26% of cases.<sup>7</sup> (Table 139.2) This is generally mild, and severe visual loss is exceptional. Vitreous seeds from necrosis of the melanocytoma can extend into the anterior chamber, sometimes producing a black pseudohypopyon. The most important factor predictive of visual loss is extension of the tumor into the retina and the presence of surrounding subretinal fluid. There have been recent reports of choroidal neovascularization adjacent to optic disc melanocytoma.<sup>27-29</sup>

**FIG. 139.1** Optic disc melanocytoma confined to the optic disc.

**FIG. 139.2** Optic disc melanocytoma with choroidal component.

**FIG. 139.3** Optic disc melanocytoma with prominent retinal component.

**FIG. 139.4** Optic disc melanocytoma with secondary disc edema and pallor.

**TABLE 139.2**

**Outcomes of Optic Nerve Melanocytoma in 116 Eyes**

Outcomes	Kaplan–Meier Estimates		
	At 5 yr	At 10 yr	At 20 yr
Tumor enlargement	11%	32%	38%
Visual acuity loss of 2 lines	10%	18%	33%
Transformation into melanoma	2/116 (2%)		

Data from Shields JA, Demirci H, Mashayekhi A, et al. Melanocytoma of the optic disc in 115 cases. The 2004 Samuel Johnson Memorial Lecture. *Ophthalmology* 2004;111:1739–1746.

Melanocytoma of the optic disc traditionally was recognized to be a stable lesion with no tendency to grow. Very rarely, it has been documented to appear in a previously normal optic disc.<sup>12</sup> Serial fundus photographs have documented that 11–15% of them show subtle enlargement over several years<sup>7</sup> (Table 139.2). This mild growth should not be misconstrued as malignant transformation.<sup>31–37</sup> In one report, an eye with a progressively growing melanocytoma underwent enucleation and the lesion

proved to be benign, despite progressive growth.<sup>32</sup> Multivariate analysis has shown that the main predictive risk factor for growth is an initial thickness of  $\geq 1.5$  mm at the time of first diagnosis.<sup>7</sup> Some tumors can grow slowly and produce ischemic optic neuropathy associated with tumor necrosis, resulting in severe visual loss.<sup>20–22</sup> Others can cause central retinal vein obstruction and visual loss.<sup>17,18</sup> In rare cases the tumor can present as neovascular glaucoma secondary to retinal vein obstruction.<sup>9</sup>

There are usually no systemic associations with optic disc melanocytoma. It has been reported in association with intracranial meningioma, type 2 neurofibromatosis,<sup>13</sup> and phakomatosis pigmentovascularis.<sup>14</sup>

The differential diagnosis of melanocytoma of the optic disc includes juxtapapillary choroidal melanoma, choroidal nevus, hyperplasia of the retinal pigment epithelium (RPE), hypertrophy of the RPE, adenoma of the RPE, and combined hamartoma of the retina and RPE. Although extremely rare, malignant melanoma can occur in the optic nerve and may be difficult to impossible to differentiate clinically from melanocytoma.<sup>31–37</sup> The clinical features of these conditions, described in other chapters, should help to differentiate them from melanocytoma in most instances.

## Pathology and Pathogenesis

On low-power microscopy, a melanocytoma of the optic nerve has a characteristic appearance as a deeply pigmented mass that occupies the optic disc and extends for a variable distance into the optic nerve itself (Fig. 139.5).<sup>1,2,30</sup> Cytologically, the most distinguishing characteristics are the dense pigmentation and the uniform appearance. Although the dense pigment prevents visualization of cell detail, bleached preparations reveal the cells to be oval or round with abundant cytoplasm, relatively small nuclei, and few prominent nucleoli, similar to those that occur throughout the uvea in patients with ocular melanocytosis (Fig. 139.6).<sup>1,2</sup> Tumors composed of similar cells have also been recognized in the iris, ciliary body, choroid, and even in the conjunctiva.

**FIG. 139.5** Low magnification photomicrograph of optic disc melanocytoma (hematoxylin and eosin,  $\times 10$ ).  
(Courtesy of Armed Forces Institute of Pathology.)

**FIG. 139.6** Cytologic features of optic disc melanocytoma (bleached, hematoxylin and eosin,  $\times 100$ ).

The pathogenesis of optic disc melanocytoma is unknown. It is generally assumed to be a congenital lesion, but, like most uveal

nevi, it is rarely seen in young children. It has developed in an adult fundus that was previously documented photographically to be normal, raising speculation that it is either acquired or occurs as an amelanotic lesion that later becomes pigmented and clinically visible.<sup>12</sup>

## Diagnostic Approaches

The diagnosis of a melanocytoma of the optic nerve usually can be made by ophthalmoscopic recognition of its characteristic clinical features. Ancillary procedures like fundus photography, fluorescein angiography, optical coherence tomography (OCT) and angiography, autofluorescence, and visual field examinations can facilitate the diagnosis and provide help in follow-up evaluations.

In most cases, fluorescein angiography of a melanocytoma of the optic nerve demonstrates hypofluorescence throughout the angiogram (Figs. 139.7 and 139.8).<sup>5</sup> This is presumably because the cells are deeply pigmented and closely compact with relatively little vascularity. In cases with optic disc edema, there is hyperfluorescence of the optic disc edema adjacent to the tumor. With OCT angiography, the radial peripapillary capillary network is accentuated overlying the mass, if there is no retinal invasion (Fig. 139.8). Deep vessels are not seen.

**FIG. 139.7** Fluorescein angiography optic disc melanocytoma. (A) Clinical appearance of lesion. (B) Angiogram in mid venous phase showing hypofluorescence of lesion.

**FIG. 139.8** Imaging of optic disc melanocytoma with fundus photography (A), autofluorescence (B), fluorescein angiography (C), optical coherence tomography (OCT) angiography (D), and OCT of the macula (E) and tumor (F).

Indocyanine green angiography (ICGA) also shows the lesion to be generally hypofluorescent.<sup>23</sup> Melanocytoma is hypoautofluorescent.<sup>25</sup> OCT using time domain or spectral domain technology shows a smooth dome-shaped prepapillary mass with dense shadowing and occasionally vitreous seeds can be

documented overlying the mass (Fig. 139.8).<sup>16,24,26</sup>

The visual field of an eye with melanocytomas is variable, depending on the size and extent of the lesion, as well as degree of optic nerve compression and atrophy. Visual field defects are relatively common, found in 40% of eyes, and include arcuate scotoma, enlarged blind spot, and others.<sup>19</sup>

If a melanocytoma is greater than 0.5 mm in elevation, it can often be demonstrated with ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI), but these techniques do not provide enough resolution to differentiate melanocytoma from other elevated lesions of the optic disc. Furthermore, ultrasonography cannot detect microscopic extension of the tumor into the retrolaminar portion of the optic nerve. MRI can help determine the gross extent of melanocytoma involvement in the retrolaminar portion of the optic nerve using gadolinium enhancement.<sup>34</sup> Extensive involvement in the optic nerve with severe visual loss suggests malignant transformation of the lesion (Fig. 139.9).<sup>31-37</sup> Malignant change is estimated to occur in about 1–2% of cases.<sup>7</sup> Only a few convincing cases of transformation into melanoma with histopathologic confirmation have been reported.<sup>31-37</sup> A study on gene expression profiling of optic disc melanocytoma led to identification of class 1A tumors, with very little risk for metastatic disease.<sup>38</sup>

**FIG. 139.9** Malignant transformation of melanocytoma of optic disc. (A) Appearance of lesion in 1982. (B) Photograph in 1988. Note the enlargement. (C) Photomicrograph showing tumor (hematoxylin and eosin,  $\times 10$ ). (D) Photomicrograph near base of tumor, showing typical melanocytoma cells (bleached, hematoxylin and eosin,  $\times 100$ ).

## Management

Since melanocytoma of the optic disc can sometimes evolve into malignant melanoma, examination and fundus photography should be performed yearly. Small degrees of growth may not signify malignant change. However, more progressive growth and visual loss should suggest malignant transformation, and fine needle biopsy confirmation followed by enucleation should be considered.

## Conclusion

Melanocytoma is an unusual variant of nevus that classically occurs in the optic nerve head. It can be confined to the optic disc or have

contiguous involvement of the choroid, sensory retina, or vitreous. It is important to differentiate this benign lesion from a malignant melanoma. Histopathologically, melanocytoma is composed of deeply pigmented round to oval nevus cells with small nuclei. Although melanocytoma rarely causes central visual loss, it can cause peripheral visual impairment with field defects. More importantly, melanocytoma can undergo malignant transformation into melanoma in 1–2% of cases. A patient with a melanocytoma of the optic disc should be examined annually.

### Introduction

Congenital hypertrophy of the retinal pigment epithelium (CHRPE) is generally an asymptomatic congenital hamartoma that occurs in three variant forms: either as solitary, or grouped, or multiple pigmented fundus lesions. Lesions are usually observed during routine ophthalmoscopy.<sup>1</sup> Multiple CHRPE may be associated with familial adenomatous polyposis (FAP), an autosomal dominant disease with numerous adenomatous polyps of the colon and rectum. FAP with prominent extracolonic manifestations has been termed Gardner syndrome (GS) or another variant as Turcot syndrome for FAP with brain tumor lesions (Fig. 140.1). The observation of CHRPE in a premature child provides evidence for the congenital nature of this lesion.<sup>2</sup>

**FIG. 140.1** Classification of CHRPE in solitary grouped and multiple forms and their systemic association.

### Epidemiology/Demographics

The reported prevalence of CHRPE is as low as 3 described cases among 2400 ophthalmic examinations (1.25%). The prevalence of FAP varies from 1 in 7000 to 1 in 22,000 individuals.

Approximately 70–90% of FAP patients have pigmented fundus lesions.<sup>3</sup>

# Clinical Findings and Classification

## Solitary CHRPE

Solitary CHRPE is typically a flat, round, hyperpigmented lesion with smooth or scalloped margins that is well demarcated from normal-appearing retinal pigment epithelium (RPE) (Fig. 140.2A). The color may vary from light gray to brown to black and is independent of the patient's race.<sup>1</sup> A marginal halo of depigmentation may surround the lesion and “punched-out” inner lacunae with hypopigmentation may be present in larger lesions. Both depigmented zones show the tendency to progress gradually over time, and eventually may involve the entire lesion.<sup>4-7</sup> The overlying retina and its vasculature appear normal in most cases, however discrete focal intraretinal pigmentation may become visible near the margin on biomicroscopy.<sup>4</sup> Some lesions may be associated with retinal vascular abnormalities including capillary and large-vessel obliteration, microaneurysmal changes, chorioretinal anastomoses, and neovascularization. The size may vary from 100  $\mu\text{m}$  to several disc diameters, occasionally occupying an entire quadrant. Lesions may be found anywhere in the fundus, with predominance in the superotemporal and equatorial region while the macula is rarely involved. Solitary CHRPE enlarge in 46–83% of cases over three or more years of follow-up. Extension into the fovea may result in reduced visual acuity.<sup>8</sup> Some heavily pigmented nodular lesions may develop within CHRPE.<sup>9</sup> Histopathologically nodular lesions proved to be adenocarcinomas in two reports.<sup>10,11</sup> Untreated nodular lesions may enlarge to form pedunculated tumors of >7 mm thickness with serous retinal detachment.<sup>11</sup> Proton beam radiation therapy may be applied in these rare cases.<sup>12</sup>

**FIG. 140.2** (A) Solitary CHRPE: A large CHRPE OD with a diameter of 3 disc diameters. (B) Grouped CHRPE: The sectorial pattern of grouped CHRPE with smaller lesions at the optic disc and larger lesions in the periphery. Larger hyperpigmentations may be separated during growth into smaller spots, surrounded by normal pigmented cells. The shape of these lesions may be sickle- or oval-shaped with convex borders, fitting into the concave borders of adjacent lesions. (C) Multiple CHRPE lesions in FAP are generally smaller (50 to 100  $\mu\text{m}$  in diameter) compared with solitary CHRPE. The ovoid, often spindle-shaped, hyperplastic lesions are black, brown, or light gray color. Lesions have a nearly meridional orientation towards the optic disc and are haphazardly distributed with no obvious predilection for any quadrant.

## Grouped CHRPE

When several lesions of varying size are arranged in a cluster, resembling the footprint of an animal (“bear tracks”), they are named “grouped CHRPE” (233800, OMIM). Grouped lesions are flat, well-demarcated round oval or geographic black spots with increasing size towards the fundus periphery. Each cluster includes approximately 3–30 lesions, which may vary in size from 100 to 300  $\mu\text{m}$  lesions (Fig. 140.2B). Etiology and development of grouped CHRPE remain unknown. The presence of grouped CHRPE and additional ipsilateral sectorial pigmented skin lesions following the “cutaneous lines of Blaschko” gave evidence for possible pigmentary mosaicism in both the eye and skin.<sup>13</sup> Therefore, grouped CHRPE are considered as a cluster of atypical hyperpigmented RPE cells, that derive from the edge of the optic

nerve and migrate along the stream of embryologic tissue lines, analogous to the “cutaneous lines of Blaschko.” The sectorial pattern of grouped CHRPE obviously reflects the stream, outgrowth, and migration path of RPE cells during embryogenesis.<sup>14</sup> Bilateral grouped CHRPE has rarely been observed. There are no systemic associations in patients with solitary and grouped CHRPE.

## Multiple CHRPE

Multiple CHRPE lesions in FAP are generally smaller (50–100 μm in diameter) compared with solitary CHRPE. They are black, brown, or light gray (Fig. 140.2C). Larger lesions may be surrounded by a depigmented halo, mottled RPE,<sup>15</sup> window-defect-type changes adjacent to retinal vessels,<sup>16</sup> may contain depigmented lacunae, and can be accompanied by small pigmented satellite lesions. Retinal invasion; glial, capillary, and pigment epithelial proliferation; and hypertrophy are typical. More than four widely spaced lesions per eye or bilateral involvement are suggestive of FAP.<sup>17</sup> Traboulsi et al. examined 16 GS families for multiple CHRPE. Of 41 GS patients, 37 (90%) had multiple CHRPE lesions.<sup>15</sup> Lesions were bilateral in 32 patients (78%). The presence of bilateral lesions or multiple unilateral lesions (>4) appeared to be a useful clinical marker (specificity, 0.95; sensitivity, 0.78) for GS. In view of the multiple, bilateral character of retinal lesions observed in FAP, they can be considered a clinical disease marker. However, the absence of CHRPE has no predictive value for absence of GS or FAP.

## Differential Diagnosis

Often CHRPE has been misdiagnosed as choroidal malignant melanoma. The latter is almost always elevated, less homogeneously pigmented and less sharply demarcated compared with CHRPE, and usually exhibits growth in all three dimensions. Choroidal nevi are flat and located below the RPE. Their color may vary from light to dark brown. The borders are less well demarcated and often are feathery because nevus cells extend along larger choroidal vessels. Frequently, drusen and pigmentary

mottling are present on the surface of nevi. Melanocytomas of the choroid have a similar appearance to CHRPE, except for their homogeneously black color. Black sunburst lesions in sickle cell retinopathy may appear as dark gray to brown convex-shaped lesions predominantly in the midperiphery. True hyperplasia of the RPE has ill-defined borders and invades the retina, often leading to retinal distortion. Focal pigmentation caused by injury, inflammation, or drug toxicity may resemble CHRPE but can be differentiated on the basis of a more irregular shape, widespread distribution, and associated clues suggesting acquired disease. Torpedo maculopathy presents as oval-shaped depigmented lesions temporal to the fovea.<sup>18,19</sup>

## Associated Extraocular Findings

Solitary, unilateral lesions and grouped CHRPE are restricted to the RPE with no other ocular or extracellular findings.<sup>20</sup> Multiple or bilateral CHRPE may be associated with autosomal dominant FAP or GS (175100, OMIM). Gardner syndrome is characterized by FAP of the large and small intestine, hamartomas of the skeleton, and various soft-tissue tumefactions.<sup>21,22</sup> Intestinal polyps generally appear during the third decade of life and invariably progress to adenocarcinomas by the fifth decade. Skeletal hamartomas, most commonly benign osteomas of mandible, skull, orbits, and long bones, become apparent in the third decade of life, as well as soft-tissue abnormalities including epidermoid and sebaceous cysts, dermal fibromas, lipomas, leiomyomas, desmoid, and mesenteric fibromatosis. Further extracolonic manifestations of GS include tumors of the thyroid, adrenal, and bladder, as well as sarcomas and hepatoblastomas. Turcot syndrome (233800, OMIM) is associated with FAP and brain tumors, e.g., astrocytomas, medulloblastomas, and ependymomas.

## Pathophysiology/Histopathology

Histopathologic studies demonstrated that most solitary<sup>1,4</sup> and grouped CHRPE lesions are a monocellular layer of hypertrophied RPE cells, densely packed with large round pigment granules instead of the wedge-shaped melanin granules frequently found in

normal RPE cell lesions (Fig. 140.3A). These large round granules represent primarily macromelanosomes.<sup>23</sup> The underlying Bruch's membrane may be thickened<sup>1,4,24,25</sup> due to widening of the basement membrane of the hypertrophied RPE cells. The remaining layers of Bruch's membrane, the choriocapillaris, and choroid appear normal. The subjacent photoreceptor layer degenerates progressively with increasing age. The inner retinal layers, including the retinal vasculature, remain normal. In the area of depigmented lacunae, both the hypertrophied RPE and photoreceptor cell layers are absent and replaced by glial cells.<sup>4</sup> The transition from the margin of CHRPE lesions to normal RPE lesions occurs abruptly. A surrounding hypopigmented halo corresponds to areas of less pigmented hypertrophied RPE cells. All lesions remain flat.

**FIG. 140.3** (A) Light microscopy shows the abrupt transition from normal to abnormal retinal pigment epithelium (RPE) and retina (*arrow*) (hematoxylin and eosin, x500). (B) Scanning electron micrograph of a pigmented fundus lesion 100  $\mu$ m in diameter composed of a cluster of enlarged RPE cells (x500). (Panel A reproduced with permission from Buettner H. Congenital hypertrophy of the retinal pigment epithelium. *Am J Ophthalmol* 1975; 79:177–189. Panel B courtesy of Traboulsi EI, Murphy SF, de la Cruz ZC, et al. A clinicopathologic study of the eyes in familial adenomatous polyposis with extracolonic manifestations (Gardner's syndrome). *Am J Ophthalmol* 1990; 110:550–561. With permission from the American Academy of Ophthalmology.)

Multiple lesions associated with FAP show hypertrophy and hyperplasia of plump RPE cells, retinal invasion, and retinal

partially vascular changes. Hyperplastic lesions with multiple layers of hypertrophied RPE cells are resembling “hamartomas,” causing an elevated appearance and present as clusters of enlarged RPE cells on scanning electron microscopy (Fig. 140.3B).<sup>22,26</sup> In another lesion, hypertrophied RPE cells traversed the full thickness of the retina. These histopathologic characteristics allow the classification of the pigmented ocular lesions in FAP as hamartomas of the RPE.<sup>26</sup> To distinguish these lesions nosologically the terms “polyposis-associated congenital hamartoma of the RPE” and “multiple RPE hamartomas (MRPEH)” from the classic lesion of CHRPE have been proposed.<sup>27</sup> In grossly normal-appearing areas of the fundus, individual and small clusters of enlarged RPE cells contain the same large spherical melanin pigment granules found in the pigmented lesions.

## Clinical Examination/Ancillary Testing

The vast majority of pigmented fundus lesions are easily recognized by indirect ophthalmoscopy or three-mirror contact lens examination after dilatation of the pupil. Color fundus photography is conventionally used to document the location, color, size, and appearance of the lesions (Fig. 140.4), and novel ultrawide-field scanning-laser ophthalmoscopy has been recommended as a screening tool.<sup>2,28</sup> However, absence of CHRPE lesions in a family with FAP does not indicate absence of the gene, since variable phenotype expression may exist or tiny lesions can be overlooked.

**FIG. 140.4** Color fundus photography is used to document the location, color, size, and appearance of the lesions. Larger lesions may present punched-out inner lacunae with hypopigmentation and tend to expand slightly in size with aging.

As small or lightly pigmented lesions may easily be missed, fundus autofluorescence (FAF) and infrared reflectivity may be helpful to identify these lesions. Since CHRPE contains predominantly melanin and only small amounts of lipofuscin these lesions typically demonstrate hypoautofluorescence. Only areas with lacunae or nonpigmented halos show a trace to moderate autofluorescence and infrared hyperreflectivity<sup>29</sup> (Fig. 140.5A).

**FIG. 140.5** (A) Fundus autofluorescence (FAF) is helpful to determine these CHRPE since the lesion contains predominantly melanin and only little

lipofuscin lesions presenting in dark hypoautofluorescence. (B) Microperimetry reveals a scotoma corresponding in size and location to the lesions. The central best corrected visual acuity is 20/80 and the central fixation was intact although the patient noticed moderate increase of the scotoma during computer work.

The majority of lesions remain asymptomatic and show no leakage of dye on fluorescence angiography (FA) or indocyanine green angiography (ICGA). CHRPE lesions appear as dark spots blocking choroidal fluorescence and augment the brightness of retinal vasculature. Only in depigmented lacunae or hypopigmented halos is a normal choriocapillaris flush observed. Leakage from retinal vessels overlying CHRPE has been reported during late phases of the angiogram.

The electroretinogram (ERG) and electro-oculogram (EOG) remain normal in eyes with CHRPE, providing evidence for the localized nature of this disease. The axial resolution of A- and B-scan ultrasound sonography is too low to document the CHRPE lesion, since the lesions demonstrate minimal or no elevation.

Spectral domain optical coherence tomography (SD-OCT) highlights the cross-sectional retinal anatomy of CHRPE lesions. A general thinning of the neural retina with a predominant photoreceptor loss becomes apparent over the CHRPE lesion<sup>30</sup> (Fig. 140.5A). Darkly pigmented CHRPE shadows the underlying choroidal structures. Areas of lacunae show absence of RPE and increased transmission of light. Retinal thinning and photoreceptor loss over CHRPE account directly for related visual field loss. On enhanced-depth imaging optical coherence tomography (EDI-OCT), CHRPE seems flat with thickened, irregular RPE and absent RPE within lacunae. A prominent feature is outer retinal loss, generally involving the outer nuclear layer to photoreceptors, occasionally with a characteristic subretinal cleft. The central sublesional choroidal thickness (126.4  $\mu\text{m}$ ) was not different compared with thickness outside the margin (126.8  $\mu\text{m}$ ).<sup>31</sup> Patients with CHRPE rarely complain of related symptoms, except when the fovea is involved. Microperimetry may reveal relative or absolute scotomas corresponding in size and location to the lesions. Microperimetric

defects tend to progress from relative to absolute scotoma and expand slightly in size with aging (Fig. 140.5B).

## Familial Adenomatous Polyposis Prognosis and Management Options

FAP, a precancerous condition, appears with hundreds to thousands of adenomatous polyps in the colon and rectum, harboring a high risk of malignant transformation and making prophylactic total colectomy necessary in the majority of patients. Untreated patients die from colorectal cancer at an average age of 40 years.

The gene responsible for FAP, called the adenomatous polyposis coli gene (*APC*), is localized on the long arm of chromosome 5 (5q21–q22), encoding a tumor suppressor protein consisting of 2843 amino acids. The APC protein influences cell cycle, cell migration, and adhesion.

The presence of extracolonic symptoms and the severity of disease correlate with the location of the mutation on the *APC* gene. Attenuated FAP (AFAP, <100 colorectal adenomas) is caused by mutations localized after codon 1595, before codon 157, and in the spliced region of exon 9. Severe FAP (>1000 adenomas) is seen in patients with mutations between codons 1250 and 1464. Mutations in the remaining *APC* gene lead to intermediate FAP (100–1000 adenomas) (Fig. 140.6).<sup>32,33</sup>

**FIG. 140.6** Distribution of the APC-germline mutations and clinical manifestation. The red box indicates the colonic manifestation and its severity. Filled black boxes present the *APC* coding region split into 15 exons. The spliced exon 9 is marked in grey. The yellow box assigns the mutation region of the *APC*

gene to the multiple CHRPE fundus lesions.

Phenotypic expression of CHRPE correlates with the localization of mutations. FAP patients with mutations between codon 446 and codon 1338 regularly present with CHRPE lesions, whereas FAP patients with mutations between 1445–1578 lack multiple CHRPE at the retinal fundus. This relationship between CHRPE manifestations and the site of the *APC* mutation points out a specific role of the APC protein in development of retinal tissue. Moreover, the CHRPE status adds important information about the location of the genetic mutation and plays a critical role in the detection of the corresponding *APC* mutations. Recent well-defined assessment criteria necessitate the presence of at least four CHRPE lesions whatever their size or at least two lesions, of which one is large, to support the diagnosis of FAP.<sup>34</sup>

Surgical

Combined hamartomas of the retina and retinal pigment epithelium (CHRRPE) are benign tumors that may cause significant visual loss depending upon location. Accurate diagnosis is essential because the lesion may resemble a choroidal melanoma or other intraocular tumor. Combined hamartomas are usually solitary, unilateral lesions located at the optic disc or posterior pole. They typically appear slightly elevated and have varying amounts of pigmentation, vascular tortuosity, and epiretinal membrane (ERM) formation. CHRRPE lesions are characterized by predominant tissue subtype, including pigment epithelial, vascular, or glial.<sup>1</sup>

## **Historical Review**

Early reports of combined hamartomas describe lesions that were clinically mistaken for choroidal malignancy. Histopathologically, these lesions were described as hyperplastic retinal pigment epithelium and were located juxtapapillary, in the posterior pole or peripherally.<sup>2,3</sup> In 1961, the term “hamartoma” was used to describe a large lesion of the posterior pole in a child.<sup>4</sup> In 1973, Gass<sup>5</sup> reported lesions in five children and two young adults and used the term “combined hamartoma.” In 1984, Schachat et al.<sup>1</sup> described 60 patients with combined hamartomas in a collaborative effort of the

Macula Society Research Committee. Gass<sup>6</sup> reported an additional 35 patients in his discussion of the Macula Society's report. Shields et al.<sup>7</sup> reported visual acuity outcomes of 77 patients from a single institution.

## Epidemiology

In the Macula Society's report<sup>1</sup> of 60 patients with combined hamartomas, the mean age at the time of diagnosis was 15 years, with a range of 10 months to 66 years. The number of males and females was equal, and three patients were black. Shields et al.<sup>7</sup> reported a mean age of diagnosis of 11.9 months with a range of 0.4–60 months. There was no apparent predilection based on sex or race. Diagnosis is likely delayed relative to the appearance of the lesions due to the gradual impact on vision of non-macular lesions.

## Clinical Manifestations

### Symptoms

Reviews of several large reports show that painless visual loss is the chief complaint followed by strabismus, floaters, leukocoria, and ocular pain. Detection during routine examination was reported in 10% of patients.<sup>1,7,8</sup>

### Visual Acuity

Visual function varies with the location of the lesion.<sup>7</sup> Direct macular involvement including the optic nerve, papillomacular bundle, or fovea may reduce visual acuity. Extramacular lesions may cause visual loss from indirect macular distortion related to tractional forces. Although uncommon, secondary causes of visual loss include choroidal neovascularization,<sup>1,9</sup> vitreous hemorrhage,<sup>10,11</sup> exudative retinal detachments,<sup>1</sup> retinoschisis,<sup>1,12</sup> and macular hole formation.<sup>13</sup> In the Macula Society report,<sup>1</sup> visual acuity was 20/40 or better in 45% of patients, and 20/200 or worse in 40%. In a review by Font et al.,<sup>8</sup> 28% were 20/40 or better, whereas 28% were worse than 20/200. Age, symptoms, and visual acuity at

presentation are related to tumor location. Compared with extramacular lesions, macular lesions were associated with younger presentation (mean age 14.2 months versus 9.5 months), strabismus (25% versus 31%), decreased visual acuity (37% versus 43%) and visual acuity  $\leq 20/200$  (25% versus 69%). Mean visual acuity of macular and extramacular CHRRPE lesions was 20/320 and 20/80, respectively.<sup>7</sup>

## Ophthalmoscopic Appearance

Combined hamartomas may be located at the optic disc and juxtapapillary region, in the macula, and in the mid-periphery. The ophthalmoscopic appearance varies depending on the location of the tumor. Lesions of the posterior pole have varying amounts of retinal pigment epithelial, vascular, and glial components, and one tumor type tends to predominate (Fig. 141.1). Clinical features include an elevated pigmented mass involving the RPE, retina, and overlying vitreous with extension of fanlike projections towards the periphery. This lesion may blend imperceptibly with the surrounding RPE with an absence of RPE or choroidal atrophy. The lesion may be covered by a thickened gray–white retinal and preretinal tissue which may show contraction of the inner surface. There is generally absence of retinal detachment, hemorrhage, and vitreous inflammation.<sup>5</sup> The Macula Society<sup>1</sup> reported retinal vascular tortuosity within the lesion in 93% of patients, hyperpigmentation in 87%, slight elevation in 80%, ERM formation in 78%, and exudation in 7%. Peripheral lesions<sup>14</sup> appear as an elevated ridge concentric with the disc. Adjacent to the lesion, larger retinal vessels appear stretched, and there are a few smaller vessels (Fig. 141.2). A dragged disc appearance has been described in patients with peripheral lesions.<sup>5,15</sup> Combined hamartomas are almost always solitary, unilateral tumors; however, cases of bilateral involvement have been reported in association with neurofibromatosis.<sup>9,16–18</sup>

**FIG. 141.1** (A) Combined hamartoma of the left optic nerve head and juxtapapillary region in a 10-year-old female with 20/80 vision. Circumferential hyperpigmentation is noted with significant gliosis overlying the optic nerve. Retinal striae with a retinal fold is present in the superior macula. Retinal vascular tortuosity and telangiectasia are evident. (B) Mid-phase fluorescein angiogram demonstrating numerous small, irregular blood vessels throughout the lesion. There is blocked fluorescence from the pigmentation. (C) Spectral domain optical coherence tomography demonstrates an elevated hyperreflective mass with disorganization of normal retinal architecture. Fibrovascular traction with retinal thickening and attenuation of the inner and outer retina with minimal attenuation of the photoreceptor layers. Evidence of a surgical plane can guide removal in these cases.

**FIG. 141.2** (A) Unremarkable left eye (OS) of a 6-month-old girl who presented with a total tractional and exudative retinal detachment of the right eye (OD). (B) Fluorescein angiography (FA) showed complete vascularization OS and normal posterior pole and midperipheral vasculature. (C) Approximately six months later, OS revealed a discrete pigmented, mildly elevated lesion with preretinal glial proliferation and contraction nasal to the optic nerve. (D) FA confirmed a CHRRPE lesion with telangiectatic vessels and blocked choroidal fluorescence surrounding the lesion. (E,F) Following two months of observation, the lesion continued to grow with additional gliosis, retinal distortion, and straightening of retinal vessels.

## Associated Ocular Findings

Extensive disc or macular lesions may be associated with a relative afferent pupillary defect. Patients with macular involvement and decreased vision often have strabismus.<sup>7</sup> Other findings include vitreous hemorrhage,<sup>10,11</sup> preretinal neovascularization peripheral to the hamartoma,<sup>19</sup> choroidal neovascularization at the margin of the lesion,<sup>1,9,20</sup> macular hole,<sup>13</sup> and peripheral hole formation.<sup>21</sup> In addition, CHRRPE lesions have been associated with X-linked juvenile retinoschisis, optic nerve head pits, optic nerve colobomas, and optic nerve head drusen.<sup>1,5,22</sup>

## Systemic Associations

Most patients with combined hamartomas do not have evidence of systemic disease; however, numerous reports describe an association with neurofibromatosis types 1 and 2.<sup>5,16-18,23-25</sup> A majority of patients with bilateral combined hamartomas have signs of neurofibromatosis.<sup>9,16,18</sup> Combined hamartomas have also been reported in patients with facial hemangiomas,<sup>5</sup> incontinentia pigmenti,<sup>1</sup> tuberous sclerosis,<sup>11</sup> Gorlin Goltz syndrome,<sup>26</sup> Poland anomaly,<sup>27</sup> branchio-oculofacial syndrome,<sup>28</sup> brachio-otic syndrome,<sup>29</sup> brachial cleft cysts,<sup>30</sup> and juvenile nasopharyngeal angiofibroma.<sup>31</sup>

## Diagnostic Evaluation

The diagnosis of CHRRPE is based upon clinical appearance and characterization by fluorescein angiography (FA) and optical coherence tomography (OCT). In the early phase of the angiogram, the degree of hypofluorescence parallels the degree of hyperpigmentation. Tractional distortion of the retina may result in marked vascular tortuosity and telangiectasia. The mid-phase of the angiogram may highlight vascular anomalies. It is not uncommon to note vascular straightening. In the late phase of the angiogram the tortuous vessels usually leak, causing late hyperfluorescence. If there is associated choroidal neovascularization, deep leakage is

evident.

OCT is an important modality for diagnosing and characterizing CHRRPE lesions. High-resolution spectral domain OCT (SD-OCT) imaging shows characteristic findings, including peaked vitreoretinal traction, retinal disorganization, thickening of the retina at the level of the RPE, and preretinal vitreoretinal interface abnormalities.<sup>32</sup> OCT imaging can delineate the transition between the abnormal retinal interface and can guide surgical intervention. Enhanced depth imaging OCT (EDI-OCT) typically shows ERM with traction, disorganization of the retinal layers, and choroidal thinning.<sup>33</sup> A detailed analysis of EDI-OCT imaging in pediatric patients shows characteristic ERM and vitreoretinal traction of the inner retina in a sawtooth (mini-peak) or full thickness retinal fold (maxi-peak) pattern. Autofluorescence may show a hypoautofluorescence over the entire lesion and hyperautofluorescence in areas with macular edema and overlying ERM.<sup>34</sup> Ultrasonography is not useful in diagnosis of these minimally elevated lesions.

## Differential Diagnosis

The differential diagnosis of combined hamartomas includes any fundus lesion that has some degree of elevation, pigmentation, vascular tortuosity, or glial proliferation. Diagnosis of combined hamartomas requires evidence of preretinal, intraretinal, and subretinal components.

## Epiretinal Membrane

The most common differential diagnostic consideration is epiretinal membrane. As for ERMs, vitreoretinal interface disruption and vascular tortuosity may be present, but the hyperpigmentation associated with CHRRPE lesions is rarely present. ERMs may show a “cellophane” light reflex or a thickened, opaque membrane with superficial retinal folds and traction lines. A review of 44 patients with childhood ERMs showed association with trauma or uveitis and were predominantly identified in males in the second decade of life.<sup>35</sup> It may be extremely difficult to distinguish between ERMs

and CHRRPE lesions in eyes with no known history of trauma or inflammation. OCT testing can be helpful for differentiating CHRRPE and ERMs. The intraretinal component of CHRRPE lesions, which is often difficult to discern by FA or clinical examination, is evident with high-resolution OCT imaging.<sup>32</sup> OCT imaging can also be useful for identifying and guiding surgical removal of preretinal traction associated with CHRRPE lesions. Preretinal components of CHRRPE lesions can be removed surgically, but the adhesion between disorganized retinal structures and thickened RPE cannot be removed. For this reason, some measure of persistence of the CHRRPE lesion is routinely noted following surgery (Fig. 141.3).

**FIG. 141.3** (A) Preoperative color fundus photograph, demonstrating presence of a CHRRPE lesion with marked dragging and distortion of the central macula. (B) Preoperative OCT showing dense hamartoma of the macula with vitreoretinal traction and evidence of a surgical plane. (C) Postoperative color fundus photo demonstrating reduction of macular distortion following

pars plana vitrectomy with membrane peeling with assistance of autologous plasmin enzyme. (D) Postoperative OCT demonstrating flattening of the central macula.

## Pigmented Choroidal Lesions

Choroidal melanomas, choroidal nevi, congenital hypertrophy of the retinal pigment epithelium (CHRPE), adenoma, and adenocarcinoma of the RPE can be misidentified as a CHRRPE lesion. Choroidal melanomas are subretinal, elevated, and lack vitreoretinal interface changes and vascular tortuosity. Choroidal nevi lack vitreoretinal interface changes and vascular tortuosity as well. Congenital hypertrophy of the retinal pigment epithelium is subretinal and flat with normal retinal vessels. Adenoma and adenocarcinoma of the retinal pigment epithelium are rare and usually jet-black in color.<sup>14</sup>

## Miscellaneous Lesions

Morning-glory disc anomaly, retinoblastoma, choroidal neovascularization, retinoschisis, and capillary hemangioma can simulate the appearance of combined hamartomas. In a large series of 604 patients with lesions simulating retinoblastoma (pseudoretinoblastoma), CHRRPE lesions were noted in 2% of cases with Coats disease (40%) and persistent fetal vasculature (28%) being the most common causes of pseudoretinoblastoma.<sup>36</sup>

## Clinical Course

Visual loss in patients with combined hamartomas is associated with macular involvement. Distortion of retinal anatomy and disorganization of retinal components can cause strabismus and amblyopia in children. Visual loss has also been associated with vitreous hemorrhage, choroidal neovascularization, macular edema, retinoschisis, peripheral and macular hole formation, and retinal detachment.<sup>1,9-13,16,20,37</sup> Peripheral lesions are generally asymptomatic, but vitreous traction may increase vascular

tortuosity and result in macular distortion. In the Macula Society report,<sup>1</sup> 66% of patients maintained their visual acuity after 4 years, 24% of patients lost 2 or more lines, and 10% of patients improved by 2 or more lines as a result of amblyopia therapy or vitreous surgery. In the Macula Society report, the mean age was 15 years. In a report of a younger population (mean age of 9.5 months), 60% of patients with macular lesions and 13% of patients with extramacular lesions lost  $\geq 3$  lines of vision after 4 years of follow-up.<sup>7</sup> The decline in visual acuity indicates the need for frequent evaluation, amblyopia therapy, and possible surgical intervention. Unfortunately, data from population-based studies is not available to confirm progression or long-term stability of asymptomatic lesions.

## Etiology and Pathogenesis

Multiple proposed etiologies of CHRRPE lesions exist. Although combined hamartomas have not been reported to be present at birth, they have been noted in infants 2 weeks of age,<sup>7</sup> which supports a congenital etiology. The association of combined hamartomas with neurofibromatosis supports a developmental etiology. Several reports have documented the development of acquired lesions. For example, an 8-year-old patient with a unilateral combined hamartoma developed a similar-appearing lesion with consequent visual loss in the fellow eye at a 2.5-year follow-up.<sup>17</sup> A more recent report by Yonekawa et al.<sup>38</sup> documents the formation of an acquired de novo lesion that developed as an incidental finding 8 months after birth (Fig. 141.2). Although a few reports of acquired hamartomas exist, these are often related to RPE trauma, inflammation, vitreomacular traction, or disc edema suggesting a hamartoma-like gliosis and hyperpigmentation as opposed to truly de novo hamartomatous lesions.<sup>39–41</sup>

## Histopathology

Early reports on combined hamartomas describe lesions that were clinically mistaken for choroidal malignancy. The histopathologic findings in combined hamartomas were obtained from eyes that

were enucleated for suspected malignancy. In general, progressive enlargement of the lesion or decreasing visual acuity prompted enucleation.

Combined hamartomas show marked disorganization of the retinal architecture with preretinal, intraretinal, and subretinal components. Proliferation of glial tissue has been described as focal areas of gliosis in the nerve fiber layer associated with wrinkling of the internal limiting membrane.<sup>3</sup> The RPE proliferates as cords and sheets within the overlying inner retina and may exhibit a perivascular distribution. In juxtapapillary lesions, there may be proliferation of the retinal pigment epithelium into the optic disc.<sup>2</sup> The peripapillary retina and optic nerve head may be thickened by increased numbers of blood vessels and by proliferated retinal pigment epithelium.<sup>42</sup> In one report, 15-year follow-up showed calcification of a longstanding CHRRPE lesion with osseous metaplasia often associated with other longstanding gliotic disorders including proliferative vitreoretinopathy membranes.<sup>43</sup>

Histologic and immunohistochemical analysis of ERMs associated with CHRRPE lesions have been previously reported.<sup>44</sup> Hematoxylin and eosin staining shows a monolayer of cells with an underlying basement membrane. The nuclei present were epithelioid, consistent with RPE elements, and spindle-shaped, consistent with fibroglial elements. Immunohistochemical staining with cytokeratin (CK), glial fibrillary acidic protein, and neuron-specific enolase revealed a mixture of RPE and retinal elements with negative RPE65 staining, indicating the absence of mature RPE cells.

## Treatment

### Medical

In patients with CHRRPE lesions, a functional component of amblyopia may be superimposed on visual loss caused by structural abnormalities, and in some cases, visual acuity has increased with amblyopia therapy.<sup>1,45</sup> One report of a macular lesion causing progressive visual loss and vascular leakage was treated with photodynamic therapy (PDT). Following PDT,

vascular closure was demonstrated with fluorescein angiography.<sup>46</sup> Visual loss from subfoveal choroidal neovascularization has been demonstrated in CHRRPE lesions. In one report, submacular surgery and removal of the choroidal neovascular membrane improved vision from 20/60 to 20/20.<sup>47</sup> In addition, anti-VEGF therapy has been successfully used to treat CHRRPE-associated choroidal neovascular membranes.<sup>48</sup>

## Surgical

As stated previously, the clinical course of macular CHRRPE lesions is progressive visual loss. In the Macula Society report,<sup>1</sup> 24% of patients lost 2 or more lines of vision after 4 years. In younger patients (mean age of 9.5 months) 60% of patients with macular lesions had a visual loss of  $\geq 3$  lines after 4 years.<sup>7</sup> The natural history of progressive visual loss indicates the importance of monitoring and evaluation for surgical intervention. Lesions generally have one predominant tissue subtype, including melanocytic, vascular, or glial. Macular lesions creating progressive visual loss with glial proliferation and vitreous traction are amenable to surgical treatment.<sup>49</sup> OCT imaging is an invaluable tool for identifying vitreoretinal interface abnormalities and determining the presence of a surgical plane (Figs. 141.1 and 141.3).

Of 60 patients reviewed by the Macula Society report, three underwent surgery, and only one had improvement of vision (20/200 to 20/40) while the other two showed no improvement.<sup>1</sup> Other authors reported poor visual outcomes following removal of CHRRPE in two adult cases. Both patients had longstanding poor vision with amblyopia likely impacting their final visual outcome.<sup>50</sup> Additional reports indicate improved surgical outcomes for CHRRPE lesions.<sup>51-57</sup> The cases described in these reports show dense ERM-like lesions with a tight adherence of the posterior hyaloid that were removed with vitrectomy and membrane peeling. Visual improvement and improvement of macular architecture were observed. In addition, a combination of pars plana vitrectomy, membrane peeling, intravitreal triamcinolone, and laser has been reported to reduce vascular activity and reduce traction associated with the abnormal vitreoretinal interface.<sup>58</sup>

A relatively large series of 11 pediatric patients (1–14 years old) with vitreoretinal interface abnormalities associated with CHRRPE has been reported.<sup>49</sup> Following surgical intervention, all of the patients demonstrated improved or stabilized vision. Surgical success was attributed to early surgical intervention by vitrectomy and membrane stripping to improve retinal architecture and lessen the affects of amblyopia. In this study, preoperative autologous plasmin enzyme was injected to assist in removing extensive vitreomacular traction and vitreoretinal proliferation.<sup>49,59</sup> A patient with bilateral CHRRPE lesions who underwent plasmin-assisted vitrectomy showed significant architectural and functional improvement<sup>60</sup> (Fig. 141.3). Another series of six patients (mean age 31 years) were evaluated by SD-OCT, fundus autofluorescence and microperimetry (MP-1) to guide surgical intervention for CHRRPE.<sup>34</sup> Using MP-1 they showed the lowest sensitivity areas corresponded to the tightest ERM adherence. The patients with the lowest sensitivity preoperatively had a worse visual outcome postoperatively, indicating prompt surgical intervention before loss of retinal sensitivity and function.

Although tractional distortion of the macula can be relieved by vitrectomy and epiretinal membrane surgery in eyes with CHRRPE, and visual acuity may improve, a common criticism is that the hamartoma persists/recurs. This is nearly universally true to varying degrees, as the hamartomatous tissue cannot be completely removed. Though excision is admittedly often incomplete, postsurgical anatomy following excision of superficial CHRRPE lesions is typically superior to the preoperative anatomy and generally remains so with consequent improvement in visual acuity as re proliferation is typically muted. Aggressive amblyopia therapy is an important component of the postsurgical care of such patients.

In summary, combined hamartomas of the retinal pigment epithelium are rare, benign tumors which may cause significant visual loss if located in the macula. Surgical intervention can result in an improvement of visual acuity and retinal architecture, in carefully selected patients.

## Introduction

Choroidal nevi are common tumors composed of collections of benign-appearing uveal melanocytes called nevus cells.<sup>1,2</sup> When encountered clinically, they are widely regarded as trivial lesions; however, they have the potential to cause substantial visual loss and can resemble or transform into malignant melanomas. Unlike nevi in the skin, their inaccessibility and proximity to delicate structures makes biopsy a daring feat. This has forced ophthalmologists to find clinical features, which may help to

forecast the future behaviors of these unpredictable tumors.

## Definitions

Lorenz Zimmerman classified the term “nevus” in its historical context as being synonymous with a congenital tumor-like tissue malformation, or hamartoma. Barring a few cases (e.g., nevus sebaceous or nevus flammeus), this word is now used to designate benign acquired or congenital tumors of neural crest-derived cells, including atypical melanocytes. Because of the considerable variation in the morphologic appearance of cutaneous nevus cells, it is difficult to characterize a “typical” nevus cell. Zimmerman described the melanocyte as being a mature melanin-producing and melanin-containing cell. Melanocytes derive from melanoblasts, which are embryonic cells capable of producing melanin.<sup>3</sup> Torczynski depicted these cells as migrating during closure of the neural tube, with melanization beginning between the 24th and 27th week of gestation, and proceeding anteriorly until birth.

## Prevalence

The exact prevalence of choroidal nevi has been variably estimated in clinical and histopathologic studies (Table 142.1).<sup>4-18</sup> In a longitudinal multicenter clinical study, Greenstein et al. found an overall prevalence of choroidal nevi in a mixed population of 2.1% via fundus photographs, but there was a significant difference in prevalence between the white (4.1%) and the nonwhite populations (Hispanics 1.2%, blacks 0.7%, Chinese 0.4%).<sup>18</sup> The increased prevalence of choroidal nevi in populations with fair complexions who have historically lived further away from the equator argues against sun exposure as a factor. In another large study looking at iris tumors, Carol Shields et al. postulated sun exposure could be a risk factor for melanocytic tumors because of their prevalence in the inferior iris quadrant, however, in that same series the inferior quadrant was also the most popular location for cystic, choristomatous, vascular, fibrous, myogenic, epithelial, xanthomatous, metastatic, lymphoid, leukemic, and secondary tumors, as well as non-neoplastic lesions simulating an iris tumor.<sup>19</sup>

**TABLE 142.1****Prevalence of Choroidal Nevi**

Reference	Prevalence (%)	Type of Study	Age (years)	Size of Study Population	Characteristics of Population

Sumich et al. (1998) <sup>16</sup>	6.5	Clinical (population based)	49–97	3654	White; “normal”
Yoshikawa (2004) <sup>17</sup>	0.34	Clinical	28–86	3676	Japanese; “normal”
Greenstein et al. (2011) <sup>18</sup>	2.1	Clinical (population based)	45–84	6814	4.1% whites, 1.2% Hispanics, 0.7% blacks, 0.4% Chinese

Generally, higher rates for choroidal nevi are found in histopathologic than clinical studies. Naumann et al. attributed the clinical underevaluation to the obscuring of lesions by retinal pigment epithelium (RPE) and choriocapillaris, lack of adequate contrast between the nevus and the surrounding normal choroid, and the hypopigmentation of many nevi.<sup>7</sup> In their series, only 10 out of 29 nevi were clinically detected in eyes with clear media. Other factors contributing to the discrepancy are probably related to the examining technique, variations in the criteria for identifying

a nevus, and characteristics of the populations under study (Table 142.1). Except for melanocytosis and, presumably, melanocytomas, choroidal nevi are not seen at birth and, like acquired cutaneous nevi, develop or become pigmented in the first three decades of life.<sup>9</sup> No significant epidemiologic data establish a relation to sex. The influence of chemicals and endogenous or therapeutic hormones on the formation of nevi has yet to be established.<sup>11,20</sup>

## Clinical Presentation

Choroidal nevi usually appear on ophthalmoscopy as flat or slightly elevated slate-gray tumors with defined, but not sharply demarcated, margins (Fig. 142.1A). They are generally located at the posterior pole, and vary in size between one-third to seven disc diameters. They are typically oval and not more than 2 mm thick.<sup>16,21</sup> Exceptional cases of giant choroidal nevi, diffuse uveal nevi, or melanocytomas have been reported.<sup>22,23</sup> The pigmentation of nevi may vary considerably, ranging from heavily pigmented melanocytomas to amelanotic nevi (Fig. 142.1B). Amelanotic nevi comprised 10% of the nevi in 3422 eyes of patients evaluated by Shields et al.<sup>24</sup> and 5.1% in the series of 373 patients of Brown et al.<sup>25</sup> In halo nevi, the lesion is surrounded by a depigmented yellow ring (Fig. 142.2A). Other associated findings include the presence of drusen (Fig. 142.1A), RPE disturbances, orange pigment (Fig. 142.2B), subretinal fluid, and choroidal neovascularization (Figs. 142.1E–F), which will be discussed further in the following sections.

**FIG. 142.1** (A) Choroidal nevus with overlying drusen. (B) Amelanotic nevus. (C) Fluorescein angiogram of a choroidal nevus. (D) Indocyanine green angiography of a choroidal nevus showing hypofluorescence. (E) Choroidal nevus with associated choroidal neovascularization. (F) Fluorescein angiogram of same lesion pictured in (E). (Panels C and D courtesy of Evangelos

Gragoudas.)

**FIG. 142.2** (A) Fundus photograph of a halo nevus in a patient with cutaneous melanoma and vitiligo-like leukoderma. (B) Suspicious choroidal nevus with overlying orange pigment. Lesion followed 5 years without growth. (Panel A reproduced with permission from Fournier GA, Albert DM, Wagoner MD. Choroidal halo nevus occurring in a patient with vitiligo. *Surv Ophthalmol* 1984;28:671–2.)

Though most nevi are incidental findings made during routine ophthalmic examination, some can induce a visual field defect, and others lead to decreased visual acuity. In patients with choroidal nevi, the percentage of patients with defects in the visual field attributed to the nevi has varied considerably. Visual field defects were found in 16 (38%) of the 42 patients of Tamler and Maumenee;<sup>26,27</sup> in 19 (86%) of 22 patients of Flindall and Drance;<sup>28</sup> in 20 (24%) of 84 patients of Naumann et al.;<sup>29</sup> in 11% of 206 patients of Gonder et al.,<sup>30</sup> and in 148 (4.3%) of 3422 eyes in a review by Shields et al.<sup>24</sup> In that same Shields study, decreased visual acuity related to choroidal nevi was found in 215 (6.5%) of 3422 eyes, and was related to tumor location (26% subfoveal vs. 2% extrafoveal). Mechanisms of visual loss are related to functional or anatomic disturbances in the overlying RPE and retina.<sup>21,30,31</sup>

## Natural History

Thirty-one percent of these lesions will enlarge over time without malignant transformation, and with an inverse relationship between growth and age.<sup>32</sup> Nevus thickness and presence of drusen tend to increase with age, but the presence of subretinal fluid, orange pigment, or RPE changes are similar throughout all age

groups.<sup>24</sup> In reviews by Masheyehki et al. and Shields et al.<sup>32,33</sup> slow growth of choroidal nevi over many years or decades, without the presence of other risk factors, may not be indicative of malignant transformation. Malignant transformation of choroidal nevi into melanomas is rare, Singh et al. estimated that one in 8845 will undergo malignant transformation every year.<sup>34</sup> Ultraviolet light has not been shown to be statistically significant for causing malignant change,<sup>35</sup> but fair skin, ability to tan, and light eye color are statistically significant risk factors.<sup>36</sup> Attempts have been made to define features suspicious for malignant change in order to establish reasonable criteria for clinical follow-up.<sup>37</sup>

Shields et al.<sup>34</sup> have identified risk factors predictive of growth of small choroidal melanocytic tumors.<sup>38</sup> If three or more factors are present, they estimate a greater than 50% risk of growth.<sup>39</sup> Additional factors predictive of growth were later found by Shields et al. and include ultrasonographic hollowness and the absence of drusen or surrounding halo. The mnemonic TFSOM UHHD for the phrase: “To Find Small Ocular Melanomas Using Helpful Hints Daily” correlates to *Thickness* >2 mm; *subretinal Fluid*; *visual Symptoms*; *Orange pigment* (Fig. 142.2B); *tumor Margin* within 3 mm of the optic disc; *Ultrasonographic Hollowness*; *absence of a surrounding Halo*, and *absence of Drusen*.<sup>33</sup> Factors predictive of metastases include posterior tumor margin touching the optic disc, documented growth, and greater tumor thickness.<sup>39</sup>

Interestingly, Shields et al. have found different factors predictive of *iris* nevus growth following the mnemonic ABCDEF, which represents *Age* (young), *Blood* (hyphema), *Clock hour* (inferior), *Diffuse configuration*, *Ectropion uveae*, and *Feathery tumor margin*.<sup>40</sup>

## Nevus Types

### Halo Nevus

Halo nevus is a rarely encountered subgroup of choroidal nevus, which is named after the depigmented annulus that surrounds the central pigmented core. It is believed that the halo is composed of large, polygonal cells with foamy cytoplasm, termed balloon nevus cells, which are similar to those found in halo nevi in other

anatomic locations.<sup>41</sup> In a review of 3422 eyes with choroidal nevi by Shields et al., 4.7% were halo nevi.<sup>24</sup> As with most other choroidal nevi, they were found almost exclusively in whites. A predilection for women (71%) was also found.

The development of the depigmented halo has been postulated to be secondary to an immune response, such as that incited by prior antigenic exposure to cutaneous melanoma, as there is a higher association of a prior diagnosis of cutaneous melanoma in patients with choroidal halo nevi. The reverse phenomenon, cutaneous halo nevi, have been documented following plaque radiotherapy for uveal melanoma.<sup>42</sup> Though vitiligo of the skin has been linked with autoimmune disease,<sup>43</sup> no such systemic association has been made for halo nevi.<sup>41,44,45</sup>

## **Giant Choroidal Nevus**

There are no definitive criteria to designate which nevus falls under the category of “giant” choroidal nevus; however, Shields et al.<sup>22</sup> included those with a basal diameter greater than or equal to 10 mm. Based on their size, these outliers may be particularly difficult to distinguish from malignant melanoma. Thankfully this is a very rare situation, with the Blue Mountain Eye Study finding only 1.5% of choroidal nevi to be larger than 4 mm.<sup>16</sup>

## **Melanocytoma (Magnocellular Nevus)**

Among nevi, melanocytomas are those that are composed mostly of uniform, densely pigmented, and plump polyhedral cells.<sup>2,46</sup> These darkly pigmented lesions are most often observed near the optic disc and have almost no malignant potential, but may simulate melanoma.<sup>47</sup> When located at the optic disc they most often cause enlargement of the physiologic blind spot, but may cause glaucomatous visual field changes and relative afferent pupillary defects.<sup>48</sup> They are relatively rare, representing only five of 907 pigmented intraocular tumors examined histopathologically by Howard and Forrest, and often demonstrate tumor necrosis and pigment dispersion with the associated sequelae.<sup>49</sup> Melanocytomas differ from choroidal nevi or melanomas in that they occur relatively more frequently in blacks, and they tend to grow more

rapidly than typical nevi.<sup>49-52</sup> They are probably congenital, but are not usually seen before the third decade of life. Though widely considered to be benign lesions, they should be monitored closely because transformation to melanoma has been documented in several case reports, one including a black teenager.<sup>53-56</sup> (Additional material concerning the malignant transformation of melanocytomas is included in [Chapter 139, Melanocytoma of the optic disc.](#))

## Ocular Melanocytosis

Melanocytosis designates a congenital hyperpigmentation of the uveal tract caused by an increased number of uveal melanocytes.<sup>2,57</sup> A slate-grey, brown, or blue patch of sclera due to this excess pigmentation is common. When accompanied by dermal melanocytosis in a distribution similar to that of the first or second division of the trigeminal nerve, this condition is termed oculodermal melanocytosis or nevus of Ota (nevus fuscoceruleus ophthalmomaxillaris) ([Fig. 142.3A](#)). The prevalence of ocular melanocytosis noted in clinical series was calculated to be 0.038% (two cases per 5251 persons) in whites, 0.014% in blacks (one case per 6915 persons), and 0.4% to 0.84% in Japanese.<sup>58-61</sup> The characteristic findings may be mistaken for complexion associated melanosis in darkly pigmented individuals. Ocular melanocytosis, unlike complexion-associated uveal pigmentation, is associated with an increased risk of melanomas.<sup>2</sup> Besides a 10% risk of open angle glaucoma,<sup>62</sup> patients with this condition have an increased (1/400) lifetime risk of transformation to malignant uveal melanoma.<sup>63,64</sup> When malignant transformation occurs, they carry twice the risk of metastasis when compared to patients matched for gender, tumor size, and location.<sup>65,66</sup> Orbital, meningeal, and cerebral melanomas have also been reported in patients with oculodermal melanocytosis.<sup>67-72</sup>

**FIG. 142.3** (A) Nevus of Ota. (B) Cutaneous dysplastic nevi. (Panel A reproduced with permission from Gonder JR, Shields JA, Albert DM, et al. Uveal malignant melanoma associated with ocular and oculodermal melanocytosis. *Ophthalmology* 1982; 89:953–60. Panel B reproduced with permission from Albert DM, Chang MA, Lamping K, et al. The dysplastic nevus syndrome. A pedigree with primary malignant melanomas of the choroid and skin. *Ophthalmology* 1985;92:1728–34.)

## Histopathology

### Cytology

Adult melanocytes are normally found in the suprachoroidal lamellae, around blood vessels and in the outer layer of the choroidal stroma.<sup>4</sup> These stellate cells with long processes contain oval membrane-bound melanin granules.<sup>49</sup> Immunohistochemical staining against S-100 antigen is the most sensitive way to label cells

of neural crest origin, which include melanocytes. Nevus cells are larger and show other morphologic differences from normal melanocytes.<sup>4</sup> The Callender classification is the most widely used and studied for describing nevus cell types, but Naumann et al.<sup>50</sup> have classified them differently, including melanocytoma and balloon cell types.

## **Callender Classification (Original)**

The Callender classification divides nevus cells into three types:

Spindle A – Thin cells with indistinct cell membranes. Slender nuclei often contain a linear fold, and the nucleoli are indistinct. Mitoses are extremely rare.

Spindle B – Plumper spindle cells than spindle A with indistinct cell membranes. Nuclei slightly larger than spindle A with coarser chromatin clumping and visible nucleoli. Occasional mitoses.

Epithelioid – Larger polygonal, pleomorphic cells with distinct cell borders. Large round pleomorphic nuclei with prominent chromatin and nucleoli and abundant mitotic figures.

There have been modifications to this classification. Tumors are classified as spindle A, spindle B, mixed (if they contain less than 50% epithelioid cells), or epithelioid. Purely spindle A tumors are now called nevi, but if any of the other cell types include mild atypia the diagnosis would change to melanoma. This classification scheme is not without controversy, with Jensen,<sup>73</sup> Gass,<sup>74</sup> and McLean et al.<sup>31</sup> voicing concerns. One of the criticisms was that, although none of the initial spindle A melanomas proved fatal, Callender did not classify them as benign or describe a spindle cell nevus type. Gass was reluctant to accept the survival curve reported by Paul et al.<sup>75</sup> from the mortality data of the spindle A portion of 2652 patients (i.e., 81.2% were survivors at 15 years). He argued that (1) only a small sample of the tumor is generally studied, leaving many areas that could contain epithelioid cells unexamined; (2) many differences exist in the interpretation of the cell types by pathologists; (3) no more than 50% of the deaths are tumor-related because most patients are elderly, and are prone to

multiple neoplasms. McLean et al.<sup>76</sup> reevaluated the sections of 105 tumors, previously called spindle A melanomas, which had been followed up for at least 5 years after their original diagnosis. They found that 15 tumors contained epithelioid cells and should be classified as mixed tumors. The other 90 tumors were divided into the following two groups:

1. The first group, consisting of 15 tumors, had the following benign cytologic features: small size, slender nucleus, fine structure of nuclear chromatin, inconspicuous nucleoli, and no mitotic activity. These tumors measured no more than 10 mm in diameter and 3 mm in elevation. They were consequently reclassified as spindle cell nevi. No tumor-related death occurred in this group of patients.
2. The second group of tumors had atypical spindle cells, increased nuclear-to-cytoplasmic ratio, clumped chromatin, and distinct nucleoli. These were called spindle cell melanomas. In this group, 11 tumor-related deaths occurred, and metastases composed of spindle A cells were documented.

McLean et al. concluded that not all spindle A melanomas are benign, as was also suggested by Gass.<sup>14</sup> The other problem with the classification is, though simple, it does not give the full spectrum of nevus cell types.

## Alternative Classification

### Plump Polyhedral Nevus Cells

Plump polyhedral nevus cells are the most common nevus cells in melanocytoma, and usually represent about two-thirds of the mass. Electron microscopic studies have demonstrated ultrastructural differences in the cells composing melanocytomas. Juarez and Tso disclosed the following two cell types:<sup>77</sup>

1. Type 1 cells are large, polyhedral, and heavily pigmented. Bleaching with potassium permanganate is necessary to visualize the small, round, and uniform nuclei that lack prominent nucleoli (Fig. 142.4A).<sup>29</sup> This, combined with their paucity of cytoplasmic organelles and prominent giant melanosomes, suggests an inactive

state.

**FIG. 142.4** (A) Melanocytoma, plump polyhedral cells. Light microscopy (hematoxylin and eosin,  $\times 480$ ). (B) Nevus. Spindle-shaped cells (*short black arrow*), plump dendritic cells (*open arrow*), and balloon cell (*white arrow*). (C) Same lesion as in (B). Plump dendritic cells (*open arrow*), plump fusiform cell (*thin black arrow*), and balloon cell (*white arrow*). (D) Nevus-like structure at the base of a melanoma that arose de novo ( $\times 480$ ).

2. Type 2 cells are small, spindle-shaped, and sparsely pigmented. They possess marked infoldings of the nuclear membrane, conspicuous nucleoli, abundant mitochondria, prominent endoplasmic reticulum, free ribosomes, and small melanosomes, suggesting high metabolic activity. These cells are believed to be

responsible for the clinical growth observed in melanocytomas over time.

### **Slender Spindle Nevus Cells**

Slender spindle nevus cells are the second most common cell type. These small, lightly pigmented or unpigmented cells have slender, intensely basophilic nuclei and are often distributed in the outer portions of the tumors (Fig. 142.4B).<sup>1,29</sup> When they make up the bulk of a nevus, the nevus is often amelanotic.<sup>25,29,52</sup>

### **Intermediate Nevus Cells**

Between plump polyhedral and slender spindle-shaped nevus cells, there exists a spectrum of cells with larger nuclei showing a less marked chromatin pattern and occasionally small nucleoli. The cytoplasmic volume and pigmentation are at intermediate amounts between those of the principal nevus cell types. According to the shape of their cytoplasmic border, they are called either plump fusiform or plump dendritic nevus cells (Figs. 142.4B–C).<sup>1,29</sup>

### **Balloon Cells**

Balloon cells are large, nonpigmented cells with abundant foamy cytoplasm (Figs. 142.4B–C). They are found in the peripheral halo surrounding skin nevi, cutaneous and choroidal melanomas, and, presumably, halo nevi in the choroid.<sup>1,41,78</sup> The significance of the cytoplasmic lipid content is not certain, but some authors have interpreted balloon cell transformation to be an apoptotic change secondary to an autoimmune response to the antigens of abnormal melanocytic cells.<sup>79,80</sup> The finding of a halo nevus associated with cutaneous melanoma and vitiligo-like leukoderma is consistent with these hypotheses.<sup>79,81</sup>

In addition to cell type, Rummelt and coworkers showed that the vascular pattern of choroidal tumors seen on light microscopy might help to differentiate malignant and benign features.<sup>82</sup> They found that the presence of “normal” vessels, a “silent” pattern (i.e., zones of avascularity), straight and parallel vessels, and the lack of closed vascular loops and networks were correlated with the diagnosis of a nevus.

## Secondary Histologic Changes in the Neighboring Tissues

### Choriocapillaris

Thick nevi induce slight narrowing and, in some cases, complete obliteration of the choriocapillaris.<sup>21,83</sup>

### Drusen

Drusen formation is frequently seen in the overlying Bruch's membrane; it was seen in 27 of the 101 nevi reported by Naumann et al.<sup>21</sup> Drusen most often are an indication of chronicity and an inactive tumor.<sup>9</sup>

### Retina and Retinal Pigment Epithelium

The RPE overlying nevi may atrophy, become hyperplastic, or undergo fibrous metaplasia. In choroidal nevi and melanomas, clumps of lipofuscin have been shown in the RPE and in macrophages overlying the tumor. This is more likely to occur in melanomas, the orange pigment being most commonly associated with risk for tumor growth.<sup>21,23,84,85</sup> Serous detachment of the RPE<sup>10,86</sup> and the neurosensory retina can be observed, which is usually due to RPE dysfunction caused by the tumor mass effect, but in rare cases can be caused by choroidal neovascularization.<sup>1,21,23,87-89</sup> Typically subretinal and intraretinal fluid are seen as worrisome signs of tumor growth, however, when chronic subretinal fluid is resorbed it can cause thinning of the overlying retinal pigment epithelium called a "retinal pigment epithelial trough." This is considered to be a sign of chronicity and stability.<sup>90</sup>

## Controversial Aspects

Two controversial issues that bear on the clinical management and differential diagnosis of nevi are still debated.

### Do All Choroidal Melanomas Arise From Nevi?

In 1966, Yanoff and Zimmerman,<sup>64</sup> reviewing the previous literature and 100 consecutive malignant melanomas of the choroid or ciliary

body, found a significant component of small, benign-appearing, and spindle-shaped nevus cells at the periphery and along the scleral edge in 73 cases. They inferred that “most malignant melanomas, perhaps all such neoplasms, have their origin in preexisting nevi.”<sup>91</sup> This theory is the foundation upon which our practice of serial follow-up of quiescent nevi is based.

Many have come to question this theory after Albert et al. found nevus-like configuration at the base of metastatic foci of skin melanoma in the choroid where no nevi had been previously examined.<sup>92</sup> Albert et al.<sup>93</sup> subsequently experimentally injected melanoma cells into the choroid of mice and found tumors comprised of predominately round epithelioid cells with a zone of flattened, benign, nevus-appearing cells appearing at the margins. De novo choroidal melanoma has been reported, in which a large choroidal melanoma arose over a 16-month period.<sup>94</sup> Previous fundus photographs and angiograms documented the absence of any pigmented tumor in this fundus, and a pigmented nevus-like structure again was found at the base of the tumor (Fig. 142.4D).<sup>94</sup> The possibility that preexistent nevi had escaped clinical examination, as claimed in a similar case by Yanoff and Zimmerman, was unlikely.<sup>95</sup>

A nevus-like configuration associated with a melanoma may have several interpretations:

1. In many instances, including skin melanomas, melanomas may arise from nevi.
2. In other instances, choroidal or skin melanomas arise de novo. At their base and periphery, these can induce a nevus-like structure by flattening normal uveal melanocytes or by the modification of the tumor cells while they infiltrate the sclera (Fig. 142.4D).
3. Nevus-like structures may result as a secondary proliferative effect of the malignancy or because of a common oncogenic stimulus.<sup>96</sup> These mechanisms have been postulated in a few cases of bilateral diffuse melanocytic tumors of the uvea composed of relatively benign-looking, spindle-shaped cells in patients with systemic carcinoma.<sup>97,98</sup>

## Secondary Clinical Changes in the Neighboring Tissues

### Retinal Pigment Epithelial and Bruch's Membrane

Secondary changes in the overlying tissues can result in the appearance of irregular pigmentation of the nevus. Green light photographs have proved helpful in demonstrating some of these changes.<sup>99</sup> Fluorescein angiography or indocyanine green angiography of nevi may demonstrate hypofluorescence induced either by the pigmentation of the nevus or by a local circulatory disturbance in the choroid. A mottled appearance of the nevus or hyperfluorescence from drusen and retinal pigment epithelial defects is sometimes seen (Figs. 142.1C–D).<sup>83,86</sup>

Drusen overlying pigmented nevi are common and were seen in 50–60% of the patients in the series of Naumann et al.,<sup>21</sup> Shields et al.,<sup>24</sup> and Mashayekhi et al. (Fig. 142.1A).<sup>90</sup> Discrete areas of pigment epithelial atrophy or bone-spicule pattern of pigment migration at the margin of a nevus may occur due to prolonged associated serous detachment. Gass suggests that this damage may be greatest during the period of maximum tumor growth early in a patient's life.<sup>9</sup>

Atrophy, hyperplasia, and fibrous metaplasia of the RPE can be seen clinically overlying and/or adjacent to choroidal nevi, and each was observed in 6–10% of cases in a review by Shields et al.<sup>24</sup> and Mashayekhi.<sup>90</sup> These findings may indicate chronicity and are therefore more likely to be associated with choroidal nevi than melanomas.

Orange pigment, corresponding to lipofuscin, can be seen overlying melanocytic lesions (Fig. 142.2B), and was observed in 6% of 3422 eyes in a review by Shields et al.<sup>24</sup> and in 4% of 240 small choroidal melanocytic lesions in a study by Singh et al.<sup>100</sup> Large geographic areas of orange pigment are more commonly found above uveal melanomas<sup>84</sup> and, according to Smith and Irvine,<sup>85</sup> Gass,<sup>23</sup> and Shields and Shields,<sup>91</sup> may indicate malignant transformation or the malignant nature of a suspicious lesion.

### Serous Detachment

In rare instances, a serous detachment of the overlying RPE or even

of the neurosensory retina can be found; 2.14% of 933 nevi in the series of Pro et al.<sup>86</sup> and 10.3% of 3422 eyes in a review by Shields et al.<sup>24</sup> were found to have subretinal fluid. Fluorescein angiograms demonstrate the classic features of these detachments with localized or diffuse leaks. These leaks may be related to the chronic, degenerative changes in the RPE.<sup>10,86</sup>

## **Choroidal Neovascular Membrane**

Rarely, subretinal neovascular membranes may be associated with choroidal nevi (Figs. 142.1E–F). The choroidal neovascularization appears similar to the choroidal neovascularization that develops in macular degenerative conditions.<sup>23,88,101</sup>

## **Choroidal Nevi and Systemic Disease**

### **Uveal Nevi and Neurofibromatosis**

Uveal nevi are considered to be quite common in association with neurofibromatosis. Melanocytes, composing the nevi, share a neural crest origin with the other tumors found in von Recklinghausen disease (neurocristopathies).<sup>102–104</sup>

### **Dysplastic Nevus Syndrome**

Reese reported an association of uveal nevi with cutaneous nevi.<sup>105</sup> The observation that cutaneous dysplastic nevi are related to increased risk of cutaneous melanoma gave a new impetus to the investigation of the association of ocular and cutaneous nevi, and it was the screening of these patients which led to the identification of families genetically predisposed to melanoma, and to the characterization of the dysplastic nevus. Clinically, a dysplastic nevus must be suspected if a melanocytic nevus harbors at least two of the following four features:<sup>1,106,107</sup> (1) ill-defined or irregular borders; (2) irregular pigmentation; (3) accentuated skin markings; and (4) large size (>5 mm). They tend to occur on sun-shielded skin (e.g., the scalp or bathing trunk area) (Fig. 142.3B).

Histopathologically, dysplastic nevi are divided into two types: (1) a mild type with aberrant differentiation (e.g., lentiginous

melanocytic hyperplasia), and (2) a severe type with melanocytic nuclear atypia, in addition to aberrant differentiation.<sup>1</sup> These dysplastic nevi are markers of both familial and nonfamilial melanoma risk.<sup>108</sup>

That the uvea might be involved in familial melanoma or dysplastic nevus patients is suggested by the following: (1) a report of a type of dysplastic nevus syndrome with primary malignant melanomas of the choroid and the uvea;<sup>109</sup> (2) an increased (although not statistically significant) frequency of iris nevi and choroidal nevi in patients with cutaneous melanoma;<sup>13</sup> and (3) a statistically significant increase in the percentage of dysplastic nevus syndrome in patients harboring iris and choroidal nevi.<sup>14</sup> Although inconclusive and controversial, attentive ophthalmologic evaluation in patients with dysplastic nevi is warranted.<sup>110</sup>

## Paraneoplastic Bilateral Diffuse Uveal Melanocytic Proliferations

Bilateral diffuse uveal melanocytic proliferation (BDUMP) is a rare paraneoplastic syndrome described in elderly patients with advanced systemic carcinomas.<sup>111-114</sup> Gass did not consider these tumors to be malignant on the basis of the relatively benign appearance of spindle cells and the rare mitotic figures, however, Zimmerman noted foci of plump spindle B and epithelioid cells in these tumors.<sup>61,115</sup> No metastases from these uveal tumors have been found at autopsy. In these cases, patchy areas of degeneration of the RPE and photoreceptors account for the rapid, irreversible visual loss, although a bilateral cataract is generally present. (Bilateral diffuse melanocytic proliferation is discussed in [Chapter 158, Miscellaneous uveal tumors.](#))

## Clinical Differential Diagnosis

The diagnosis of choroidal nevi is usually easily made with ophthalmoscopic examination. In rare instances, various other types of lesions can mimic nevi. In addition to the conditions discussed in the following paragraphs, material on the differential diagnoses of choroidal nevi can be found in the following chapters:

Chapter 140, Congenital hypertrophy of the retinal pigment epithelium; Chapter 141, Combined hamartoma of the retinal pigment epithelium and retina; Chapter 155, Choroidal metastases; Chapter 157, Circumscribed choroidal hemangioma, and in the sections examining choroidal melanomas, see Chapter 148, Eucleation for choroidal melanomas.

## Freckles

Freckles are flat foci of increased choroidal pigmentation with irregular borders. Histologically, there is no hyperplasia of uveal melanocytes, but an increase in density of the melanocytes. They do not disturb the normal choroidal architecture, and choroidal vessels can be seen passing through them.<sup>116</sup> The main relevancy of this distinction is the lack of malignant potential of these lesions.<sup>91</sup>

## Subretinal Hemorrhages

While red-colored hemorrhages are rarely mistaken for nevi, large areas of dark-colored hemorrhagic detachment of the RPE may be mistaken for a large nevus or melanoma.<sup>23</sup> Diagnostic ultrasonography is usually helpful in demonstrating high reflectivity of hemorrhage versus the medium-to-low reflectivity of a melanocytic tumor. Optical coherence tomography (OCT) can be helpful as well.

## Congenital Hypertrophy of the Retinal Pigment Epithelium

Congenital hypertrophy of the retinal pigment epithelium (CHRPE) and CHRPE-like lesions may be confused with nevi but are usually able to be distinguished on ophthalmoscopic examination. CHRPE are typically unilateral, darkly pigmented, round, well-circumscribed, flat lesions at the level of the RPE. They often have a surrounding pigmented or nonpigmented halo or a double halo consisting of pigmented and nonpigmented rings. They may enlarge over time and tend to accumulate intralesional lacunae. CHRPE-like lesions, associated with familial adenomatous polyposis (FAP), are similar in appearance, but are bilateral,

multiple, and pisciform in shape.<sup>117</sup>

## Small Melanomas

Small melanoma should always be kept in the differential since the clinical distinction between a small melanoma and a large nevus may be subtle. While small melanocytic lesions classified as choroidal nevi may show slow, limited growth, especially in a younger patient,<sup>9</sup> the rapid growth of an indeterminate lesion (large nevus versus small melanoma) is generally the determining factor in reclassifying the lesion as a melanoma and considering treatment.<sup>85,86,95,96</sup> Clinical observations that may help differentiate a small melanoma from a choroidal nevus are indications of dormancy (nevus) or growth (melanoma). A melanoma should be suspected if (1) the thickness of the tumor is >2 mm;<sup>85,86,97-99</sup> (2) there is orange pigment overlying the tumor (Fig. 142.2B);<sup>9,23,85</sup> (3) a clinical neurosensory detachment is present without evidence of choroidal neovascularization (detachment only seen on ancillary studies does not meet this criteria); or (4) visual symptoms are present.<sup>21,98</sup> Evidence of biologic dormancy favoring a diagnosis of nevus includes (1) drusen overlying the tumor;<sup>14</sup> (2) choroidal neovascularization;<sup>100</sup> and (3) smaller size.

## Ancillary Studies

Careful follow-up observation with photography is most important for accurate determination of growth or change. This is more reliable than descriptions about shape or size; however, slight misalignment of the axis of the fundus camera can filter the pigmented edges of melanocytic tumors, leading to an erroneous diagnosis of growth or malignant transformation, with subsequent unnecessary treatment.<sup>101</sup> Other diagnostic tests may be helpful in the initial evaluation and follow-up of a presumed nevus.

Ultrasound is invaluable in determining tumor thickness and documenting subsequent growth, and is the most sensitive imaging modality for ruling out extraocular extension (more sensitive than MRI).<sup>118</sup> Due to interoperator variability it is recommended that the same machine be used by the same operator for every measurement

if possible.<sup>119</sup> Initial height >2.0 mm is more likely to be a small melanoma.<sup>14,85,86,97-99</sup> Acoustic hollowness due to low internal reflectivity on ultrasound is more suggestive of melanoma than a choroidal nevus.<sup>102</sup>

Duplex ultrasound and color Doppler may help in the differential diagnosis of choroidal tumors by quantifying tumor blood flow. Wolff-Korman and colleagues detected a pulsatile blood flow at the tumor base of 62 choroidal melanomas where no Doppler signals were elicited in a series of 18 choroidal nevi.<sup>120</sup>

Redlight photography has been described as helpful in the analysis of choroidal vascularization.<sup>83</sup> The vascularization of choroidal tumors has been studied with indocyanine green (ICG) angiography. Choroidal melanomas may demonstrate abnormal vascular patterns such as dilation, tortuosity, vascular loops, and branching;<sup>121</sup> delayed maximal fluorescence;<sup>122</sup> and marginal late dye leakage.<sup>123</sup> Confocal ICG scanning enables serial sectioning through the tumor. This technique may be capable of further detecting microvascular patterns predictive of growth.<sup>124</sup> A small flat choroidal nevus may appear hypofluorescent throughout the ICG angiogram (Fig. 142.1D).<sup>125</sup>

Fluorescein angiography of choroidal nevi without overlying RPE changes, occupying the inner or full thickness of the choroid, will demonstrate hypofluorescence throughout the angiogram. Overlying drusen usually fluoresce early in the angiogram and stain in the late stages (Fig. 142.1C). Fluorescein angiography is helpful in demonstrating choroidal neovascularization (Fig. 142.1F), RPE alterations, or permeability of the RPE overlying a nevus.<sup>23,126</sup> Multiple points of leakage (hot spots) from the surface of a tumor may indicate more acute pigment epithelial damage and a higher probability of growth.<sup>9,127</sup>

Standard OCT is not helpful for detecting the internal characteristics of melanocytic tumors.<sup>128</sup> OCT readily demonstrates retinal and RPE/choriocapillaris abnormalities associated with choroidal nevi. Retinal findings include intraretinal cysts, retinal edema, retinal thinning, photoreceptor attenuation, and subretinal fluid (Fig. 142.5A). Abnormalities of the RPE/choriocapillaris include drusen, RPE fragmentation and detachments, and thickening of the RPE/choriocapillaris (Fig. 142.5A). In a review by

Shields et al.<sup>129</sup> regarding the OCT qualities in 120 patients with choroidal nevi, two-thirds of the nevi were hyporeflective, one-third were isoreflective, about 10% were hyperreflective, and about half revealed hyperreflectivity at the level of the RPE/choriocapillaris. They found that OCT was more sensitive than ophthalmoscopy in detecting almost all retinal/RPE abnormalities except for the presence of drusen. Retinal edema, photoreceptor attenuation, and drusen suggest chronicity, whereas subretinal fluid without retinal atrophy may suggest a more active lesion. EDI SD-OCT (enhanced depth imaging spectral-domain optical coherence tomography), a method that allows for the evaluation of deeper portions of the choroid, may be useful in measuring the diameter and height of lesions that are too small to be detected by ultrasonography (Fig. 142.5B).<sup>130</sup> EDI SD-OCT has also been shown to be more precise in the measurement of posterior choroidal nevi than ultrasound, with ultrasound generally overestimating the height of lesions.<sup>131</sup>

**FIG. 142.5** (A) Optical coherence tomography (OCT) image of a choroidal nevus showing drusen, attenuation of the photoreceptor layer, and thickening/hyperreflectivity of the retinal pigment epithelium/choriocapillaris overlying a choroidal nevus. (B) Spectral domain OCT enhanced depth imaging demonstrating a choroidal nevus corresponding to a fusiform choroidal lesion with medium to low reflectivity. The demarcation of the inner sclera is visible. (Panel A adapted from Yannuzzi LA. *The retinal atlas*. Philadelphia: Saunders/Elsevier; 2010, p. 671. Panel B reproduced with permission from Torres VLL, Brugnoli N, Kaiser PK et al. *Optical coherence tomography enhanced depth imaging of choroidal tumors*. *Am J Ophthalmol* 2011;151:586–93.)

Swept-source OCT (SS-OCT) improves on this technology, being significantly better than EDI SD-OCT at depicting intralésional characteristics in melanotic lesions by using a longer wavelength to penetrate melanin.<sup>132</sup>

Fundus autofluorescence (FAF) imaging is a relatively new technique that allows visualization of light emitted from certain substances that possess autofluorescent properties, particularly lipofuscin.<sup>133</sup> Drusen may be slightly hyper-, iso-, or hypofluorescent, while orange pigment is brightly autofluorescent, and much brighter than the fluorescence seen with drusen (Fig. 142.6). In amelanotic lesions, lipofuscin may appear clinically as hyperpigmented areas and go unrecognized without the use of FAF imaging. Subretinal fluid is hyperfluorescent with the peripheral rim of fluid being slightly more hyperfluorescent. Hypofluorescence was found in more chronic RPE degenerative changes, such as RPE hyperplasia, fibrous metaplasia, and RPE atrophy.<sup>134,135</sup> No characteristic autofluorescent patterns were found for choroidal nevi or melanoma in Gunduz's study, however, Albertus et al were able to distinguish between clinically benign and malignant lesions based off of digital autofluorescence measured in "Index of Retinal Autofluorescence" (IRA) units.<sup>135,136</sup>

**FIG. 142.6** (A) Fundus photograph of a pigmented choroidal nevus with overlying drusen. (B) The drusen demonstrate moderate autofluorescence. (Panels A and B reproduced with permission from Shields CL, Pirondini C, Bianciotto C, et al. Autofluorescence of choroidal nevus in 64 cases. *Retina* 2008;28:1035–43.)

As advocated by most authors, the best way to determine the malignant nature of a melanocytic tumor is a careful follow-up, showing either significant growth or a virtually unchanged appearance. Due to the normal limited, slow growth of benign nevi, a definite distinction between a nevus and a small melanoma may be problematic.

## Management of Nevi

The management of choroidal nevi is generally governed by the same concepts of conservative management that are applied to small melanomas. If growth indicates that the lesion is a melanoma, then the treatment is for a malignancy.

### Nonsuspicious Nevi

Observe nonsuspicious nevi on a yearly basis. Documentation with photographs serves as an aid in follow-up.

### Suspicious Nevi

Evaluate suspicious nevi with dilated ophthalmoscopy, fundus photographs (Fig. 142.2B), and ultrasound every 6 months for suspicious changes. Fluorescein angiography (Fig. 142.1C), ICG angiography (Fig. 142.1D), fundus autofluorescence (Figs. 142.6A–B), and OCT (Fig. 142.5A) may be of value when the clinical picture merits their use.

## Serous Detachment and Choroidal Neovascular Membrane

Due to the rarity of choroidal neovascularization (Figs. 142.1E–F) and serous retinal detachments associated with choroidal nevi, treatment options of these conditions have not been well studied. Intravitreal injection of anti-VEGF agents has widely been used for treatment of choroidal neovascular membrane (CNVM) associated with a variety of conditions and also appears to be effective for

treatment of CNVM associated with choroidal nevi.<sup>137-139</sup> Photodynamic therapy with verteporfin may also be effective for the treatment of choroidal neovascularization secondary to choroidal nevus.<sup>140,141</sup> Though transpupillary thermotherapy (TTT) is not first line for melanoma treatment due to its inability to reach intrascleral tumor,<sup>142</sup> subthreshold TTT has been shown to be effective in controlling subretinal fluid associated with pigmented choroidal lesions.<sup>143</sup> In cases of angiographically demonstrated leaks, argon laser photocoagulation can be directed at those areas, according to criteria similar to those used in the treatment of central serous choroidopathy.<sup>10,86</sup> Successful treatment of CNVM using transpupillary thermotherapy has also been reported.<sup>144</sup>

Diet and Smoking

Geography

Occupational and Chemical Exposures

Mobile Phone Use

Other Environmental Exposures

**Conclusion**

## Introduction

The underlying causes of uveal melanoma are not clearly established. Because we do not have a means to prevent this disease, epidemiologic research is key to determine associated factors and to better understand the mechanisms of disease development. This chapter will focus on posterior uveal melanoma (choroidal and ciliary body melanoma) and will not include a discussion of iris melanoma, which can be reviewed elsewhere.<sup>1</sup>

Posterior uveal melanoma is an uncommon disease with an incidence of 5–6 cases per 1 million population per year. It is usually diagnosed in the sixth decade of life, and its incidence rises steeply with age. It is the most common primary intraocular malignancy, and the leading primary intraocular disease, which can be fatal in adults. Although posterior uveal tract melanoma is the most common noncutaneous form of melanoma, the incidence rate is one-eighth that of cutaneous melanoma in the United States.<sup>2</sup>

Despite a few reports of sporadic family clusters, most patients with posterior uveal melanoma have no known family history of the disease. It is thought that some types of environmental exposure may help to initiate the development of posterior uveal melanoma, and sunlight has been proposed as an environmental risk factor because it is known to cause alterations in skin melanocytes leading to cutaneous melanoma. Heavily pigmented individuals rarely get skin or posterior uveal melanoma. Genetic susceptibility also likely plays a role in development of this cancer, and environmental exposures may have different effects and manifestations depending on the host's underlying attributes. In this chapter we discuss the known epidemiology of posterior uveal

melanoma and evaluate the available evidence for host and environmental risk factors.

## Incidence

According to the most recent report of data obtained from the Surveillance, Epidemiology, and End Results (SEER) program database in the United States (1973–2008), the mean age-adjusted incidence estimate for ocular melanoma in the United States is 5.1 cases per 1 million population.<sup>3</sup> Similar estimates for uveal melanomas of the choroid and ciliary body<sup>4,5</sup> or the choroid, ciliary body, and iris<sup>5–7</sup> have been reported for individual states or regions within the United States. Other surveys of primarily white populations have found incidence rates similar to those of the United States (Table 143.1).<sup>8–17</sup> The incidence rate in black Africans is unknown but thought to be extremely low.<sup>18–21</sup> In the United States, the rate of the disease in African Americans is less than one-eighth of the rate for whites.<sup>2</sup> Although small fluctuations in several populations have been observed,<sup>22,23</sup> the incidence and mortality rates of uveal melanoma have been shown to be fairly stable over the past several decades.<sup>24,25</sup> It is important to note that comparative incidence rates across populations must be interpreted with caution, since differences in case definition, methods of case ascertainment, and methods of age-adjustment could affect the relative incidence rates.

## Host Factors

### Age and Sex

Uveal melanoma is rare in children.<sup>26–28</sup> In most series, the median age at diagnosis is 55 years.<sup>9,12</sup> In Jensen's series,<sup>12</sup> rates of disease decreased in males after age 69 years. An evaluation of uveal melanoma cases reported to the Finnish Cancer Registry between 1953 and 1982<sup>9,10</sup> found that rates of disease in females leveled off beginning in the mid-60s, but in males of the same age, rates continued to increase. Data from Norway show rates dropping in both sexes after age 70 years.<sup>15</sup> This is in contrast to the majority of adult cancers in which incidence increases exponentially with age.

In many large surveys of uveal melanoma patients, there is a slight predominance of males.<sup>2,6,12,16,29</sup> Higher rates in males have been reported in many studies that presented gender-specific rates of ocular melanoma. Higher rates in males have also been found in studies that used all eye cancers in persons aged 15 years or older

as a surrogate for ocular melanomas.<sup>22,23,25</sup> It has been shown in white populations that over 90% of these eye cancers are ocular melanomas<sup>22</sup> with the majority involving the uveal tract.<sup>3</sup> In New England, however, the overall rate during a 6-year period was similar in males and females.<sup>8</sup> Age-specific incidence rates were 2.3 per million for persons aged 15–44 years, 15 per million for persons aged 45–64 years, and 25.3 per million for persons aged 65 years and older.

## Race and Ancestral Origin

Uveal melanoma is rare in nonwhite races. Data from the Third National Cancer Survey indicate that in the United States, whites have more than eight times the risk of developing the disease than blacks.<sup>3</sup> The New England incidence survey data for a 6-year period suggest that the rate among whites is 9.4 times that of African Americans.<sup>8</sup> A recent analysis of population-based registry data in the SEER program<sup>30</sup> found a relative risk of ocular melanoma for white males compared with African American males of 7.4; the risk for white women in comparison with African American women was 5.3. Surveys of eye disease in African populations reveal the same low risk in black Africans.<sup>18–21</sup> The risk of uveal melanoma is also low among Chinese, Japanese, and Thais.<sup>31–33</sup> In the United States the disease is rare among Americans of Asian extraction.<sup>3</sup> A series of three posterior uveal melanomas in Vietnamese Asians with clinical and cytogenetic characteristics was reported by McCannel et al.<sup>34</sup> The small number of cases reported among Native Americans and Hispanics in the United States suggests that this diagnosis is also rare in these groups. Two cases of ocular melanoma among southwestern Native Americans were found in a review of the New Mexico tumor and melanoma registries,<sup>35</sup> and one report described four Native Americans with choroidal melanoma evaluated for the Collaborative Ocular Melanoma Study (COMS).<sup>36</sup> A series of 20 choroidal melanoma patients of Hispanic origin was described by Hudson et al.<sup>37</sup>

Among whites with uveal melanoma, ancestral origin from more northern latitudes was the strongest risk factor found in a large case–control study.<sup>38</sup> Northern European ancestry was associated

with more than a sixfold increased risk, and British ancestry was associated with more than a twofold increased risk, as compared with southern European and Mediterranean heritage. The roles of ancestry and race were examined in an evaluation of the incidence of uveal melanoma using data from the Israeli Cancer Registry.<sup>17</sup> Jews immigrating to Israel from Europe or North America and Israeli-born Jews had a threefold to fourfold increased incidence compared with Jews from Asia or Africa; non-Jews had the lowest risk.

## Cancer Genetics

A number of clusters of uveal melanoma occurring among blood relatives have been reported. Familial clusters of uveal melanoma cases have been identified in several large series of patients. Among 1600 patients with uveal melanoma treated by proton beam irradiation over a 10-year period, only 11 families were found to have more than one verified case of the disease.<sup>39</sup> In a series of 4500 cases diagnosed between 1976 and 1993, 27 families having at least two blood relatives with a uveal melanoma diagnosis were identified.<sup>40</sup> Although the overall incidence among familial cases in that study was small, it was significantly higher than the expected incidence of sporadic cases. Therefore, it was presumed that the familial clustering was associated with inherited genetic or common environmental factors.

Although family history of uveal melanoma is rare, some cases may have a heritable component. A mutation in germline BRCA-associated protein 1 (BAP1) gene has been identified as associated with uveal melanoma and other cancers among family members. A germline mutation in BAP1 has been described to be responsible for what has been termed the BAP1-tumor predisposition syndrome. Mesothelioma, cutaneous melanoma, uveal melanoma and renal cell carcinoma have been associated with this condition. Although phenotypic characterization is not yet understood, it appears that patients with BAP1-tumor predisposition syndrome have a poorer prognosis with regards to cancer metastasis.<sup>41a-41d</sup> Mutations in G- $\alpha$  proteins, which are believed to be responsible for tumor development, have been identified in uveal melanoma and may be

present in at least 84% of tumors. Among the most common of these somatic G- $\alpha$  protein mutations are GNAQ<sup>41e</sup> and GNA11,<sup>42</sup> which are mutually exclusive. Cutaneous melanoma is now recognized as an inherited disease in as many as 10% of all cases.<sup>43</sup> Recent evidence suggests that family members of persons with cutaneous melanoma who have large numbers of dysplastic nevi have several hundred times the risk of developing cutaneous melanoma compared with the general population.<sup>43</sup> Reports of cutaneous melanoma and uveal melanoma occurring as double primary malignancies, some in the presence of dysplastic nevi,<sup>44-46</sup> and melanomas of both sites occurring among family members,<sup>43,46-49</sup> have led to speculation that cutaneous and uveal melanoma may have a common heritable variant. Persons with cutaneous melanoma have been found to be more likely to possess iris nevi<sup>50</sup> or have a larger number of iris nevi<sup>51</sup> compared with controls. These studies reported similar, although not statistically significant, patterns for choroidal nevi. A potential bias is that the examiners were not masked with respect to the diagnosis of skin melanoma, and nevi may have been more likely to be identified in patients with skin melanoma. There have been no reports of a higher frequency of ocular melanoma among persons with cutaneous melanoma.

The occurrence of bilateral tumors has been suggested as indicative of genetic predisposition to cancer.<sup>52</sup> However, few cases of bilateral primary uveal melanoma have been reported,<sup>46,52,53</sup> and most reported cases did not exhibit other characteristics associated with genetically inherited cancer predisposition, such as early age of onset or familial clustering of uveal melanoma.<sup>52</sup>

Cytogenetic analyses of uveal melanoma tissue have revealed that alterations in chromosomes 3 and 8 may be associated with increased metastasis-related mortality.<sup>54-56</sup> Jay and McCartney<sup>57</sup> documented an unusual family with eight presumed cases of malignant ocular melanoma spanning four generations; mutations in the p53 tumor-suppressor gene were detected in the two tumors for which preserved material was available. It is possible that a germline BAP1 mutation could explain the hereditary nature of uveal melanoma in this family.

## Ocular and Cutaneous Nevi and Melanocytosis

Nevi on the skin have been shown to increase the risk of cutaneous melanoma.<sup>58,59</sup> Similarly, the majority of uveal melanomas are thought by some to arise from preexisting choroidal nevi.<sup>60</sup> However, the available literature suggests that the risk of choroidal and ciliary body melanomas associated with nevi of the uveal tract is low. Ganley and Comstock<sup>4</sup> estimated that 3% of the population over the age of 30 years have choroidal nevi posterior to the equator of the eye. Because nevi may also occur anterior to the equator,<sup>61</sup> the prevalence of choroidal nevi may be as much as twice that reported. Each year, only 1 in 5000 persons with such nevi develop a melanoma (assuming all melanomas arise from preexisting nevi).<sup>4</sup> Because of the low risks associated with these conditions, current guidelines and recommendations for management and follow-up may not be cost-effective.

Other melanocytic conditions that have been linked to uveal melanoma include ocular (melanosis oculi) and oculodermal (nevus of Ota) melanocytosis. These are typically congenital, unilateral conditions involving hyperpigmentation of the episclera and uveal tract in ocular melanocytosis and of the periorbital skin in oculodermal melanocytosis. Both conditions are more common in females, and the highest prevalence has been reported in Asians.<sup>62</sup> Gonder et al.<sup>63</sup> found that the prevalence of both forms of melanocytosis was higher in persons with uveal melanoma compared with a clinic population. Singh et al.<sup>64</sup> estimated the lifetime prevalence of uveal melanoma in white patients with ocular or oculodermal melanocytosis to be 2.6 cases per 1000 population, as compared with an estimated prevalence of uveal melanoma of 7.5 cases per 10,000 in the general population.

Case-control studies suggest that presence of cutaneous nevi may be a risk factor for uveal melanoma.<sup>38,65,66</sup> A significant trend for an increase in the risk of uveal melanoma with more cutaneous nevi was found by Seddon et al.<sup>38</sup> Dysplastic nevus syndrome (DNS)<sup>41</sup> and atypical mole syndrome<sup>65,67</sup> also have been associated with uveal melanoma. In one study, persons with dysplastic nevi were more likely to possess conjunctival, iris, and choroidal nevi.<sup>68</sup>

Results of a case–control study comparing the presence of DNS in Hungarian patients with uveal melanoma or with cutaneous melanoma and in volunteer controls indicated that DNS was significantly more common in both groups of melanoma patients than in the control group (the odds ratio for uveal melanoma as compared with controls was 4.36).<sup>69</sup> Van Hees et al.<sup>67</sup> reported a dose–response relationship between number of atypical nevi and uveal melanoma. After adjustment for age and sex, the presence of one or two atypical nevi was associated with nearly a threefold increased risk, and the presence of three or more atypical nevi with a fivefold increased risk of melanoma in comparison with absence of atypical nevi. Similarly, Bataille et al.<sup>65</sup> found a trend of increasing odds ratios for greater numbers of atypical nevi. Although DNS and ocular nevi have been linked to risk of uveal melanoma, DNS was not found to be associated with the prevalence of iris or choroidal nevi in a case–control study from Sweden,<sup>70</sup> nor was a higher-than-expected rate of dysplastic nevi demonstrated in a group of patients with ocular melanoma evaluated by Taylor et al.<sup>71</sup> The association between DNS and uveal melanoma remains uncertain.

## Hormones and Reproductive Factors

Hormonal influences are suspected to be a factor in cutaneous melanoma based on reports of an increased risk for women in their childbearing years<sup>72,73</sup> and the seemingly adverse influence of pregnancy on prognosis.<sup>74–76</sup> Pregnancy may also pose an added risk for uveal melanoma, although reports of presentation<sup>77–81</sup> and tumor growth<sup>79</sup> during pregnancy are rare. Increases in mortality resulting from tumors of the eye<sup>73</sup> and in the incidence of ocular melanomas<sup>2</sup> during the childbearing years have been reported. On the other hand, the hormonal environment had no appreciable influence on risk of metastases in younger women with uveal melanoma in one series.<sup>82</sup> Potential mechanisms are speculative and include a hormonal effect from estrogens or melanocyte-stimulating hormone. However, one study showed an absence of estrogen receptors in melanoma and surrounding choroidal tissue.<sup>79</sup>

Epidemiologic studies comparing uveal melanoma cases to

controls without melanoma have evaluated hormonal and reproductive factors.<sup>83,84</sup> Findings suggest a weak or no association and are not consistent between the two reports. For example, one found an increased risk<sup>83</sup> and the other a decreased risk<sup>84</sup> for ever having been pregnant. Similarly, increased risk<sup>83</sup> and no change in risk<sup>84</sup> for use of postmenopausal estrogens were reported. Further studies are needed to evaluate these relationships.

## Eye and Skin Color

Some studies suggest that persons with light irides are at increased risk of developing uveal melanoma.<sup>33,66,85</sup> In one of these studies,<sup>86</sup> persons with blue or gray eyes were found to have three times the risk of disease (unadjusted for other host factors) compared with persons with brown eyes. In a larger study of over 400 cases that combined melanoma of the iris with other uveal melanomas, the risk for blue-eyed persons was 1.7 times that of persons with brown eyes. Hair and skin color were not found to be independent risk factors after adjusting for eye color.<sup>85</sup> Similarly, Holly et al.<sup>66</sup> found a twofold risk for lighter eye color. However, in a case-control study with sibling and population-based controls, Seddon et al. found that skin color was significantly associated with uveal melanoma after adjusting for ancestral origin, with a relative risk of 3.8 comparing light to darker skin color among whites with uveal melanoma, but lighter eye color was only weakly related and was not significant in multivariate analyses.<sup>38</sup>

The iris is the only part of the uveal tract positioned in front of the lens, an effective ultraviolet filter. One study found a higher prevalence of blue and gray eyes among patients with iris melanoma compared with controls with ciliary body and choroidal melanoma.<sup>87</sup> Kliman et al.<sup>88</sup> also found that light irides were more common in persons with melanocytic lesions of the iris but suggested that such lesions may simply be more noticeable in lighter irides. However, the well-documented tendency for iris melanomas to occur in the inferior sector of the eye,<sup>9,12,89-91</sup> where exposure to sunlight is presumably greatest, supports the view that the origin of these iris tumors may be environmentally related.

## History of Nonocular Malignancy

To examine whether persons with a previous diagnosis of other cancers are at increased risk for uveal melanoma, a few epidemiologic studies have compared patients with melanoma with controls regarding their past medical history of other malignancies.<sup>92-94</sup> In a comparison of a series of uveal melanoma cases with population data from the Connecticut Tumor Registry, prevalence of previous malignancy was found to be significantly higher in women with uveal melanoma but not in men.<sup>94</sup> An investigation using SEER data identified an elevated risk of ocular melanoma among women with a history of invasive ovarian cancer, suggesting a possible common hormonal etiology.<sup>95</sup> A recent report from the Liverpool Ocular Oncology Center described a prevalence of 4.3% of self-reported other nonocular primary in uveal melanoma patients over a 20 year period.<sup>96</sup> In general, the results of these studies do not support a consistent association between prior malignancies and subsequent diagnosis of uveal melanoma. A weak and nonsignificant increased relative risk of melanoma associated with history of skin cancers was noted in several studies.<sup>93-95,97</sup> This suggests that cutaneous malignancies and uveal melanoma may share some common risk factors. Further studies are needed to evaluate this potential association.

## Environmental Factors

### Sunlight Exposure

Sunlight exposure has been examined as a potential environmental risk factor for a number of ocular diseases, including age-related macular degeneration<sup>98,99</sup> and senile cataract,<sup>100</sup> as well as melanoma of the uveal tract.<sup>37,38,66,85,86,89</sup> Incident cases of choroidal melanoma in a consecutive series of patients demonstrated a strong predilection for initial presentation at the perifoveal area. Initiation rates decreased with distance from the macula; this gradient decrease correlated with decreasing illuminance of light on the retina from macula to periphery, suggesting a possible role of sun exposure in uveal melanoma.<sup>101</sup> However, a meta-analysis by Shah et al. revealed that chronic ultraviolet exposure both in birth latitude and

occupational sunlight exposure was not a significant risk factor for uveal melanoma development.<sup>102</sup> Earlier and more frequent presentation of perifoveal tumors is likely due to visual symptoms related to the location of these tumors. Intermittent ultraviolet exposure in the form of welding was found to have a possible association with uveal melanoma,<sup>66</sup> described in the meta-analysis by Shah et al.<sup>102</sup> See section below on “[Geography](#).”

## Diet and Smoking

There are currently no data in the literature regarding the influence of diet on the incidence of uveal melanoma. A study was conducted looking at dietary intake in enhancing the recurrence-free interval, but both numbers of subjects and follow-up time were small.<sup>103</sup> A population-based case–control study in Germany found that smoking and alcohol consumption were not associated with an increased risk for uveal melanoma.<sup>104</sup> In a large prospective study, the risk of metastases the first 3 years after radiation was not altered by smoking.<sup>105</sup>

## Geography

Uveal melanoma may differ from cutaneous melanoma in that there does not appear to be a strong latitudinal gradient with regard to the incidence of ocular disease.<sup>2,9,22,23</sup> In one study of patients in Veterans Administration hospitals, higher rates of uveal melanoma were reported in southern hospitals,<sup>106</sup> but this may have reflected a tendency for elderly veterans to retire to the southern United States. In a Canadian study, altitude, not latitude, was positively correlated with the incidence of uveal melanoma.<sup>11</sup> The association of exposure to solar radiation early in life with risk of ocular melanoma was evaluated using state of birth among cases identified from SEER data;<sup>107</sup> birth in a southern state or in a state with higher levels of solar radiation was not found to be related to the risk of ocular melanoma.

There are several possible explanations for the lack of a clear latitudinal gradient in uveal melanoma rates, assuming that sunlight is an etiologic factor in the disease. First, higher rates of uveal melanoma might not be seen in southern latitudes because

the greater intensity of overhead sunlight in the south may be offset by the greater reflection of ultraviolet radiation as a result of snow cover in the north.<sup>108</sup> Second, the quality of correlational studies depends on both uniform case ascertainment and risk for disease throughout the populations studied. Geographic patterns could be obscured by variations in the completeness of case finding, a problem in several of the studies described above. Regional differences in the racial or ethnic mixes of the populations with different susceptibilities to melanoma may also obscure differences in rates for this rare tumor. Northern latitudinal ancestry is a risk factor among whites,<sup>38</sup> whereas sunlight exposure is greatest at lower latitudes.

A problem with the possible link between sunlight exposure and uveal melanoma lies in establishing whether ultraviolet radiation actually reaches the uveal tract through the effective filters of the cornea and lens. In both animal models and studies of enucleated eyes,<sup>109</sup> it has been shown that virtually no ultraviolet (UV)-A or UV-B radiation is transmitted through both the lens and cornea in adults. The juvenile lens, on the other hand, may transmit small amounts of ultraviolet radiation.<sup>110</sup> Others have argued, however, that tissues directly overlying uveal tract structures, including the retina, would provide the necessary protection if significant amounts of ultraviolet radiation penetrated the lens.<sup>111</sup> The net effect then would be the total blockage of ultraviolet radiation from direct contact with the choroid and ciliary body at all ages.

In addition to a direct effect, sunlight may also act indirectly by causing a systemic alteration in immunologic function<sup>112</sup> or by production of a "solar" circulating factor.<sup>113</sup> Such compromise of the immunologic system by ultraviolet radiation would make ocular parameters less important than other bodily exposures. There may be certain genetically predisposed individuals who are more susceptible to the direct or indirect effects of sunlight exposure.

A few studies have compared sunlight exposure histories of patients with uveal melanoma with those of controls.<sup>38,66,85,86,114,115</sup> All but one<sup>86</sup> of these studies suggest a low to moderate adverse effect of certain UV exposures on the risk of uveal melanoma, but results are not consistent. These exposures include residence in the southern United States, use of sunlamps, and history of intense sun

exposure;<sup>38</sup> occupational exposure to UV light;<sup>114</sup> tendency to sunburn and welding burn or sunburn;<sup>66</sup> and gardening and lack of eye protection when outdoors.<sup>85</sup> In the study that did not find an association between sun sensitivity or exposures and uveal melanoma,<sup>86</sup> the sample size was small, and hence the power to detect weak or moderate association was low.

In observational studies such as these, potential biases may be problematic. For example, uveal melanoma patients may be more likely to recall certain exposures than persons without the disease. Also, uncontrolled confounding is likely. There may be other risk factors that are not yet known and therefore not controlled for in the analysis. UV exposure may play some role in the etiology of uveal melanoma, but its relationship with this disease remains inconclusive.

## Occupational and Chemical Exposures

A number of rare cancers are caused by chemical or radiation exposures occurring in the workplace,<sup>116</sup> and an occupational exposure has also been sought in the etiology of uveal melanoma. Jensen<sup>12</sup> found approximately the same occupational distribution among patients with uveal melanoma as was found in the general population of Denmark. Swerdlow<sup>23</sup> reported that patients with eye cancer in England and Wales were more likely to be nonmanual than manual laborers, and a higher risk was found among electrical workers in particular. Gallagher et al.<sup>86</sup> did not find an elevated risk for electrical workers or any other specific occupation in western Canada but noted an excess of cases of uveal melanoma among government workers, a managerial job classification. Four patients with uveal melanoma and none of the controls reported having worked as a welder in one of the case–control studies discussed above.

A population-based case–control study evaluated occupational exposures<sup>117</sup> using two systems of coding occupations and industries. Results suggested an increased risk of uveal melanoma for the group of agricultural, fishery, and forestry occupations and industries, as well as for those exposed to certain chemicals, but these associations were weak and not statistically significant. This

exploratory study suggested possible areas for future research that could test these and other specific hypotheses. In another case–control study,<sup>115</sup> associations between ocular melanoma and exposure to welding and asbestos were identified; specific occupations at high risk included chemical-related, maritime, and health-related occupations.

Several reports of occupational or community clusters of uveal melanoma cases have led to speculation regarding a common etiologic occupational or chemical exposure. One report described a cluster of cases that occurred among employees of a chemical plant in West Virginia.<sup>118</sup> Four cases were diagnosed between 1972 and 1978, and a fifth case had been diagnosed in 1952. In a small Pennsylvania community, three choroidal melanomas were diagnosed over a 2.5-year period.<sup>119</sup> A cluster of four cases in a manufacturing plant in Louisiana was also reported.<sup>120</sup> However, on investigation, no specific causative agent could be identified in any of these clusters.

Ocular melanomas and other ocular tumors have been produced in laboratory animals after administration of methylcholanthrene,<sup>121</sup> N-2-fluorenylacetamide and ethionine,<sup>122</sup> radium,<sup>123</sup> and nickel subsulfide.<sup>124</sup> In the cluster of cases identified in the Pennsylvania community,<sup>119</sup> although no common exposure was identified among the patients with choroidal melanoma, laboratory mice given community water developed anterior lens capsule abnormalities that were not seen in control mice. The basis for this association is not clear.

## Mobile Phone Use

Over the past decade there has been public concern regarding microwave energy in mobile or wireless phone use and the development of cancer. Using a questionnaire, a case–control study of over 400 uveal melanoma case patients were matched to controls to identify mobile phone use, and logistic regression analyses revealed that regular mobile phone use was not associated with risk of developing uveal melanoma.<sup>125</sup>

## Other Environmental Exposures

A number of other environmental exposures may contribute to the etiology of uveal melanoma. Albert et al.<sup>50</sup> have summarized the available evidence for a viral cause of the disease. Melanoma-like tumors have been induced in laboratory animals after injection of viral-transformed uveal tissue.<sup>50</sup> In addition, virus and virus-like particles have been demonstrated in human uveal melanomas.<sup>126</sup> However, the meaning of these findings is unclear, since virus particles are often constituents of normal tissues. Trauma has been cited as a possible cause of some cutaneous melanomas<sup>127,128</sup> and there are a few reports of uveal melanomas<sup>129,130</sup> occurring at the site of a previous injury.

## Conclusion

Our understanding of the epidemiology of uveal melanoma continues to evolve gradually. Host factors remain the strongest known risk factors for this disease, particularly ethnic ancestry. Degree of pigmentation and cutaneous moles may be markers of possible risk. There are also rare reports of uveal melanoma occurring in blood relatives, which suggest a possible heritable component in some cases.

Acute or intense UV exposures might increase the risk of uveal melanoma, but the role of sunlight exposure and the mechanisms involved remain uncertain. Potential hormonal influences among females are supported by plausible biologic mechanisms, but findings to date are weak and inconsistent. These factors, as well as occupational and other potential risk factors, merit further research. New studies in cancer genetics have identified G- $\alpha$  mutations to be important in the development of uveal melanoma, and these and other genetic factors may be important in understanding the biology of uveal melanoma and the development of future therapeutic approaches. Additional epidemiologic studies are warranted to further explore the risk and protective factors associated with this potentially fatal cancer, which may lead to preventive measures and better treatments.

**Conclusion**

Uveal melanoma, an uncommon malignant tumor, can lead to vision loss and death. Gaining a better understanding of factors that may influence prognosis is an important step toward successful management of the disease. Studies of patients treated for uveal melanoma have shown tumor-related mortality rates on the order of 50% within 10–15 years after enucleation. The most established and accurate prognostic risk factor for metastasis is loss of one copy of chromosome 3, or monosomy 3 of the primary tumor. In this chapter, we review the current knowledge concerning both ocular prognosis for various local treatment modalities and systemic prognosis in terms of metastases and death among patients with uveal melanoma.

## **Ocular Prognosis of Globe-Conserving Therapies**

Treatment of primary choroidal melanoma without evidence of metastasis involves either globe-conserving therapy or enucleation. In a randomized clinical trial of patients with primary choroidal melanoma treated with globe-conserving iodine-125 brachytherapy versus enucleation, the Collaborative Ocular Melanoma Study (COMS) demonstrated no significant difference in mortality 5, 10,

and 12 years following treatment between brachytherapy and enucleation.<sup>1-3</sup> Thus, increasing emphasis has been placed on globe-conserving therapy for choroidal melanoma. Reported rates of local treatment failure vary between treatment modalities and between centers using similar modalities. Radiation therapy overall results in lower rates of local treatment failure compared to nonradiation-based treatment approaches.

## Radiation

Maintaining the integrity of the eye after globe-conserving treatment for choroidal melanoma is an important outcome in evaluating the success of a specific treatment. Local treatment failure or local tumor recurrence is associated with morbidity consisting of either need for reirradiation or organ loss by enucleation. Iodine-125 plaque radiotherapy is the most common primary treatment modality for choroidal melanoma. Among the largest published series reporting local treatment failure with iodine-125, the COMS medium tumor trial reported the risk of treatment failure at 5 years, as measured by local recurrence rate in 650 patients to be 10.3%.<sup>4</sup> A report by Sagoo et al. of 650 juxtapapillary tumors indicated a local treatment failure rate of 21% at 10 years.<sup>5</sup> For iodine-125 brachytherapy the local treatment failure rate in the literature ranges from 0% to 27% among centers with varying follow-up intervals and sample sizes.<sup>6-22</sup> Series by McCannel et al.<sup>6</sup> and Tabandeh et al.<sup>8</sup> reported very low local failure rates with iodine-125, 0% and 1.7%, respectively; both centers use intraoperative ultrasonography which minimizes the risk of edge-miss. Among the treatment modalities that involve radiation, Rouberol et al. reported a 21.7% and 24.3% rate of local recurrence after 5 and 10 years, respectively, after ruthenium brachytherapy in 213 patients treated from 1983 to 1995.<sup>23</sup> Wilson also reported in a retrospective review a higher local treatment failure rate using ruthenium plaques compared to both proton beam irradiation and iodine-125 brachytherapy.<sup>24</sup> In a series of 368 patients treated with proton beam, Mosci reported a local treatment failure rate of 8.4%.<sup>25</sup> In another group of 1922 patients treated with proton beam irradiation, a local recurrence rate of 3.2% and 4.3% at

5 and 10 years, respectively, was reported.<sup>26</sup> Published data indicate that the use of ruthenium results in higher rates of local treatment failure than iodine-125. Proton beam radiotherapy has a variable rate of local failure depending on the experience of the treatment center. Direct comparisons between iodine-125 and proton therapy have been scarce; however, recently, Mishra and colleagues reported a local failure rate of 2% and 21% with helium ion charged particle and iodine-125 therapy, respectively, at 12 years follow-up at their center.<sup>27</sup> Iodine-125 is the most commonly used form of local treatment for uveal melanoma in North America and rates of local treatment failure vary between centers.

## **Silicone Oil as Vitreous Substitute for Radiation Attenuation**

Although the traditional delivery of radiation by brachytherapy remains an extraocular treatment, a new method that has been adopted at a few Ocular Oncology Centers is vitreoretinal surgery with Silicone Oil 1000 centistokes placement for radiation attenuation. Initially reported by Oliver et al.,<sup>28</sup> and subsequently corroborated by Ahuja et al.,<sup>29</sup> Silicone Oil 1000 centistokes results in a 50–60% reduction in iodine-125 radiation compared to water or aqueous. A matched case–control series comparing iodine-125 brachytherapy with and without Silicone Oil 1000 centistokes revealed an improvement in radiation maculopathy at 2 years.<sup>30a</sup> A recent case-control analysis by McCannel et al.,<sup>30b</sup> showed significant visual benefit in large uveal melanoma treated with vitrectomy and silicone oil for vitreous attenuation.

## **Nonradiation Therapy**

Nonradiation local treatment of uveal melanoma includes laser photocoagulation, Visudyne photodynamic therapy, and transpupillary thermotherapy. The main theoretical advantages of laser over radiation include minimizing collateral damage to healthy ocular tissues compared to radiation, minimizing radiation exposure to the patient and operator, and a more simplified treatment approach not requiring radiation oncology or use of an

operating theater. However, laser overall has been found to be less successful in achieving local tumor control compared with most forms of radiation-based treatment. The literature is sparse on reports utilizing argon laser photocoagulation to treat choroidal melanomas, but there are many reports of failures, and the prevailing opinion is that argon laser is not an adequate primary treatment for choroidal melanoma of any size.<sup>31-33</sup> There are few reports of photodynamic therapy for uveal melanoma in the literature; only two case reports exist using this technique for small atypical amelanotic choroidal melanoma.<sup>34,35</sup> Barbazetto et al. reported a case series of four patients treated by photodynamic therapy with recurrent tumors treated with other modalities, resulting in eventual enucleation of two eyes.<sup>36</sup>

Following the discontinuation of transpupillary thermotherapy (TTT) as a therapy for age-related macular degeneration, a noticeable interest in this form of thermal laser for use in posterior segment tumors occurred. However, the largest series using TTT reported high rates of local treatment failure. Shields et al. reported a 22% local treatment failure rate at 3 years in a series of 256 posterior uveal melanoma treated by transpupillary thermotherapy.<sup>37</sup> Aaberg et al. reported a rate of 23% at 5 years in a series of 135 patients.<sup>38</sup> Zaldivar described eight cases with histologic findings in eyes enucleated after failed TTT. Although the height of the tumor decreased, extrascleral extension and lateral spread of the tumor ensued.<sup>39</sup> Harbour found that not only was there no significant difference in visual outcome between TTT and plaque radiotherapy, but also that the recurrences were substantially higher when TTT was used compared with iodine-125 plaque.<sup>40</sup> Currently, the use of TTT has been limited to an adjunct to primary brachytherapy to compensate for edge-miss in plaque placement by some operators.<sup>41,42</sup>

## Surgery

Surgical approaches involving excision of the tumor have been described using a transscleral approach (transscleral endoresection or local resection) or an internal approach with vitrectomy and resection of the tumor with the vitrectomy probe. The former

technique may pose technical difficulties due to the requirement for systemic hypotensive anesthesia to reduce the risk of choroidal hemorrhage. In the reports described below, there are higher rates of ocular complications and a lower rate of overall globe retention comparing surgical transscleral endoresection to standard brachytherapy. Despite these significantly higher rates of local treatment failure and enucleation, there may be select cases where one might consider tumor resection over standard brachytherapy.

Peyman et al.<sup>43</sup> studied a group of 34 patients treated by eye wall resection with an average follow-up of 5.3 years and reported that 11 (32.3%) required enucleation (mainly because of evidence of tumor cells in resected margins) and 13 (38.2%) retained 20/200 or better vision after treatment. No patient had local treatment failure, and two patients had died of metastatic melanoma at the time of that report. In a matched case–control study, 81 of 49 pairs of patients undergoing either transscleral resection at one center or iodine brachytherapy at another, Kivela and colleagues found fewer recurrences with plaques than resection, but no difference in 8-year mortality.<sup>44</sup> Furthermore, only eyes undergoing radiation experienced neovascular glaucoma, radiation retinopathy, cataract, or ischemic changes. Shields et al.<sup>45</sup> described a series of 95 patients with choroidal or ciliary body tumors, or both, who were managed by partial lamellar sclerouvectomy. A total of 81 cases (85%) were uveal melanoma; vitreous hemorrhage occurred in 79 (83%); intraretinal or subretinal hemorrhage in 33 (35%); retinal detachment in 26 (28%); and cataract in 32 (34%) patients. Retinal detachment surgery was necessary in 16 patients (17%), and enucleation was necessary in 15 (16%) patients. Distant metastases developed in five patients (5%) with a median follow-up of 2.5 years. In the largest series of transscleral endoresection by Damato et al., the local treatment failure rate at 3 years was 20%.<sup>46</sup> Puusaari et al. in a series of 33 patients reported a local treatment failure rate of 40% by 5 years.<sup>47</sup> Garcia-Arumi<sup>48</sup> reported in a series of 34 cases of vitrectomy with tumor endoresection with average follow-up of 70 months a local treatment failure rate of 5.8%, which is comparable with reports of others who have used vitrectomy with endoresection.<sup>49,50</sup>

## Systemic Prognosis for Metastasis and Death

The most common site for metastasis in uveal melanoma is the liver. At least 50% of all patients diagnosed with uveal melanoma develop metastatic disease.<sup>51</sup> The COMS study reported liver metastasis with median survival once metastasis was diagnosed between 6 and 12 months.<sup>52</sup> In an analysis of metastatic uveal melanoma patients by Rietschel et al., the authors found that the most common nonhepatic first-metastatic site to be diagnosed was the lung.<sup>53</sup> Patients who were younger than age 60 had metastasis to the lung, had a longer interval between treatment of the melanoma and discovery of metastasis, and had better survival after a diagnosis of metastatic disease.

There is a lack of substantial difference in survival for local globe-preserving therapies compared with enucleation in the early posttreatment years, which may be related to the possibility that metastases occur before the tumor is treated, perhaps before it is diagnosed.<sup>54</sup> Another consideration in evaluating the apparent similarity in survival outcome of conservative therapies in comparison with enucleation is that selection of patients with small-to medium-sized tumors and other more favorable prognostic indicators for eye-sparing treatment methods may bias survival results in favor of these therapies. It is therefore important to control for these prognostic factors to the extent possible in nonrandomized studies. A data collection and management system for studies of prognosis and treatment was developed in the 1980s in order to standardize these measures in observational cross-sectional and longitudinal studies and was used to identify several factors relevant to metastasis.<sup>55-58</sup> In the initial studies evaluating prognosis after treatment with proton beam or enucleation,<sup>57,58</sup> the Cox proportional hazards model was first used in ophthalmology to study prognosis and survival after treatment of uveal melanoma. Epidemiologic methods were applied to standardize variables and control for differences in demographic factors as well as tumor-specific variables: tumor height, tumor diameter, location of the tumor posterior to the equator, anterior to the equator, and involvement of the ciliary body. Larger tumor size and anterior

location decreased rate of survival, and treatment type did not have a significant effect. Length of observation period or evidence of growth prior to treatment has not been shown to affect prognosis. Visual outcomes after proton beam irradiation were also evaluated using these methods.<sup>59,60</sup>

## Radiation Therapy

### Metastasis and Survival

Actuarial survival rates following radiation therapy of uveal melanoma have been reported to be 75%<sup>61</sup> to 80%,<sup>62</sup> and 89%<sup>63</sup> 5 years after treatment. For 96 patients treated by cobalt plaque, the 5-year survival rate (without death from metastatic melanoma) was approximately 75%.<sup>61</sup> In a study of 128 patients treated by proton beam irradiation,<sup>62</sup> with a median of 5.4 years of follow-up, the probability of metastasis-free survival at 5 years was 80%.

Lommatzsch<sup>64</sup> reported a 5-year survival of 89% in a group of 309 patients treated by ruthenium. In that study, tumors measured up to 5 mm in height and 15 mm in diameter, and the mean follow-up was 6.7 years. Similar survival estimates were observed in a series of ruthenium-treated patients in Germany,<sup>65</sup> Sweden,<sup>66</sup> and Finland.<sup>67</sup> In an update of an earlier report, Char reported on long-term outcomes in 218 patients treated with helium ion irradiation and followed for an average of 12 years.<sup>68,69</sup> The mean tumor thickness in this cohort was 6.7 mm, and the mean largest tumor dimension was 11.9 mm; 5-, 10-, and 15-year survival were estimated to be 73%, 61%, and 54%, respectively. Series of patients treated by iodine-125 irradiation<sup>70,71</sup> have also been described.

Prognostic factors for patients treated by irradiation have been evaluated in several studies. Using the tumor registry and analytic methods developed by Seddon and colleagues,<sup>55-60</sup> the first 780 patients treated by proton beam irradiation were evaluated,<sup>62</sup> of whom 64 had developed metastasis at the time of the study. Similar to the earlier studies, leading predictors of metastasis were tumor diameter larger than 15 mm, ciliary body involvement, extrascleral extension, and age at treatment of 60 years or older. Surgical localization of the tumor and elevated pretreatment liver enzymes were not statistically significant prognostic factors. They found no

survival advantage of proton beam irradiation compared with enucleation.<sup>57,72</sup> In an investigation of the role of hormonal factors in the development of metastasis,<sup>73</sup> among women of childbearing age who had been treated by proton beam irradiation for uveal melanoma neither postirradiation pregnancy history nor oral contraceptive use were associated with the rate of metastasis.

Tumor regression is closely monitored following treatment. Rashid et al. have reported that the specific regression pattern of tumors can be heterogenous and other clinical features in addition to tumor height could be evaluated in assessing treatment response.<sup>74</sup> Augsburger and coworkers studied tumor regression as a prognostic factor for metastasis following cobalt plaque irradiation. Findings of this preliminary study suggest that rapid tumor regression is a poor prognostic sign.<sup>75</sup> Tumors regressing more rapidly were significantly more likely to metastasize concurrently with their regression in a series of patients treated by proton beam irradiation.<sup>76</sup> However, recently Correa and Augsburger evaluated the relationship of rate of posterior tumor flattening and molecular risk category by gene expression profiling at 6 months post treatment and reported that there was no association between risk of metastases and faster shrinkage when the effect of initial tumor thickness was controlled.<sup>77</sup> Rather than more biologically aggressive uveal melanomas responding more rapidly to treatment, large tumors have a greater likelihood of shrinking after treatment compared to small tumors due to the original size of the tumor rather than its activity.

## **Local Treatment Failure and Metastatic Prognosis**

Local tumor recurrence or local treatment failure may increase the risk of metastases from uveal melanoma.<sup>78,79</sup> This appeared to be the case in a cohort of patients with juxtapapillary melanoma treated by brachytherapy.<sup>80</sup> In that study, rates of melanoma metastasis were 13%, 16%, and 37% at 5, 10, and 15 years, respectively; tumor recurrence (defined as any amount of regrowth), larger tumor diameter, and superior location of the tumor were found to predict occurrence of distant metastasis. This may be due in part to technical difficulties in placement of the plaque, resulting in undertreatment of the tumor (or overtreatment of the normal

retina). Harbour et al.<sup>81</sup> evaluated the prognostic significance of patterns of tumor regrowth after irradiation. The relative risk for death resulting from metastasis was significantly higher among patients with increased tumor thickness than among those whose tumor spread at the margin (5.1 vs. 2.2, respectively, relative to those without tumor recurrence). The mean rate of metastasis was also significantly higher in patients with increased tumor thickness compared with those with marginal spread. Recently, analyses of data from an online tumor data registry of over 3000 uveal melanoma patients revealed that 5- and 10-year metastasis-free Kaplan–Meier estimates for the recurrence-free group were 87% and 82% vs. 71% and 62% for the local recurrence group, and these differences were statistically different.<sup>82</sup> Reducing local treatment failure is critical in the management of primary uveal melanoma for the sake of preserving the eye, with questionable evidence of significant influence on the development of systemic metastasis.

## Prognosis After Enucleation

Metastasis from uveal melanoma may occur at any time after the onset of tumor diagnosis. Jensen,<sup>83</sup> in his 25-year follow-up of Danish patients, found that the peak incidence of metastasis occurred during the first year after enucleation, and over half of those who developed metastasis did so within 3 years of treatment. However, it is a well-known but poorly understood fact that patients may develop metastasis decades after enucleation. Due to hypotheses that enucleation itself might cause increased mortality,<sup>84</sup> the COMS study compared enucleation to pre-enucleation radiation for large tumors, and did not find a difference in mortality.<sup>51</sup>

Comprehensive and long-term studies of survival after enucleation derive from Denmark and Finland. These reports have the advantage of being population based with few losses to follow-up. Raivio compiled a roster of all patients diagnosed with uveal melanoma between 1923 and 1966 in Finland.<sup>85</sup> Of 359 identified cases, survival status at 10 years was known for all but five patients; 314 cases (89%) had 15 or more years of follow-up available, and 214 cases (60%) had at least 20 years. The 5-, 10-, and 15-year survival rates based on melanoma-related deaths were 65%, 52%,

and 46%, respectively. Of the 42 patients who survived at least 20 years, nine later developed metastasis. Jensen<sup>83</sup> evaluated survival at least 25 years after enucleation in Danish patients with uveal melanoma. The majority of patients included in the original series had died (82%); 51% of those deaths were due to metastasis. Actuarial survival rates at 5, 10, and 15 years were similar to those reported by Raivio.<sup>85</sup> A novel deficit survival analysis of 230 patients in 1984 by Lavin and colleagues indicated no overall survival advantage after enucleation.<sup>86</sup>

Metastasis from uveal melanoma usually occurs within the first few years after enucleation. The liver is usually the first site of metastasis after treatment.<sup>87-90</sup> There is some evidence to suggest that metastasis may occur several years before the diagnosis of hepatic metastasis is made.<sup>54,91,92</sup> Other organs that may be affected include the lung, bone, skin, and central nervous system.<sup>89</sup> The majority of patients with hepatic involvement succumb within a few months of detection of the metastatic lesion.<sup>90</sup>

## Visual Prognosis and Ocular Morbidity

Rates of complications and visual loss after radiation depend on the type of treatment and the size and location of the tumor within the eye. Severe complications requiring enucleation have been reported to occur in 10%<sup>93</sup> to 22%<sup>69</sup> of patients. Rubeosis iridis and neovascular glaucoma<sup>94</sup> and radiation retinopathy or optic neuropathy<sup>64,88,95,96</sup> have been reported as the major complications that may occur in irradiated eyes. Lens opacification is a common complication of helium ion<sup>97</sup> and proton beam<sup>98</sup> radiotherapy, occurring in over 40% of cases in published series. Development of cataracts is also relatively common after episcleral plaque therapy<sup>71,99,100</sup> with reported 5-year incidence ranging from about 20%<sup>71</sup> to 37%.<sup>100</sup>

Vision after proton beam irradiation has been studied,<sup>59,60</sup> and greater tumor thickness and proximity to the disc or macula (or high dose to these structures) were found to increase the risk of vision loss to worse than 20/200. Curves demonstrating cumulative

probability of visual acuity loss according to height and distance of the tumor from the optic disc and fovea are presented in [Fig. 144.1](#). When patients were evaluated according to combined tumor characteristics, the probability of retaining vision of 20/200 or better at 3 years was 91% in the low-risk group (tumors 5 mm in height and more than two disc diameters from the macula and disc), 61% in the intermediate-risk group (tumors that were tall or close to the disc or macula), and 24% in the high-risk group (tumors that were tall and close to the disc or macula).

**FIG. 144.1** Cumulative probability of visual acuity loss according to height and distance of the tumor from the optic disc and fovea. “Close” refers to less than or equal to 2 disc diameters, or approximately 3 mm from the structure. (Reproduced from Seddon JM, Gragoudas ES, Polivogianis L, et al. Enucleation vs cobalt 60 irradiation of melanomas. *Ophthalmology* 1986;93:666, with permission from the American Academy of Ophthalmology ©1986.)

Visual field deficits have also been demonstrated after proton

beam irradiation.<sup>101</sup> Visual acuity outcomes similar to those in proton beam-irradiated patients were seen after iodine-125 plaque.<sup>102</sup> In a review of 93 patients undergoing plaque therapy for juxtapapillary lesions,<sup>80</sup> 72% of patients lost at least 3 lines of visual acuity as measured on a Snellen chart by 4–5 years after treatment. The risk of losing this amount of vision was related to initial visual acuity; patients with better initial visual acuity (i.e., 20/20–20/40) were more likely to experience a loss of 3 or more lines than those with initial visual acuity of 20/50–20/100 or worse than 20/100 (67%, 64%, and 8%, respectively, at 5 years after treatment). In another study of 186 patients treated by helium ion irradiation, 49% retained 20/200 or better vision in the treated eye, with a median follow-up time of 26 months.<sup>103</sup>

In addition to measured visual acuity, visual functioning is a major concern after treatment for uveal melanoma. Augsburger et al.<sup>104</sup> evaluated vision-related changes in employment and ability to drive, read, and watch television by standardized interview in patients treated by plaque radiotherapy or enucleation. Among 51 patients in the plaque radiotherapy group followed for a mean interval of 87 months after treatment, over 90% had no loss of vision-related performance. Similar results were reported in 51 enucleated patients followed for an average of 89 months. Thus, despite potential acuity loss in the affected eye, the vast majority of patients treated with plaque radiotherapy or enucleation retained full functioning in vision-related activities.

## **Clinical Prognostic Indicators for Metastasis**

### **Tumor Size and the American Joint Committee on Cancer (AJCC) Classification Stage**

Tumor size is an important prognostic factor for eventual metastasis. Size has been variously defined in different studies as the largest tumor dimension: height and diameter;<sup>55–60</sup> largest diameter in contact with the sclera;<sup>105</sup> combination of largest

diameter and height;<sup>106</sup> area of the tumor base;<sup>107</sup> and tumor volume.<sup>108,109</sup> These differences should be considered when comparing studies of tumor size and prognosis. Kaplan–Meier survival curves that show steadily worsening prognosis with every 2 mm increase in largest tumor dimension are presented in Fig. 144.2.<sup>58</sup>

**FIG. 144.2** Cumulative probability of not dying of melanoma and largest tumor dimension. (Reproduced with permission from Seddon JM, Albert DM, Lavin PJ, et al. A prognostic factor study of disease-free interval and survival following enucleation for uveal melanoma. *Arch Ophthalmol* 1983;101:1894–1899. ©1983 American Medical Association. All rights reserved.)

Flocks et al.<sup>108</sup> were among the first to recognize the importance of tumor size. Using Armed Forces Institute of Pathology data, they estimated tumor volume as the product of the tumor's largest diameter, diameter perpendicular to the largest diameter, and height. When tumors were divided into two groups, based on whether they were larger or smaller than the median value of 1344 mm<sup>3</sup>, the 5-year mortality rates were 15% and 54% for the smaller and larger tumors, respectively. McLean et al.<sup>109</sup> reported a somewhat higher 6-year mortality for tumors less than 1400 mm<sup>3</sup> (25%), one difference being that Flocks et al. had excluded tumors with extrascleral extension.

The great majority of subsequent studies have confirmed the influence of tumor size on prognosis. Most of these studies have considered small tumors to be those no larger than 10 mm in largest

diameter and 2–3 mm in height. Warren<sup>106</sup> studied 108 patients from eastern Iowa with five or more potential years of follow-up. No deaths from metastases occurred in the group of 10 patients with tumors up to 10 mm in diameter and 2 mm in thickness. Tumors were considered medium-sized if they were no larger than 15 mm in diameter and 5 mm in height, and nine of 24 patients (37%) in this group died of metastasis. Mortality was highest in patients with large tumors; over half of patients (57%) died of the disease in this group. Shamma and Blodi<sup>105</sup> updated this series with additional cases, bringing the total to 293 and classified tumors according to largest diameter in contact with the sclera. Actuarial 6-year survival rates dropped with increasing tumor diameter from 87% for tumors 10 mm or less, to 30% for tumors larger than 12 mm. Long-term survival was found by Jensen<sup>107</sup> to be quite poor even in patients with small tumors. He reported that of the 30 patients whose tumors were less than 10 mm in diameter and 3 mm in height, 12 (40%) died of metastatic disease. The corresponding figure for tumors with largest cross-sectional area >100 mm<sup>2</sup> was 63%. Among clinical parameters available before treatment, largest tumor dimension (classified as <10 mm, 10–15 mm, or >15 mm) was found to be the most useful predictor of metastasis and mortality in a series of 111 patients.<sup>86</sup> In that study, the sensitivity, specificity, and positive and negative predictive value of largest tumor dimension were similar to those of cell type. Other reports including meta-analyses and reviews of large series of patients with uveal melanoma confirm the importance of tumor size.<sup>110,111</sup>

The American Joint Committee on Cancer (AJCC) anatomic stage classification for uveal melanoma has been reported to predict prognosis, with higher stage correlating with higher risk for distant metastasis.<sup>112,113</sup> Furthermore, Bagger and colleagues indicated that chromosome 3 status together with AJCC stage provided a more accurate prediction of survival compared to AJCC stage alone.<sup>114</sup>

## **Histopathologic Prognostic Indicators for Metastasis**

### **Histopathology and Immunogenetics**

In 1931, Callender<sup>115</sup> published the first classification system of uveal melanoma according to histopathologic type. Callender described five histologic types: spindle cell subtypes A and B, epithelioid, fascicular, and mixed cell-type tumors composed of both spindle cells and epithelioid cells. Although this original system has undergone some refinement, it still serves as the basis for histologic typing of uveal melanomas.

The Callender classification system has been found in many studies to be a useful method for distinguishing tumors with varying degrees of malignancy. Jensen<sup>107</sup> evaluated mortality according to cell type in his series of 226 Danish patients and compared his results with those of the previously published series of Zimmerman et al.<sup>116</sup> In these reports, 10-year mortality ranged from 11% to 19% in spindle A tumors; 21–36% in spindle B tumors; 63–79% in mixed-cell tumors, and 72–100% in epithelioid tumors.

Limitations of the Callender system have been recognized. First, there are no histologic criteria to distinguish spindle A cell tumors from nevi. Second, there are no criteria for classification of a tumor composed of a mixture of spindle A and spindle B cells and no differentiation among the large group of tumors classified as mixed. To quantify these histologic observations, a standard measurement was created and new parameters were assessed, including the number of epithelioid cells per high-power field and inverse standard deviation of nucleolar area,<sup>117</sup> which were found to predict metastatic death. These methods require enucleation of the globe in order to obtain histopathology. Increasingly, globe-conserving therapies are the preferred treatment approach for local tumor control when possible. Furthermore, the cytology provided by the use of fine-needle aspiration biopsy in nonenucleated tumors is considered inadequate for evaluation of cellular morphology. Thus, molecular risk factors, discussed below, are of increasing value for determining prognosis.

## Tumor Microvasculature

The presence of epithelioid cells,<sup>117</sup> extravascular matrix patterns that reflect the arrangement of tumor microcirculation,<sup>118–121</sup> high microvascular density,<sup>122–124</sup> and large numbers of tumor-infiltrating

macrophages<sup>125,126</sup> in primary uveal melanoma are independently associated with shorter time to metastatic death. These associations may be either markers of aggressive tumors without direct contribution to the metastatic cascade or they may indicate direct participation in tumor progression to metastasis. Toivonen et al. found that the presence of epithelioid cells and microvascular density were closely associated with progression of uveal melanoma from primary tumor to metastasis, in a cross-sectional histopathologic analysis of hepatic metastasis and the corresponding primary choroidal tumor. High microvascular density may help to predict survival after detection of hepatic metastases.<sup>127</sup>

Microvascular patterns within tumor tissue have been studied. Folberg et al. described nine distinct vascular patterns observed in tissue from 234 enucleated uveal melanomas.<sup>118</sup> Two observers independently reviewed slides from each tumor and assessed the presence or absence of each vascular pattern. The presence of networks of three or more contiguous closed vascular loops was highly predictive of melanoma-related and all-cause mortality. Kaplan–Meier estimates of 10-year survival were 50.7% when networks were present and 88.3% in the absence of networks. McLean,<sup>120</sup> in a series of 496 eligible uveal melanoma patients from the registry of ophthalmic pathology, confirmed Folberg's observation of the prognostic significance of vascular loops, despite the use of different measurement techniques. Foss et al. investigated vascular patterns and microvessel density in a cohort of 120 patients with available tissue blocks and survival follow-up (mean, 77 months).<sup>123</sup> Vessel count was highly predictive of melanoma-related death; vascular patterns as described by Folberg<sup>118</sup> were less clearly correlated with melanoma mortality in this study. Principal component analysis of vascular patterns from this cohort of patients<sup>128</sup> identified three combinations of patterns, two of which – disordered growth and emergence of rapidly growing subclones – were predictive of melanoma mortality. However, as with histopathology, tumor microvasculature cannot be evaluated in this manner unless the tumor is enucleated.

## Extrascleral Extension

Another factor shown in many studies to increase the risk of tumor-related death after enucleation is extrascleral extension of the tumor. Histopathologic evidence of orbital extension is usually found in 8–14% of cases.<sup>129–131</sup> Shammam and Blodi<sup>131</sup> reported that only eight of 30 patients with extrascleral extension and 5 potential years of follow-up survived to 5 years. The majority died within 16 months after enucleation. The 5-year survival rate was 26% in patients with orbital extension and 78% in those without extension. In Jensen's 25-year follow-up of patients,<sup>107</sup> the long-term survival estimate for patients with orbital extension was 29%. The relationship between the probability of not dying of melanoma and the presence of extrascleral extension was evaluated in another group of patients using new statistical methods in 1983, including Kaplan–Meier survival curves and Cox proportional hazards models.<sup>58</sup> Much poorer survival was seen in the group with extrascleral extension. There are no data to suggest that exenteration improves mortality in patients with extrascleral extension.<sup>129,131,132</sup>

## Molecular Prognostic Indicators for Metastasis

Tumor cytogenetic studies have revealed that abnormalities in chromosomes 3, 6, and 8 in the tumor tissue itself have been linked to metastatic death.<sup>132–139</sup> A loss of chromosome 3 is associated with a poor prognosis; gains in chromosome 8 are associated with a worse prognosis, and abnormalities in chromosome 6 are associated with a good prognosis. Rather than simply markers of tumor progression, gross chromosomal changes may be associated with specific mutations that become manifest with chromosomal aberration.

White et al.<sup>140</sup> performed cytogenetic analyses on 54 tumor patients and correlated the results with the patient clinical outcome. It was found that abnormalities in both chromosomes 3 and 8 were important in predicting metastasis; abnormalities in chromosome 6, despite abnormalities in 3 and 8, portended a good prognosis. Prescher et al.<sup>141</sup> examined 180 uveal melanoma patients in whom

primary enucleation was the selected treatment. Tumor histology, cytogenetics, and clinical data were obtained from the tumor specimens. The tumors of 30 patients had monosomy 3. This resulted in 57% of these patients succumbing to metastasis and the 3-year relapse-free survival rate was 50%. Of the 24 patients with a normal chromosome 3, none developed metastasis. Monosomy 3, tumor location, and tumor diameter were the most significant predictors of poor prognosis. Furthermore, histologic subtype, age, sex, extrascleral growth and tumor thickness had no predictive value. Scholes et al.<sup>142</sup> also found that monosomy 3 and the development of metastasis did not correlate with tumor size or histologic subtype, emphasizing the likely inadequacy of size and histology alone as good predictors for metastasis. Thus, cytogenetically speaking, uveal melanoma appears to fall into two largely mutually exclusive cytogenetic groups: those patients who will go on to develop fatal metastasis (monosomy 3 of the tumor) and those patients who will not (absence of monosomy 3). Work by Onken et al.<sup>143</sup> has demonstrated the results of gene expression profiling in 25 primary choroidal melanoma specimens. The tumors clustered into two groups that correlated strongly with metastatic risk. A "Class 1" tumor designation indicated a low-risk for metastasis; a "Class 2" designation indicated a high risk for metastasis.

Prognosticating the risk of developing metastatic uveal melanoma has traditionally been based on clinical and histopathologic characteristics of the primary tumor, as discussed previously. However, as the majority of uveal melanomas are now being treated with globe-sparing surgery, analysis of molecular and cytogenetic information from uveal melanoma fine-needle aspiration biopsy has evolved and is becoming increasingly common.<sup>144-147</sup> Both DNA and RNA can be analyzed from the tumor. Cytogenetic testing can be performed for chromosomes of interest using fluorescence in situ hybridization (FISH). FISH testing may be performed in a hospital clinical cytogenetics laboratory. However, other assessment techniques that are investigational and less widely available include whole-genome single-nucleotide polymorphism (SNP), multiplex ligation-dependent probe amplification (MLPA) and microsatellite analysis

(MSA).

Whole-genome SNP analyses assess all regions of all chromosomes; however, MLPA and MSA examine a limited number of chromosomes that are believed to be of interest. Although SNP testing provides information across the entire genome, it is considerably more costly to perform compared to MLPA or MSA. A commercially available RNA-based assay for choroidal melanoma is available to categorize tumors as Class 1 (low-metastatic risk) and Class 2 (high-metastatic risk); however, because this test does not provide cytologic confirmation of the presence of melanoma tissue being sampled, a meaningful test result is assured in combination with cytopathology for diagnostic confirmation. A recent report by Klufas and colleagues indicated that nonmelanoma tumor tissue may also give Class 1 and Class 2 test results, despite there being no melanoma cell type present.<sup>148</sup> Molecular prognostic tests with results specific to uveal melanoma (such as DNA-based tests identifying monosomy 3) may provide more valid information.

Although the specific chromosomal abnormalities, namely monosomy 3, may be important in predicting cancer prognosis with respect to metastasis, the use of molecular markers and/or mutations of biologic relevance have yet to be discovered. In the future, tumor tissue may be screened for these markers, which might help tailor therapies for uveal melanoma metastasis when such treatments exist. Currently, despite treatment with current chemotherapeutic regimens, patients with metastases from uveal melanoma usually die within 2–14 months after the diagnosis of disseminated disease and the prognosis has not significantly improved over the decades. We need a better understanding of the biologic mechanisms contributing to development and progression of metastatic uveal melanoma.

## **Improving Prognosis With Early Treatment of Uveal Melanoma**

Although the COMS established that there was no survival advantage after treating uveal melanoma with plaque versus

enucleation, data in support of higher metastatic risk for larger-sized uveal melanomas suggest that early treatment prior to significant tumor growth may improve survival for patients. This has been debated with skeptics citing the likelihood of lead-time bias for the development of metastasis when smaller tumors are treated. Damato and colleagues reported that patients who were younger at treatment had smaller tumors and had a lower rate of metastatic outcome. Results based on outcomes in over 3000 patients over about a 20-year interval suggest that treatment may prevent tumor growth, dedifferentiation, and metastatic disease in some patients, especially those with smaller tumors.<sup>149</sup>

Achieving local tumor control with radiotherapy or enucleation may prevent further accumulation of chromosomal aberrations, which could influence the ability of the tumor to metastasize. In a series of 452 uveal melanomas where MLPA was used to determine aberrations in chromosomes 3, 6, and 8, Damato, Dopierala, and Coupland found that chromosomal abnormalities accumulated with tumor growth, in keeping with genomic instability, which is a feature of malignant neoplasia.<sup>150</sup> One explanation for a higher rate of distant metastasis in uveal melanoma with local recurrence after treatment is that unchecked tumor growth may select for an aggressive cytogenetic phenotype, thereby enabling the metastatic process. With earlier detection and improvement in the ability to diagnose, biopsy, and treat small choroidal melanomas, evaluation of metastatic outcome will be critical. It may be possible to not only achieve local tumor control in patients with small choroidal melanoma, but also influence metastasis in this subset of patients.

## Conclusion

Uveal melanoma is an uncommon but life-threatening intraocular malignancy. Available evidence suggests that observation of small, inactive tumors does not substantially increase the risk of metastasis. For patients managed by initial observation, the decision to treat and the timing of treatment depend on clinical judgment. Approximately 50% of patients diagnosed with uveal melanoma develop metastasis within 10–15 years after enucleation, with rates varying depending on chromosome 3 status of the tumor

and tumor size. Despite the continual emergence of new eye-conserving therapies, radiation is the superior treatment of choice to minimize the serious morbidity of local treatment failure. Unfortunately, selection of treatment does not prevent tumor-related death. A better understanding of the molecular events leading to metastasis, including cellular differentiation, adhesiveness, and vascular biology, may help in the development of new systemic therapies. With the increasing use of fine-needle aspiration biopsy to obtain molecular information for metastatic prognosis, an opportunity for studying primary tumor biology exists which could lead to a better understanding of uveal melanoma metastasis and prognosis.

## Introduction

Uveal melanoma (UM) represents only 5% of all melanomas. However, it is the most common primary intraocular malignancy in adults, affecting approximately 5–11 individuals per million per year.<sup>1</sup> UMs arise from melanocytes within the uveal tract (i.e., iris, ciliary body, and choroid). Iris melanomas are relatively benign; however, ciliary body and choroidal melanomas still present significant diagnostic and therapeutic challenges.<sup>2</sup> Indeed, choroidal melanomas – the most common ocular melanoma – result not only in vision loss, but also in metastasis, which is uniformly fatal. Metastases most commonly target the liver, and the detection of hepatic metastatic lesions predicts a dismal outcome, with a median survival of only a few months.<sup>3</sup> Despite advances in the diagnosis and treatment of the primary tumor, we have not witnessed a corresponding improvement in patient survival.

Current treatment for local disease, including eye-sparing approaches (e.g., radioactive plaque therapy, external beam radiation, laser therapy), often leads to profound vision loss;<sup>4</sup> the identification of novel targets could provide gene product-targeted therapeutic options, which may avoid local tissue destruction. To this end, it is essential that we determine the molecular mechanism(s) that promote the initiation and progression of UM. In the past decade, emerging evidence suggests that a complex series of molecular steps occurs in which uveal melanocytes elude their antiproliferative and proapoptotic harnesses to form a melanoma, and in up to half of patients, metastasize hematogenously to the liver and other organs.<sup>5</sup> It is therefore critical that we identify patients at risk for metastasis early, so that we may provide adjuvant systemic therapy in an effort to delay or perhaps prevent the progression to clinical metastatic disease. It is equally important that patients not at risk for metastasis are spared from unnecessary treatment with systemic chemotherapy with their attendant risks and side-effects. Here, we provide an overview of how our current

understanding of the molecular genetics of choroidal melanoma has provided insight into the pathogenesis of this devastating ocular cancer, and how it may influence the diagnosis, treatment, and survival of these patients.

## Cutaneous Melanoma, Uveal Melanoma, and the RAS/BRAF/MEK Pathway

Early work exploring the molecular genetics of UM was based upon the genetic studies in cutaneous melanoma. Specifically, activating mutations in *RAS* and *BRAF* oncogenes had been shown to play a fundamental role in the development of cutaneous melanoma, occurring in more than 80% of these tumors.<sup>6</sup> Mutations of *RAS* and *BRAF* promote the activation of MEK1/ERK (or the mitogen-activated protein kinase (MAPK) pathway), thereby promoting cell proliferation and survival.<sup>7</sup> Uncontrolled proliferation is a key feature of malignant transformation, and activation of the MAPK pathway is a common target for malignant progression. Early work demonstrated that the vast majority of primary UM tissue exhibits immunohistochemical evidence of activation of the MAPK pathway.<sup>8,9</sup> Based upon these promising findings, several groups have investigated the mutational status of *RAS*, *BRAF*, and *MEK1* in primary UM, as well as in liver metastases from patients with UM. Surprisingly, these studies have been overwhelmingly negative.<sup>10,11</sup> Indeed, despite arising from the same cell type, there appear to be more dissimilarities between the molecular genetics of UM and cutaneous melanoma than there are similarities.

## GNAQ and GNA11 Mutations in Uveal Melanoma

A breakthrough in our understanding of the development of UM came from the discovery in UM tissue of activating mutations in genes encoding for members of the  $G\alpha_q$  family of large G proteins. Mutations in genes encoding for heterotrimeric G-protein  $\alpha$

subunits have been reported in a variety of cancers.<sup>12</sup> A genetic screen of UMs demonstrated that approximately half exhibit mutations in the gene encoding for  $G\alpha_q$  (*GNAQ*).<sup>13</sup> Interestingly, over half of UMs lacking a mutation in *GNAQ* exhibit a mutation in the gene encoding for the related protein,  $G\alpha_{11}$  (*GNA11*).<sup>14</sup> G proteins are a family of heterotrimeric proteins that signal from cell surface, 7-transmembrane spanning (G protein-coupled) receptors (GPCRs).<sup>15</sup> Upon ligand binding to its GPCR, the GDP bound to the  $G\alpha_{Q/11}$  subunit is exchanged for GTP, resulting in a conformational change and the subsequent dissociation of the  $G\alpha_{Q/11}$  from the  $G\beta\gamma$  subunits. These subunits are then able to regulate various second messengers. The  $G\alpha_{q/11}$  family mediates its activity through stimulation of phospholipase C- $\beta$  (PLC $\beta$ ), which leads to activation of protein kinase C (PKC), and ultimately activates downstream intracellular signaling pathways, including the MAPK signaling pathway.

However, preclinical studies in choroidal melanoma cell lines suggest that this classic  $G\alpha_{q/11}$ -mediated signaling pathway is not sufficient to explain the proliferative capacity of choroidal melanoma tumor cells.<sup>16</sup> Instead, it was recently demonstrated that  $G\alpha_q$  promotes melanocyte cell transformation through a novel mechanism.  $G\alpha_q$  binds to and activates Trio, a guanine nucleotide exchange factor (GEF) for the small GTPases RhoA and Rac1, leading to their activation, and the expression of growth promoting genes.<sup>16</sup> Preventing Trio activation diminished choroidal melanoma tumor formation in animal models without affecting ERK.<sup>16</sup> Instead,  $G\alpha_q$  was shown to trigger nuclear translocation of the transcriptional coactivator, YAP, a critical component of the Hippo signaling pathway that controls organ size in mammals.<sup>17,18</sup> This, in turn, stimulated YAP-dependent transcription, independent from PLC $\beta$  stimulation, but requiring the activation of Trio, and the subsequent activation of the small GTPases RhoA and Rac1 and their associated signaling networks (Fig. 145.1).<sup>17</sup>

factors associated with advanced UM.<sup>19</sup> Although patients with blue nevi are at higher risk for UM, blue nevi are not malignant. Moreover, although activating mutations in *GNAQ/11* can promote transformation of immortalized melanocytes, mutation of either gene is not sufficient for malignant transformation. Collectively, these findings suggest that driver mutations in *GNAQ/11* occur early during UM development, but that *GNAQ/11* mutations alone may not help identify patients who are at higher risk for later developing metastases. Nonetheless, as GPCRs are the target – directly or indirectly – of 50–60% of all present pharmacologic agents,<sup>15</sup>  $G\alpha_{q/11}$  may still provide a novel precision medicine target for the treatment of UM.

## Chromosomal Abnormalities in Uveal Melanoma

Interestingly, several cytogenetic or chromosomal abnormalities have been linked statistically to metastatic death in UM patients.<sup>20–23</sup> However, among these markers, gain of chromosome 6p and loss of one copy of chromosome 3 (monosomy 3) have proved to be the most reliable predictors of metastasis and survival. Gain of chromosome 6p occurs mainly in nonmetastasizing tumors and carries a better prognosis. Conversely, loss of one copy of chromosome 3 (monosomy 3) occurs most frequently in metastasizing tumors and predicts a poor outcome.<sup>24</sup> Of note, isodisomy 3, in which one copy of chromosome 3 is lost and the remaining (faulty copy) is duplicated, occurs in 5–10% of cases of patients with UM and is prognostically equivalent to monosomy 3.<sup>25</sup> Tumors with monosomy 3 have also been found to contain greater numbers of additional chromosomal abnormalities (aneuploidy) than tumors with disomy 3, suggesting that loss of chromosome 3 may promote the genomic instability observed in more aggressive tumors, complicating the interpretation of the prognostic significance of some chromosomal abnormalities in UM.<sup>26,27</sup>

## Gain of 6p, Loss of 3: the Genetic Bifurcation

## in Uveal Melanoma

Interestingly, gain of chromosome 6p and monosomy 3 are almost completely mutually exclusive,<sup>22</sup> representing a genetic bifurcation in UM progression (Fig. 145.2). This observation has prompted efforts to use this unique molecular distinction to predict which patients are at higher risk for later developing metastases. To distinguish between these two populations of UM patients, initial efforts focused on cytogenetic analysis. However, this technique requires highly trained cytogeneticists, and the accuracy of the results is limited by sampling error attributable to analysis of only a few tumor cells, and to the inability to detect small genetic changes. Moreover, standard karyotyping is unable to identify isodisomy 3, resulting in a missed identification in up to 10% of UM. Other techniques that also rely on direct analysis of intact chromosomes include fluorescence in situ hybridization (FISH), spectral karyotyping (SKY), and earlier forms of comparative genomic hybridization (CGH).<sup>28</sup> Although these techniques provide some advantages over karyotyping, they are still prone to sampling error attributable to analysis of a small subset of tumor cells, and they are also unable to detect isodisomy.

**FIG. 145.2** Schematic depicting the molecular events that occur during the progression from uveal melanocyte to metastatic melanoma. Initial mutations in *GNAQ* or *GNA11* promote melanocyte survival and proliferation, but alone are not sufficient for melanocyte transformation. Additional (yet unknown) mutation(s) are necessary for progression to a melanoma. At this stage, the melanoma chooses one of two mutually exclusive paths, gain of chromosome 6p or loss of chromosome 3, leading to the development of less aggressive (lower metastatic rate) or more aggressive (higher metastatic rate) tumors, respectively. The additional loss of 8p in the more aggressive tumors further increases the risk for metastasis. These chromosomal changes correlate with the classic clinical and histologic features of uveal melanoma (UM) that were previously used to characterize (and later predict) the aggressiveness of UMs.

More recent automated techniques (e.g., array-based CGH, microsatellite analysis (MSA), single-nucleotide polymorphism (SNP) analysis, multiplex ligation-dependent probe amplification (MLPA)), evaluate multiple regions across individual chromosomes

using specific molecular probes. By allowing larger numbers of tumor cells to be examined, these techniques reduce the risk of sampling error and increase the ability to detect smaller abnormalities compared with karyotyping and FISH. Additionally, MSA and SNP can detect the presence of isodisomy 3. The prognostic accuracy of these techniques compared with standard karyotyping is unclear.<sup>29</sup>

## Gene Expression Profiling

Recent advances in DNA microarray technology have enabled transcriptional or gene expression profiles (GEP) of remarkably small tissue samples at relatively low cost, providing scientists and clinicians insight into the complex pathophysiologic mechanisms of cancer and other diseases. This technology not only allows comparison of gene profiles in normal and pathologic tissues or cells, but also among different stages of disease progression, and has proven to be particularly useful in studying cancer. In cancer, GEP enables the simultaneous measurement of messenger ribonucleic acid (mRNA) expression using microarrays (glass slides or chips, carrying DNA representing thousands of genes), to which the labeled cRNA isolated from tumor cells is applied to determine gene activity. Thus, rather than examining the genetic abnormalities themselves, GEP enables the quantitation of the changes in gene expression in the tumor that (presumably) are the biologic consequence of the chromosomal abnormalities.

The gene expression data are then analyzed using statistical methods, with the aim of identifying gene clusters that correlate with the patients' clinical outcome. Specifically, using “supervised” clustering methods for tumor classification guided by knowledge of clinical outcomes, gene clusters are identified. A subset of gene markers can then be identified and used as a “prognosis classifier” that can help predict the later appearance (“poor prognosis”) or absence (“good prognosis”) of clinical metastasis. This approach has been previously applied to other cancers to more accurately classify tumors,<sup>30,31</sup> and has recently been tested with UM (Fig. 145.3).<sup>32</sup>

**FIG. 145.3** Schematic depicting the basic steps involved in genetic testing in a biopsy from a patient with a uveal melanoma (UM). (A) Intraoperatively, either transscleral (anterior UM) or transvitreal (posterior UM) fine-needle aspiration biopsy (FNAB) is performed to obtain tissue for testing. (B) Once the cells are obtained, the quality of the tissue is often first confirmed by histopathology prior to testing (in this case, gene expression profiling). (C) Using gene expression profiling, tumors can be classified into one of four classes, based on the expression pattern of specific genes. (D) The specific class to which a tumor belongs can then be used to predict the likelihood of metastasis (and, in turn, the probability of survival). How these data can be used in the clinical setting remains unclear. (Modified with permission from Landreville S, Agapova OA, Harbour JW. Emerging insights into the molecular pathogenesis of UM. *Future Oncol* 2008;4:629–36, and with the permission of Dr William J. Harbour.)

The information derived from GEP in UM has proven to be a useful tool in predicting a patient's clinical outcome.<sup>33,34</sup> In patients

with UM, GEP has identified two major subgroups referred to as class 1 and class 2; approximately half of UM fall into each subgroup.<sup>32</sup> Patients with class 1 tumors have a lower risk of metastasis and patients with class 2 tumors have a higher risk of metastasis.<sup>35</sup> Interestingly, the class 2 gene expression profile is closely associated with previously identified prognostic features, such as larger tumor size, epithelioid cytology, extravascular looping matrix patterns, and monosomy 3.<sup>36</sup> The prognostic accuracy of the class 2 expression profile has been reported to be greater than for any of these other features (individually or in combination).<sup>32</sup> The identification of a subset of genes has enabled a polymerase chain reaction (PCR)-based platform that further increased the prognostic accuracy of GEP for UM.<sup>37</sup> This PCR-based method requires less tissue and has further proven useful for the analysis of archival (formalin-fixed, paraffin-embedded) samples.

The two classes have further been subdivided into four prognostically significant subclasses (1A, 1B, 2A and 2B), based on gene-expression profiling.<sup>32</sup> The metastasis-free survival is longest for class 1A and shortest for class 2B. The subclass 1B signature corresponds closely to gain of chromosome 6p, and the subclass 2B signature corresponds closely to loss of chromosome 8p. Molecular forecasting of the outcome of UM using GEP has proven remarkably reliable, offering a significant advance on existing prognostic methods.

## Clinical Implications of Genetic Prognostication

The additional information provided by our greater understanding of the molecular genetics of UM raises new questions about both the disease and how and when we should treat patients with UM. Importantly, who should be offered testing (Fig. 145.4)? Should testing be limited to patients who undergo enucleation or local tumor resection or should it include patients who undergo brachytherapy, which would require fine-needle biopsy as an extra procedure? Does tumor location or size influence the decision? What (if any) is the role for genetic testing on patients with a suspicious nevus? Clearly, genetic testing, and the information it

provides, can be a valuable part of our understanding of UM and has the potential to be helpful both in the diagnosis and treatment of this devastating disease. Nonetheless, many questions remain unanswered.

**FIG. 145.4** Different types of choroidal melanocytic lesions that may prompt consideration for genetic testing. (A) A typical small (<2 mm in diameter), flat, pigmented choroidal lesion with few small overlying drusen, no orange pigment, no associated subretinal fluid, detected during a routine eye examination. Similar benign nevi occur in 3–10% of the Caucasian population and are unlikely to be considered appropriate for fine-needle aspiration biopsy (FNAB) for genetic testing. (B) A slightly larger (approximately 5 mm in diameter and 1 mm in height) pigmented choroidal lesion, also with few small overlying drusen, no orange pigment, no associated subretinal fluid, detected during a routine eye examination. Although, the size of the lesion and the location next to the optic nerve may prompt closer follow-up, it too is unlikely to be considered appropriate for FNAB for genetic testing. (C) A larger pigmented choroidal lesion (approximately 9 mm in diameter and 1.9 mm in height) also adjacent to the optic nerve, but with overlying orange pigment, but no associated subretinal

fluid, and no clinical symptoms. The role for FNAB and genetic testing for this lesion remains under debate. (D,E) Large pigmented (D) and nonpigmented (E) choroidal lesions, both over 3 mm in height in symptomatic patients with features concerning for melanoma (overlying orange pigmentation, associated subretinal fluid). Both patients underwent radioactive plaque brachytherapy. In many centers these patients would have undergone FNAB and genetic testing. However, the role for these tests, how to interpret the results, and how this should influence treatment and surveillance, remains under debate.

## Tissue Procurement

If genetic testing is to be considered “good clinical practice,” then the next question is how should we obtain the tissue? Reasonable disagreement remains as to whether the short-term or long-term risks of transscleral (for anterior UM) or transvitreal (for posterior UM) fine-needle aspiration biopsy (FNAB) outweigh the potential benefits of this procedure in patients who would otherwise not require intraocular surgery. What risks should be shared with the patient (e.g., transient vitreal hemorrhage, retinal tear or detachment, subretinal hemorrhage, endophthalmitis, tumor dissemination)? It is also unclear if less-invasive single sample procurement is sufficient for accurate and reliable diagnoses or whether multiple samples are required to address concerns of intratumoral genetic heterogeneity. Additionally, determining what preliminary testing is necessary to confirm that the tissue is appropriate for testing is still unclear.

## Which Test(s) Should We Use?

Until alternative (noninvasive) approaches are available, many clinicians agree that transscleral or transvitreal FNAB is the most safe and effective means to obtain tissue for genetic testing. However, the best test to perform for genetic testing remains unresolved. And there remains significant confusion and controversy in the ocular oncology field regarding the use of these

prognostic tests in the clinical management of UM. The future of UM diagnostic/prognostic tests may rest in the use of microarray technologies, either for the evaluation of changes in copy number or for gene expression profiling. Although these techniques have historically been technically demanding and expensive, emerging PCR-based platforms may provide less expensive and more accurate assays for genetic prognostication. Ultimately, studies looking at molecular prognostic testing in UM have been retrospective in nature; prospective validation of these tests is essential before they can be considered routine for patients in clinic.

## Genetic Testing in Clinical Trials

Knowledge that there are two classes of UMs may influence the success of future clinical trials designed to examine the response of these tumors to novel treatments. A limitation of the Collaborative Ocular Melanoma Study (COMS)<sup>38</sup> may have been that the consequence of the two classes of UMs (class 1 and 2) were not previously recognized at the time of the study's design. The good outcome of half the patients in the trial (class 1) may have been largely independent of treatment, and may have limited our ability to uncover a therapeutic advantage to one of the treatment arms. It should be noted that eligibility of patients in future trials, which includes patients who have received local treatment, may be limited to those patients who either have already had genetic testing or who have tissue available for genetic testing prior to entry into the trial. Recognizing that there are two classes of UM patients may further help in the identification of new and/or more accurate (noninvasive) biomarkers for the development of metastasis in high-risk (class 2A/2B) patients. There is little doubt that the additional information provided by genetic studies of UM will provide a fund of knowledge that may benefit future patients with this disease.

Genetic testing in UM has, and will continue to have, a significant impact on our understanding of the molecular pathogenesis of the disease. Certainly, the gene expression profile of class 2 UMs has provided clues as to the molecular events that promote progression and metastasis in this subset of tumors. For example, mutations in

the BRCA1-associated protein 1 gene (*BAP1*) are detected in approximately 47% of primary UM lesions.<sup>39</sup> *BAP1* mutations arise after the activating mutations of *GNAQ* or *GNA11* and are associated with class 2 UMs and a high likelihood of metastasis.<sup>39</sup> *BAP1* maps to chromosome 3p21 and *BAP1* mutations in UMs are accompanied by primarily somatic complete or partial loss of chromosome 3, providing a possible molecular link between chromosomal abnormalities in UM and tumor metastasis.<sup>39</sup> However, preclinical studies have failed to demonstrate a role for *BAP1* in tumor cell proliferation, migration, invasion, or tumorigenicity. It is unclear whether *BAP1* will serve as a therapeutic target for the prevention or treatment of metastatic choroidal melanoma. But it is likely that the presence of *BAP1* mutations could influence the survival of UM patients in clinical trials. Recent large cancer genome sequencing efforts (The Cancer Genome Atlas – TCGA <http://cancergenome.nih.gov/>) have revealed additional recurrent mutations in UM, including genes for the splicing factor *SF3B1* (26%), the translation initiation factor *EIF1AX* (14%), the protein arginine methyltransferase *PRMT8* (7%), and the GPCR *CYSLTR2* (4.2%). The relevance of these novel gene mutations for UM prognosis and treatment is still unclear and will warrant further investigation.

## Diagnosis and Treatment of Current Uveal Melanoma Patients

Outside the setting of a clinical trial, a key ethical consideration for patients who undergo genetic testing is informed consent. Most specialists would agree that it is important to inform patients that the test has not yet been proven to be of benefit in either guiding management or prolonging survival. However, reasonable disagreement remains as to whether genetic testing for UM should only be performed in a research setting.<sup>29</sup> For patients requiring FNAB, the purpose of the procedure, along with its potential complications, must also be explained to the patient.

Nonetheless, the potential impact of genetic testing on the early diagnosis of UM patients who are more likely to develop

metastases (prognostication) is a compelling argument for its use for these patients. However, as in other settings in medicine, disease prediction continues to outpace our ability to treat or cure metastatic UM, resulting in a therapeutic rift between what we know and what we can do. This raises the reasonable, albeit philosophical question, as to whether there is an inherent value to simply knowing that a patient will – or will not – develop metastatic disease. Although emerging evidence suggests that the survival of patients with solitary metastatic nodules can be prolonged with early detection and treatment (e.g., resection, chemoembolization, or intrahepatic arterial infusion),<sup>40</sup> the value of genetic testing even in this setting remains a topic of debate.

It has also been suggested that prognostic tests can be used to determine which small suspicious UMs should be treated and which may be safe to observe. However, this approach assumes that class 2 tumors have not already metastasized, in which case local treatment may not benefit patient survival. Conversely, it is possible that treatment of class 1A tumors (rather than observing) may prevent them from converting to class 2 tumors. It has also been proposed that genetic testing may influence surveillance for metastasis. Patients with class 1 tumors may require less frequent monitoring than patients with class 2 tumors. This is complicated by the fact that genetic prognostication is not an exact science. Thus, despite the paucity of treatments for metastatic disease, the risk of potentially delaying the diagnosis of metastasis by decreasing the frequency of surveillance remains controversial. While some patients may find comfort in knowing that they have a lower risk for metastases based on the genetics of their tumors, there is a real potential for adversely affecting the quality of life of a patient who is told that they have a high risk of metastases given that there is currently no effective adjuvant therapy available for metastatic UM.

These tests may still play an essential role in predicting treatment response. For example, it is more likely that therapies specifically targeting *GNAQ* or *GNA11* would be effective in primary tumors with activating mutations in *GNAQ/11*. Similarly, patients with metastases that harbor specific mutations in genes that promote metastasis (e.g., *BAP1*<sup>39</sup>) may be more responsive to adjuvant systemic chemotherapies that are designed to target these genes.

Clearly, as new therapeutic options for metastatic UM are introduced, the value of genetic prognostication will continue to evolve.

## Conclusion

In the past few years, we have begun to appreciate the complex series of molecular steps by which normal uveal melanocytes progress from a benign nevus to a metastatic melanoma. These steps include specific mutations and chromosomal changes, which are now detectable with diagnostic testing. These tests have recently become available to clinicians and their patients and have led to remarkable advances in genetic prognostication for patients with UM. Although they have provided (and will continue to provide) a wealth of information regarding the molecular pathogenesis of this cancer, the role of these tests in the diagnosis and treatment of patients with UM remains unresolved. Nonetheless, it is clear that emerging insight into the molecular pathogenesis of UM may ultimately provide new hope for patients who suffer from this devastating and incurable disease.

## **Introduction**

The diagnosis of choroidal melanoma is made clinically by fundus examination and ultrasonography. In equivocal cases, a tumor may be biopsied and evaluated by an ophthalmic pathologist.

Examination of cytologic features and immunohistochemical stains, provided there is a sufficient amount of tissue, allows for a reliable diagnosis. Gross and microscopic examination of enucleated eyes harboring a uveal melanoma provides relevant prognostic information, e.g., cell type, invasion of vortex veins, and extraocular growth. Implementation of the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC) TNM classification in the pathology report allows for uniform staging. Assessment of complications due to brachytherapy such as radiation retinopathy and plaque failure with subsequent tumor growth may lead to improvements in clinical care. Increased

knowledge of the molecular genetic aspects of choroidal melanoma including tests such as chromosome 3 status and gene expression profiling provides clinically relevant information. All in all, close cooperation between ophthalmic oncologists and pathologists within the framework of scheduled tumor conferences optimizes patient care. This chapter describes the pathologic findings in choroidal melanoma.

## Processing of Specimens

Appropriate processing of tissue specimens is necessary for adequate pathologic evaluation. In the following sections, we, the authors, share our protocol.

### Fixation

For routine pathologic examination, tissue specimens are fixed in paraformaldehyde or formaldehyde (4–10%) immediately after surgery. As formalin diffuses at a rate of approximately 1 mm/hour, an entire globe (about 24 mm in diameter) should be fixed at least 12 hours prior to further processing. If tissue is going to be sent for molecular genetic analysis, an appropriate amount of material should be obtained prior to formalin fixation, though testing of formalin-fixed paraffin-embedded tissue is also possible.

### Gross Examination

Different types of tissue obtained include cytologic material, a tumor biopsy (incisional or excisional), or an enucleated globe. Clinical information and the type of fixative are noted. Gross examination depends on the submitted specimen.<sup>1-4</sup> For cytologic material, the submitted material (e.g., number of slides, quantity and appearance of fluid) is registered. For tumor biopsies, the number of pieces, size (three dimensions if possible), and descriptive features (e.g., color) are noted. A globe should be evaluated according to the guidelines of the Association of Directors of Anatomic and Surgical Pathology.<sup>1-4</sup> After orientation of the globe, careful inspection for extraocular growth is followed

by transillumination to localize the tumor and to measure its basal diameter. Vortex veins are submitted in different cassettes labeled respective to their localization. A standard section of the globe incorporates the pupil–optic nerve (p–o) section and the tumor. Detailed macroscopic examination and photodocumentation of the entire globe as well as a thorough description (including evidence of previous treatment) and tumor measurements are recommended.

## Staining

Routine stains for choroidal melanoma comprise hematoxylin and eosin (H&E), periodic acid Schiff (PAS), and bleached H&E stains, to reveal the cytologic features in heavily pigmented tumors ([Fig. 146.1](#)). Immunohistochemical stains are not routinely used for the diagnosis of uveal melanoma but may be helpful in selected cases, including fine-needle aspiration biopsy (FNAB) samples.

**FIG. 146.1** Choroidal melanoma (molecular profile class I) in a 43-year-old woman. (A) On gross examination, a heavily pigmented uveal melanoma is present. (B) The extracellular matrix pattern of the tumor with vascular loops and arches is detected with a PAS stain (PAS, ×40). (C) The uveal melanoma consists of spindle cells and epithelioid cells (mixed-cell type) and exhibits pigmentation in uveal melanoma cells and pigment-laden macrophages (H&E, ×400). (D) Bleached sections enable the evaluation of the cytologic features (bleached H&E, ×400).

## Gross Appearance of Choroidal Melanoma

The gross examination of intraocular tumors is the basis for clinicopathologic correlations as it allows for a detailed macroscopic

evaluation and measurement of the tumor size including the prognostically relevant largest basal diameter.<sup>5,6</sup> The largest basal diameter can be reliably assessed on gross examination, although the tumor size may be underestimated when measured after fixation due to tumor shrinkage.<sup>7</sup> Choroidal melanomas exhibit an oval or fusiform shape (Fig. 146.2) when confined by Bruch's membrane or a collar-button/mushroom configuration (Fig. 146.3) when the tumor has broken through Bruch's membrane.

**FIG. 146.2** (A) Oval-shaped, heavily pigmented choroidal melanoma (molecular profile class I) in a 66-year-old man. (B) Histologically, a mixed-cell type melanoma (*asterisk*) is present within the uvea (H&E, ×400). Bruch's membrane (*arrow*) is intact, the overlying retinal pigment epithelium and retina display atrophic changes.

**FIG. 146.3** (A) Collar-button-shaped pigmented choroidal melanoma in a 70-year-old woman. (B) Histologic examination shows the tumor breaking through Bruch's membrane (*arrow*) (H&E, ×400).

Ocular structures may be invaded by choroidal melanomas. Invasion into the ciliary body may be detected macroscopically, whereas invasion into the sclera, retina, and optic nerve, as well as invasion into the vitreous, iris, and anterior chamber, is usually detected by microscopic examination. Extraocular extension ([Fig. 146.4](#)) usually occurs along vortex veins or emissary canals and, dependent on the extent, may be diagnosed clinically or on gross examination.

**FIG. 146.4** An 86-year-old woman presented with (A) extraocular extension of a uveal melanoma (molecular profile class II). (B) On gross examination, extraocular extension (*arrow*) of a mildly pigmented bilobulated tumor was detected that invades the choroid and the ciliary body. (C) Histologic examination (H&E, ×100) shows the extraocular part of the tumor (*asterisk*) composed of epithelioid cells. The patient died from

liver metastasis less than 1 year after enucleation.

The amount of pigmentation of uveal melanomas varies from tumor to tumor or even within a single tumor and may be related to overall survival.<sup>5,8</sup> Most tumors exhibit mild to moderate pigmentation, although heavily or nonpigmented (amelanotic) choroidal melanomas (Fig. 146.5) may be observed.

**FIG. 146.5** Mildly pigmented, mushroom-shaped choroidal melanoma in a 24-year-old male patient.

## Histopathologic Features of Tumor Cells and Their Prognostic Relevance

The prognosis of choroidal melanoma is based on clinical, histologic, and genetic parameters (see [Chapter 145](#), Molecular genetics of choroidal melanoma). Some parameters such as ciliary body invasion, extraocular extension, and the largest basal diameter are incorporated into the TNM classification.<sup>9</sup> Histopathologic examination allows for further characterization of the tumor, including its cytologic features. In FNAB specimens, the cell type is more difficult to determine than in enucleated eyes or completely excised tumors due to the scarce amount of tissue and artifacts ([Fig. 146.6](#)).

**FIG. 146.6** Fine-needle aspiration biopsy (FNAB) exhibiting basophilic tumor cells with high nuclear-to-cytoplasmic ratios and prominent nucleoli, surrounded by debris (pink) (H&E,  $\times 400$ ).

Choroidal melanomas usually arise de novo but may also arise from a nevus or a melanocytoma (magnocellular nevus). In these cases remnants of the underlying nevus consisting of spindle A cells (spindle cell nevus: [Fig. 146.7](#)) or extremely rare magnocellular nevus cells (melanocytoma<sup>10,11</sup>), may be histologically detected.

**FIG. 146.7** (A) Choroidal melanoma arising in a choroidal nevus (H&E,  $\times 4$ ). There is vitreous spread of melanoma cells present (*arrow* and inset). (B) Higher magnification reveals nevus cells (spindle A cells, *arrow*) at the base of the choroidal lesion (H&E,  $\times 100$ ). Some of these cells are pigmented. The RPE (*arrowhead*) shows degenerative changes and underlying drusen and exudates.

## Cytologic Features

First developed by Callender in 1931,<sup>12</sup> the so-called “Callender classification” distinguished five types of uveal melanomas depending on the most prominent cell type: spindle cell subtype A; spindle cell subtype B; epithelioid type; fascicular type; and mixed cell type (consisting of mixtures of spindle and epithelioid cells) of

uveal melanoma.

Addressing the disagreement about the interpretation and application of Callender's classification, a "modified Callender classification" was introduced by McLean and associates in 1983, comprising three different types in uveal melanoma based on cell morphology:<sup>13</sup> spindle cell melanoma (composed of spindle B cells); epithelioid cell melanoma, and melanoma of mixed-cell type. Spindle A cells were no longer regarded as malignant cells and were recognized as benign nevus cells. In addition, a new cell type was introduced, the small epithelioid cell (intermediate cell), that was smaller than the Callender's epithelioid cell and exhibited features intermediate between spindle B and epithelioid cells.

The classification of uveal melanomas into either spindle cell (composed of spindle B cells), mixed-cell type (most common), or epithelioid cell still is widely accepted. The main cell types are depicted as follows:

- **Spindle A cells** are fusiform, cohesive cells with poorly defined cell borders. The nucleus is also spindle-shaped and its central fold can be seen light microscopically as a dark stripe (Fig. 146.8A). This cell type is regarded as a benign nevus cell, but can be observed in uveal melanomas arising from a nevus.

**FIG. 146.8** (A) Fusiform spindle A cells (representing benign nevus cells) with a central fold are depicted (*arrow*) (H&E,  $\times 400$ ). (B) Spindle B cells that are plumper than spindle A cells exhibit a prominent nucleolus (*arrow*) (H&E,  $\times 400$ ). (C) Epithelioid cells characteristically contain a round, large nucleus with a prominent nucleolus (*arrow*) (H&E,  $\times 400$ ). (D) Small epithelioid cells (intermediate cells) represent a cell type intermediate between spindle B and epithelioid cells (*arrow*) (H&E,  $\times 400$ ). Mitotic figures are also present (*arrowhead*).

- **Spindle B cells** are also fusiform and cohesive with poorly defined cell borders but are plumper than spindle A cells. Prominent nucleoli are detected in the spindle-shaped nucleus ([Fig. 146.8B](#)). This is the most common cell type in choroidal melanoma.
- **Epithelioid cells** are noncohesive cells with defined cell borders. The round, large nucleus contains a prominent nucleolus ([Fig. 146.8C](#)). This cell type is associated with a poor outcome.
- **Intermediate cells** (small epithelioid cells) are a frequent cell type

intermediate between spindle B cells and epithelioid cells (Fig. 146.8D).

Although not incorporated into the TNM classification, the cell type of uveal melanomas is also an important prognostic parameter.<sup>6</sup> Melanomas solely composed of spindle cells have a more favorable prognosis than mixed-cell type tumors. Epithelioid cell melanomas are associated with monosomy 3 and class 2 molecular profile, a higher metastatic and mortality rate – and thus display the worst prognosis.<sup>6,14,15</sup>

Evaluation of the number of mitotic figures per high-power field in the tumor cells (Fig. 146.8D) is part of the routine evaluation of choroidal melanomas. It serves as an indicator for the proliferative activity and is thus a prognostic parameter.<sup>6</sup>

Morphometry (measurement of the largest nucleoli using a digital filar micrometer) as well as measurements of the nuclear DNA ploidy (DNA content) by image cytometry of Feulgen stained sections, are historical approaches to establish criteria with regard to long-term survival in patients with uveal melanoma.<sup>6,16</sup> These tests were replaced by newer approaches such as analysis of the chromosome 3 status,<sup>15</sup> gene expression profiling,<sup>14</sup> and further genomic analyses.<sup>17</sup>

## Immunohistochemical Features

The most important immunohistochemical markers expressed by the tumor cells are HMB45, S100, Melan A, MITF, and tyrosinase.<sup>18–22</sup> HMB 45 (Fig. 146.9) and Melan A are melanocytic markers. While Melan A stains melanocytes in general, HMB45 is predominantly expressed in “activated” melanocytes and is therefore more suggestive of malignant melanocytic lesions.<sup>22,23</sup> S100 is expressed in different types of cells including melanocytes and very often used in combination with HMB45 as a marker for uveal melanoma.<sup>22</sup> Microphthalmia transcription factor (MITF) is essential for the development and survival of melanocytes and therefore expressed in various melanocytic lesions including uveal melanoma.<sup>19–21</sup> Tyrosinase is an enzyme that is involved in the metabolism of melanocytes and was recently introduced as a melanoma marker.<sup>18</sup> At least two markers (e.g., HMB45 and S100)

should be employed for the diagnosis of uveal melanoma if the diagnosis cannot be made on histologic features alone.

**FIG. 146.9** Immunohistochemical staining for HMB 45 showing strong cytoplasmic positivity in a choroidal melanoma.

Ki67 antigen – a proliferation marker expressed in the nucleus – is suitable to detect the proliferative activity in tumors and has prognostic relevance.<sup>24,25</sup> Immunohistochemical stains for Phospho-Histone H3 Ser10 (PHH3) may help to detect mitotic figures in uveal melanomas.<sup>26</sup>

## Electron Microscopy

The different cell types in choroidal melanoma such as spindle A, spindle B, and epithelioid cells can also be differentiated by transmission electron microscopy, although the ultrastructural differences between the cell types are not clear-cut.<sup>27</sup>

Spindle A cells appear elongated and show spindle-shaped nuclei with marked indentations and an unsuspecting nucleolus. In the cytoplasm, there are cell organelles present such as mitochondria, a relatively small number of free ribosomes, rough-surfaced endoplasmic reticulum (RER), largely immature melanin granules (premelanosomes), and numerous cytoplasmic filaments.<sup>27</sup>

The shape of spindle B cells (Fig. 146.10A) is similar to spindle A cells except they have a plumper cell body. The nucleoli of spindle B cells are also larger and show a reticular pattern. While spindle B cells have more RER and free ribosomes in their cytoplasm, the number of cytoplasmic filaments is decreased compared to spindle

A cells.<sup>27</sup>

**FIG. 146.10** (A) Transmission electron microscopy shows a spindle-shaped cell with a lot of rough-surfaced endoplasmic reticulum (RER) in the cytoplasm ( $\times 1900$ ). The reticulated and slightly indented nucleus is also spindle-shaped and contains a nucleolus. There are a few melanin granules (empty vacuoles) present. (B) Epithelioid cell with cell organelles within the scanty cytoplasm ( $\times 4800$ ). The round nucleolus is reticulated and exhibits an indentation.

The largest nucleolus is found in the round to polygonal epithelioid cells (Fig. 146.10B) and exhibits a reticular pattern. The nucleolus of the epithelioid cells can have indentations but they are less prominent than in spindle cells. Many cell organelles, in particular mitochondria – some of them exhibiting a bizarre form and structure – and free ribosomes, but only a few filaments, are present in the cytoplasm.<sup>27</sup>

In summary, the ultrastructural features are consistent with the present consensus that the cellular malignancy increases from spindle A (nevus cells) through spindle B to epithelioid types of melanoma cells in conjunction with an increasing number of cell organelles (e.g., mitochondria, free ribosomes) and increasing size of nucleoli that are regarded as signs of activity.<sup>27</sup>

## Other Histopathologic Characteristics and Their Prognostic Relevance

In addition to cytologic features, other histologic tumor characteristics may be assessed in choroidal melanomas.

## Tumor Stroma

As choroidal melanomas metastasize hematogenously (Fig. 146.11), much attention has been paid to “intratumoral vessels and vascular-like structures” – nine different morphologic patterns can be distinguished: normal, silent, straight, parallel, parallel with crosslinking, arcs, arcs with branching, closed vascular loops (large “vessel” occluded by tumor cells), and vascular networks (at least three back-to-back closed vascular loops) (Fig. 146.12).<sup>28</sup> These vascular-like structures have been later shown to reflect fibrovascular septae rather than microvasculature leading to the term “vasculogenic mimicry.”<sup>29,30</sup> However, vasculogenic mimicry is regarded as an alternative pathway of blood supply. The presence of these extravascular matrix patterns that are identified, for example, by a PAS stain is associated with death from metastatic melanoma and may be used as an additional predictor of prognosis.<sup>28</sup> Connections between vasculogenic mimicry and the so-called cancer stem cells as well as epithelial-mesenchymal transformation of tumor cells have been found.<sup>31,32</sup>

**FIG. 146.11** (A) Liver metastasis of a choroidal melanoma with basophilic melanoma cells (*arrow*) next to hepatocytes (*arrowhead*) (H&E, ×400). (B) The primary tumor consists predominantly of epithelioid cells (*arrow*) (H&E, ×400) and exhibits extraocular extension (not shown).

**FIG. 146.12** (A) Choroidal melanoma with extracellular matrix patterns such as arches (*arrow*) (PAS,  $\times 40$ ) and (B) loops (*arrow*) (PAS,  $\times 40$ ). (C) Vascular channels within the tumor are also present (*arrow*) (PAS,  $\times 40$ ).

Microvascular density (MVD) itself has been identified as prognostically relevant,<sup>28,33</sup> and the presence of tumor cells in intratumoral blood vessels is also regarded as a factor for unfavorable outcome.<sup>34</sup>

A high number of tumor-infiltrating/associated lymphocytes (TILs/TALs) (Fig. 146.13) is associated with a more aggressive behavior and a higher risk of metastasis than a low number of TILs<sup>35</sup> – and so are tumor-infiltrating/associated macrophages (TIMs/TAMs).<sup>6,36,37</sup> In particular, M2 macrophages that exhibit proangiogenic and antiinflammatory characteristics (in contrast to M1 macrophages with antibacterial and antiangiogenic features) and a high M2/M1 ratio are linked to increased microvascular density, ciliary body involvement, genetic profiles, and thus a worse prognosis for survival.<sup>38,39</sup>

**FIG. 146.13** (A) Choroidal melanoma infiltrated by pigmented macrophages (*arrow*) (H&E,  $\times 40$ ). (B) Higher magnification shows pigment-laden macrophages (*arrow*) (H&E,  $\times 400$ ). (C) An

immunohistochemical double-stain for CD68 and CD163 reveals M2-macrophages (inset; CD68–CD163 double staining, ×400). Lymphocytes are also present within the tumor (*arrow*) intermixed with epithelioid cells (*arrowhead*) (H&E, ×400).

The degree of pigmentation varies between different tumors and also within one tumor. Tumor cells, as well as pigment-laden macrophages (that are typically larger than tumor cells), contribute to the degree of pigmentation that is roughly classified into amelanotic, mildly, moderately, and heavily pigmented (see [Figs. 146.1](#) and [146.5](#)). In heavily and moderately pigmented tumors, bleaching is mandatory in order to analyze the cytologic features. The degree of pigmentation in comparison with other features has only weak prognostic value.<sup>5,6</sup>

“Melanoma-associated spongiform scleropathy (MASS)” is a degenerative, noninflammatory process in the sclera underlying the tumor that occurs in 38% of enucleated eyes harboring uveal melanoma.<sup>40</sup> MASS is associated with age and basal tumor diameter (extent of direct contact between tumor and sclera) but not with long-term survival.<sup>41</sup> A high incidence of MASS is found in eyes with scleral invasion and extrascleral extension as altered sclera collagen may allow for tumor invasion. On gross examination, whitish spindle-shaped areas within the sclera adjacent to the tumor may be detected.<sup>40</sup> Degraded collagen fibers and glycosaminoglycan accumulation leading to the typical picture of spongiotic areas surrounded by feathery fragmented collagen fibers are microscopically observed ([Fig. 146.14](#)).<sup>40</sup>

**FIG. 146.14** Melanoma-associated spongiform scleropathy (MASS, *arrows*) within the sclera adjacent to a choroidal melanoma (*asterisk*) (H&E, ×100). A feathery appearance of the degenerated collagen fibers can be histologically observed (H&E, ×400).

## Tumor Extension

Choroidal melanomas may invade into several ocular tissues: most uveal melanomas invade into the sclera ([Fig. 146.15](#)). Continuous horizontal growth may lead to invasion of the adjacent ciliary body and is associated with a worse prognosis. Choroidal melanomas invading into the ciliary body do not necessarily also invade into the iris, and tumor growth is usually restricted by the reticulum of Müller. Once the tumor has broken through Bruch's membrane it may invade into the retina but rarely gains access to the vitreous cavity with vitreous spread ([Fig. 146.16](#)).<sup>42</sup> Melanoma cells in the anterior chamber and trabecular meshwork are rarely observed in choroidal tumors that do not continuously invade into the ciliary body and iris ([Fig. 146.16](#)). Peripapillary uveal melanomas may invade into the optic nerve head, but rarely extend far retrolaminary ([Fig. 146.17](#)).<sup>6</sup>

**FIG. 146.15** (A) Overview of a 48-year-old man's eye harboring a mushroom-shaped choroidal melanoma (H&E). (B) Scleral invasion of the mixed-cell type tumor (*arrow*) is present and associated with melanoma-associated spongiform scleropathy (MASS).

**FIG. 146.16** (A) Partially necrotic choroidal melanoma (status post brachytherapy) in an 80-year-old female patient (H&E,  $\times 40$ ). (B) Tumor cells are present adjacent to the zonules (*arrow*) (H&E,  $\times 100$ ). (C,E) Superficial retinal invasion can be observed (*arrows*) (C, H&E,  $\times 10$ ; E, H&E,  $\times 400$ ). (D) The chamber angle and the iris are also noncontinuously infiltrated by tumor cells (H&E,  $\times 40$ ). Higher magnification of the cells in the chamber angle exhibits choroidal melanoma cells and macrophages (inset).

**FIG. 146.17** (A) Peripapillary choroidal melanoma compressing the optic nerve head (*asterisk*) (H&E,  $\times 40$ ). (B) There are islands of tumor cells in an emissary canal (*arrow*) adjacent to the optic nerve (*asterisk*) (H&E,  $\times 100$ ). (C) The tumor is composed of spindle cells and epithelioid cells (H&E,  $\times 400$ ).

Extraocular extension occurs most frequently along emissary canals which include ciliary nerves and vascular channels, in particular vortex veins, as well as aqueous channels (Fig. 146.18).<sup>43</sup> Extension via the optic nerve or through iatrogenic wounds has also been described.<sup>43-45</sup> Extensive orbital extension is rarely observed (Fig. 146.19). Histologic examination of step sections of the globe and vortex veins enables pathologists to issue reliable reports that include these prognostically important parameters. Extraocular extension of uveal melanoma is associated with a significant risk for liver metastases and an increased local recurrence rate.<sup>46</sup>

**FIG. 146.18** (A) Gross appearance of a vortex vein invaded by a mixed-cell type choroidal melanoma (molecular profile class II). (B) Tumor cells (*asterisk*) are detected in the lumen of a vortex vein (*arrow*) (H&E,  $\times 100$ ).

**FIG. 146.19** (A) Eye of an 87-year-old female patient with a uveal melanoma breaking through the cornea. (B) On gross examination a heavily pigmented uveal melanoma filling nearly the entire globe and extending through the cornea (*arrow*) and into the optic nerve (*asterisk*) is seen. (C) The melanoma (*asterisk*) exhibits extraordinary massive optic nerve invasion (*arrow*) (H&E,  $\times 100$ ). (D) Higher magnification reveals epithelioid and spindle cells within and around the optic nerve (H&E,  $\times 400$ ).

## Degenerative Changes

Accompanying degenerative changes may be observed in the retinal pigment epithelium (RPE) and the retina ([Fig. 146.20](#)). The RPE may exhibit atrophy or proliferation. Secondary drusen and orange pigment may also be found. The retina overlying the tumor usually displays atrophy with or without edema. Serous retinal detachment may occur at the margin of as well as opposite to the tumor ([Fig. 146.20](#)).

**FIG. 146.20** (A) Retinal degeneration with massive atrophy of the outer retinal layers and retinal pigment epithelium atrophy is seen (H&E,  $\times 400$ ). Remnants of Müller cells are still observed (*arrow*). (B) Cystoid retinal edema within the inner nuclear and outer plexiform layer accompanied by massive epiretinal gliosis (H&E,  $\times 100$ ).

Orange pigment histologically corresponds to lipofuscin accumulation in macrophages on the tumor surface (within and under the neurosensory retina) and proliferating RPE cells, and occurs secondary to necrotic changes and/or as a sign of metabolic activity (Fig. 146.21).<sup>47</sup>

**FIG. 146.21** (A) Choroidal melanoma (*asterisk*) with overlying subretinal fibrous membrane (*arrow*) (H&E,  $\times 40$ ). (B) Higher magnification reveals atrophy of the retinal pigment epithelium and the retina. (C) Higher magnification of the tumor surface with orange pigment accumulation.

photoreceptor layer (H&E, ×100) (C) as well as lipofuscin-laden macrophages that correspond clinically to “orange pigment” (*arrow*) (H&E, ×400).

## Special Types of Uveal Melanoma

### Diffuse Uveal Melanoma

A diffuse growth pattern of uveal melanoma, defined as a tumor <5 mm in height that involves at least 25% of the uveal tract,<sup>48</sup> is rare as it affects only 3% of all melanoma patients<sup>49</sup> and exhibits horizontal rather than vertical growth (Fig. 146.22). It is associated with a worse prognosis than mound-shaped or fusiform growth patterns.

**FIG. 146.22** (A) Overview showing a diffuse uveal melanoma (*arrowheads*) (H&E). (B) Histologically, a tumor is present within the choroid (H&E, ×100) and (C) is composed of spindle and epithelioid cells (H&E, ×400). (Courtesy of Milton Boniuk, MD.)

### Multifocal Unilateral Uveal Melanoma

Multifocal unilateral uveal melanomas are extremely rare, and only a few cases have been reported (Fig. 146.23).<sup>50</sup> Serial sections should be employed in order to exclude local contiguous spread.

**FIG. 146.23** (A) Overview illustrating a multifocal melanoma (*arrows*) (H&E). (B) Histologically, the tumor is pigmented in parts (H&E,  $\times 100$ ) and (C) is composed of spindle cells and epithelioid cells (H&E,  $\times 400$ ). (Panel A courtesy of Aperio.)

## Bilateral Uveal Melanoma

Bilateral uveal melanoma occurs rarely (either simultaneously or lagged) and has to be distinguished from metastasis of uveal melanoma to the fellow eye.<sup>51,52</sup>

## Clear Cell Differentiation of Uveal Melanoma

Uveal melanoma may rarely exhibit clear cell differentiation with cytologic features similar to clear cell tumors elsewhere in the body (Fig. 146.24).<sup>53</sup> The clear cells are typically oval, contain centrally placed nuclei with malignant features, and their clear cell appearance can be attributed to cytoplasmic glycogen accumulation in melanoma cells. These tumors have to be carefully distinguished from metastatic (renal) clear cell carcinoma to the choroid.

**FIG. 146.24** (A) Gross appearance of a mildly pigmented tumor within the choroid in a 77-year-old female patient (*arrow*). (B) The tumor is composed in parts of clear cells that exhibit a centrally placed nucleus in a glycogen-containing cytoplasm (H&E,  $\times 400$ ). (C) Transmission electron microscopy (TEM) examination reveals large nuclei within a granular cytoplasm (TEM).

## Balloon Cell Melanoma

Balloon cell melanoma is pathogenetically associated with degradation of melanosomes and exhibits cells with vacuolated, foamy cytoplasm due to degenerative changes with lipid accumulation.<sup>54</sup> Uveal melanomas may exhibit varying amounts of balloon cells. A “true” balloon cell melanoma is rarely observed. Balloon cells may also occasionally be observed in eyes treated with brachytherapy or proton beam irradiation (Fig. 146.25).<sup>55</sup>

**FIG. 146.25** (A) Mixed-cell type choroidal melanoma with occasional balloon cells (*arrow*) (H&E,  $\times 100$ ). (B) The balloon cells are intermixed beyond normal-appearing melanoma cells and exhibit a large cell body

with foamy cytoplasm (H&E, ×400).

## Necrotic Melanoma

A necrotic melanoma consists of mostly necrotic cells with undetectable cytologic features (Fig. 146.26). This entity can lead to melanomalytic glaucoma, which is a rare kind of secondary open angle glaucoma in uveal melanoma occurring in the setting of spontaneous necrosis of uveal melanoma. Macrophages that phagocytose necrotic melanoma cells (melanomacrophages) accumulate in the trabecular meshwork resulting in an increased intraocular pressure.<sup>56</sup>

**FIG. 146.26** Necrotic choroidal melanoma with free cell debris, pigment and occasional still identifiable tumor cells (*arrow*; H&E, ×400).

## Retinoinvasive Melanoma

Retinoinvasive melanomas are an absolute rarity and tend to evolve from a ring melanoma.<sup>57</sup> In contrast to other diffuse growing uveal melanomas that only erode the overlying retina, this specific and obviously slow-growing type of uveal melanoma nearly replaces the retina and may infiltrate the optic nerve although it spares the choroid (Fig. 146.27).

**FIG. 146.27** Retina (*arrow*) effaced by uveal melanoma cells (H&E,  $\times 100$ ) with spindle and epithelioid cell features (inset; H&E,  $\times 400$ ). (Courtesy of Tero Kivelä, MD.)

## Histologic Changes After Treatment

### Brachytherapy

Brachytherapy has been shown by the Collaborative Ocular Melanoma Study (COMS) to be equally effective as enucleation with regard to patient survival for choroidal melanomas  $\leq 16$  mm basal diameter and 2.5–10 mm in height.<sup>58</sup> Histologic changes after brachytherapy may be studied in eyes that undergo enucleation for treatment failure or therapy-resistant neovascular glaucoma.

Histopathologic findings after brachytherapy (Fig. 146.28) include degenerative changes such as necrosis (sometimes present as hemorrhagic necrosis) with balloon cell or signet ring cell formation, vacuolization (cystic degeneration), lipoidal degeneration, and fibrosis of the tumor stroma. Viable tumor cells may be found, especially spindle cells, as epithelioid cells are more sensitive to radiation. Mitotic activity is lower than in nonirradiated tumors.<sup>59–61</sup> Vascular damage includes hyalinization of vessels walls and vascular obstruction within the tumor and the retina. The retina displays gliosis and atrophy, and an exudative retinal detachment may be present adjacent to the tumor. Subretinal gliosis, RPE irregularities and atrophy, chorioretinal atrophy, and scleral scarring/necrosis are also observed within the field of radiation.<sup>59–61</sup>

**FIG. 146.28** (A) Uveal melanoma treated with brachytherapy in a 45-year-old female patient. (B) The tumor is accompanied by a serous retinal detachment. (C) The melanoma shows typical signs of irradiation such as a “lobular appearance.” A serous retinal detachment is present (*asterisk*) (H&E, ×100). (D) Higher magnification reveals viable and necrotic tumor cells and occasional balloon cells (*arrow*) (H&E, ×400).

Inflammatory cell infiltrates and the accumulation of tumor infiltrating (melano)macrophages are also present after brachytherapy,<sup>59-61</sup> as well as macrophages in extratumoral tissue including the adjacent choroid, sclera, ciliary body, and subretinal space (Fig. 146.29).<sup>62</sup> Pigmented macrophage-related episcleral deposits are also frequently found in eyes with uveal melanoma after brachytherapy.<sup>62</sup>

**FIG. 146.29** (A) Fundus appearance of an irradiated

uveal melanoma with macular hyperpigmentations in a 43-year-old female patient. (B) Examination shows a uveal melanoma with a necrotic part (*white asterisk*) (H&E, ×40). The overlying retina displays atrophy, gliosis, and intraretinal edema (*arrow*). (C) Subretinal pigment-laden macrophages (*arrow* and inset with higher magnification) are present in the areas corresponding to the clinically detected hyperpigmentation. (Fundus photograph in panel A courtesy of Chris Bergstrom, MD, OD.)

Inadequate plaque treatment such as an undersized plaque (Fig. 146.30) or plaque tilt, as well as radioresistance of the tumor, are accounted for treatment failure with subsequent tumor growth.<sup>63,64</sup> Histopathologic evaluation may assist with the evaluation of the reason for treatment failure.

**FIG. 146.30** (A) Eye enucleated for regrowth of choroidal melanoma after brachytherapy (H&E, ×100). (B) Histologically, there is a demarcation between the irradiated necrotic part of the melanoma on the right side and viable (nonirradiated) tumor on the left side of the black line. The overlying retina displays atrophy and intraretinal edema. Higher magnification shows partly pigmented spindle cells from the nonirradiated part of the tumor (H&E, ×400).

## Proton Beam Irradiation

Proton beam irradiation shows histologic findings similar to those described for plaque brachytherapy, including degenerative changes in melanoma cells such as cytoplasmic lipid vacuoles,

pyknotic nuclei, and balloon cell formation, areas of necrosis within the tumor, vascular changes, and chronic inflammatory cell infiltrates (Fig. 146.31).<sup>55,65</sup>

**FIG. 146.31** (A) Choroidal melanoma treated with proton beam displaying small lobules of tumor cells (H&E,  $\times 400$ ). (B) Cells revealing signs of irradiation such as a swollen irregular nucleus are present (H&E,  $\times 400$ ).

## Radiation Retinopathy

Radiation retinopathy (Fig. 146.32) occurs in approximately 42% of eyes within 5 years after brachytherapy (or proton beam irradiation) for uveal melanoma and often leads to irreversible visual impairment.<sup>66</sup> Radiation retinopathy manifests an acute transudative and slowly progressive occlusive vasculopathy with nonproliferative and/or proliferative retinopathy.<sup>67,68</sup> Histologic features are characterized as an obliterative endarteritis with endothelial cell loss and capillary occlusion as the primary vascular event leading to the development of dilated capillary collaterals and microaneurysms due to limited capillary regeneration.<sup>67,68</sup> Large telangiectatic vascular channels with fibrin and exudates in their vessel wall are pathognomonic for radiation retinopathy. Because of inner retinal ischemia, the retinal parenchyma appears edematous with associated intraretinal exudates, necrosis, and gliosis. Development of proliferative radiation retinopathy as a response to severe longstanding ischemia is observed in less than 10% of irradiated eyes.<sup>69</sup>

**FIG. 146.32** (A) Histologic findings after radiation retinopathy include intraretinal cholesterol clefts (H&E,  $\times 100$ ); (B) intraretinal exudative edema (H&E,  $\times 100$ ); and (C) edema with exudates in the wall of a retinal vessel (H&E,  $\times 400$ ).

## Transpupillary Thermotherapy (TTT)

TTT is used as a primary treatment for choroidal melanoma or as an adjunct to plaque brachytherapy. Histologic findings include necrosis, cytolysis, and occluded tumor blood vessels within the tumor as well as fibrotic and degenerative changes of the retina and RPE in the area of the tumor (Fig. 146.33).<sup>70-72</sup> Signs of marked inflammation are usually not observed.<sup>72</sup> Scleral damage is usually insignificant and intrascleral tumor cells may be present after treatment and are regarded as a possible source for treatment failure.<sup>72</sup> The presence of pigment-laden macrophages in the subretinal space are also observed after TTT.<sup>73</sup> Histopathologic effects of TTT also include damage to adjacent structures and are related to both energy level and fundus pigmentation.<sup>74</sup>

**FIG. 146.33** (A) Choroidal melanoma after

transpupillary thermotherapy treatment (TTT) exhibiting areas of necrosis (*arrow*) within the tumor (H&E, ×40). (B) The retina displays degenerative changes. Higher magnification shows viable tumor cells adjacent to apoptotic cells (*arrow*) with swollen cytoplasm and a marginalized nucleus (H&E, ×400).

## Appendix: Histologic Differential Diagnoses

The histologic differential diagnoses of choroidal melanoma include:

- Nevus
- Melanocytoma
- Other choroidal neoplasms
- Choroidal metastases
- BDUMP (bilateral diffuse uveal melanocytic proliferation)
- Choroidal neovascularization (CNV) with hemorrhage.

A **choroidal nevus** represents a benign lesion and consists therefore mainly of spindle A cells with a varying degree of pigmentation (Fig. 146.34). The distinction between a choroidal nevus and a melanoma is more important with regard to an incidental finding in an enucleated or eviscerated eye, as usually only eyes with large choroidal melanomas (that are not clinically confused with a nevus) are enucleated.

**FIG. 146.34** (A) Choroidal nevus (H&E, ×40) consisting

predominantly of spindle A cells (B) (H&E, ×400).

**Melanocytomas** (synonym: magnocellular nevus) are jet-black lesions that predominantly occur on the optic nerve head. They are benign and rarely exhibit malignant transformation.<sup>11</sup> In contrast to melanocytoma of the optic disc, the diagnosis of uveal melanocytoma is rarely made on clinical appearance because of the difficulty to distinguish it from malignant melanoma.<sup>75</sup> Histology confirms the diagnosis as it reveals a tumor composed of uniform deeply pigmented cells with melanosomes (Fig. 146.35). After bleaching, round or slightly polyhedral plump cells with abundant cytoplasm and small uniform nuclei with inconspicuous nucleoli (type I cells) as well as spindle-shaped, sparsely pigmented cells (type II cells) become visible. Mitotic figures are uncommon.<sup>76</sup>

**FIG. 146.35** (A) Magnocellular nevus (melanocytoma) composed of heavily pigmented cells (H&E, ×400). (B) After bleaching, the polygonal cells with their unsuspicious nuclei are visible (bleached H&E stain, ×400).

**Other choroidal tumors** such as hemangioma or lymphoma may usually be distinguished from malignant melanoma by clinical studies such as ultrasonography. These tumors also exhibit distinct histopathologic features.

**Choroidal metastases** (Fig. 146.36) exhibit characteristics of the primary tumor (predominantly carcinomas, 82%). Most frequently found are breast (47%) and lung cancer (21%), followed by

gastrointestinal tract (4%), kidney (2%), skin (2%), prostate (2%), and other cancers (4%). There is a relatively high rate of unknown primary malignancies after systemic evaluation (17%).<sup>77</sup>

**FIG. 146.36** (A) Choroidal mass consistent with a breast carcinoma metastasis composed of tumor cells arranged in a papillomatous configuration (H&E,  $\times 40$ ). (B) Higher magnification shows glandular-like structures (H&E,  $\times 100$ ) and large tumor cells with prominent nucleoli (inset).

**Bilateral diffuse uveal melanocytic proliferation (BDUMP)** is a rare paraneoplastic syndrome with a typical clinical presentation including multiple round to oval, slightly elevated choroidal patches and an associated “leopard spot” appearance on fluorescein angiography (FA). Except for one unilateral case,<sup>78</sup> BDUMP occurs bilaterally – in contrast to choroidal melanoma. Histologic examination usually reveals a diffuse or poorly defined choroidal infiltrative process with small hypopigmented spindle-shaped benign-appearing melanocytes.<sup>79,80</sup> The choriocapillaris is often spared and the overlying RPE is depigmented (Fig. 146.37).

**FIG. 146.37** (A) Overview illustrating a bilateral diffuse uveal melanocytic proliferation (BDUMP) invading the choroid (*arrows*) (H&E). (B) The lesion effaces the entire choroid (*arrows*) but spares the choriocapillaris (H&E,  $\times 40$ ). (C) The lesion is composed of hypopigmented bland melanocytes (H&E,  $\times 400$ ).

(Courtesy of Curtis E. Margo, MD.)

CNV with an associated large hemorrhage may exhibit a fundusoscopic appearance similar to choroidal melanoma, although the two may be distinguished by clinical tests including ultrasonography, FA, and optical coherence tomography (OCT).

# Introduction

Posterior uveal melanoma is a serious, life-threatening malignancy.<sup>1-83</sup> It is estimated that approximately 7095 cases of uveal melanoma are detected annually, with 4747 in white non-Hispanic, 738 in Hispanic, 1286 in Asian, and 316 in black patients.<sup>2</sup> In the United States the mean age-adjusted incidence of uveal melanoma is 4.3 per million.<sup>3</sup> This figure has remained relatively stable over the past five decades. Comprehensive clinic-based analysis has revealed that this malignancy tends to occur in whites at a mean age of 58 years with symptoms of photopsia, floaters, visual field loss, or visual acuity loss.<sup>1,4</sup>

There have been numerous publications on the management of uveal melanoma and this topic remains controversial.<sup>1-83</sup> Depending on the clinical circumstances, observation, transpupillary thermotherapy, plaque radiotherapy, charged particle irradiation, external resection (exoresection), internal resection (endoresection), enucleation, orbital exenteration, systemic chemotherapy, and systemic immunotherapy are alternatives.<sup>1,5,6</sup> There is a trend toward detection of melanoma at its earliest stage using multimodal imaging rather than relying strictly on ophthalmoscopy. Imaging with fundus photography, spectral domain and swept source optical coherence tomography, autofluorescence, multispectral imaging, and ultrasonography are critical for early tumor detection, sometimes even at a point when the tumor is almost subclinical. Clinical risk factors for tumor growth and metastasis for the smallest choroidal melanocytic lesions have been identified and are useful for determining the malignant potential of a small mass and deciding when to treat.<sup>7-10</sup> Consequently, there is an evolving trend away from observation of suspicious small melanocytic lesions and towards earlier treatment of lesions with risk factors.<sup>8,9,11</sup> This introductory chapter provides an overview of the current methods for management of patients with ciliary body and choroidal melanoma. In the subsequent chapters, several authorities address the specific details of the

various therapeutic modalities.

The general concepts discussed here are based on personal experience in the field of uveal melanoma management at the Ocular Oncology Service at Wills Eye Hospital for more than 40 years. This experience, combined with a review of the literature, has been written as objectively as possible, but our opinion could be different than the opinions of others.

## General Considerations

Historically, enucleation was once considered to be the only appropriate management for a patient with a posterior uveal melanoma.<sup>5</sup> At that time, most patients presented late in the course with large melanoma, retinal detachment, secondary glaucoma, and often extrascleral extension of the tumor, at a point when enucleation was the only option. Several years ago, however, some authorities challenged the effectiveness of enucleation for prevention of metastatic disease and even proposed that enucleation could somehow promote or accelerate metastasis, an idea termed the “Zimmerman hypothesis.”<sup>12,13</sup> The validity of those arguments was soon challenged by others, who believed that early enucleation offered the patient the best chance of cure.<sup>14,15</sup> This controversy over enucleation was responsible for initiating a trend away from enucleation and the increasing use of more conservative therapeutic methods. One-quarter century later, this hypothesis was reevaluated and, based on clinical, epidemiologic, statistical, and experimental data, the transient rise in posttherapeutic mortality was confirmed, but the authors believed it was not likely due to enucleation but more plausibly a result of early micrometastasis of uveal melanoma before therapy.<sup>16</sup>

Depending upon several clinical factors, the most common methods of management today include observation, transpupillary thermotherapy (TTT), radiotherapy, local resection, enucleation, orbit exenteration, and various combinations of these methods. There is currently an increasing variety of methods to treat or prevent metastatic disease that are beyond the scope of this short chapter. The most frequently employed treatment methods today are radiotherapy and enucleation. The Collaborative Ocular

Melanoma Study (COMS) was organized to address several clinical and therapeutic issues related to posterior uveal melanoma and important information has been obtained from that study.<sup>17-23</sup> Nevertheless, each case must be individualized and the recommended treatment should be the most suitable to provide the best systemic prognosis, while preserving as much vision as possible. If possible, the patient should be referred to an ocular oncologist or other ophthalmologist who has experience in managing patients with uveal melanoma.

## Periodic Observation

Most small melanocytic tumors ( $\leq 3$  mm thickness) are best managed by periodic fundus photography and imaging with optical coherence tomography, autofluorescence, and ultrasonography to document lesion stability or growth. Stable lesions are monitored every 4–6 months and thereafter on a 6–12-month basis. Long-term monitoring for all choroidal melanocytic lesions, including freckle, nevus, or inactive larger lesions, should be advised.

Factors statistically predictive of growth of a small melanocytic lesion have been identified (Table 147.1). Lesions with documented growth or those with three or more risk factors are generally considered for treatment<sup>1,8-11</sup> (Table 147.1). Identified risk factors for metastasis from small melanoma ( $\leq 3$  mm thickness) include tumor thickness  $> 2$  mm, tumor within 3 mm of the optic nerve, presence of visual symptoms from the melanoma, and prior documented growth.<sup>8</sup> Since documented growth can be associated with a worse systemic prognosis, there is a trend to treat patients with risk factors, without necessarily waiting for documentation of growth.<sup>8,9,11</sup>

**TABLE 147.1**

**Factors for Early Detection of Choroidal Melanoma: the TFSOM–UHD Mnemonic (to Find Small Ocular Melanoma – Using Helpful Hints Daily)**

Hazard	Nevus Growth Into	Nevus Growth Into
--------	-------------------	-------------------

Initials	Mnemonic	Features	Ratio <sup>a</sup>	Melanoma if Feature Present (%)	Melanoma if Feature Absent (%)
T	To	Thickness > 2 mm	2	19%	5%
F	Find	Fluid	3	27%	5%
S	Small	Symptoms	2	23%	5%
O	Ocular	Orange pigment	3	30%	5%
M	Melanoma	Margin $\leq$ 3 mm to disc	2	13%	4%
UH	Using Helpful	Ultrasound hollow	3	25%	4%
H	Hints	Halo absent	6	7%	2%
D	Daily	Drusen absent	na	na	na

na, The risk factor of drusen absent was identified in other studies to be significant so it was included in this mnemonic for risk factors.

Adapted from information listed in Shields et al.<sup>9</sup>

## Laser Photocoagulation

Laser photocoagulation was once a commonly used method to treat small choroidal melanomas.<sup>24-28</sup> It was originally performed with xenon arc photocoagulation but argon laser and diode laser subsequently became more commonly employed. Studies showed that xenon photocoagulation achieved better tumor control but argon laser was associated with fewer complications.<sup>25</sup> More recently, TTT and photodynamic therapy (PDT) have largely replaced laser photocoagulation for treatment of selected small melanomas that are less than 3 mm in thickness and located more than 3 mm from the foveola.<sup>20</sup>

## Transpupillary Thermotherapy

Transpupillary thermotherapy (TTT) is a recently popularized method of treating selected small and medium-sized choroidal melanomas using subphotocoagulation heat in the infrared range using a modified diode laser delivery system.<sup>29-33</sup> This method does not produce as much damage to the sensory retina as does laser photocoagulation. Recent observations have clarified the limitations and complications of TTT.<sup>33,34</sup> Currently, our strategy for primary

TTT includes low-grade melanocytic borderline tumors outside the macular and juxtapapillary region and those with only one or two risk factors.<sup>34</sup> Tumors with greater number of risk factors should be treated with methods other than TTT.<sup>34</sup> TTT is used frequently as a supplement to plaque radiotherapy.<sup>32</sup>

## Photodynamic Therapy

PDT involves the coupling of a light-activating photosensitizing dye, verteporfin, that leads to free radicals causing vascular occlusion and other toxic effects at the cellular level. This method has been found useful for amelanotic tumors, and even for selected amelanotic melanoma.<sup>35</sup>

## Radiotherapy

Radiotherapy is still the most widely employed treatment for posterior uveal melanoma. The most commonly used form of radiotherapy has been the application of a radioactive plaque.<sup>6,18-22,36-42</sup> Several years ago, most melanomas were treated with a cobalt-60 plaque.<sup>36</sup> Today, iodine-125 and ruthenium-106 plaques have replaced Cobalt-60 at most institutions due to their lower radioactivity, improved tumor control, and fewer complications.<sup>6,37-42</sup> The COMS found that plaque radiotherapy provided equivalent tumor control compared to enucleation for medium-size melanoma.<sup>21</sup> The COMS did not address plaque radiotherapy control of small or large melanomas, but studies have shown that iodine-125 is effective for various tumor sizes and even those in the ciliary body, those with extrascleral extension, and those with juxtapapillary, epipapillary, and circumpapillary tumors.<sup>6,37-45</sup> Enucleation is generally advised for eyes that fail plaque radiotherapy.<sup>46,47</sup>

Another method of radiotherapy is charged particle irradiation.<sup>48-53</sup> This technique can provide a collimated beam to theoretically limit radiotherapy to the precise area of the tumor, but clinical experience shows radiation retinopathy and papillopathy can occur, similar to plaque radiotherapy.<sup>51</sup> Compared to plaque radiotherapy, proton beam radiotherapy provides similar results

for tumor control, globe salvage, visual outcomes, and patient survival. On the basis of published information, patients treated with radiotherapy have a survival rate similar to those treated by enucleation.<sup>21</sup> Furthermore, there is probably no significant difference between plaque radiotherapy and charged particle radiotherapy with regard to short-term and long-term complications. Studies have shown that between 5% and 10% of patients treated with radiotherapy ultimately require enucleation because of tumor recurrence or radiation complications.<sup>46,47</sup>

## Local Resection

Local resection of melanoma involving the ciliary body and choroid continues to be popular in some centers.<sup>54–58</sup> Our technique of partial lamellar sclerouvectomy without retinectomy has been successful for removal of ciliary body and peripheral choroidal melanoma, leaving the retina and vitreous intact, often with excellent visual acuity.<sup>54,56</sup> This modality is especially suitable for thick tumors to avoid long-term radiation consequences.<sup>57</sup>

Local resection of a posterior uveal melanoma offers several theoretical advantages over enucleation and radiotherapy. In contrast to enucleation, it is designed to preserve vision and to maintain a cosmetically normal eye. In contrast to radiotherapy, theoretically it has fewer long-term complications if the initial surgery is successful. However, it does have more potential immediate complications, such as vitreous bleeding, retinal detachment, and cataract, while radiotherapy is almost never associated with such immediate complications. Furthermore, local recurrence is greater following resection compared to radiotherapy, especially for thick tumors.<sup>57</sup> However, some degree of retinopathy and cataract are common long-term complications of all forms of therapy. There is no current evidence that local resection of posterior uveal melanomas is any different from enucleation or radiotherapy with regard to patient survival.

Some authorities have reported experience with endoresection of choroidal melanoma, by removing tumor with a vitrectomy approach, and a few authorities are now using endoresection to remove choroidal melanoma after charged particle irradiation.<sup>59–62</sup>

remove choroidal melanoma after charged particle irradiation.<sup>59-62</sup> In selected cases, endoresection can reduce the long-term risk of neovascular glaucoma.<sup>62</sup> Long-term follow-up will be necessary to determine the validity of endoresection techniques.

## Enucleation

As mentioned earlier, the traditional method of treating uveal melanoma by enucleation was challenged several years ago.<sup>12,13</sup> Others continued to believe that enucleation was an appropriate method of management.<sup>14,15</sup> Enucleation is generally indicated for advanced melanoma that occupies most of the intraocular structures and for those that have produced secondary glaucoma or extraocular extension. Another relative indication for enucleation is a melanoma that has invaded the optic nerve, in which removal of a long section of the optic nerve with the globe seems more reasonable. However, many juxtapapillary melanomas, that have not actually invaded the nerve, can be managed by custom-designed notched radioactive plaques.<sup>41-43</sup> The so-called “no touch enucleation” was introduced years ago to minimize surgical trauma and theoretically to lessen the chance of tumor dissemination at the time of surgery.<sup>63</sup> An essential aspect of this technique was to freeze the venous drainage from the tumor prior to cutting the optic nerve. The “no touch” technique has been modified to a minimal manipulation technique of enucleation without the use of the cryoprobe.<sup>64-67</sup>

There have been recent advances in the types of orbital implants used following enucleation. The polymer-coated hydroxyapatite implant or polyethylene implant, designed to improve ocular motility in patients undergoing enucleation, is still used widely.<sup>64-67</sup>

Pre-enucleation radiotherapy (PERT) had been advocated by some authorities, using 2000 cGy of external beam radiotherapy to the affected eye to reduce risk for tumor dissemination at enucleation. Data from the COMS have supported prior nonrandomized studies that suggested that PERT is not advantageous over standard enucleation alone.<sup>18</sup>

The subject of orbital exenteration for uveal melanoma with extrascleral extension is also controversial.<sup>68,69</sup> Orbital exenteration should not be performed in cases of mild extrascleral extension <3 mm as this can be successfully controlled with radiotherapy.<sup>39</sup> However, in the rare instance of massive orbital extension in a blind, uncomfortable eye, primary orbital exenteration is justified. In most instances of orbital extension of uveal melanoma, it is not necessary to sacrifice the skin of the eyelid. The eyelid-sparing exenteration skin provides a satisfactory cosmetic appearance.<sup>68,69</sup>

## Genetic Testing

Cytogenetic analysis of uveal melanoma using DNA or RNA methods can add to the confirmation and prognostication of uveal melanoma.<sup>70-77</sup> Sampling for genetic prognostication is performed at the time of treatment. Regarding DNA evaluation, original work in 1996 demonstrated that uveal melanoma in enucleated eyes often showed chromosome 3 monosomy and this imparted poor prognosis.<sup>72</sup> Others found additional mutations in chromosome 8 (53%), chromosome 6 (46%), and chromosome 1 (24%) and concluded that monosomy 3 and largest tumor diameter were the most significant factors in determining patient survival.<sup>73,74</sup> An evaluation of 452 choroidal melanomas for DNA using multiplex ligation-dependent probe amplification (MLPA) revealed high predictive value with 10-year melanoma-related mortality of 0% for those with disomy compared to 55% for those with monosomy 3 and 71% for those with monosomy 3 plus 8q gain.<sup>74</sup> An analysis of 500 consecutive eyes with melanoma sampled by fine-needle aspiration biopsy at the time of radiotherapy concluded that tumors with complete monosomy 3 showed 3-year cumulative probability of metastasis at 0% for small, 24% for medium, and 58% for large melanomas.<sup>75</sup>

Regarding RNA evaluation, gene expression profiling (GEP) has been employed. This technique is a measure of genetic material within melanoma using messenger RNA expression from multiple genes. In 2003, GEP with 12,500 probes identified two groups of melanoma that correlated with monosomy 3 and disomy 3 tumors.<sup>76</sup> In 2004, GEP confirmed the presence of two classes of

melanoma in which class 1 (low grade) showed 95% survival and class 2 (high grade) showed only 31% survival at 8 years.<sup>77</sup> Further refinements of both DNA and RNA testing have allowed for remarkable predictive value.

## Management of Systemic Metastasis

Ideally, the best management of uveal melanoma would be to use methods of prevention of micrometastasis in the early stages of this malignant intraocular disease.<sup>5</sup> There are currently trials for high-risk patients based on cytogenetic testing. Patients found to have chromosome 3 monosomy by DNA testing or those with class 2 by RNA testing are entered into therapeutic trials.<sup>71-77</sup> In one trial of prophylactic sunitinib (Sutent) for prevention of melanoma metastasis, improved overall survival was found compared to observation.<sup>78</sup> Studies to further interest in prevention of metastasis based on cytogenetic or tumor markers are underway.

Most patients with uveal melanoma have no detectable evidence of systemic metastasis at the time of diagnosis of the uveal melanoma. However, it is believed that micrometastatic disease occurs early in the course of melanoma, thus neoadjuvant therapy should be considered for those at high risk. Once a uveal melanoma has metastasized to liver and other organs, the patient's prognosis is poor. If the metastasis occurs as a solitary lesion, increased survival has been achieved with local resection of the metastatic focus.<sup>79</sup> Most previous general chemotherapy protocols have provided little response with melanoma metastasis. One trial with selumetinib found slight improved outcomes compared to standard chemotherapy for metastatic disease.<sup>80</sup>

Targeting of embolized chemotherapy, immunotherapy, and local radiotherapy through the hepatic artery for liver metastasis has provided some promise.<sup>81,82</sup> Recent studies have provided hope that chemoembolization and immunoembolization may prolong survival<sup>81,82</sup> but further research is needed to determine the efficacy. Buder et al. reviewed systemic therapies for metastatic uveal melanoma by searching all published reports on Pubmed/Web of Knowledge database and the American Society of Clinical Oncology website between 1980 and 2013 and identified 40 studies

with 841 evaluable patients.<sup>83</sup> They found complete or partial remission (overall response rate, ORR) to be poor at 4.6% and median overall survival was 5.2 to 19.0 months. Patients with best responses occurred following chemoimmunotherapy (ORR 10.3%). They indicated that immunotherapy or innovative treatment strategies should be explored to improve the poor ORR.

There are few studies on immunotherapy for metastatic uveal melanoma. Bol et al. treated 14 patients with metastatic uveal melanoma with autologous dendritic cell vaccination and found tumor-specific immune response in 4 (29%) and median patient survival of 19.2 months, longer than other therapies.<sup>84</sup> Ipilimumab, an immune-stimulating medication that works at the T-cell level by inhibiting cytotoxic T-lymphocyte associated protein 4 (anti-CTLA-4), has been studied for uveal melanoma. Maio et al. treated 82 patients with metastatic uveal melanoma that failed previous treatments using ipilimumab and found 5% demonstrated a response and 29% had stable disease lasting 3 months or more, with median overall survival at 6 months.<sup>85</sup> Luke et al. reported a multicenter retrospective analysis of 39 patients with uveal melanoma metastasis treated with ipilimumab and found response (tumor regression plus stable disease) in 28% at week 23 and overall survival at 9.6 months, but adverse events occurred in 71% of patients.<sup>86</sup> Joshua et al. studied an analogous medication, tremelimumab (anti-CTLA-4 agent) and published similar modest response rates. These reports indicate that ipilimumab/tremelimumab should be further explored regarding their exact role for uveal melanoma therapy.<sup>87</sup>

On the treatment horizon is the use of T-cell immunomodulation to engineer these cells to identify and then lyse cancer cells.<sup>70</sup> This strategy is used for some types of leukemia and now for cutaneous melanoma. Hopefully this will be applicable for uveal melanoma in the near future.

## Counseling the Patient

Regardless of the method of management selected by the clinician, it is important that the affected patient be informed of all available options. The expected results and potential complications should be

explained to the patient and family members in detail. The patient should be informed of the availability of a second opinion from other physicians familiar with uveal melanoma. The final decision regarding management should be made by the patient with guidance of his or her physician.<sup>88</sup>

## Conclusion

This chapter has provided an update on some general principles of management of posterior uveal melanoma. Small asymptomatic melanocytic tumors of the posterior uvea that exhibit lack of clinical risk features can be observed periodically without intervention. Imaging with fundus photography, optical coherence tomography, autofluorescence, and ultrasonography is important in conservative follow-up. Small choroidal melanoma that show several clinical risk factors or documented growth are provided therapy.

Transpupillary thermotherapy is employed for low-grade melanocytic tumors. Radiotherapy is reserved for active tumors and is delivered by episcleral plaque brachytherapy or charged particles. Selected melanomas of the ciliary body and peripheral choroid can be treated by local resection techniques. Local resection has theoretical advantages, but the surgery takes longer and the immediate complications are potentially greater.

Enucleation is generally indicated for most large melanomas, greater than 20 mm in diameter and greater than 12 mm in thickness. It is also generally indicated for tumors that have invaded the optic nerve. Pre-enucleation radiotherapy does not appear to improve patient survival.

Orbital exenteration is justified for advanced uveal melanoma with massive extraocular extension. Its value in the management of smaller degrees of extraocular extension is uncertain.

The future of uveal melanoma therapy will be focused on earliest detection of the tumor with multimodal imaging at a point where the tumor is perhaps only 1–2 mm in thickness and amenable to minimally invasive local therapy. Systemic treatment for high-risk patients, as identified by cytogenetic markers or cell membrane markers, with targeted chemotherapy or immunotherapy to prevent metastasis will be provided. Targeted therapies designed to

markers, with targeted chemotherapy or immunotherapy to prevent metastasis will be provided. Targeted therapies designed to recognize cell membrane markers or to stimulate the immune system using T cells against cancer could provide improved patient survival.

Special Considerations

Optic Nerve Invasion and Limited Extrascleral  
Extension

Complications

## **Conclusion**

## Introduction

Approximately 5% of all melanomas occur in the eye and surrounding adnexal structures, and 85% of these are uveal in origin.<sup>1</sup> Uveal melanomas are the most common primary intraocular malignant tumor.<sup>2</sup> According to one report, the overall incidence of uveal melanomas is 5.1 per million and 80–90% of uveal melanomas involve the choroid.<sup>3</sup>

Forty years ago, Zimmerman investigated the benefit of enucleation in eyes with choroidal melanoma.<sup>4</sup> He observed a peak in mortality 2–3 years after enucleation and suggested that the rise of post-enucleation mortality was a direct result of the enucleation.<sup>4</sup> This controversy led to the trend away from enucleation towards vision and eye-sparing treatments. Subsequent studies have demonstrated that the observed post-enucleation rise in mortality was a reflection of the natural history of the primary tumor and its metastases rather than direct effects of enucleation causing iatrogenic tumor seeding. Metastasis was independent of the method of treatment.<sup>5</sup>

For the treatment of the primary tumor, there are many therapeutic options, such as observation, transpupillary thermotherapy, plaque radiotherapy, local resection, and enucleation.<sup>2</sup> In the United States the two most frequently used methods of treatment are plaque radiotherapy and enucleation.<sup>2</sup> The Collaborative Ocular Melanoma Study (COMS) demonstrated no statistical difference in all-cause mortality between the brachytherapy and enucleation arms in either medium or large choroidal melanomas.<sup>6</sup>

As mortality data show, there is no significant difference between enucleation and brachytherapy, therefore, quality-of-life (QOL) measurements become important in deciding on a therapeutic plan. The COMS ascertained QOL measures of driving difficulties, near vision activities, activities requiring stereopsis, anxiety levels, and depression levels.<sup>7</sup> Patients reported higher levels of function for driving and peripheral vision in the brachytherapy arm compared to the enucleation arm for the first 2 years following treatment, but these differences diminished 3–5 years after treatment.<sup>7</sup> Patients in the brachytherapy arm also had more symptoms of anxiety after

treatment compared with the enucleation group.<sup>7</sup> Enucleation still remains a viable treatment option for choroidal melanoma in the proper setting.

The COMS group demonstrated a cumulative metastasis rate of 25% at 5 years and 34% at 10 years.<sup>8</sup> Once metastasis occurs, the median survival time is 3.6 months, and death is almost always inevitable as there are no effective treatment options at present.<sup>8,9</sup>

## Purpose of Enucleation

Enucleation should remove malignancy with clear margins and restore cosmesis by allowing for the comfortable use of an ocular prosthesis coupled to an underlying orbital implant.

## Indications

The main indications for primary enucleation are large tumor size, neovascular glaucoma, optic nerve invasion, blind painful eye, localized extrascleral extension, and patient preference. Enucleation is also considered for the treatment of medium-sized choroidal melanoma with poor vision (<20/400) or absence of potential for visual recovery. Functional status of the other eye and patient preference are also important considerations in the decision-making process. The indications for secondary enucleation are local treatment failure and ocular pain secondary to radiation-related complications.

## Implant Description

An ideal implant should restore volume, transmit motility, possess a low complication rate, and demonstrate cost-effectiveness.<sup>10</sup> To transmit motility, the extraocular muscles should attach to the implant directly or surround the implant indirectly.<sup>10</sup> An implant of proper size restores volume.<sup>11</sup> Current orbital implant designs fall into two general categories: solid spheres and porous, integrated implants. Solid spheres include silicone and polymethyl methacrylate (PMMA), while porous implants include coralline hydroxyapatite and porous polyethylene.<sup>10</sup> Bioceramic and other

implants also exist.<sup>10</sup> Porous materials allow for fibrovascular ingrowth which may induce epithelization of a drill hole to accept a prosthesis coupling peg to improve motility. Pegged hydroxyapatite implants offer subjective improved motility over unpegged implants and vascular ingrowth possesses some theoretical advantages, including decreased rates of infection, exposure, and extrusion.<sup>10,12</sup>

Coralline hydroxyapatite (HA) is a porous, nontoxic implant composed of inorganic, nonreplenishable marine coral.<sup>13</sup> High-density porous polyethylene is a porous, synthetic implant that can be molded into various shapes.<sup>14</sup> Hydroxyapatite has a brittle nature, which precludes direct suturing to the implant surface.<sup>15</sup> Pore sizes and interconnectivity vary, which could affect vascularization.<sup>16</sup> Some surgeons drill holes into porous implants to facilitate integration.<sup>17</sup> The use of porous materials adds additional costs of the implant, wrapping material, and imaging studies, and possesses higher complication rates.<sup>18</sup>

Some surgeons wrap porous implants to protect the anterior tissues from hydroxyapatite bone spicules and to facilitate muscle attachment and implantation. However the perceived benefits have not been proven.<sup>15</sup> Wrapping materials include donor sclera, autogenous fascia, or polyglycolic acid mesh. While some surgeons wrap porous polyethylene implants, the extraocular muscles can be directly sutured to polyethylene.<sup>19,20</sup> Wrapping materials may pose infection risk and decrease vascularization rates.<sup>17</sup>

When surveyed in 1995, the majority (56%) of the American Society of Ophthalmic Plastic and Reconstructive Surgeons (ASOPRS) preferred hydroxyapatite implants and human donor sclera wrapping in enucleations.<sup>21</sup> When resurveyed in 2002, the majority (43%) of ASOPRS surgeons preferred porous polyethylene and only 27% preferred hydroxyapatite.<sup>18</sup> In the later survey, most implants (60%) were not wrapped and only 25% were wrapped in human donor sclera.<sup>18</sup> The majority (92%) of implants were left unpegged.<sup>18</sup> In 2007, a survey from the UK supported these trends, demonstrating that 55% of surgeons used porous implants, 57% wrapped the implant (with autogenous sclera being most popular; 20%), and only 7% pegged the implants.<sup>22</sup> Custer<sup>23</sup> demonstrated no significant difference in motility between unpegged hydroxyapatite

and solid implants and Harbour et al.<sup>24</sup> demonstrated no significant differences in complication rates between patients receiving donor sclera-wrapped hydroxyapatite and polyethylene orbital implants. The potential advantages of using porous implants and wrapping materials should be weighed against the risks, morbidity, and additional cost.<sup>20</sup> If the surgeon does not plan to peg, if the patient has systemic illnesses or factors that may limit fibrovascular ingrowth, or if a porous implant may not improve a patient's quality of life, the surgeon should give consideration to a solid implant.

## Implant Sizing

Proper implant sizing is essential for cosmesis, volume restoration, and to minimize extrusion, exposure, and sulcus deformities. Most adult patients require at least a 20 mm implant. Traditionally, surgeons use a set of sizing spheres to individualize implant size and use standard volume tables to maximize volume restoration. Alternatively, orbital implant size can be determined using the contralateral eye axial length measurements subtracted by 2 mm, or by 3 mm for hyperopia.<sup>11</sup> Another algorithm subtracts the volume of an ideal 24 mm eye by the volume of sclera and 2 mL to determine implant volume.<sup>25</sup>

## Enucleation Technique

Enucleation techniques vary but all employ certain principles. Enucleation is usually performed under general anesthesia. However, local anesthesia with monitored anesthesia care can also be used in conjunction with a supraorbital nerve, an infraorbital nerve, and a modified van Lint block. In either case, analgesia and improved hemostasis may be achieved with a retrobulbar or peribulbar block consisting of 3–4 mL of 1% lidocaine with 1 : 100 000 epinephrine and 8.4% sodium bicarbonate in a 1 : 10 ratio with 50 units per 10 mL of hyaluronidase. An additional 1 mL of the same solution is injected subconjunctivally. The surgeon must avoid penetration or perforation of the eye with the needle.

The authors' technique is as follows: A 360° peritomy is created

with blunt Westcott scissors. Conjunctiva and the Tenon layer are dissected from underlying sclera using Stevens scissors (Fig. 148.1). The Stevens scissors are used to bluntly dissect in each oblique quadrant (Fig. 148.2), and each rectus muscle is isolated on a muscle hook. The Tenon layer attachments to the rectus muscles are stripped and the muscle is secured on a double armed 6–0 polyglactin 910 suture through its insertion. Each muscle is disinserted from the globe using blunt Westcott scissors or Abley scissors (Fig. 148.3).

**FIG. 148.1** A 360° peritomy is performed using blunt Westcott scissors.

**FIG. 148.2** Stevens scissors are used to bluntly dissect into each oblique quadrant.

**FIG. 148.3** Each rectus muscle is isolated on a muscle hook, secured using 6-0 polyglactin suture, and disinserted using blunt Westcott scissors or Abley scissors.

The inferior oblique muscle insertion is identified and isolated with a muscle hook in the inferotemporal quadrant. To minimize

bleeding, the inferior oblique muscle is cauterized prior to transection. The superior oblique muscle is then identified in the superomedial quadrant and cut.

A muscle hook is swept against the globe to identify any remaining attachments that require lysis, and a rent is created in the posterior Tenon layer using Stevens scissors. To maintain hemostasis, the optic nerve may be clamped with a long curved hemostat. The hemostat is inserted with the blades closed to palpate and strum the optic nerve prior to clamping. A second hemostat or locking toothed forceps is placed over the medial rectus muscle stump to assist in elevating the globe. The optic nerve is transected using enucleation scissors, and the globe is removed using the hemostat or forceps on the medial rectus stump. The optic nerve stump is cauterized with the bipolar cautery unit under direct visualization using malleable retractors.

The orbital implant is placed using an injector or periosteal elevators with modest posterior digital pressure. If the implant is wrapped, then four windows can be created just posterior to the rectus muscle attachments. If a wrapping material is not employed, the muscles are sutured directly to or over the implant. Direct attachment of the vertical recti muscles to each other may lead to fornix insufficiency. We suture each rectus muscle to the adjacent rectus muscle suture using a 4-0 polyglactin 910 suture to create a physiologic attachment of the extraocular muscles over the implant with a diameter of approximately 10 mm (Fig. 148.4). The anterior Tenon layer is closed using a running 4-0 polyglactin 910 suture (Fig. 148.5). Finally, the conjunctiva is closed using a running 6-0 plain gut suture (Fig. 148.6).

**FIG. 148.4** A suitable-sized implant is placed using an injector or periosteal elevators and the muscular attachments are sutured onto the implant.

**FIG. 148.5** Tenon layer is closed in running fashion.

**FIG. 148.6** The conjunctiva is sutured in running fashion, creating a multilayered closure.

Antibiotic ointment and a small plastic conformer are placed into the socket and the eyelids are sutured closed using a 6-0 Prolene suture. A pressure patch is placed for one week.

## Special Considerations

### Optic Nerve Invasion and Limited Extrascleral Extension

Overall, choroidal melanoma rarely invades the optic nerve.<sup>26</sup> The COMS demonstrated extrascleral extension in only 8.2% of 1527 enucleated eyes.<sup>27</sup> Limited extrascleral extension does not contraindicate enucleation. However, the approach to the optic nerve transection may have to be modified if there is evidence of limited extrascleral extension. Limited extrascleral extension may be suspected based on echographic or radiologic imaging.<sup>28</sup> It is recommended that the quadrant opposite to the extrascleral extension be used to introduce the enucleation scissors so as to avoid transecting the extrascleral extension. In some cases, greater access to the posterior orbit may be obtained via lateral orbitotomy approach to transect the optic nerve and for en bloc removal of the extrascleral extension.<sup>29,30</sup>

## Complications

Complications of enucleation are rare and include pyogenic granuloma, conjunctival inclusion cyst formation, conjunctival wound dehiscence causing exposure or extrusion, implant displacement or migration, infection, orbital hemorrhage, socket contracture, and ptosis.<sup>18,31</sup> In the COMS large tumor trial, patients who received pre-enucleation radiation had an overall complication rate of 8% and patients who had not received radiation had a complication rate of 4%.<sup>31</sup>

Additional complications of pegged implants include peg malposition, peg cracking, and an audible peg click.<sup>18</sup> Reports on overall complication rates vary widely for porous and nonporous implants and for pegged and unpegged implants. However, general trends among the various implant choices exist.

Nunery et al. demonstrated a higher exposure rate in HA versus silicone implants.<sup>32,33</sup> Exposed porous implants may not extrude as often as solid implants because of fibrovascular ingrowth, but nearly all exposures ultimately require repair.<sup>32</sup> Exposure rates range from 0% to 33.3% for porous implants.<sup>13,34-40</sup> The American Society of Ophthalmic Plastic and Reconstructive Surgery (ASOPRS) survey revealed an exposure rate of only 3% with the majority (81 of 82) of events occurring with porous implants rather than solid implants.<sup>18</sup> A meta-analysis of exposure rates of all implants demonstrated a 1.3% (2/153 cases) rate with silicone, a 4.9% rate (96/1959 cases) with coralline hydroxyapatite, and an 8.1% rate (41/507 events) with porous polyethylene.<sup>35</sup> For pegged implants, all complication rates are greater, including pyogenic granuloma formation (14%), exposure (6%), infection (5%), and peg malposition (5%).<sup>18</sup> Fay et al. evaluated the necessity and usefulness of prophylactic postoperative antibiotics in patients undergoing enucleation in 435 patients and found no statistical difference in postoperative infection rate between those who received antibiotics to those who did not.<sup>41</sup>

## Conclusion

Enucleation is the typical treatment option for eyes with large tumors, limited extrascleral extension, optic nerve invasion, and

blind painful eyes secondary to neovascular glaucoma or postradiation effects. Enucleation is also considered for treatment of medium-sized choroidal melanoma with poor vision (<20/400) or absence of potential for visual recovery. Functional status of the other eye and patient preference are also important considerations. Various implant options after enucleation exist. Porous implants have theoretical advantages that have not delivered as much benefit as anticipated. Currently, most surgeons choose not to peg implants despite the higher morbidity associated with porous implants. Nonporous implants represent a safe and cost-effective option.

## Conclusion

## Introduction

Brachytherapy is the application of radiation from isotopes over very short distances in contact with a surface. The goal of ocular brachytherapy is to deliver a curative dose of radiation to the tumor while delivering the least possible dose of radiation to normal ocular structures.

Treatment of choroidal melanoma with brachytherapy was first reported by Moore in 1930.<sup>1</sup> These early studies by Moore with radon seeds paved the way for the use of other forms of radiation at clinical centers around the world, including cobalt-60,<sup>2-5</sup> ruthenium-106,<sup>6-8</sup> gold-198,<sup>9</sup> iodine-125,<sup>10-18</sup> and palladium-103.<sup>19-21</sup> Iodine-125 (I-125) is currently the most commonly used isotope in brachytherapy for choroidal melanoma in the United States, whereas ruthenium-106 and palladium-103 continue to be popular at some centers. Brachytherapy offers an alternative to enucleation in the treatment of choroidal melanoma, allowing globe-salvaging with the possibility of maintaining useful vision. The Collaborative Ocular Melanoma Study (COMS) was a prospective, randomized study that provided clinicians with statistically sound evidence supporting the use of radiation in the treatment of choroidal melanoma. The study investigated more than 1300 patients with medium-sized melanoma and randomized to I-125 brachytherapy or enucleation.<sup>22</sup> After 12 years of follow-up, there was no statistically significant difference between these two modalities of treatment with regard to mortality.<sup>22,23</sup> Although treatment protocols and selection of tumors for plaque treatment must be individualized and differ among clinical centers, generally acceptable indications for plaque brachytherapy include (1) selected small choroidal melanomas exhibiting growth or malignant transformation; (2) medium-sized choroidal and ciliary body melanomas in eyes with visual potential; (3) large melanomas with

dimensions up to 16 mm in diameter and 8–10 mm in thickness; and (4) larger melanomas, especially in monocular patients. However, despite success in sparing enucleation, radiation has profound effects on the surrounding retina and optic nerve, with vision limited by the resulting radiation retinopathy and optic neuropathy.<sup>24–28</sup> These complications can have profound effects on quality of life, with 209 patients from the COMS reporting no significant difference in visual function 3–5 years posttreatment for plaque brachytherapy versus enucleation.<sup>29</sup> Continued research and investigation are needed to identify efficacious supplemental therapies for these universally common radiation-related complications.

Although enucleation can still be considered for choroidal melanomas, the COMS study laid the framework for the adoption of globe-salvaging treatment modalities by providing evidence for the efficacy of plaque brachytherapy. As a result, clinicians can confidently recommend radiation to patients, offering a treatment to save the eye as well as a chance at maintaining some useful vision. However, despite the lack of difference in survival between the two treatments, metastatic death continues to occur in a significant percentage of patients. Further research is needed to develop adjuvant therapies to alter this disturbing statistic.

## Dosimetry

The optimal tumoricidal radiation dose for uveal melanoma remains unclear,<sup>30,31</sup> but doses range between 50 and 100 Gy, with doses less than 50 Gy being associated with significant treatment failures.<sup>30</sup> Kindy-Degnan et al.<sup>32</sup> used helium ion radiation and reported on tumor apex dosages ranging between 50 and 80 Gy, showing that regardless of whether 50, 60, 70, or 80 Gy was used, there were no differences in tumor regression, survival, complications, or visual outcomes. Initially, the COMS decided to deliver 100 Gy to the tumor apex with a delivery rate of 50–125 cGy/h (tumors <5 mm in height are managed as if they were 5 mm thick).<sup>33</sup> However, in 1996, based on newer dosimetric measurements and the recommendations of the American Association of Physicists in Medicine (AAPM), the COMS modified

the prescription dose to deliver 85 Gy to the tumor apex with a delivery rate of 43–105 cGy/hour.<sup>34</sup> Based on these modifications, with the AAPM-recommended calculation and revised prescription dose, the actual dose delivered to the tumor is the same. As a result, when analyzing studies prior to 1986 that utilized iodine-125, the actual dose to the tumor is 85% of the stated dose. Furthermore, the American Brachytherapy Society has presented the COMS dose recommendation as the guideline for the treatment of choroidal melanoma.<sup>35</sup> As more accurate estimates for some of the assumptions used and better calculation algorithms have become available, dosimetry has been further refined and recalculated incorporating anisotropy, line source approximation, and Silastic and gold shield attenuation. Tables of dose to the tumor apex and various other ocular structures have been presented for the various size plaques.<sup>36</sup> On average, the dose to the apex of the tumor appears to be 0.89 of the 85 Gy that has been assumed using the AAPM formalism.<sup>36</sup> The physics of brachytherapy has been reviewed in several publications.<sup>36–38</sup>

## Isotope Selection

The radiation is distributed over a short distance from a surface or within the target tissue. [Table 149.1](#) presents physical characteristics for the commonly used isotopes in brachytherapy. The table breaks isotopes into two broad categories: (1) those that emit gamma ( $\gamma$ )-rays or X-rays; (2) those that emit beta ( $\beta$ )-particles (electrons). [Table 149.1](#) footnotes explain some of the simplifications. The half-value (HVL) in water for a narrow beam is useful in comparing isotopes for the penetration of their radiations in tissue. The tenth-value layer (TVL) in lead for a broad beam is useful in evaluating penetration in shielding materials.

**TABLE 149.1**

**Physical Characteristics of Commonly Used Isotopes for Brachytherapy<sup>a</sup>**

Nuclide	Half-Life	Energy (MeV)	HVL <sup>b</sup> (cm)	TVL <sup>c</sup> (cm)	Exposure Rate Constant (R/cm <sup>2</sup> per mCi per hour) <sup>d</sup>
GAMMA-RAY OR X-RAY EMITTERS					

Cobalt-60	5.3 years	1.25 dV	10.8	4.6	13.1
Palladium-103	17.0 days	0.02	~2.0	~0.003	1.5
Iodine-125	60.2 days	0.03 <sup>e</sup>	~3.0	~0.01	1.4

<b>BETA-EMITTERS</b>					
Strontium-90 <sup>f</sup>	28.0 years	2.27	1.5	0.04	–
Ruthenium-106 <sup>f</sup>	368.0 days	3.54	2.4	0.07	1.7

<sup>a</sup>Data from references 7, 38–41.

<sup>b</sup>HVL, half-value layer: thickness of water required to reduce exposure (dose) from the nuclide to 50% (narrow beam).

<sup>c</sup>TVL, tenth-value layer: thickness of lead required to reduce exposure (dose) from the nuclide to 10% (broad beam).

<sup>d</sup>Exposure rate constant measures exposure rate (R/hour) at 1 cm distance from a 1-mCi sample of the nuclide.

<sup>e</sup>Average gamma-ray or X-ray energy.

<sup>f</sup>In equilibrium with daughter isotopes.

The most commonly used sources for brachytherapy are iodine-125, palladium-103, and ruthenium-106, which have largely replaced iridium-192, cesium-137, radium-226, radon-222, and cobalt-60. Half-life will determine whether the isotope can be used practically, is feasible for commercial production, or can be reused. Isotopes such as gold-198 and radon-222 have very short half-lives and are impractical for regular use.

The energy of  $\gamma$ -rays or X-rays relates to their penetration in matter in a complex way. The more energetic rays penetrate to a greater extent and are more difficult to shield; these two factors are dealt with in the last two columns of [Table 149.1](#).

The HVL in water is an index of the extent to which the energy of the radiation is absorbed in water (or tissue). At short distances, important for application in localized tumors of the eye, the

inverse-square law largely governs the radiation penetration in tissue. Fig. 149.1 displays the depth–dose curves for iodine-125, iridium-192, and cobalt-60. Because of the small height (up to approximately 1 cm) of the tumors treated, this inverse-square law is far more important in determining scleral (or choroidal blood vessel) dose for a given dose to the tumor apex. The dose rate falls more rapidly near the source than further away. Thus, the scleral dose relative to the dose at the apex of the tumor may be reduced by simply introducing a space between the source and the sclera. In the orbit, only size constraints limit the magnitude of the space, with 1 mm being the maximum in plaques used for ocular brachytherapy. With greater distances and less energetic rays, tissue absorption begins to play a more important role. For the  $\beta$ -emitters, absorption in tissues, which is complex and related to the energy of the  $\beta$ -particle, must be measured.

**FIG. 149.1** Computer-generated curves identifying depth–doses of radiation at varying distances in tissue from three different radiation sources. A single seed (1.0 mCi; 37 MBq) of each radioisotope was used.

The TVL of lead is an index of the shielding that must be used around sources for the protection of personnel or the normal adjacent tissues. All the  $\gamma$ -ray or X-ray emitters except for iodine-

125 and palladium-103 have values >1 cm. In 1976, Sealy et al.<sup>42</sup> first reported the use of iodine-125 in the management of melanoma. One reason this isotope was chosen was because the radiation could be almost completely shielded by a thin sheet (0.4 mm) of lead or gold.

The exposure rate constant is an expression of dose rate at a standard distance from a specified amount of isotope. More atoms of an isotope with a low constant can achieve the same dose rate as one with a higher constant, the other characteristics being equal. The curves of dose rate versus depth in tissue for different isotopes can nearly be superimposed by adjusting the amount of each isotope in inverse ratio to the ratio of the exposure rate constants (Fig. 149.2).<sup>43</sup>

**FIG. 149.2** Normalized curves (at 1 cm using a single seed of radioisotope) showing that depth–doses of radiation are nearly identical with the three radiation sources until beyond 15 mm, at which depth the radiation from iodine-125 begins to fall off. (Reproduced with permission from Earle J, Kline RW, Robertson DM. Selection of iodine-125 for the Collaborative Ocular Melanoma Study. Arch Ophthalmol 1987;105:763–4. American Medical Association. All rights reserved. ©1987.)

Beta-emitters, such as ruthenium-106, have been shown to be successful in tumor control for small to medium tumors, potentially up to 16 mm in diameter and up to 8 mm in thickness when used alone with calculated apex doses, or combined with transpupillary

thermotherapy (TTT) when apex doses are insufficient.<sup>44</sup> The presumed advantages of these lower-dose radiation sources are a decrease in the potential risk to adjacent structures as well as decrease in the risk of radiation retinopathy.<sup>45,46</sup> However, studies have not shown a reduction in treatment-related visual decline,<sup>44</sup> as doses are thought to still be above those maximally tolerated by the retina, vasculature, and optic nerve.

A final consideration is the ready commercial availability of well-packaged, calibrated, quality-controlled sources with a spectrum of activities. The COMS chose iodine-125 as a convenient, easily available isotope with favorable properties of half-life, shielding, tissue penetration, and physical form. As a result, iodine-125 is the most commonly used isotope in the United States. However, with high rates of radiation retinopathy and visual morbidity, other centers around the world are investigating the use of other isotopes, namely palladium-103 and ruthenium-106, in attempts to minimize the treatment-related side-effects while still maintaining equivalent tumor control rates.

## Plaque Design

The I-125 plaque design used in the COMS evolved from that used by Rotman et al.<sup>47</sup> and Robertson et al.<sup>17</sup> and consists of a gold plaque that is approximately 0.4 mm thick with a lip around its perimeter that resembles a smooth bottle cap (Fig. 149.3).<sup>43</sup> The shielding device decreases lateral spread of radiation and results in a collimated beam of radiation. Plaques may be customized with notches or indentations of the gold rim to allow placement adjacent to the optic nerve sheath for juxtapapillary tumors. Notched plaques attempt to minimize the likelihood of plaque tilting secondary to placement next to the optic nerve sheath, as this tilt may result in excess radiation to the optic nerve, while decreasing the dose to the tumor apex. Other unique plaque designs and concepts include slotted plaques,<sup>48</sup> which may aid in the treatment of juxtapapillary tumors, including circumpapillary tumors, which prove difficult to treat. Within the gold plaque is a soft, pliable plastic (Silastic) seed carrier insert with evenly spaced troughs that accept the iodine-125 seeds. The carrier is designed so that the seeds

are adjacent to the gold. The thickness of the seed carrier separates the seeds from the sclera surface by 1 mm. Eyelets facilitate anchoring of the plaque to the sclera with sutures. Eyelet placement proves important to minimize the potential for plaque tilt, with those with circumferential eyelets posing decreased likelihood of tilting. The relative dose distribution associated with a particular radioactive plaque is in large part determined by the arrangement (distribution) of the seeds in the plaque. The dose distribution from seeds within a plaque, such as shown in Fig. 149.3, is demonstrated by the schematic in Fig. 149.4. By distributing iodine seeds over the area of the plaque and having a 1-mm spacer between the seeds and the sclera, the scleral dose delivered by an I-125 plaque is approximately the same as that delivered by a cobalt-60 plaque. Monte Carlo calculations by Chiu-Tsao et al.<sup>49</sup> demonstrate a lower scleral dose for iodine-125 compared to cobalt-60, for a point source model. Plaques used to treat uveal melanoma are designed to deliver the prescription dose of radiation, or greater, to the entire tumor. The Collaborative Ocular Melanoma Study (COMS) used custom-designed plaques to create uniform isodose curves, encompassing the tumor. Others have created software to improve the distribution of radiation to the target tissues while minimizing radiation to the surrounding normal tissues, and they have reported their results.<sup>50</sup> In the future, radiation delivery may be further improved with three-dimensional modeling software advances.

**FIG. 149.3** Iodine-125 plaque designed for the Collaborative Ocular Melanoma Study (COMS), consisting of gold housing and seed carrier insert.

**FIG. 149.4** Schematic displaying isodose lines from iodine-125 (left) and cobalt-60 (right) therapeutic plaques, both delivering 100 Gy to the apex of a tumor 7 mm thick. A 1-mm spacer separates iodine-125 seeds from the sclera. (Reproduced with permission from Earle J, Kline RW, Robertson DM. ## Indications for Treatment

### Medium Tumors

The Collaborative Ocular Melanoma Study (COMS), a prospective, randomized study funded by the National Eye Institute, compared survival in patients with medium-sized tumors randomized to brachytherapy or enucleation.<sup>32</sup> The rationale for this study was outlined by Robertson in 1989.<sup>51</sup> Results of the COMS medium-size tumor trial became available in 2001.<sup>21</sup> Medium tumors were

defined as tumors with a thickness between 2.5 and 10 mm, as well as a maximal basal diameter  $\leq 16$  mm. Stringent inclusion and exclusion criteria were used, including patient-related factors, such as a history of any prior cancer, comorbidities that may influence survival, and immunosuppressive therapy, as well as tumor characteristics such as juxtapapillary tumors (tumors within 1 mm of the optic nerve), diffuse (ring) melanomas, and melanomas with a primary ciliary body location. With 1317 patients enrolled and randomized between enucleation and I-125 brachytherapy in the medium-size COMS study, the 5-year mortality rates were not statistically different. This trial had  $>80\%$  power to conclude that neither treatment altered the mortality by as much as 25% from each other. The COMS study group refined survival rates to include 12-year data.<sup>22</sup> Overall, cumulative all-cause mortality at 12 years for patients treated with either enucleation or plaque radiotherapy was 41% and 43%, respectively. For melanoma-specific mortality, the rates for I-125 brachytherapy were 10%, 18%, and 21% at 5, 10, and 12 years, respectively. For patients that received primary enucleation, melanoma-specific death rates were 11%, 17%, and 17%. These statistics emphasize that even at longer follow-up, there were no statistically significant differences in survival between I-125 plaque brachytherapy and enucleation.

Long-term studies utilizing plaques other than iodine-125 have demonstrated success in the treatment of choroidal melanoma. For palladium-103, Finger et al.<sup>52</sup> reported on 400 patients treated with plaque brachytherapy and a mean follow-up of 51 months. Metastatic rates were found to be 6%, with estimated 5- and 10-year risks of metastasis of 7.3% and 13.4%, respectively. For ruthenium-106 plaques, Verschueren et al.<sup>44</sup> reported on 425 patients treated with plaque brachytherapy, with and without TTT, and a median follow-up of 50 months. Failure of local tumor control was 3.9%, with estimated metastasis rates of 24.5% and 30.9% at 5 and 10 years, respectively, and overall survival of 79.6% and 68.2%. Investigators utilizing ruthenium-106 plaques have shown that tumors  $>5$  mm had increased risk of local recurrence.<sup>53</sup> As a result, for tumors  $>5$  mm or those tumors with insufficient doses to the tumor apex, adjuvant TTT has been suggested.<sup>44,53</sup> Therefore, tumors up to 8 mm in thickness and 16 mm in diameter may

potentially be treated with ruthenium-106.<sup>44</sup>

The extended COMS report that included 12-year mortality rates also assessed prognostic factors for metastasis and death, reporting a correlation with advanced age at baseline, as well as larger maximum basal tumor diameter. Shields et al.<sup>54</sup> conducted an in-depth analysis of tumor size and risk for metastasis, reporting on the millimeter-by-millimeter risk for metastasis. In a series of 8033 patients with ciliochoroidal melanoma, tumor size was significantly associated with rates of metastasis. For small melanomas (height 0–3.0 mm), rates of metastasis were 6%, 12%, and 20% at 5, 10, and 20 years, respectively. For medium melanomas (height 3.1–8.0 mm), the rates of metastasis were 35%, 49%, and 67% at 5, 10, and 20 years, respectively. The rates for large tumors (height >8.0 mm) were 25%, 49%, and 67%, respectively. Of note, advanced baseline age and increasing tumor size were confirmed as risk factors for metastatic disease, as well as ciliary body location and clinical findings such as a brown tumor, subretinal fluid, and extraocular extension.

## Small Tumors

In 1978 Curtin et al.<sup>55</sup> reported on the management of small choroidal melanomas with serial observation, in an era when enucleation was the gold standard. Forty-six patients with small melanomas were managed with serial observation until growth was documented, and then offered enucleation. Over 14 years, 20 of the 46 patients were treated with enucleation. The melanoma-specific mortality was 6.5%. Other authors have reported on similar rates of melanoma-related mortalities for tumors that received either prompt treatment or delayed treatment.<sup>56,57</sup> The COMS enrolled 204 patients with small melanoma in a nonrandomized, prospective follow-up study.<sup>58,59</sup> The COMS classified small melanomas as tumors with an apical height of 1–3 mm and a maximal basal diameter between 5 and 16 mm. Upon study enrollment, 16 patients (8%) had treatment, while 67 patients (33%) required treatment at follow-up. Estimates of the need for treatment of small melanomas were 21%, 33%, and 38% at 2, 5, and 7 years, respectively. Overall, there were 27 deaths, with six melanoma-related. Five- and 8-year

melanoma-specific mortalities were 1% and 3.7%, respectively. Importantly, the study identified risk factors that were found to be predictive of tumor growth, including initial tumor thickness, the presence of orange pigment, the absence of drusen, and the absence of RPE changes surrounding the tumor (absence of halo). Other risk factors for the malignant transformation of small melanomas include subretinal fluid, patient symptoms, margins close to the optic nerve, and ultrasound hollowness.<sup>54,60</sup> Of note, there has been a trend toward treatment of smaller tumors, and many of the lesions in this observational study would be treated today.

A more recent series by Sobrin et al.<sup>61</sup> reported on 154 patients with small choroidal melanomas who were observed for signs of malignant transformation (tumor growth or presence of orange pigment). A total of 45 patients (29%) who were observed needed treatment, with a mean interval to treatment of 4.1 years. All patients with observed transformation were treated with I-125 plaque brachytherapy utilizing intraoperative ultrasound for plaque localization. Of those treated, 4.5% developed metastasis, with only one death during the follow-up period. Additionally, one patient (2%) had local tumor recurrence necessitating enucleation. Notably, for those patients with small melanomas that continued to be observed for a mean of 8.1 years, no patient developed metastasis or died secondary to melanoma. Vision at baseline was 20/25, with final visual acuities of 20/30 for patients who were observed and 20/50 at 2 years for patients that were treated with plaque brachytherapy. Radiation retinopathy and optic neuropathy were observed in 56% and 31% of patients, respectively.

Treatment with enucleation or brachytherapy has significant morbidities regarding visual function. Therefore, with current evidence suggesting a low incidence of mortality with small choroidal melanomas along with the potential for significant morbidity of treatment; an open, individualized discourse with each patient is a requisite. Despite no long-term, randomized clinical trials addressing this question, prompt or delayed treatment appears to be a reasonable strategy for small choroidal melanomas.

Finally, transpupillary thermotherapy (TTT) has been proposed for the treatment of small choroidal melanomas that have a tumor height <4 mm. Numerous authors have reported on TTT in these

lesions, with rates of tumor recurrence ranging from 8% to 56%, without standard inclusion criteria.<sup>38,62-69</sup> A systematic review of the literature by Singh et al.<sup>70</sup> reported a mean local tumor recurrence rate of 17% including 7% with extrascleral extension at a mean follow-up of 37 months. Although TTT may cause less visual morbidity in the treatment of small choroidal melanomas, the sole use of this therapy has the potential for high recurrence rates, which have been shown to be associated with an increased risk of metastasis.<sup>71</sup> As a result, the sole use of TTT in the treatment of small choroidal melanomas should be carefully considered.

## Large Tumors

With the COMS establishing the widespread use of plaque brachytherapy for medium-sized choroidal melanoma, most eyes are salvaged, but not without severe visual morbidity secondary to the effects of radiation on the eye. The maximum tumor size that can be effectively treated with radiation without causing severe radiation complications is not known with certainty. Gragoudas<sup>72</sup> suggested that eyes harboring tumors that involve up to 30% of the eye can usually be treated and salvaged after radiation. Char et al.<sup>73</sup> reported information that suggested an upper size limit for tumors treated with radiation. Nearly 50% of the eyes with tumor thickness >10 mm eventually required enucleations after treatment with helium ions. The COMS reported that enucleations were more common for tumors with greater thicknesses and greater base dimensions, although percentages were not given.<sup>71</sup> The American Brachytherapy Society Ophthalmic Oncology Task Force recently published consensus brachytherapy recommendations that, rather than describing a specific range of melanoma sizes or locations appropriate for treatment, recommended exclusion criteria for brachytherapy that include tumors with gross (T4e or >5 mm) extraocular extension, eyes without light perception, and blind, painful eyes.<sup>74</sup>

By COMS definition, large melanomas are tumors that are >10 mm in thickness or >2 mm in thickness with basal diameter >16 mm. The COMS investigated the use of radiation pre-enucleation versus primary enucleation for large choroidal melanomas. At 10

years, survival rates did not show statistically significant differences, with melanoma-specific death rates of 40% for enucleation, compared to 45% for patients that received radiation prior to enucleation.<sup>75</sup> Although the COMS only looked at brachytherapy for medium-sized tumors, several studies have investigated the use of brachytherapy for large melanomas as an alternative to enucleation.<sup>76-78</sup> Wilson et al. reported on 124 patients with large tumors of the ciliary body and choroid treated with I-125 brachytherapy and concluded that tumor thickness >8 mm in height or 16 mm in maximal basal diameter can be effectively treated with a favorable expectation of globe salvage, but limited vision conservation. Puusaari et al.<sup>77</sup> came to a similar conclusion based on 96 eyes with large choroidal melanomas. The authors found that they had a fair chance of globe conservation with acceptable cosmesis, as well as a reasonable chance of conserving useful vision for 1–2 years. Shields et al.<sup>78</sup> reported on 354 large choroidal melanomas (>8 mm in thickness) that were treated with plaque brachytherapy. Failure in local tumor control was estimated in 9% and 13% of tumors at 5 and 10 years, respectively, and enucleation was necessary in 24% and 34% at 5 and 10 years, respectively. Metastasis of melanoma was estimated in 30% and 55% at 5 and 10 years, respectively. Notably, estimates of poor visual acuity (20/200 or worse) were 97% at 15 years. Similar results have recently been reported using palladium-103 in a small series of patients with large tumors.<sup>79</sup>

Ruthenium-106 has also been used to treat large choroidal melanomas, but high doses at the sclera limit the thickness of tumors that can be treated. Kaiserman et al.<sup>80</sup> reported on 63 large tumors treated with ruthenium-106. With a mean follow-up of 69.6 months and mean tumor thickness of 9.29 mm, 23.8% failed local tumor control. Estimated rates of metastasis were 22.5% and 48.1% at 5 and 10 years, respectively, while melanoma-specific mortality was found to be 20.5% and 46.2%. Interestingly, 70.8% of patients maintained vision better than 20/200. Large tumors treated with ruthenium-106 had a higher risk for local tumor recurrence, when compared with tumors treated with iodine-125.<sup>78</sup> Other investigators suggest the use of adjuvant TTT in cases of tumors treated with ruthenium-106.<sup>81,82</sup> Investigators have shown that large

tumors can be effectively treated with brachytherapy, but visual morbidity is high secondary to the large amounts of radiation to obtain effective tumor control.

## Juxtapapillary Tumors

Treatment of juxtapapillary tumors (touching or located within 1 mm from the optic nerve) presents a unique situation of providing appropriate radiation dosages to the tumor apex while attempting to minimize the exposure to the optic nerve. In the past, the majority of these tumors were enucleated, and studies treating eyes with tumors in a juxtapapillary location have higher rates of local tumor recurrence when compared to tumors in other locations.<sup>83</sup> Intraoperative ultrasound during plaque placement shows frequent tilting of plaques placed near the optic nerve sheath. Notably, juxtapapillary tumors were excluded from the COMS Medium Tumor Trial, resulting in exclusion of 9% of otherwise eligible tumors. Advanced plaque design has opened up the use of plaque brachytherapy as a globe-salvaging treatment alternative for these eyes.

Notched plaques are designed with an indentation in the plaque rim to allow flush placement adjacent to the optic nerve sheath. In addition, novel designs incorporating a slot in the plaque may allow for the successful treatment of juxtapapillary, and even circumpapillary, tumors.<sup>48</sup> In 1994, De Potter et al.<sup>84</sup> reported on 127 patients with juxtapapillary melanomas treated with either enucleation or plaque brachytherapy. Despite being a nonrandomized, retrospective study with a small percentage of patients treated with plaque brachytherapy (28%), the authors found that the treatment modality did not affect risk for metastasis. Sagoo et al.<sup>83</sup> reported on the use of notched I-125 plaques in the treatment of circumpapillary tumors (tumors encircling the optic nerve). Recurrence rates were shown to be 14%, while the metastatic rate was 4% with no melanoma-specific deaths observed with a mean of 52 months follow-up. Preservation of visual acuity was poor, with greater than 60% manifesting with vision less than 20/200. Emphasizing the importance of notched plaques with placement confirmation by intraoperative ultrasound, Hui et al.<sup>85</sup>

reported on control rates of 100% at 30 months using notched plaques, compared to 89% at 25 months for non-notched plaques. Sagoo et al.<sup>86</sup> reported on 650 juxtapapillary tumors treated with notched plaque brachytherapy with or without TTT with a mean follow-up of 52 months. Overall incidence of tumor recurrence was 11%, while metastasis was 10% with a melanoma-specific death rate of 3%. Kaplan–Meier estimates of tumor recurrence at 10 years were shown to be 21%, with metastasis and death of 24% and 9%, respectively. Finger et al.<sup>87</sup> recently reported 100% local tumor control in 24 patients with tumors near, touching, or surrounding the optic disc, treated with a custom 8-mm wide slotted plaque design, with a mean follow-up of 23 months.

To address the higher rate of local tumor recurrence in juxtapapillary melanomas, TTT has been used as an adjunctive treatment. In the prior study by Sagoo et al.,<sup>88</sup> TTT was utilized as an adjunctive treatment in 56% of eyes. Overall, tumor recurrences with TTT were 9% (compared to 14% for no TTT), metastasis was 9% (compared to 10%), with a death rate of 2% (compared to 5%). However, differences in recurrences and metastasis were not statistically significant when TTT was used as an adjuvant treatment in juxtapapillary tumors.

In conclusion, juxtapapillary tumors may be treated with plaque brachytherapy, with notched plaques and intraoperative ultrasound contributing to successful treatment. Proton beam irradiation (PBI) has also been shown to be efficacious in the treatment of peripapillary and parapapillary melanomas,<sup>89</sup> as compared to notched plaques for juxtapapillary tumors.<sup>90</sup> TTT may be used as an adjunctive therapy with uncertain benefits. However, as a result of the close proximity to the macula and optic nerve, rates of visual compromise are high, with the majority of patients losing visual acuity to <20/200.

## Plaque Placement Technique

One of the first and most important steps in plaque placement is determining an accurate clinical estimate of the tumor base and height. This allows for the correct sizing of the plaque, and this information must be precisely communicated to the radiation

oncologist and radiation physicist. Estimates of tumor dimensions utilize a number of technologies, including photography, indirect ophthalmoscopy with and without measuring grids, ultrasound, and transillumination. Intraoperative localization utilizes indirect ophthalmoscopy, ultrasound, and transillumination with fiberoptic light sources.

With advancements in ophthalmic photography, including wide-angle photography, tumors are more often captured *in toto* as single or montage images. Tumor dimensions can then be estimated by approximating the basal tumor diameter in disc diameters (using the horizontal diameter of the optic disc as 1.5 mm) or by using calipers. Wide-angle photography has been shown to be more accurate than ultrasound in measuring the basal diameter in some eyes, as it potentially captures those margins or pigmentation that are not determined on ultrasound secondary to lack of elevation.<sup>91,92</sup> It is important for the ultrasonographer to rotate the B-scan probe around the center of the tumor to determine the longest tumor diameter, as this might not correspond to the longitudinal and transverse images most typically obtained. Ultrasound (quantitative A-scan or B-scan) is usually used to determine tumor thickness and to evaluate for the presence or absence of extraocular extension. For tumors that are unable to be captured completely by photographs, basal dimensions can be measured using a technique first described by Hilton,<sup>93</sup> where a grid is placed over the 20-D lens with each square representing 1 disc diameter. The tumor is viewed monocularly through the grid, allowing an approximate calculation of the basal diameter. The presurgical tumor estimates are used to create the plaque. Plaque sizes are chosen to ensure that the plaque covers the entire tumor base, along with 2–3 mm of tumor-free perimeter. For example, a tumor with a base diameter of 12 mm is treated with a 16 mm in diameter plaque.

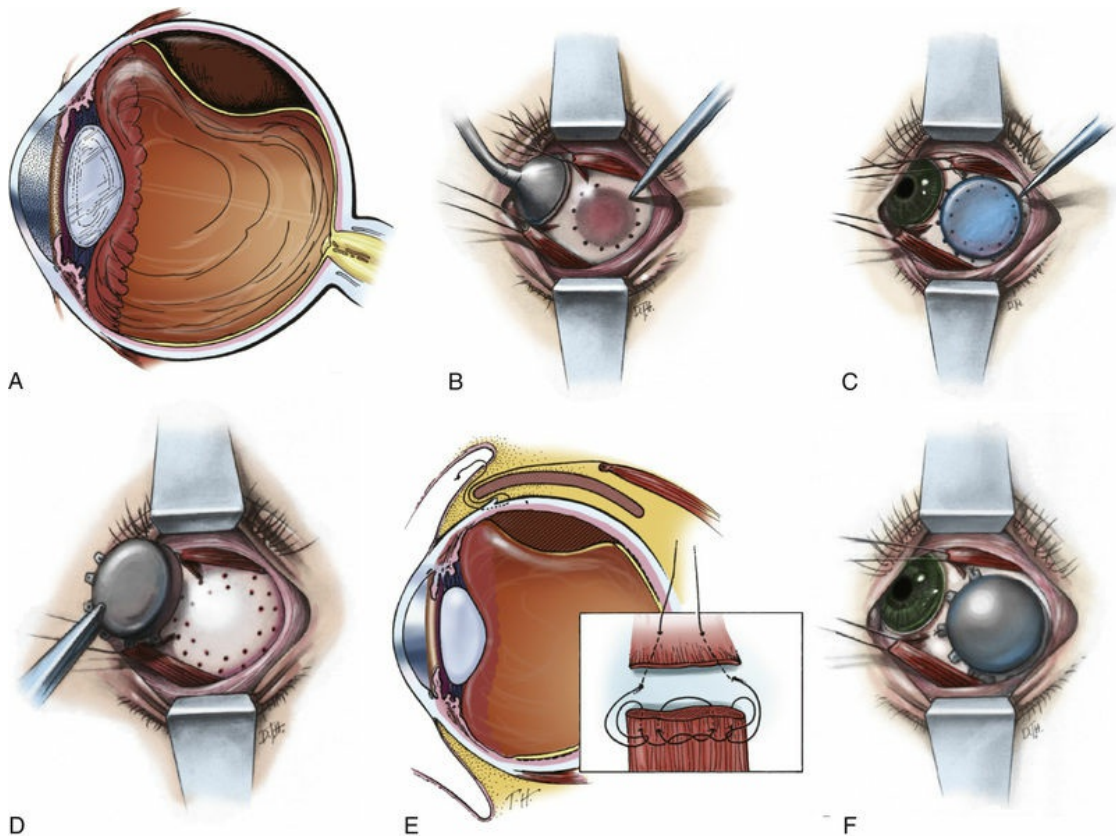

Estimation of tumor diameters for large tumors or tumors located anterior to the equator can be difficult, rendering it useful to know several distance approximations. In an emmetropic eye, the distance between the equator and the ora is approximately 5 mm in the vertical meridians, 5.5 mm in the nasal meridian, and 6 mm in the temporal meridian. Also, with the COMS considering tumors >16 mm too large to be eligible for plaque brachytherapy, it is

convenient to remember that 3 clock-hours at the equator and 4 clock-hours at the ora are each equivalent to a chord length of approximately 16 mm. The choice of anesthesia is left to the discretion of the surgeon. After an adequate peritomy, the surface of the sclera corresponding to the tumor is exposed. If extraocular extension is observed within a pseudoencapsulated focus  $\leq 2$  mm in thickness, a limited peritomy (if the focus is anterior) and tenonectomy is performed, and the plaque is carefully placed over the tumor base and the extension. Because an extraocular extension of  $< 2$  mm may not worsen the prognosis for survival,<sup>94</sup> proceeding with brachytherapy as intended is reasonable. As an alternative, an I-125 plaque without a gold shield could be placed over the extension to allow radiation of orbital tissues adjacent to the visible extension. Ultrasound frequently detects extraocular tumor extensions  $> 2$  mm in height,<sup>95</sup> but extensions of this size occur infrequently.<sup>94</sup> As a result, discovery of large extraocular extensions ( $> 2$  mm) at surgery should rarely occur. For example, there have been virtually no such instances for globes enucleated in COMS.

At surgery, the tumor base is localized with standard localization techniques used for retinal breaks or transillumination (or both). For anteriorly located tumors with even minimal pigmentation, the shadow of the tumor often can be outlined on the sclera while the globe is transilluminated through the cornea with a fiberoptic light source (Fig. 149.5B). Surgeons need to be cautious, as some of the fiberoptic light sources used for nonocular procedures may be too bright to use for ocular transillumination and can cause corneal burns or damage to the retina. The tumor diameter can be measured and recorded using calipers, followed by estimation of 2 mm perimeter beyond the tumor borders. A transparent acrylic dummy plaque with a diameter equal to that of the therapeutic plaque can be used to facilitate localization and later placement of the opaque therapeutic plaque. The dummy plaque is placed on the sclera, covering the scleral marks that identify the tumor perimeter. The dummy plaque must completely cover the base of the tumor, as well as a tumor-free perimeter of 2 mm or more (Fig. 149.5C). After the perimeter of the dummy plaque has been marked on the sclera, it is removed, and the therapeutic plaque is placed within this ring of scleral marks and anchored with two or three intrascleral sutures

(Figs. 149.5D, F). If the therapeutic plaque is the same size or smaller than the boundary of the tumor base as marked on the sclera, the procedure is terminated, and a larger plaque is prepared and placed on the eye later.

**FIG. 149.5** (A) Sketch showing a cross-section of an eye harboring a melanoma located in the midperipheral fundus. (B) A fiberoptic light source has been placed over the cornea, and the shadow of the tumor is visible on the exposed sclera. A marking pencil has outlined the shadow of the tumor. (C) A transparent dummy plaque that is 4 mm greater in diameter than the estimated diameter of the tumor base has been centered over the area of the tumor base. A second row of marks has been made around the dummy plaque to facilitate placement of the opaque therapeutic plaque, which will overlap the boundary of the tumor by 2 mm on each side. (D) Gold-backed iodine-125 plaque being readied for placement. (E) When a rectus muscle must be detached because of an anteriorly located tumor, a double-armed mattress suture can be used to secure

the end of the transected muscle and the muscle can then be allowed to retract. Each arm of the suture is passed intrasclerally just posterior to the insertion. When the plaque is removed, the sutures are tightened and tied, thus drawing the muscle to the insertion, allowing the center of the muscle to hang back slightly. (F) Therapeutic plaque anchored in position with three 5-0 nylon intrascleral mattress sutures.

The location of the radioactive plaque can be confirmed with the traditional technique using indirect ophthalmoscopy and scleral indentation along the circumference of the plaque. Confirmation of the relationship of the tumor and plaque position usually can be obtained using B-scan ultrasonography.<sup>96-98</sup> Harbour et al.<sup>96</sup> showed that standard techniques for localizing plaque placement were suboptimal in 21% of patients, primarily in tumors in a posterior or juxtapapillary location. Intraoperative ultrasound allowed for identification of malpositioned plaques, affording the opportunity to reposition the plaque while still in the operating room. However, despite successful intraoperative positioning, tilting can worsen postoperatively. Almony et al.<sup>99</sup> found that whereas only 9% of patients had plaque tilt >1 mm at insertion, approximately 53% of plaques had tilt >1 mm at removal. Plaque tilt, which is not detected using indirect ophthalmoscopy or transillumination, is associated with a reduction in radiation doses to the tumor apex. Plaque tilt occurs most frequently in plaques adjacent to the optic nerve, but also occurs due to episcleral hematomas or displacement by the inferior oblique muscle. As a result, intraoperative ultrasound should be considered for use in combination with other localization techniques to ensure sufficient plaque placement and identify suboptimal or tilted plaques to allow for immediate repositioning. Postoperative ultrasound performed several days following plaque placement also can identify tilting that was not present intraoperatively, or tumor edema or hemorrhage that has occurred following plaque placement. Adjustments in duration of the brachytherapy can be performed to assure the entire tumor receives the prescribed dose of radiation, or TTT could be performed at the time of plaque removal to tumor that received less than the intended dose of radiation. Prior to altering the treatment plan, the

surgeon should communicate the ocular status with the radiation oncologist and work together to create an optimal management strategy. Although no long-term studies have been reported, intraoperative ultrasound may minimize the risk of local treatment failures.

There has been much debate about the learning curve for plaque placement, including whether ultrasound confirmation is needed in the hands of an experienced ocular oncologist. A study by Shah et al.<sup>100</sup> analyzed the learning curve associated with plaque placement for uveal melanoma over a 20-year period. The authors found that, initially, 21% of plaques required repositioning. This rate decreased to 12% after a period of 10 years, and further decreased to 4% after approximately 20 years. The study estimated that 1275 plaque cases were needed to obtain a precision rate of 90%.

Tumors with margins close to the optic nerve present a unique situation regarding plaque placement. Although the diameter of the intrascleral portion of the optic nerve measures 1.5 mm, the diameter of the optic nerve and surrounding sheath posterior to the globe increases to about 4–6 mm.<sup>101</sup> As a result, for tumors that are within 2 mm from the optic nerve, applying a plaque abutting the sclera with a 2-mm tumor-free margins is not possible. An alternative approach involves the design of plaques with an indentation or notch to fit around the optic nerve. Additionally, the rim of the plaque may be removed in the area adjacent to the optic nerve, to allow lateral spread of radiation to treat those margins that are unable to be covered by the plaque. However, this latter option exposes the optic nerve to a higher dose of radiation with increased likelihood of significant visual morbidity.

Rectus muscles may be detached to facilitate plaque placement and minimize pressure on the globe, with understanding that transection of a muscle may cause a hematoma and plaque tilt, which may increase the likelihood of local failure. The insertion of the inferior oblique can be cauterized and partially disinserted to allow placement of plaques beneath the macula.

Another localization technique utilizes a fiberoptic light source, using a technique similar to that described by Robertson et al.<sup>102</sup> An angled fiberoptic probe combined with indirect ophthalmoscopy can be used to provide transscleral transillumination around the

boundary of the plaque. As the probe moves along the plaque, the light can be visualized in the choroid and its location relative to the tumor base can be readily seen. For anteriorly located tumors, transscleral illumination around the plaque boundary is ordinarily satisfactory, as standard B-scan ultrasonography proves difficult in discerning anterior segment structures. However, newer technologies such as ultrasound biomicroscopy (UBM) and anterior segment optical coherence tomography may open new avenues for anterior segment image acquisition.<sup>103</sup>

After placement of the plaque, the rectus muscle may be sutured to the original insertion or anchored to the side of the plaque or anterior to the plaque. An adjustable suture placed at the time of plaque placement may be preferable if the muscle must remain detached during the brachytherapy period, as this will facilitate reattachment of the muscle at the time of plaque removal. Muscles are usually engaged with a double-armed absorbable suture posterior to the insertion, and disinserted. The ends of the double-armed suture are passed just posterior to the muscle insertion and loosely tied with a bow tie for later access when the plaque is removed (Fig. 149.5E).

Close evaluation of the tissue area of plaque placement must be emphasized, as any episcleral tissue around the optic nerve sheath, inferior oblique muscle, and posterior ciliary vessels and nerves may create added distance of the plaque away from the tumor.<sup>104–108</sup> On completion of plaque placement, the conjunctiva is closed over the plaque with sutures, although risk for complications is low for anteriorly located tumors where the conjunctiva is not able to be closed completely over the plaque or if conjunctiva retracts postoperatively.

Radiation plaques are kept in place for 3–7 days, with patients often staying as inpatients during the course of treatment, based on state radiation safety protocols. With conclusion of plaque treatment, plaque removal is usually performed with local anesthesia. Following the removal of the plaque, muscles that have been transected are reattached by approximating the sides of the muscle to the original insertion, allowing the central portion to drape posteriorly (in general, a slight recession of the muscle approximately 1.5 mm may compensate for the tendency of the

shortened reattached muscle to cause overaction). For preplaced sutures, the muscle is drawn up to the site of the suture passage and secured.

Thermoluminescent ring dosimetry measurements were utilized early in the treatment of choroidal melanoma with plaque brachytherapy to determine the risk of radiation exposure to the surgeon's hands during plaque placement. However, minimal radiation exposure was found,<sup>109</sup> and the use of these radiation-detection devices was discontinued.

Postoperatively, patients are followed serially until their conjunctiva has healed. Ultrasound examinations are difficult to interpret in the first few months, as even successfully treated tumors can exhibit early swelling, stability, or shrinkage. Tumor margins are typically stable during the first few months, so photographic imaging is usually not needed during this time.

## Local Tumor Response

Most choroidal melanomas treated with brachytherapy show evidence of shrinkage, with almost half of all tumors decreasing 50% from the pretreatment thickness. Shrinkage may not be observed in the first several months, but is usually seen at 6 months and progresses over 2–3 years, then remains stable thereafter. Regression to a flat scar is rare. With tumor regression, echographic findings change concurrently, showing an increase in the internal reflectivity along with a decrease in intrinsic tumor vascularity. Choroidal melanomas that have broken through Bruch's membrane to form a collar-button configuration have a distinct regression pattern.<sup>110</sup> The body of these tumors tends to shrink while the collar-button portion becomes more prominent and darker, and may shed pigmented debris into the vitreous cavity. Histopathologically, this debris usually consists of pigment-laden macrophages, melanoma cells, or a combination of both.

Following initial postoperative healing, patients with choroidal melanomas should be evaluated at regular intervals for any signs of growth. Most centers follow patients at 3–6-month intervals. This interval can be modified based on the likelihood of secondary complications. Some centers increase the interval after about 5 years

for stable patients. If the tumor thickness increases by 300  $\mu\text{m}$ , or if any of the tumor borders advance by 250  $\mu\text{m}$ , the tumor is highly suspected of expansion. These tumors should be observed more frequently and if continued growth – 300  $\mu\text{m}$  increase in thickness or 250  $\mu\text{m}$  increase of any border – is observed, plaque brachytherapy is considered a failure and further treatment is recommended. Although several investigators have reported successful retreatment with brachytherapy leading to local tumor control,<sup>8,12,111</sup> definitive enucleation should be discussed. Tumors that recur following plaque brachytherapy may have a greater likelihood of metastasis (see below); therefore, maximizing primary treatment response is imperative.

## Recurrences

Failure to control tumor growth after plaque brachytherapy has been shown to vary from 1.7% to 16%,<sup>12,105,112-114</sup> depending on the institution, isotope, and the length of follow-up. Wilson and Hungerford<sup>115</sup> observed a recurrence rate of only 4% with iodine-125, compared to 5% with PBI and 11% with ruthenium-106. In addition, Fontanesi et al.<sup>116</sup> reported a recurrence rate of 2.3% for 144 patients treated with iodine-125. The COMS enucleated 10% of eyes secondary to suspected or documented tumor recurrence.<sup>71</sup> More recently, a recurrence rate of 1.7% was reported for 117 patients with choroidal melanoma treated with I-125 plaque brachytherapy.<sup>114</sup> The study emphasized the importance of confirming proper plaque placement using intraoperative ultrasound at the time of surgery. Data from other plaques, ruthenium-106 and palladium-103, have also demonstrated low rates of local tumor failure at 3.9%<sup>44</sup> and 3%,<sup>52</sup> respectively.

Efforts to reduce the rate of recurrences following plaque brachytherapy are important, as patients with tumors with local recurrences, despite undergoing enucleation, have an increased risk of metastasis. Gragoudas et al.<sup>72</sup> reported a risk ratio of 2.44 among patients treated with PBI. Vrabec et al.<sup>113</sup> reported nearly three times greater estimated 5-year mortality (42% vs. 13%) among patients treated with cobalt-60. Harbour et al.<sup>117</sup> reported a 5-year actuarial rate of local recurrence of 10%, with metastasis occurring

in 19% of patients with horizontal (marginal) recurrences (relative risk 2.2), and increasing to 49% if the recurrence was vertical and diffuse (relative risk of 5.1). In the COMS, tumors with local recurrence had a calculated risk ratio of 1.5 for metastasis.

## Visual Outcomes and Radiation Complications

Early brachytherapy reports by Stallard<sup>5</sup> in 1968 appeared to indicate a satisfactory 5-year survival rate among 100 patients treated with cobalt-60; however, other early studies identified severe vision loss and ocular complications that were disturbingly prevalent. Despite the use of lower-energy isotopes and modern plaque design with shielding to minimize radiation exposure to vital structures, radiation-related complications are commonly encountered, necessitating further research into their treatment. The earliest changes manifest as macular edema secondary to the leakage from capillaries with poor endothelial support. The clinical onset of radiation retinopathy is between 1 and 2 years. Horgan et al.<sup>118</sup> reported that optical coherence tomography (OCT) detected macular edema due to radiation retinopathy an average of 5 months before the clinical onset of radiation maculopathy. Notably, when macular edema was evident by OCT, only 38% of patients had clinical signs of radiation retinopathy, and the median visual acuity was still good at 20/40. Later manifestations of radiation that lead to impaired vision include macular capillary nonperfusion, proliferative retinopathy with vitreous hemorrhage, and optic neuropathy. Some of these changes are due to direct effects of radiation on the vascular endothelium, and some are likely due to the melanoma or its vascular supply, acting indirectly (so-called “toxic tumor syndrome”).

The complications of radiation maculopathy and optic neuropathy are dependent on the total amount of radiation delivered to the macula and optic nerve, respectively. The resultant dose received by these structures depends on the tumor size and location, with increased risk in tumors with increased height and basal diameter, and located in close proximity to the fovea and

optic nerve. Other factors, such as concomitant use of chemotherapeutic agents and diabetes mellitus, may lower the threshold for developing radiation damage. Biologic variability also likely serves as another factor. Histopathologic studies have shown loss of endothelial cells that line blood vessels, resulting in capillary dropout, microaneurysms, and other changes similar to those seen with diabetic retinopathy.<sup>40</sup> Patients may present with macular edema, microaneurysms, telangiectatic vessels, capillary nonperfusion as seen on fluorescein angiography, neovascularization, vitreous hemorrhages, or optic disc edema.<sup>24,41</sup>

Brown et al.<sup>23,24</sup> indicated that the lowest doses of radiation generally causing macular retinopathy were 45 Gy from cobalt-60 plaques and 36 Gy from external beam radiation. Optic neuropathy was observed to occur from doses as low as 35 Gy from cobalt-60 and 36 Gy from external beam radiation. Visual prognosis has been shown to be less favorable when foveal or optic nerve radiation is in excess of 50 Gy.<sup>26</sup> The same group<sup>26</sup> reported severe visual loss from radiation doses to the fovea as low as 21, 23, and 30 Gy, emphasizing the variability in biologic response to treatment. These cases showed visual loss from nonproliferative radiation retinopathy or exudative retinal detachments.

Studies by Garretson et al.<sup>11</sup> found that visual acuity of 26 patients treated with iodine-125 remained within 2 Snellen lines in 54% of patients. Of those that developed radiation changes, mean duration to onset was approximately 32 months. Although the proponents of iodine-125 had hoped that the lower energy emission, combined with greater space between source and sclera and lateral shielding, would delay or lower the incidence of radiation complications, long-term results have been disappointing, with almost 50% of eyes treated with brachytherapy sustaining vision loss to  $\leq 20/200$  at 5 years. For patients treated with iodine-125 and with at least 3 years median follow-up, rates for radiation maculopathy range between 13 and 52%,<sup>108,119-123</sup> while rates of optic neuropathy range between 0 and 46%.<sup>11,108,111,116,119-124</sup> The upper range for radiation complications was shown in large tumors as based on COMS criteria.<sup>123</sup> Krohn et al.<sup>119</sup> found that patients with radiation maculopathy had a median dose of 49 Gy to the macula, while Stack et al.<sup>120</sup> found that patients who received  $>90$  Gy to the

macula had a 63% risk of maculopathy. Juxtapapillary melanomas tend to have less favorable visual outcomes and more radiation complications than tumors elsewhere. In 650 juxtapapillary melanomas treated with brachytherapy, visual acuity was 20/200 or worse at 5 and 10 years in 54% and 87% of patients, respectively, with high rates of papillopathy (61% and 77%), maculopathy (56% and 65%), and secondary enucleation (16% and 26%).<sup>86</sup> Although radiation is known to significantly affect the retina, Boldt et al.<sup>125</sup> documented that 49.2% of patients in the medium tumor trial of the COMS had abnormalities in the posterior pole prior to plaque treatment, with rates increasing to >90% at 5 and 8 years posttreatment. Proliferative radiation retinopathy was found to occur in 5.2% of patients at 5 years, while optic neuropathy had an incidence of 27.4%. These observations suggest that, in addition to the treatment effects of plaque brachytherapy, inflammatory and angiogenic factors of tumors may contribute to retinopathy.

The visual outcome in eyes treated with iodine-125 is similar to that reported for other forms of radiation therapy (helium ion, 53% 20/200 or less,<sup>126</sup> PBI 42% 20/200 or less<sup>127</sup>) suggesting that research should continue to be directed toward ways to reduce or treat radiation complications. The COMS estimated that nearly 50% of patients treated with iodine-125 would lose substantial vision by 3 years (loss of  $\geq 6$  lines of vision), with 43% having visual acuity less than 20/200.<sup>21</sup> Other recent studies with at least 3 years follow-up report between 42–74% of patients treated with plaque brachytherapy lose  $\geq 2$  lines of vision.<sup>119–121,128</sup> In a small study of 95 patients with melanomas measuring 1.5–5.0 mm in thickness, reducing the dose of radiation for tumors less than 5.0 mm from a prescription point of 5.0 mm (the COMS protocol standard) to the apical height of the tumor reduces radiation complications for smaller lesions, with excellent local tumor control.<sup>129</sup> The COMS presented quality of life data for 209 patients treated with either enucleation or brachytherapy.<sup>28</sup> At 2 years, patients treated with brachytherapy reported peripheral vision and vision for driving that was significantly better than patients who were treated with enucleation. However, following 3–5 years, these findings were not significantly different. This timing corresponds to the visual decline observed for brachytherapy-treated eyes secondary to

complications of radiation retinopathy.

Other isotopes have been used to treat ocular melanoma with success. Although the physical characteristics of certain isotopes may allow better shielding with a greater differential radiation dose between tumor apex and sclera, the  $\gamma$ -rays, X-rays, and  $\beta$ -particles must still obey physical laws, which may limit the potential benefits. Besides iodine-125, two of the most commonly used isotopes for plaque brachytherapy are palladium-103 and ruthenium-106. Ruthenium-106 is a  $\beta$ -emitter and first reported to be efficacious in 11 melanomas by Lommatzsch in 1974.<sup>130</sup> A later series of 309 patients treated with ruthenium-106 with a mean follow-up of 6.7 years showed efficacy of treatment in 70% of eyes, with 23% retaining vision 6/12 or better.<sup>131</sup> In a smaller subset of patients with juxtapapillary melanomas treated with ruthenium-106, Lommatzsch et al. showed that the probability of developing complete radiation optic neuropathy was 23% and 53% at 5 and 10 years, respectively. Additionally, the probability of retaining 20/40 vision was 38% and 26% at 5 and 10 years. Verschueren et al.<sup>44</sup> reported on 425 patients with small to medium-sized choroidal melanomas treated with ruthenium-106. The authors found that rates of radiation complications (maculopathy, retinopathy, and optic neuropathy) were 40% and 65% at 2 and 5 years, respectively. In addition, almost 38% had a decrease in vision to  $\leq 20/200$ .

For palladium-103, the Palladium-103 for Choroidal Melanoma Study Group<sup>52</sup> reported on 400 patients treated with plaque brachytherapy. With regards to visual acuity, 79% and 69% of patients had vision 20/200 or better at 5 and 10 years, respectively. Finger et al.<sup>132</sup> also correlated the incidence of radiation maculopathy with tumor location, tumor height, and radiation doses in 384 patients treated with palladium-103. Tumors in an anterior location were much less likely to manifest with maculopathy versus tumors with a posterior location (7% compared with 41%). Additionally, when compared with radiation doses to the fovea of  $<35$  Gy, doses between 35–70 Gy had a risk of maculopathy of 1.74, while those  $>70$  Gy had a risk of 2.43. This study compares similarly with the incidence of maculopathy following I-125 brachytherapy. Semenova<sup>133</sup> recently reported on 72 patients with melanoma with apical height  $\geq 1.5$  and  $\leq 2.4$  mm

treated with brachytherapy using palladium-103. With mean follow-up of 54 months, there was 100% local tumor control, and the mean visual acuity decreased from 20/32 pretreatment to 20/63 at final exam. Palladium-103 emits lower-energy photons than iodine-125, resulting in radiation that is more readily absorbed by the tumor and less absorbed by tissues in close proximity to the plaque.<sup>134-136</sup> Disadvantages of palladium-103 compared with iodine-125 include an increased scleral dose directly beneath the plaque (a disadvantage in treating tumors at or very near the fovea), a relatively short half-life (17 vs. 60 days), and less available information on the dosimetry of palladium-103.

Current research is focused on decreasing treatment morbidity through considerations of lowered radiation dose (alternative isotopes, lowered planned dose delivery,<sup>137</sup> enhanced localization with smaller treatment margins, eccentric placement of plaques to just cover the posterior margin of posterior tumors,<sup>138</sup> radiation shielding agents), combined treatment applications (supplemental laser, anti-VEGF, vitrectomy), and personalized medicine (utilizing tumor molecular genetic markers). Reduction of radiation dose to normal tissues is likely to improve visual outcomes, but it should not come at the expense of decreased local tumor control.

A novel approach to the reduction of radiation complications involves replacement of the vitreous by silicone oil, perfluorocarbons, and other vitreous substitutes in vitro to attenuate radiation, potentially minimizing the effects to the vital eye structures.<sup>139,140</sup> McCannel and McCannel<sup>141</sup> recently reported a 1 : 1 matched case–control series with 20 patients receiving treatment with vitrectomy and silicone oil with vitrectomy, matched with control patients who underwent brachytherapy alone. With an average follow-up time of 22 months, there was a nonsignificant trend toward improved visual acuity in the patients receiving silicone oil. In addition, there was statistically less macular thickness and less cataract surgery performed in patients receiving oil. Although perioperative complications were limited, further studies with longer follow-up will be required to determine if this treatment has a role in the management of specific patients with melanoma.

# Management of Radiation-Related Complications

Treatment options for radiation complications to the retina and optic nerve have included anti-VEGF agents, corticosteroids, and laser photocoagulation.

## Anti-VEGF

Vascular endothelial growth factor (VEGF) has been shown to be elevated in eyes with choroidal melanoma, with the highest levels being found in those treated with radiation.<sup>142,143</sup> VEGF is a potent vascular permeability factor that may contribute to macular edema and has been suggested to play a role in radiation maculopathy.<sup>118</sup> Additional cytokines may also factor into the retinal response to radiation toxicity. Anti-VEGF agents have generally been used as a treatment after vision damage from radiation maculopathy has begun. Macular edema and retinal neovascularization often decrease, but not all studies demonstrate improvements in visual acuity.<sup>144-148</sup> Shah and Houston et al.<sup>149</sup> reported a retrospective study of 159 patients with brachytherapy for melanoma who were evaluated at 2–4-month intervals after treatment and treated with bevacizumab at the first sign of macular edema on spectral domain OCT. Patients received a mean of five bevacizumab injections over 18 months. Fifty-one percent of patients retained 20/50 or better vision at a median follow-up of 3 years, significantly better than the results of the COMS study. In 2014, Shah and Shields et al.<sup>150</sup> reported a nonrandomized study of intravitreal bevacizumab injections given every 4 months for 2 years following brachytherapy, versus observation (292 in the injection arm and 126 in the control arm). Injections were initiated immediately following plaque removal, prior to the development of radiation retinopathy. Over a 2-year period, patients receiving bevacizumab, when compared to controls, demonstrated OCT-evident macular edema, clinically evident radiation retinopathy, moderate vision loss, and poor visual acuity less frequently. There was no statistically significant difference in clinically evident radiation papillopathy. These studies set the stage for a prospective study to address the

management of radiation maculopathy with anti-VEGF agents. There may also be a role for anti-VEGF therapy in the management of radiation optic neuropathy. Finger and Chin<sup>147</sup> reported on 14 patients with radiation optic neuropathy due to brachytherapy who were treated with intravitreal bevacizumab. They noted a reduction in optic disc edema and hemorrhage in all patients while visual acuity was stable or improved in 9 of 14 patients.

## Corticosteroids

Horgan et al.<sup>151</sup> reported on the use of periocular triamcinolone in 108 patients at the time of plaque placement followed by repeat dosing at 4 and 8 months, finding that at 18 months there was a significant decrease in the risk of macular edema and the risk of moderate to severe vision loss was decreased from 48% to 31%. Side-effects included increased intraocular pressure as well as progression of cataracts. In a single center series of 31 patients, a single injection of intravitreal triamcinolone led to stable or improved vision in 91% of patients, but the effect was not long lasting.<sup>152</sup> Combining intravitreal triamcinolone with bevacizumab for the treatment of severe radiation retinopathy demonstrated overall stabilization of visual acuity, with improvement to 20/50 or better vision in 365 of patients.<sup>153</sup> Recently, Baillif et al.<sup>154</sup> reported on five patients with radiation macular edema following proton beam therapy for choroidal melanoma, treated with intravitreal dexamethasone 0.7-mg implant. There was a significant improvement in macular edema in 4 of 5 patients. Visual acuity improved for 3 patients (+4, +9, and +15 letters) and remained unchanged for 2 patients, with a beneficial effect that lasted for up to 5 months. There may also be a role for intravitreal corticosteroids and anti-VEGF agents in managing radiation optic neuropathy, Shields et al.<sup>155</sup> reported on 9 patients treated with intravitreal triamcinolone for radiation optic neuropathy. They noted rapid improvement in the optic disc edema and hyperemia, with modest improvement in visual acuity. Further studies with longer follow-up are needed to assess the effect of VEGF inhibitors, corticosteroids, or combination of the two on maculopathy and optic neuropathy, with focus on the early identification with OCT

and early treatment prior to significant visual decline.

## Laser Photocoagulation

Laser photocoagulation has also been investigated in the treatment of radiation retinopathy. Focal laser therapy of 19 patients was shown to have an initial effect with improvement in vision and radiation-associated cystoid macular edema (CME) at 6 months; however, at 12 and 24 months, there was no significant difference between treated and untreated eyes.<sup>156</sup> In another study with a mean follow-up of 39 months, 12 patients treated with focal laser for radiation-associated CME resulted in 67% with improvement in visual acuity and 50% with resolution in CME.<sup>157</sup> With a mean follow-up of 109 months, 38 patients with CME were treated with focal laser therapy, revealing that although both treated and untreated groups had a decrease in visual acuity post-plaque treatment, those treated with laser showed a better final vision.<sup>158</sup>

In an alternative strategy using laser photocoagulation, Finger and Kurli treated 45 patients who developed radiation retinopathy following plaque brachytherapy with sector laser photocoagulation on the surface of the tumor and 2–3 mm of the margins.<sup>159</sup> With a mean follow-up of 48 months, approximately 65% had regression of radiation retinopathy and 47% had regression of maculopathy. However, almost 47% had loss of  $\geq 3$  lines of vision. Interestingly, when 16 tumors were treated prior to the development of radiation retinopathy or maculopathy, only three patients developed radiation complications, which regressed with additional laser. Of note, compared with the group that received treatment after development of retinopathy, no (0) patients treated with prophylactic laser lost  $>3$  lines of vision. Laser photocoagulation may have a role in the treatment and prevention of radiation retinopathy, and this study emphasizes the importance of early identification and treatment of radiation complications. Larger studies with additional patients are needed to determine the efficacy of laser treatment for radiation retinopathy.

## Adjuvant Therapy

To increase the number of neoplastic cells made nonviable within a choroidal melanoma during treatment and to reduce unwanted complications of radiation, some investigators have suggested the use of adjuvant therapies, including hyperthermia, chemotherapy, and antiangiogenic agents. Transpupillary thermotherapy (TTT) uses a diode laser and near-infrared irradiation to elevate the temperature within the tumor. TTT may induce tumor cell necrosis up to 3 mm in depth and has been investigated as primary treatment for small melanomas,<sup>62</sup> however, 22% had failure of local tumor control at 3 years, with evidence of extraocular extension in some cases.<sup>160</sup> As a result, TTT has been used more frequently as an adjuvant therapy. Authors propose that adjuvant TTT may allow the use of lower radiation doses in order to decrease the risk for radiation complications, treat larger melanomas, as well as treat juxtapapillary tumors with margins close to the optic nerve precluding adequate plaque coverage of these margins.

Additionally, TTT may be used for tumors that fail local control. Shields et al.<sup>161</sup> reported on 270 patients with combined plaque brachytherapy and TTT, showing that failure of local control was estimated to be 2% and 3% at 2 and 5 years, respectively. TTT was applied at 4-month intervals in three sessions following treatment with plaque brachytherapy. Other authors have reported on the efficacy of combined treatment,<sup>44,162,163</sup> with a slight trend toward better visual acuity for those treated with adjuvant TTT.<sup>44</sup>

Additionally, adjuvant TTT combined with plaque brachytherapy may be beneficial for juxtapapillary tumors as discussed above.<sup>88</sup>

Choroidal melanoma has been shown to have a unique spatial distribution of vasculature, with mature vessels found in the basal aspects of tumors and immature neovessels radiating apically and peripherally. Vessel maturation was also shown to be associated with histopathologic predictors of poor prognosis. However, with the rich vasculature of these tumors, treatment with antiangiogenic agents has been proposed.<sup>164</sup> Additionally, cell lines of choroidal melanoma have been shown to secrete VEGF,<sup>165</sup> while others have shown increased concentrations of VEGF in the vitreous of eyes with choroidal melanoma.<sup>143</sup> Missotten et al.<sup>142</sup> reported increased concentrations of VEGF in eyes with choroidal melanomas compared to controls, with significant correlations with increasing

tumor height and basal diameter. Interestingly, VEGF concentrations were found to be higher after treatment with plaque brachytherapy. As primary treatment for choroidal melanoma, a small case series reported that antiangiogenic agents when used alone were not effective at delaying tumor progression.<sup>166</sup> Adverse effects were mild, including hypertension, with no heart attacks, strokes, or deaths. Some investigators have proposed adjuvant treatment of choroidal melanoma with intravitreal bevacizumab combined with plaque brachytherapy. However, timing may prove to be an important factor for the efficacy of this treatment. Although treatment prior to plaque placement may result in tumor size reduction, this strategy may be associated with closure of tumor vasculature with resultant hypoxia of tumor cells. Hypoxic cells have been shown to be resistant to radiation therapy and chemotherapy. Other investigators have shown a reduction in tumor size and resolution of exudative retinal detachment when melanomas were treated with intravitreal bevacizumab upon plaque removal.<sup>167,168</sup> Further studies with more patients and longer follow-up are needed to determine the efficacy and safety of antiangiogenic inhibitors in the treatment of choroidal melanoma.

## Conclusion

Radiation therapy, both plaque brachytherapy and proton beam irradiation, have been shown to have comparable results regarding local tumor control, survival/metastasis, and globe-salvage.<sup>169-180</sup> However, rates of radiation complications with resultant visual loss remain high regardless of treatment type. The COMS Medium Tumor Trial established the use of I-125 plaque brachytherapy as a primary globe-salvaging treatment for choroidal melanoma. Plaque brachytherapy and enucleation were shown to have similar rates of melanoma-specific deaths. In addition, small, large, and juxtapapillary tumors have been successfully treated with plaque brachytherapy. Intraoperative ultrasound provides valuable information regarding plaque placement. Ultrasound may allow for the repositioning of plaques that have tilted, shifted, or were inaccurately placed. Intraoperative ultrasound provides a valuable tool to aid in plaque placement and maximizes the likelihood of

local tumor control. Despite eye preservation, visual morbidity is high secondary to radiation-related complications, including radiation maculopathy and optic neuropathy. Alternative radioisotopes have been investigated to minimize treatment-related effects without significant reductions in visual loss. As a result, a better understanding of the mechanisms involved in radiation damage is needed, along with the development of treatment strategies for these visually devastating complications. Current studies provide hope that the early identification and treatment of radiation retinopathy may be helpful in maintaining useful vision.

## Introduction

Radiotherapy is currently the most widely used method for treating intraocular melanomas, having replaced enucleation as the standard of care for most tumors. It offers the advantage of eye salvage and retention of vision in many cases, although a survival advantage has not been demonstrated.<sup>1</sup>

There are two major radiotherapeutic techniques for the treatment of uveal melanomas: radioactive plaques<sup>2,3</sup> sutured on the sclera over the area of the tumor, and external beam irradiation including use of charged particles, such as protons,<sup>4</sup> and helium ions,<sup>5</sup> and stereotactic photon radiotherapy.<sup>6,7</sup> The advantages of charged-particle irradiation are based on the physical characteristics of particles, which make possible highly localized dose distributions<sup>8-10</sup> and provide highly attractive depth-dose distribution patterns.<sup>11</sup> Although effective, helium ion irradiation<sup>5</sup> is no longer in use due to its high cost. Local control was observed in 93% of patients at 10 years after treatment<sup>6</sup> in a large series of patients ( $n=212$ ) treated with stereotactic radiotherapy, but radiation retinopathy developed in approximately two-thirds of patients by 5 years after treatment.<sup>7</sup> In a recent study comparing proton therapy to stereotactic radiosurgery,<sup>12</sup> similar rates of local control were observed, but the group who received proton therapy experienced better visual outcomes than those who received stereotactic therapy.

Protons are positive, singly charged particles that have minimal scatter and a well-defined, finite, and energy-dependent tissue range. Proton beams can be collimated to deliver maximum density of ionization in a sharply focused, localized volume because of the inherent Bragg peak at the end of the beam path. The Bragg peak

can be broadened to cover a tumor at any depth (Fig. 150.1). The uniform dose of radiation delivered to the whole tumor and the sharp reduction of the dose outside the treated area allow tumors located near critical structures to be treated with the possibility of retaining visual acuity. Larger tumors can be treated because the overall irradiated volume is reduced. These properties should improve the therapeutic ratio of local control versus complications.

**FIG. 150.1** Depth–dose curve measured with diode in water phantom. In this example, proton energy is modulated to provide a relatively uniform dose over a distance of 5 mm, from a depth of 18–23 mm.

Early experimental work in monkey eyes, followed by clinical and histopathologic studies in humans, provide evidence of the advantageous properties of protons. The Bragg peak of small-diameter collimated beams positioned on the fundus by stereotactic radiography produced lesions confined to the intended radiation field.<sup>13</sup> Normal retinal architecture as close as 1 mm from the edge of radiation-induced lesions was seen in irradiated monkey eyes more than 3.5 years after proton treatment.<sup>14</sup> Similar data on humans substantiate the favorable effects obtained with protons. Using mathematical superimposition of fundus photographs, computer treatment plans, and visual fields, correlation between patterns of visual loss and radiation isodose calculations was established.<sup>15,16</sup> Histologic examination of irradiated tumors revealed vessel thrombosis exclusively in retina overlying the tumor<sup>17</sup> and reduced or absent choroidal vasculature and RPE beneath and above the tumor but intact tissue adjacent to it.<sup>18</sup>

Tens of thousands of patients with uveal melanomas have been treated with proton radiation worldwide. In the United States, several proton centers have opened, making proton irradiation a viable treatment option for more patients with uveal melanomas.

## Treatment

### Patient Selection

Patients with uveal melanomas up to 28 mm in diameter and 14 mm in height may be treated with charged-particle irradiation. In general, patients with larger tumors located at the peripheral fundus can be treated and maintain visual potential because the beam can enter the eye directly in the area of the tumor and does not need to traverse as many noninvolved ocular structures. Our experience indicates that the eye can tolerate irradiation of up to 30% of its volume with the doses currently used. Tumors with small extrascleral extensions and tumors involving the macula, the optic disc, or both can be irradiated.

### Operative Technique

The conjunctiva is incised, and the tumor is localized by transillumination, indirect ophthalmoscopy, or both. The episcleral tissues over the area of the tumor are examined carefully for evidence of extrascleral extension. The edges of the tumor are marked with a surgical marking pen, and four tantalum rings, 2.5 mm in diameter, are sutured to the sclera at the margins of the tumor. Ring-to-limbus distances and distances between the rings are measured. Highly elevated tumors can cast a variable shadow during transillumination, depending on the angle of illumination, which may result in an overestimate of the dimensions of the tumor. Therefore, the angle of illumination in the most precise shadow must be carefully chosen. For tumors that extend into the ciliary body and iris, rings are placed at the posterior margin of the tumor and accurate measurements are made of the distance from the rings to the anterior margin of the lesion. If tumors are in contact with the optic nerve, rings are placed only at the anterior

and lateral margins of the lesion, and the distance from the rings to the posterior margin is estimated from fundus photographs. The tumor is transilluminated again after suturing of the rings (Fig. 150.2), the distances from the rings to the edges of the tumor are measured, and careful drawings of the tumor margins in relation to the rings are made. No operation is necessary for lesions confined to the ciliary body. The margins of the tumor in relation to anatomic landmarks of the iris and conjunctiva are defined by transillumination on the ocular surface.

**FIG. 150.2** Tantalum rings sutured to the sclera at the edges of the tumor, seen by transillumination.

## Treatment Planning

An interactive three-dimensional treatment planning computer program (EYEPLAN, Martin Sheen, Clatterbridge Centre for Oncology, Bebington, UK) facilitates the selection of the appropriate fixation angle, which is chosen to minimize irradiation of the lens, optic disc, and fovea.<sup>19</sup> Such a program helps to select the best direction of gaze relative to the proton beam line; design the shape of the field-defining aperture; determine the proton range modulation necessary to encompass the target volume; determine the extent to which important structures are included within (or excluded from) the beam; and indicate the relative positions of the
