Of course, one major advance in the last few years is our ability to identify mutations that cause RP by whole-genome sequencing. In the near future we will no doubt be able to sequence each person's entire genome, and this could be done at birth. Identifying individuals who will get RP, well before the retina undergoes extensive degeneration, might allow curative strategies to be implemented at times that avoid some of the problems associated with remodeling.

In addition to the above diseases that disrupt the gross morphology of the retina, there also are diseases with less severe effects. One group results in night blindness, without any degeneration of retinal cell types. These are called congenital stationary night blindness (CSNB). The result is a greatly diminished amplitude of the electroretinogram b-wave, indicating lack of or poor signal transmission between photoreceptors and bipolar cells. Careful analyses of the electroretinogram indicate that there are two forms, incomplete and complete.<sup>362</sup> The genetic defects that give rise to these defects are now known to be caused by mutations in genes that are involved in release of glutamate from photoreceptors (incomplete, iCSNB) or absence of signaling in depolarizing bipolar cells (complete, cCSNB). Mouse models for iCSNB reveal that the dendritic arbors of ON bipolar and horizontal cells are abnormal. They extend across the OPL into the ONL and often reach the outer limiting membrane.<sup>363</sup> By contrast, models of cCSNB have no morphologic abnormalities, although in some there appears to be some abnormal expression of synaptic proteins, resulting in ribbon synapses being present in dendrites of depolarizing bipolar cells.<sup>364</sup>

## Conclusions

In one sense, our understanding of the mammalian retina is very advanced in that most of the cell types have been described and numerically accounted for, more so than in any other part of the CNS. While the rabbit was the preferred model for a long time, our ability to manipulate the mouse genetically means it is increasingly becoming the main model organism. Of course it has major drawbacks with respect to human retina, the most obvious of which are a lack of a fovea and red–green color vision.

Similar data, though less complete, are available for other mammals, particularly rodent and primate. In fact, experimental reasons often govern the choice of species for investigation and, in this regard, fish and salamander still have much to contribute to the understanding of visual processing.

Rods are specialized for high sensitivity at night, while cones provide high acuity and color vision in daylight. Adaptation in the phototransduction cascade plays a crucial role in adjusting sensitivity. Now, we know there are dedicated pathways for rod and cone vision throughout the retina. Horizontal cells provide feedback to photoreceptors and probably subtract a large version of the average background. Visual pathways diverge dramatically into multiple bipolar cell types with outputs at different levels or addresses in the IPL. One role of amacrine cells is to provide another level of negative feedback at bipolar cell terminals, but amacrine cells are extremely diverse and probably serve many other functions, including feature extraction, lateral inhibition, and various types of adaptation to the image parameters. Ganglion cells are the output neurons of the retina. In central primate retina, the midget system dominates with one cone to one midget bipolar cell to one midget ganglion cell. This system may also carry color signals. There are at least 30-40 different types of ganglion cell, each of which is thought to carry a different channel of visual information. Some of these parallel channels represent spatial vision at several bandwidths, but others are involved with eye movements, image tracking, pupil control, and resetting the circadian clock.

While an outline and the gross cell count may have been

completed, much work remains to describe specific circuits and cellular connections, which we refer to as the functional anatomy of the retina. Several obvious problems challenge our current understanding: the role of horizontal cells and the mechanism of horizontal cell feedback, the reason for the presence of two horizontal cell types, the circuitry underlying color vision, the connections of the diffuse cone bipolar cells, a full description of the mGluR6 cascade, the switch from rod to cone pathways, the mechanism of directional selectivity, the reasons for the extensive electrical coupling of neurons in the retina, the circuits that control sensitivity and adaptation, the specific visual function of the many ganglion cell types – in other words, the role of each channel. We could go on. Our ability to combine new imaging modes with electrophysiology will provide a major contribution to many of these problems, and rapid progress may be anticipated in the next few years. The requirement of functional anatomy is to describe the exact neuronal connections that underlie specific pathways and circuits in the retina. These are the building blocks of the visual system.

## Acknowledgments

This work was supported by National Eye Institute grants EY 12354 (RGG), EY 014701 (MMC), EY 06515 (SCM), National Eye Institute core grant EY 10608 (SCM), and unrestricted grants from Research to Prevent Blindness to the Departments of Ophthalmology and Visual Science (University of Texas and University of Louisville). SCM is the Elizabeth Morford Professor of Ophthalmology and the grateful recipient of fellowships from the Hanse-Wissenschaftskolleg, Delmenhorst, Germany, and Research to Prevent Blindness.

Thanks to past and present members of our laboratories who contributed figures: Chris Kittila, Brady Trexler, Steve Mills, Wei Li, Jennifer O'Brien, Feng Pan, and John Koomen. Special thanks to Jennifer O'Brien, who prepared many of the figures, and David Marshak, Steve Mills, and John O'Brien for many discussions. And finally, thanks to all those investigators who contributed figures. The authors regret that due to space limitations the outstanding

work of many investigators could not be included or referenced in this brief review.

## Immune Privilege and the Immune Response

### Transport of Nutrients, Ions, and Water

### Secretion of Cytokines and Growth Factors

The retinal pigment epithelium (RPE) forms a monolayer of highly specialized neuroectodermally derived pigmented cells located between the neurosensory retina and the vascular choroid. The RPE mediates functions essential for normal outer retinal physiology, including participation in the visual cycle, phagocytosis of shed photoreceptor outer segments (OS), maintenance of the outer blood–retinal barrier, secretion of neurotrophic, inflammatory, and vasculotrophic growth factors, water transport out of the subretinal space, and regulation of bidirectional ion and metabolic transport between the retina and choroid. The RPE is a primary site of pathology in major blinding diseases, including age-related macular degeneration (AMD) and proliferative vitreoretinopathy (PVR).

## Embryology

At day 27 postconception, the optic vesicles invaginate to form the optic cup and the neuroepithelium differentiates and thickens. By day 30, the basic cellular relationship of the outer retina is established with the prospective RPE layer closely apposed to the developing neural retina. Several transcription factors play a critical role in the determination and specification of RPE, among which are microphthalmia-associated transcription factor (Mitf), orthodenticle homeobox (Otx)1/2, and paired box (Pax) 6.<sup>1</sup> The Sonic hedgehog (Shh) signaling pathway is also critical; the distinct expression pattern of its members in central and peripheral RPE suggests multiple regulatory roles during RPE differentiation.<sup>2</sup> By day 35, melanin pigment granules are identified in the RPE; this is the earliest site of pigmentation in the body. By the 6th week of gestation, the RPE elaborates basement membrane material that initiates the formation of Bruch's membrane. Between 4 weeks and

6 months of gestation, RPE cells exhibit a high rate of proliferation, peaking at 4 months of gestation.<sup>3</sup> Meanwhile, the RPE develops polarity with apical microvilli that extend into the subretinal space, which coordinates photoreceptor differentiation.<sup>4</sup> Studies indicate that the Shh pathway,<sup>5</sup> retinoic acid,<sup>6</sup> bone morphogenetic protein (BMP),<sup>7</sup> Notch,<sup>8</sup> and Wnt/ $\beta$ -catenin<sup>9</sup> pathways all participate in RPE differentiation.<sup>10</sup> In addition, ezrin, a member of the ezrin/radixin/moesin (ERM) family, directs the morphogenesis of apical microvilli and basal infoldings.<sup>11</sup> RPE polarity is also required for choroid and scleral development.<sup>12</sup> Readers are referred to [Chapter 15](#) (The development of the retina), for a more comprehensive review of the development of the RPE and retina.

## Anatomy and Histology

The adult human eye contains approximately  $3.5 \times 10^6$  RPE cells. Since they are postmitotic and do not remain in the cell cycle, this population remains stable during adult life in the absence of disease.<sup>13</sup> The RPE extends from the optic nerve to the ora serrata, and is continuous with the ciliary body pigment epithelium. The fovea contains the highest density of RPE cells, with a progressive decrease in density to the periphery. These cobblestone-shaped cells with highly polarized structure form a monolayer between the neurosensory retina and the choroid. Their apical microvilli interdigitate with photoreceptor outer segments, while their basal side attaches to the RPE basement membrane of Bruch's membrane. Readers are referred to [Chapter 22](#) (Structure, function, and pathology of Bruch's membrane) for a detailed description of Bruch's membrane physiology and interaction with the RPE.

The RPE, with its brown melanin granules, contributes to the typical patterned fundus appearance due to variations in RPE pigmentation. Typically, the highest concentration of pigment in the RPE is found in the peripheral retina, while the lowest is in the macula.<sup>14</sup> With age, the RPE gradually loses melanin granules, in part from the effects of photo-oxidation.<sup>15</sup> The retina and RPE are separated by a potential space known as the subretinal space. Although the retina conforms to the shape of the adjacent RPE and underlying sclera, it is not firmly attached to the RPE except at the

optic disc and ora serrata; attachments elsewhere are weak and can be disrupted by relatively weak forces. [Chapter 21](#) (Mechanisms of normal retinal adhesion) provides complete discussion of retinal adhesion.

## Heterogeneity and Polarity of the RPE

RPE cells exhibit regional heterogeneity in morphology and function.<sup>16</sup> They have cuboidal morphology and appear polygonal in shape when viewed en face, a pattern that is maintained in culture when grown to confluence ([Fig. 18.1](#)). The morphology varies by fundus location. In the macula, the cells are tall and narrow, while they are flat, spread out, and may be binucleated in the periphery.<sup>13</sup> Due to regional differences in requirements for RPE function, RPE cells vary regionally in growth potential,<sup>17</sup> expression of vimentin and phosphotyrosine,<sup>16</sup> distribution of Na/K adenosine triphosphatase (ATPase) pumps,<sup>18</sup> and kinetics of rod OS binding and ingestion.<sup>19</sup> Age-related expression of lysosomal enzymes, superoxide dismutase-2, and accumulation of lipofuscin vary by fundus region,<sup>20-22</sup> suggesting that this heterogeneity contributes to pathologic changes in the RPE.

**FIG. 18.1** Cultured human retinal pigment epithelium (RPE) cells. A monolayer of early-passage human RPE cells demonstrates the polygonal appearance of the cells when grown to confluence (phase microscopy,  $\times 25$ ).

RPE cell polarity is characterized by distinct ultrastructural features and specialized functions in the apical and basolateral domains (Fig. 18.2). The apical cell membrane elaborates numerous microvilli (3–7  $\mu\text{m}$  in length) that interdigitate and ensheath photoreceptor OSs<sup>23</sup> (Figs. 18.3 and 18.4). These interdigitations, in conjunction with the extracellular matrix (ECM), and neural cell adhesion molecule (N-CAM) expressed on the RPE apical surface, allow adhesion between the retina and the RPE. Between 30 and 45 photoreceptors are in contact with each RPE cell.<sup>24</sup> The RPE engulfs and degrades nearly 30,000 shed OS each day such that one RPE cell will ingest and degrade hundreds of millions of discs during its lifetime.<sup>25,26</sup>

**FIG. 18.2** Electron micrograph of a retinal pigment epithelium (RPE) cell and adjacent outer segments (OS) of the rod photoreceptor cells. Note the apical

microvilli (*mv*) of the RPE cell. Darkly stained melanin granules are seen apically, while mitochondria (*mit*) are predominantly basal. The cell rests on the basal Bruch's membrane (*bm*). The nucleus (*N*) is present in the basal third of the cytoplasm. A phagolysosome (*arrowhead*) containing degrading rod OS material is seen in the cytoplasm at low ( $\times 21,500$ ) and high (inset,  $\times 50,000$ ) magnification.

**FIG. 18.3** Scanning electron micrograph of rod photoreceptor outer segments (OS) fractured across their long axis, surrounded by apical folds extending from the surface of the retinal pigment epithelium. The membrane forms a sheath around each of the rod OSs. (Reproduced with permission from Hollenberg MJ, Lea PJ. High resolution scanning electron microscopy of the retinal pigment epithelium and Bruch's layer. *Invest Ophthalmol Vis Sci* 1988;29:1380–9.)

**FIG. 18.4** Scanning electron micrograph of the apical surface of a bovine retinal pigment epithelium (RPE) explant. Note the abundant microvilli on the apical surface of the RPE cells. Approximately a dozen RPE are shown.

The functional polarity of RPE cells results from the differential apical–basal distribution of membrane proteins ([Table 18.1](#)). The RPE shares many common characteristics with other transporting epithelia, but uniquely exhibits “reversed polarity” of certain proteins, such as the Na/K-ATPase pump, ECM metalloproteinase inducer (EMMPRIN), and N-CAM. In contrast to other epithelia, these proteins are apically rather than basolaterally located. In a proteomic study of RPE apical microvilli,<sup>27</sup> 283 proteins were identified, which could be divided into different functional categories, including retinoid-metabolizing, cytoskeletal, enzymes, ECM components, membrane proteins, and transporters.  $\alpha\text{v}\beta\text{5}$  integrin ([Fig. 18.5](#)), mannose receptors, and CD36 are localized to the apical membrane domain, specifically in the microvilli, where they play critical roles in OS phagocytosis.<sup>28–30</sup> Na/K-ATPase is mainly apically located, where it is critical for trans-RPE ion transport.<sup>31</sup> The membrane protein chloride intracellular channel 4 (CLIC4) is enriched in apical RPE microvilli, possibly for modulating the activity of cell surface channels/transporters.<sup>32</sup> The RPE basal membrane domain is characterized by infoldings that are approximately 1  $\mu\text{m}$  in length ([Fig. 18.6](#)). The basal membrane

contains  $\alpha 3\beta 1$ ,  $\alpha 6\beta 1$ , and  $\alpha v\beta 3$  integrins, which mediate RPE attachment to Bruch's membrane (see Fig. 18.5). The basal infoldings also express Bestrophin-1, a chloride anion channel, that regulates voltage-dependent L-type  $\text{Ca}^{2+}$  channels by interacting with the beta-subunits of the  $\text{Ca}^{2+}$  channels.<sup>33</sup> Ezrin, localized to both apical and basolateral membranes, promotes morphogenesis of apical microvilli and basal infoldings, respectively.<sup>34</sup> A number of transporters work together in apical and basal domains. For example, glucose transport from the choroid to the photoreceptors is mediated by basally and apically located glucose transporter (GLUT) 1.<sup>35</sup> In contrast, elimination of lactic acid from the subretinal space is mediated by different monocarboxylate transporters in the apical (MCT1) and basolateral (MCT3) membranes.<sup>36</sup> The lateral membrane domain of the RPE cell demonstrates specialized junctions important for cell–cell attachment and communication, which will be discussed below.

**TABLE 18.1**  
**Polarized Cell Surface Molecule Expression in Retinal Pigment Epithelium**

Location	Protein	Function
Apical membrane	Na/K-ATPase	Na flux
	N-CAM	Adhesion to retina, phagocytosis
	$\alpha v\beta 5$ integrin	Phagocytosis
	CD36	Phagocytosis
	Ezrin	Apical microvilli
	CLIC4	Channels/transporters
	GLUT1	Glucose transport
	MCT1	Monocarboxylate transporter
Lateral membrane	Occludin	Tight junction
	Cadherin	Adherens junction
	Connexin	Gap junction
Basolateral membrane	$\alpha 3\beta 1$ , $\alpha 6\beta 1$ , $\alpha v\beta 3$ integrin	Attachment to Bruch's membrane
	Ezrin	Basal infoldings
	GLUT1	Glucose transport
	MCT3	Monocarboxylate transporter
	Bestrophin-1	Chloride anion channel

Na/K-ATPase, Na/K adenosine triphosphatase; N-CAM, neural cell adhesion molecule; CLIC4, chloride intracellular channel 4; GLUT1, glucose transporter 1; MCT1, monocarboxylate transporter 1.

**FIG. 18.5** Subcellular distribution of integrin receptors in adult rat retinal pigment epithelium by indirect immunofluorescence. For reference, a methylene blue-stained section of intact retina is shown at the top.  $\beta 1$  integrins are exclusively basal.  $\alpha v$  integrin receptors are apical and basolateral and stain cytoplasmic vesicles.  $\beta 5$  integrins are located apically, and  $\beta 3$  integrins are restricted to a basal location. Scale bar: 5  $\mu\text{m}$ . (Reproduced with permission from Finnemann SC, Bonilha VL, Mamorstein AD, et al. Phagocytosis of rod outer segments by retinal pigment epithelial cells requires  $\alpha v\beta 5$  integrin for binding but not for internalization. *Proc Natl Acad Sci USA* 1997;94:12932–7.)

**FIG. 18.6** Transmission electron micrograph of intact bovine retinal pigment epithelium (RPE) cells. Note the apical microvilli (*mv*), the pigment granules (*pg*) in the apical region of the RPE cytoplasm, and the basal infoldings (*bi*) in contact with Bruch's membrane (*bm*). In the upper left portion of the figure, the apically located junctional complex is seen between two retinal pigment epithelia, including the more apical zonula occludens (tight junction) and adjacent zonula adherens. The junctional complex (*jc*) is shown at higher magnification in the inset. The junctional complex is associated with a cytoplasmic band of actin filaments (*af*). Scale bar: 1.8  $\mu\text{m}$ ; bar in inset: 1  $\mu\text{m}$ .

The intracellular distribution of cell organelles in the RPE also exhibits polarization and heterogeneity (see [Figs. 18.2](#) and [18.6](#)).<sup>37</sup> Melanin granules, which are 2–3  $\mu\text{m}$  in diameter, are ovoid or spherically shaped, and are located in the apical region adjacent to the endoplasmic reticulum. At the ora serrata, the RPE contain many dense, round melanin granules throughout the cell while at the equator and macula, melanin granules are more apical, less abundant, and ovoid. The nucleus, with a diameter of 8–12  $\mu\text{m}$ , is located in the basal aspect of the cell. Mitochondria also reside in

the basal RPE due to the high oxygen pressure originating from the choriocapillaris, and are most prominent in the macula.<sup>38</sup> Other cytoplasmic elements, such as microperoxisomes, lysosomes, autophagosomes, and phagosomes, do not have a distinct distribution. However, inhibition of lysosomal degradation in the RPE can induce exocytosis of phagocytic residual material at the basolateral plasma membrane.<sup>39</sup>

## Cellular Junctions

The outer blood–retinal barrier is formed by the RPE, in which the lateral domains of adjacent cells are connected by apical zonulae occludens (tight junctions) and adjacent zonulae adherentes (adherens junctions), which form a barrier that regulates transepithelial diffusion through the paracellular spaces (Fig. 18.6).<sup>40</sup> These junctions seal off the subretinal space from the choriocapillaris, forming the so-called Verhoeff's membrane. The two major zonulae occludens proteins are the claudins and the occludins. The interaction between the extracellular domains of adjacent occludin molecules leads to high transepithelial resistance and an intact blood–retinal barrier. They maintain cell polarity by preventing the lateral diffusion of integral membrane proteins between the apical and lateral/basal surfaces, which compartmentalizes specialized functions, such as molecule transport.<sup>41</sup> The cytoplasmic domain of occludens interact with several other proteins, including zonula occludens (ZO)-1 and ZO-2, to form a complex that interacts with the actin cytoskeleton and components of various signal transduction pathways (Fig. 18.7). ZO-1 regulates cell proliferation and gene expression by inhibiting the activity of the Y-box transcription factor ZONAB, indicating they are critical for the differentiation and homeostasis of the RPE.<sup>42</sup> Early expression of the assembly proteins, including junctional adhesion molecule-A (JAM-A), AF-6, PAR-3, and PAR-6, corresponds to the initial establishment of the adherens and tight junctions,<sup>43</sup> whereas diffusible factors secreted by the neural retina act synergistically with basolateral stimulation to regulate the structure and function of RPE tight junctions.<sup>44</sup> Of the claudins, claudin 19 is the dominantly expressed isoform in human fetal RPE

cells.<sup>45</sup> JAM-C localizes specifically in the tight junctions of human fetal and adult native RPE, and regulates the recruitment of N-cadherin and ZO-1 to cell–cell contacts.<sup>46</sup> Under pathologic conditions such as oxidative stress,<sup>47</sup> inhibition of Na/K-ATPase,<sup>48</sup> matrix metalloproteinase (MMP)-9, interferon-gamma (IFN- $\gamma$ ), tumor necrosis factor,<sup>49</sup> and amyloid-beta(1–42)<sup>50</sup> could decrease tight junction protein expression, resulting in the disruption of the outer blood–retina barrier. In contrast, nitric oxide is involved in the maintenance of blood–retina barrier integrity.<sup>49</sup>

**FIG. 18.7** Immunofluorescent stain of a bovine retinal pigment epithelium (RPE) monolayer explant stained with an antibody against the ZO-1 protein, a protein associated with the zonula occludens, or tight junction, demonstrating the polygonal shape and tight adherence of the RPE ( $\times 440$ ).

The zonulae adherentes (adherens junction) form a 200 Å junction that are associated with circumferential microfilament bundles.<sup>51</sup> The transmembrane cadherins of the adherens junction require calcium to maintain cell-cell adhesion. Their cytoplasmic domains interact with catenins, which in turn, form a complex with  $\alpha$ -actinin and vinculin. The adherens junctions organize the actin

cytoskeleton to maintain the cell's polygonal shape.<sup>52</sup> Gap junctions, which are also present in the lateral cell membranes, contain connexins which exchange ions and metabolites between cells. For example, connexin 43 mediates communication between the retina and RPE that is essential for the correct pacing of retinal organogenesis.<sup>53</sup> Connexin 43 participates in the release of ATP through hemichannels, influencing both neural retinal cell division and proliferation.<sup>54</sup> The basal cell membrane contains various integrins that are involved in focal adhesion points with the ECM.<sup>55</sup> Desmosomes, which are variably present in RPE cells among different species, are not necessary for establishment of a polar, functioning RPE layer.<sup>56</sup>

## Cytoskeleton

Apart from the general role of the cytoskeleton, the RPE cytoskeleton has unique functions, including as melanosome transport and phagocytosis.<sup>57,58</sup> These vital functions are disrupted in diseases like PVR, caused by RPE cell proliferation and myofibroblastic transdifferentiation, where there are prominent rearrangements of the cytoskeleton.<sup>59</sup> The cytoskeleton is composed of three major elements: the actin microfilaments (diameter 7 nm), microtubules (diameter 25 nm), and intermediate filaments (diameter 10 nm). Microfilaments and microtubules are dynamic structures that undergo polymerization and depolymerization, and are critical for intracellular transport. Microtubules participate in mitosis, and the movement of subcellular organelles and pigment granules. Actin microfilaments are located in the microvilli and throughout the cytoplasm where they are arranged in loose arrays or bundles. They help to generate and maintain cellular shape and participate in cell migration.<sup>60</sup>

Myosins are cytoskeletal motors that generate the forces to establish cell structure and actin-dependent cell motility. Multiple myosin family members are expressed by the RPE.<sup>61</sup> In addition, myosins are involved in the movement and biogenesis of melanosomes.<sup>62</sup> Intermediate filaments provide a structural framework that links the nucleus with the cell membrane, as well as to microfilaments and microtubules. In human RPE cells,

intermediate filaments of type I (acidic keratins), type II (basic/neutral keratins), and type V (lamins) have been identified. In the RPE, cytokeratin filament expression varies with cellular differentiation, changes in cellular polarity, intercellular association, and cell culture conditions.<sup>63,64</sup> Human RPE cells in vivo express keratins 8 and 18.<sup>65</sup> In cell culture, the RPE coexpresses keratins 7 and 19. The presence of keratin 18/19 has been correlated with migration in cultured RPE cells.<sup>65</sup>

## Role of RPE in Bruch's Membrane Synthesis and Remodeling

The basal surface of the RPE has elaborate basal infoldings that attach to Bruch's basement membrane, an acellular layer separating the RPE from the choriocapillaris.<sup>66</sup> Besides the attachment site for the RPE, Bruch's membrane serves as a selective conduit for nutrients transported to the retina from the choriocapillaris and for metabolic wastes transported from the retina to the circulation. Bruch's membrane is a pentalaminar matrix composed of consists of the RPE basement membrane, the inner collagenous layer, the middle elastic layer, the outer collagenous layer, and the choriocapillaris endothelium basement membrane.<sup>67</sup> In mice, the RPE basement membrane and the choriocapillaris endothelial basement membrane are synthesized first, followed by the deposition of a collagenous layer between the two basement membranes. Finally, the elastic layer is synthesized and deposited within the collagenous layer, eventually separating it into an inner and outer collagenous layer.<sup>68</sup>

The RPE and choriocapillaris endothelial basement membranes (1.4–1.5  $\mu\text{m}$  thick) are similar to other basement membranes in composition, containing collagen type IV, laminin, fibronectin, and sulfated polysaccharides,<sup>69–71</sup> and serve to anchor subjacent cells, act as a barrier and a filter, and stabilize the tissue structure.<sup>72</sup> The choriocapillaris basement membrane also contains collagen type VI, which is not present in the RPE basement membrane, which is involved in capillary endothelial cell stabilization. The inner collagenous (1.4  $\mu\text{m}$  thick) and outer collagenous (0.7  $\mu\text{m}$  thick) layers are composed of collagens type I, II, and V, which are

organized in a lattice-like network embedded in an amorphous collection of glycosaminoglycans.<sup>73</sup>

Collagen XVIII,<sup>74</sup> which gives rise to the endostatin, an inhibitor of choroidal neovascularization, is distributed through all layers of Bruch's membrane.<sup>75</sup> Booij et al.<sup>76</sup> have shown that both the RPE and choroid express most of the genes necessary for the formation and maintenance of Bruch's membrane. Specifically, the RPE maintains its basement membrane while the choriocapillaris endothelium maintains its basement membrane, whereas the inner, outer collagenous, and the elastic layers are maintained cooperatively by both cell types. Age-related biochemical alterations in the composition and three-dimensional organization of ECM molecules in Bruch's membrane may affect this function, and are described in detail in [Chapter 22](#) (Structure, function, and pathology of Bruch's membrane).

The apical domain of RPE cells is embedded in the interphotoreceptor matrix (IPM), which is produced by the RPE and photoreceptor inner segments. A major proportion of IPM proteins are involved in retinoid transport between the photoreceptors and the RPE, and include the interphotoreceptor-binding protein (IRBP), retinol-binding protein (RBP), and transthyretin (TTR).<sup>77-80</sup> Retinal adhesion to the RPE is mediated in part by RPE transport of water and ions from the IPM toward the choriocapillaris. The IPM contains the neurotrophic pigment epithelial-derived factor (PEDF) that is secreted by the RPE with a 1000-fold greater abundance than vascular endothelial growth factor (VEGF), which is mainly secreted to the basolateral side.<sup>81</sup> Proteomic analysis of the porcine IPM indicates the wide array of functions possible by the IPM, such as neuroprotective phosphoproteins enriched in astrocytes (PEA)-15, peroxiredoxin 5,  $\alpha$ B crystallin, macrophage migration inhibitory factor, 78-kDa glucose-regulated protein (GRP78), protein disulfide isomerase (PDI), and PEP-19.<sup>82</sup> Notably,  $\alpha$ B crystallin is secreted by the RPE and maintains a neuroprotective outer retinal microenvironment.<sup>83</sup>

Degradation of ECM is regulated in part by both matrix metalloproteinases (MMPs) and the urokinase-type plasminogen activator (uPA) cascade,<sup>84</sup> which are activated by multiple types of cells, including leukocytes, endothelial cells, and RPE. MMPs are a

family of zinc-binding, Ca<sup>+</sup>-dependent endopeptidases that degrade both collagen and proteoglycans during physiologic and pathologic ECM remodeling. The MMPs are tightly regulated by their tissue inhibitors of metalloproteinases (TIMPs), whose impairment may lead to progressive alterations in Bruch's membrane.<sup>85</sup> Normal RPE express the membrane-bound type 1 (MT1-MMP), type 2 (MMP-2) metalloproteinase,<sup>86</sup> and the metalloproteinase inhibitors TIMP-1 and TIMP-3.<sup>87</sup> ECM degradation is also promoted by uPA, a serine protease that activates plasminogen to active plasmin, which degrades fibrin, fibronectin, laminin, and other ECM components.<sup>88</sup> uPA activity can be blocked by two endogenous inhibitors, plasminogen activator inhibitor-1 and -2 (PAI-1 and PAI-2),<sup>89</sup> which belong to the serpin protease superfamily.

## Specialized Functions of the RPE

### Absorption of Light

The RPE absorbs light that passes beyond the photoreceptors. This light absorption serves to both sharpen vision by removing stray photons of light and protect the RPE from photo-oxidative stress.<sup>14</sup> Within the RPE, the melanin pigment granules absorb the stray light photons (see [Fig. 18.6](#)).

### Phagocytosis of Photoreceptor Outer Segments

The apical microvilli of the RPE interdigitate with the photoreceptor OS. This interaction enables the shedding of OS that are ingested and degraded by the RPE that renews the phototransduction machinery and maintains a constant OS length. In all vertebrates examined, nocturnal and diurnal, cold-blooded and warm-blooded, rod OS shedding occurs maximally at or shortly after light onset, a daily rhythm which is established early after birth, irrespective of the lighting conditions during development. In fact, in rats the daily rod OS shedding rhythm is established by 2 weeks postnatally, and is maintained even after optic nerve transection, indicating that the rhythmic process of OS

shedding is controlled by intrinsic, ocular signals.<sup>90,91</sup> The temporal pattern of cone OS shedding is variable since in some species it occurs at night,<sup>92</sup> whereas in others, cones and rod OS are shed just after light onset.<sup>93</sup>

The disposal of the continuously shed OS is accomplished by phagocytosis of the OS at the expense of heightened metabolic activity and energy expenditure.<sup>94,95</sup> It has been estimated that, during an 80-year span, one RPE cell has internalized and degraded about 200 million discs.<sup>96</sup> The phagocytosis of OS material can be visualized in normal rat eyes using confocal microscopy to visualize rhodopsin<sup>+</sup> phagolysosomes by enucleating the eye 2 hours after onset of light (Fig. 18.8). As reviewed in reference 97, rod OS phagocytosis is a highly specialized receptor-mediated, multistep process that comprises recognition, attachment (receptor-ligand interactions), internalization (transmembrane signaling and contractile proteins), and degradation of the ingested OS. The first step in the phagocytosis is recognition, a receptor-mediated process through integrin  $\alpha v \beta 5$ , which interacts with phosphatidylserine of rod OS plasma membranes.<sup>98</sup> Although  $\alpha v \beta 3$  and  $\alpha v \beta 5$  are instrumental for substrate binding, they do not directly bind phosphatidylserine, but instead, they bind an opsonin that recognizes the “eat-me” signal of their phagocytic targets. Gas6, protein S, and milk fat globule epidermal growth factor (MFG)-E8 are soluble bridging elements.<sup>99</sup> Recently, Tubby and tubby-like protein (Tulp) 1, which are secreted by photoreceptors, have also been identified as bridging molecules that bind to MerTk (a member of the TAM receptor tyrosine kinase subfamily) at their N-terminal region and to the rod OS at their C-terminal region.<sup>100</sup>

**FIG. 18.8** Phagocytosis of rod outer segments. A section of outer retina was obtained from an eye enucleated 2 hours after light exposure in a pigmented rat. The section was evaluated using confocal microscopy after fluorescent labeling for rhodopsin (red), cytoplasm (green), and nuclei (blue). The figure shows the rhodopsin<sup>+</sup> outer segment and punctate labeling of rhodopsin in the phagolysosomes within the retinal pigment epithelium (*arrows*); shown at higher magnification in insert. *IS*, inner segments of photoreceptors; *ONL*, outer nuclear layer; *OS*, outer segment; *RPE*, retinal pigment epithelium.

After binding the rod OS, the RPE plasma membrane invaginates

around the OS, leading to its ingestion into a phagosome. Cytoskeletal elements, particularly the microfilaments in the microvilli, reorganize during the initial stages of ingestion. An actin feltwork forms at the sites of attachment that extend into the pseudopods which surround and engulf the OS to form the phagosome.<sup>101</sup> This process includes an undefined, presumably G-protein-coupled transmembrane signal that stimulates the assembly of an appropriate contractile apparatus that, in turn, provides the motive force for internalization of the attached particle.<sup>102</sup> OS internalization is mediated by the receptor tyrosine kinase, c-mer, and its ligand Gas6.<sup>103</sup> Once inside the cytoplasm, phagosomes are transported to the basal aspect of the cell by microtubules.<sup>104,105</sup> Transport may also be partially mediated by myosin VIIa, an unconventional myosin that is mutated in patients with Usher syndrome.<sup>106</sup> Cytokines such as transforming growth factor (TGF)- $\beta_1$  and basic fibroblast growth factor (FGF) regulate rod OS phagocytosis.<sup>107</sup>

Basally transported phagosomes then fuse with lysosomes where they are degraded. The lysosome–phagosome interaction occurs in two steps. First, small lysosomes fuse with phagosomes. Subsequently, larger lysosomes appear to interact with phagosomes via pore-like structures. Following fusion, lysosomal enzymes hydrolyze the sequestered OS into small molecules that diffuse out of the RPE cell or are reused within the cell. Of the wide array of lysosomal enzymes capable of hydrolyzing photoreceptor OS, cathepsin D and S are among the most important because they degrade rhodopsin, the major protein in the OS.<sup>108–110</sup> With age and/or pathologic changes, degradation of OS within the phagolysosome leads to the formation of lipofuscin granules.<sup>111,112</sup>

Autophagy is a normal homeostatic process of cells that manages cellular stress by protein degradation and turnover of damaged organelles. The degradation products are then used as building blocks for continued cell survival. Recently, Kim et al. found that a form of autophagy designated LC3 associated phagocytosis (LAP) is central to the processing of engulfed OS.<sup>113</sup> RPE phagocytosis coincided with the enzymatic conversion of LC3 to its lipidated form, which initiated single-membrane phagosomes containing engulfed POS in an Atg5-dependent manner. This process required

Beclin1, which then enables the lysosome to fuse with the phagosome and form the phagolysosome, ultimately leading to degradation of the ingested OS. Degradation products are subsequently removed from the RPE by transport to the choroid, whereas some materials are recycled to the photoreceptors to maintain vision. LAP was found to be essential for the recovery of vitamin A for 11-*cis*-retinal (11-*cis*-RAL) synthesis. This finding demonstrates the interplay of phagocytosis and autophagy within the RPE that is required for both OS degradation and the maintenance of retinoid levels to support vision.

## Role in Visual Cycle

The first step in the visual process is absorption of light by the opsins of rod and cone photoreceptors as well as by the melanopsin of retina ganglion cells. Melanopsin is involved in the regulation of circadian rhythms, pupillary light reflex, and other nonvisual responses to light,<sup>114</sup> although recently it has been shown that melanopsin in ganglion cells may contribute directly to pattern vision.<sup>115</sup> The light-absorbing chromophore of opsins is 11-*cis*-RAL, which is delivered to the rod photoreceptors by the RPE cells. The RPE cells possess the enzymatic mechanism to convert vitamin A to 11-*cis*-RAL and deliver it to the photoreceptors.

Light perception by the retina is initiated by the reaction of photons with light-sensitive pigments that are part of the membranes of photoreceptor OS. Cooperation between the photoreceptors and the RPE allows these visual pigments to be recycled through a complex series of oxidation–reduction reactions and transport mechanisms that are referred as the “visual cycle” (Fig. 18.9).

**FIG. 18.9** The visual cycle takes place in the photoreceptors (left), the retinal pigment epithelium (right), and the intervening interphotoreceptor matrix. See text for description of components of the cycle: CRALBP, cellular retinal-binding protein; IRBP, interphotoreceptor-binding protein; LRAT, lecithin retinol acyltransferase; RAL, retinal; RDH, retinol dehydrogenase; RE, retinyl esters; Rho, rhodopsin; ROL, retinol.

The visual cycle is initiated by a photon reacting with rhodopsin, which comprises a G-coupled receptor protein, opsin (rods) or cone-opsin (cones), and the chromophore 11-*cis*-RAL. Reaction with light changes 11-*cis*-RAL into all-*trans*-RAL, which is released from the opsin and reduced to all-*trans* retinol (all-*trans*-ROL). ABCA4, a member of the A subfamily of ATP-binding cassette proteins, supports the processing of highly reactive all-*trans*-RAL and prevents the buildup of A2E, an insoluble toxic compound that is shed from the photoreceptors, phagocytosed by RPE, and accumulates as lipofuscin.<sup>116</sup> All-*trans*-ROL passes into the IPM, where it binds to IRBP and is transported into the adjacent RPE cells. IRBP is a 140-kDa glycoprotein secreted by the photoreceptors, which enhances the translocation of 11-*cis*-RAL from the RPE to the photoreceptors<sup>117</sup> and the translocation of all-*trans*-ROL from the photoreceptors to the RPE.<sup>118</sup> IRBP is essential for normal visual cycle function. In fact, mice that lack IRBP have significant photoreceptor degeneration.<sup>119</sup>

In the RPE, all-*trans*-ROL is esterified to fatty acids through the action of lecithin retinol acyltransferase (LRAT) to yield all-*trans* retinyl esters (all-*trans*-RE), which are the substrates for RPE65 isomerase. RPE65 isomerase converts the all-*trans*-RE to 11-*cis*-ROL, which is bound by cellular retinaldehyde-binding protein, reduced to 11-*cis*-RAL, transferred to the IPM where it binds to IRBP, and translocated to the photoreceptors where it binds to opsin to start the cycle anew.

## Protection From Oxidative Stress

The RPE resides in a high oxidative stress environment due to a combination of unique factors. The retina obviously processes light for vision. As a result, photo-oxidative stress is a unique source of exogenous oxidative stress. Since the work of Ham et al. in 1978,<sup>120</sup> photo-oxidative stress has been linked with oxidative damage to the retina, RPE, and choroid. Vision is an energy-expensive process, which generates a high degree of reactive oxygen species (ROS).<sup>121</sup> To meet the energy demands, the retina requires a high level of oxygen. As a result, the RPE lives in high ambient oxygen partial pressures of 70–90 mm Hg.<sup>122</sup> The phagocytosis of outer segments is another unique source of ROS because H<sub>2</sub>O<sub>2</sub> is produced by NADPH oxidase in phagosomes or from  $\beta$ -oxidation of OS lipids in peroxisomes.<sup>123,124</sup> Thus, the RPE is armed with a substantial antioxidant system to protect itself in this high oxidative stress environment.

A number of antioxidant systems are regulated through various transcription factors, including Nf- $\kappa$ B, AP1, the FoxO family, or PGC-1 $\alpha$ . Central to the RPE's antioxidant response is the transcription factor nuclear factor-erythroid 2 p45-related factor 2 (Nrf2), which regulates a coordinated, comprehensive transcriptional program that maintains cellular redox homeostasis and protects the cell from oxidative injury<sup>125–127</sup> (Fig. 18.10). Under basal conditions, Nrf2 interacts with the negative regulator Kelch-like ECH-associated protein 1 (Keap1), keeping Nrf2 in the cytoplasm. Keap1 also functions as a substrate adaptor protein for a Cul3-dependent E3 ubiquitin ligase complex, which targets Nrf2 for proteolysis by the ubiquitin-proteasome pathway.<sup>128</sup> With oxidative

stress, Keap1 undergoes a conformational change of its multiple cysteine residues, which releases Nrf2 and prevents Keap1-mediated proteasomal degradation of Nrf2. Nrf2 then translocates to the nucleus where it dimerizes with Maf proteins, and binds to the antioxidant response element (ARE) in the promoters of antioxidant target genes to initiate the transcription.<sup>129,130</sup> Importantly, Nrf2 signaling plays an essential antioxidant role in the RPE.<sup>131-134</sup>

**FIG. 18.10** Schematic of Nrf2 signaling. Normally, Nrf2 is sequestered in the cytoplasm by Keap1, which also functions as a substrate adaptor protein for a Cul3-dependent E3 ubiquitin ligase complex, which targets Nrf2 for proteolysis by the ubiquitin-proteasome pathway. Upon oxidative stress, reactive oxygen species (ROS) induce a conformational change to Keap1, which releases Nrf2. Nrf2 translocates to the nucleus where, along with Maf proteins, they bind to antioxidant response elements (ARE) to induce cytoprotective gene expression including phase 2 detoxifying enzymes and antioxidant stress proteins.

The Nrf2 signaling response regulates both an early acute phase to H<sub>2</sub>O<sub>2</sub>, 4-hydroxy-2-nonenal, hypoxia/hyperoxia, inflammation, and toxic drugs, as well as lipid signaling agents such as ceramide<sup>135</sup> through actions of the “direct” enzymes, such as catalase or SOD, which neutralize H<sub>2</sub>O<sub>2</sub> and superoxide, respectively.<sup>136,137</sup> Nrf2 signaling regulates chronic oxidative stress by maintaining cellular glutathione and thioredoxin systems through glutathione (GSH),<sup>138</sup> thioredoxins (Trx),<sup>139</sup> glutaredoxins (Grx),<sup>140</sup> methionine sulfoxide reductases (Msrs),<sup>141</sup> and glutathione peroxidase.<sup>142</sup> Nrf2 also regulates the expression of xenobiotic metabolism enzymes that produce reducing equivalents, such as NADPH quinone oxidoreductase-1 (NQO-1).<sup>143</sup> In the cytosol, the glutathione and thioredoxin 1 systems are essential for maintaining normal cellular function. When ROS depletes cellular glutathione, Nrf2 signaling is activated with an accompanying compensatory upregulation of glutathione S-transferase, gamma glutamylcysteine synthetase, and glutathione peroxidase-1.<sup>144,145</sup> Trx1 also protects against oxidative stress in the cytoplasm; overexpression or intravenous injection of Trx1 protects RPE cells from oxidative injury.<sup>140,146</sup> Should glutathione or Trx1 levels drop sufficiently, cells can die from oxidatively induced apoptosis.<sup>147,148</sup>

Mitochondria continuously produce 90% of cellular ROS, an amount that can increase 10-fold when damaged.<sup>149</sup> Due to the high energy demands for vision, maintenance of the mitochondrial antioxidant pool is critical to prevent mitochondrial and cellular dysfunction. Mitochondrial antioxidants are pivotal, first line defense that protects mitochondria from excessive ROS to ensure cellular homeostasis. These include the thioredoxin 2 (Trx2) system including Trx reductase 2 (TrxR2), and peroxiredoxin 3 (Prx3) and the glutathione (GSH) system including glutathione reductase (GR), glutathione peroxidase (GPx-1 and -4).<sup>150</sup> Sulfiredoxin (Srx), a cytosolic protein, is an additional member of the Trx2 system after it translocates to the mitochondria.<sup>151</sup> Nrf2 is involved in the regulation of mitochondrial antioxidants including Trx2, Prx3, and Srx.<sup>152-154</sup> Most mitochondrial ROS are produced as superoxide anion (O<sub>2</sub><sup>-</sup>), which is rapidly converted to H<sub>2</sub>O<sub>2</sub> by superoxide dismutase-2 (SOD2). Since mitochondrial catalase levels are very low, H<sub>2</sub>O<sub>2</sub> is neutralized by the GSH and Trx2 systems, which

protect against retinal injury.<sup>142,155</sup> Despite 100-fold lower levels than GSH,<sup>156</sup> Trx2 redox regulation is essential for survival and is more sensitive than GSH to oxidative stress because enhanced ROS reduces Trx2 before GSH.<sup>157</sup>

## Role in Maintaining Avascular Outer Retina

The avascularity of the subretinal space is dependent on the antiangiogenic activity of PEDF and endostatin, the 20-kDa C-terminal fragment derived from type XVIII collagen by proteolysis. PEDF is synthesized and secreted by the RPE into the IPM,<sup>158,159</sup> where it acts as a neuroprotective factor for photoreceptors and neural retina ganglion cells. PEDF is also a most potent and selective antiangiogenic factor that inhibits vascular growth, mediates regression of newly formed blood vessels without affecting preexisting vessels, and in the retina, prevents the growth of blood vessels into the subretinal space.<sup>160–162</sup> The importance of PEDF in maintaining the avascularity of the outer retina is apparent from its retinal distribution of PEDF. The expression of PEDF is highest in the developing fovea of mid-gestation human retinas and in the fovea of monkeys aged between fetal day 55 and 11 years of age.<sup>163</sup> In normal adult eyes, PEDF is 10-fold higher than VEGF in the macula, but not in the retinal periphery, strongly suggesting that PEDF is responsible for subretinal macular avascularity.<sup>164</sup>

In addition to PEDF, avascularity of the subretinal space is dependent on endostatin. Endostatin is cleaved from collagen XVIII in Bruch's membrane by the action of RPE-derived MMP-9 and cathepsin L. Laser-induced choroidal neovascular lesions in *Col18a1*<sup>-/-</sup> mice, which lack endostatin, develop marked vascular permeability and form large, confluent areas of subretinal neovascularization. In contrast, choroidal neovascular lesions in control mice remain small and clearly circumscribed. Administration of recombinant endostatin to *Col18a1*<sup>-/-</sup> mice decreases the lesion size to that observed in control mice.<sup>165</sup>

## Immune Privilege and the Immune Response

Immune privilege refers to the fact that foreign-tissue grafts placed in the immune-privileged site are tolerated and survive for

prolonged, often indefinite, intervals, while placement of such grafts at conventional body sites leads to acute irreversible immune rejection. Ocular immune privilege was demonstrated by Sir Peter Medawar in 1948 when skin allografts survived when implanted into the anterior chamber of the eye.<sup>166</sup> Only in the past 20 years has research supported the subretinal space as a relatively immune-privileged space.<sup>167,168</sup> The RPE is a major source of subretinal immune privilege, evolving from a concept of passive physical barriers (tight junctions between RPE; lack of lymphatic drainage from the subretinal space; low levels of major histocompatibility antigen expression) to an active process. The RPE express both soluble (TGF- $\beta$ , PEDF) and cell surface molecules (TGF- $\beta$ , CD95 (FAS) ligand, CD59, CD46) that promote immune privilege. TGF- $\beta$  has been identified as a major factor in the inhibition of T-cell proliferation and IFN- $\gamma$  production, and the generation of T-regulatory cells (Tregs) in ocular immune-privileged sites.<sup>168</sup> Recently, immune privilege in the aqueous humor was shown to require a role for both TGF- $\beta$  and retinoic acid in the generation of Tregs; however, whether this is also true for the subretinal space is currently unknown.<sup>169</sup>

The RPE possesses significant capability of eliciting an immune response. The RPE expresses many components of innate immunity. For example, the RPE expresses Toll-like receptors 1–7, 9, and 10, which participate in host defense response to either bacteria or damaged molecules.<sup>170</sup> The RPE expresses many components of the complement system, which can be induced in response to a stress as a protective early response.<sup>171</sup> Recently, the RPE has been found to produce the NLRP3 inflammasome in response to a number of inciting factors including Alu RNAs, ROS, and extracellular ATP.<sup>172</sup> These different arms of innate immunity are designed to eliminate dangerous molecules. They are an intricate, finely balanced network that responds definitively to an inciting trigger. Disruption of this delicate balance can result in a dysregulated response that causes tissue injury critical for maintaining the health of the RPE while a dysregulated response can impair RPE health. A full discussion of the blood–retinal barrier and immune privilege is found in [Chapter 29](#) (Blood–retinal barrier, immune privilege, and autoimmunity).

## Transport of Nutrients, Ions, and Water

RPE cells are responsible for delivering nutrients from the circulation to the photoreceptors, and water and metabolic waste from the photoreceptors to the circulation. Since the RPE forms a tight barrier to diffusion, nutrients are taken up by active transport mechanisms that are specific for each nutrient and ion.

Of the nutrients that the RPE must deliver, glucose is one of the most important. RPE cells express very high levels of the glucose transporters, GLUT1 and GLUT3.<sup>173,174</sup> GLUT1 glucose transport is dependent on metabolic demand, and its expression is regulated by the glucose level. Low glucose levels increase its expression whereas high glucose levels decrease it.<sup>175</sup> GLUT3 is a high-affinity glucose transporter that is responsible for the basal transport of glucose to maintain resting-level activity. GLUT1 also mediates the uptake of vitamin C. In RPE cells, this may be important since the high energy requirements of the retina produce ROS, which are neutralized by vitamin C.<sup>176</sup>

Vitamin A is essential for vision. Vitamin A is transported from the circulation to the RPE bound to a complex of RBP and TTR. Upon reaching the RPE basal membrane, retinol is released to the membrane retinol receptor STRA6 (stimulated by retinoic acid 6), which transfers vitamin A into the cell, where it is converted to the active chromophore 11-*cis*-retinal.<sup>177</sup>

Ions are transported in and out of RPE cells through selective channels. For example, calcium, which in the RPE is essential for growth factor secretion, phagocytosis, ion exchange, and water transport, is mediated by a number of channels. These include L-type and T-type voltage-gated calcium channels,<sup>31,178,179</sup> as well as calcium channels of the transient receptor potential canonical (TRPC), specifically TRPC1 and TRPC4.<sup>180,181</sup> Two calcium transport channels, TRPV5 and TRPV6, with a calcium–sodium selectivity of more than 100:1 for calcium, have also been identified in RPE cells.<sup>182</sup>

The RPE removes water, ions, and catabolites from the retina to the choriocapillaris. However, RPE cell tight junctions prevent the paracellular transport of water, ions, and other solutes between the subretinal space and the choriocapillaris. Instead, they are actively transported across the RPE. For example, lactic acid is removed

from the subretinal space by monocarboxylate transporters in the apical (MCT1) and basolateral (MCT3) membranes.<sup>36,183</sup> Apically located Na<sup>+</sup>,K<sup>+</sup>-ATPase provides the energy for transepithelial transport, and regulates sodium and potassium ion flux across the RPE plasma membrane, which maintains proper ion balance in the IPM and establishes membrane potentials. Water is formed during the high metabolism of vision in the retina, and is removed from the subretinal space through active transport of chloride ion channels across the RPE to the choroid.<sup>182</sup> Water movement across the RPE is also facilitated by Aquaporin-1 channels.<sup>184,185</sup> Impaired egress of water will result in macular edema, exudative retinal detachment, and if chronic, RPE and photoreceptor degeneration that results in blindness.

## Secretion of Cytokines and Growth Factors

RPE cells secrete many cytokines and growth factors that regulate many of the cellular pathways necessary for function, survival, and response to injury. The best known of these factors are VEGF and PEDF. VEGF, which is constitutively secreted from the basal surface of the RPE towards the choriocapillaris, has two main functions: (1) to provide prosurvival signals to the choroidal vascular endothelial cells; and (2) to maintain the fenestrations of the choriocapillaris endothelium.<sup>186</sup> PEDF is predominantly secreted from the apical RPE surface where it promotes an antiangiogenic and neuroprotective environment for the photoreceptors.<sup>81</sup> Many of these factors show dysregulated expression in retinal diseases such as AMD, diabetic retinopathy, and PVR. The most common of these factors are listed in [Table 18.2](#).

**TABLE 18.2**  
**Growth Factors Produced by Retinal Pigment Epithelium Cells**

Factor	Function	References
Pigment epithelial-derived factor (PEDF)	Neuroprotection, neurogenesis, antiangiogenesis	81, 158, 159
Vascular endothelial growth factor (VEGF)	Angiogenesis, endothelial cell survival factor, maintenance of choriocapillaris fenestrations	81, 164, 186
Nerve growth factor (NGF)	Survival and maintenance of sympathetic and sensory neurons. Ocular immune response	187, 188
Brain-derived neurotrophic	Supports the survival of existing neurons, and	188, 189

factor (BDNF)	fosters the growth and differentiation of new neurons and synapses	
Neurotrophin-3 (NT-3)	Stimulation and control of neurogenesis	189
Insulin-like growth factor (IGF-1)	Regulation of neurogenesis, myelination, synaptogenesis, and dendritic branching and neuroprotection after neuronal damage	190, 191
Neuroprotectin 1 (NPD1)	Protects neural tissues from injury caused by free radicals and other oxidative stress	192
Transforming growth factor- $\beta$ (TGF $\beta$ )	Regulation of many cellular processes in the adult and developing embryo, including cell growth and differentiation and cellular homeostasis	193
Granulocyte-macrophage colony-stimulating factor (GM-CSF)	Stimulation of stem cells to differentiate into granulocytes and monocytes	194
Monocyte chemotactic protein-1 (MCP-1)	Monocyte chemoattractant	195
Hepatocyte growth factor (HGF)	Hepatocyte growth factor regulates cell growth, cell adhesion, cell motility, and morphogenesis	196
Erythropoietin (EPO)	Regulates red blood cell production. EPO protects retina from physiologic and pathologic light-induced oxidative injury	197
Platelet-activating factor (PAF)	Phospholipid activator and mediator of platelet aggregation, inflammation, and anaphylaxis	198
Melanoma growth-stimulatory activity/growth-regulated protein (MGSA/GRO)	Enhances chemotaxis of neutrophils and enhances the secretion of elastase and other matrix-degrading enzymes	199
Endothelin 1	Vasoconstriction	200
Fibroblast growth factor	Mitogenic and cell survival activities. Involved in embryonic development, cell growth, morphogenesis, tissue repair, tumor growth, and invasion	201
Bone morphogenetic protein	Regulation of differentiation, senescence, and apoptosis	202
Interleukin-6	Pleiotropic cytokine with a role in inflammation, hematopoiesis, angiogenesis, cell differentiation, and neuronal survival	203
Interleukin-8	Interleukin-8 attracts and activates neutrophils	204
Connective tissue growth factor	Intraocular fibrosis	205

## Introduction

The human retina contains three main types of glial cells: microglia and two types of macroglia, astrocytes and Müller cells (Fig. 19.1A). Microglial cells are the primary resident innate immune cells of the retina. They play (in close relationship to macroglial cells and blood-derived immune cells; Fig. 19.2A) important roles in the host defense against microorganisms, the initiation of inflammatory processes, and tissue repair. Astrocytes are associated with the nerve fibers and blood vessels of the superficial vascular plexus (Fig. 19.1A). Müller cells are the principal macroglia of the retina (Figs. 19.1A–B).<sup>1</sup> In virtually every retinopathy, activated glial cells contribute to neuroprotection and neurodegeneration in the retina.<sup>2</sup>

**FIG. 19.1** Retinal glia. (A) Schematic drawing of the cellular constituents of a human retina. Müller cells (*M*) span the entire thickness of the neuroretina, and are arranged in a regular pattern. The perikarya of Müller cells are localized in the inner nuclear layer (*INL*). The funnel-shaped endfeet of Müller cells form the inner surface of the retina. In the outer (*OPL*) and inner plexiform layers (*IPL*), side branches which form perisynaptic membrane sheaths originate at the stem processes. Both astrocytes (*AG*) and Müller cells contact the superficial blood vessels and the inner surface of the retina. In the outer nuclear layer (*ONL*), the stem process of Müller cells forms membrane sheaths which envelop the perikarya of rods (*R*) and cones (*C*). Microvilli of Müller cells extend into the subretinal space which surrounds the photoreceptor segments (*PRS*). Microglia (*MG*) are located in both plexiform layers and the ganglion cell layer (*GCL*). *A*, amacrine cell; *B*, bipolar cell; *G*, ganglion cell; *H*, horizontal cell; *P*, pericyte; *RPE*, retinal pigment epithelium. Panels B–D: Confocal images of guinea pig retina preparations. (B) Retinal section. Müller cells are green-labeled; synapses and the outer segments of photoreceptor cells are blue-stained. (C,D) “Horizontal sections” through a flat-mounted retina, illustrating the regular pattern of Müller cell stem processes (green) in the inner plexiform layer (C) and the almost total occupation of the ganglion cell layer by the Müller cell endfeet (green; *M*); only the somata of the ganglion cells (*G*) appear “empty” (D).

**FIG. 19.2** Retinal microglia activation. (A) Interaction of blood-derived monocytes/macrophages and retinal glia in a rabbit model of early PVR induced by intravitreal

injection of the protease dispase. Retinal slices were stained against immune cells (red), glial fibrillary acidic protein (GFAP) (*green*; a marker of activated Müller cells), and cell nuclei (blue). Under control conditions, microglia (*red*) are restricted to the innermost retinal layers, and Müller cells do not express GFAP. The retina of the dispase-treated eye displays “hot spots” of glial reactivity characterized by upregulation of GFAP in Müller cells (green) and activated microglia that begin to migrate toward the outer retina (*arrow*). Blood-borne monocytes/macrophages adhere to the vitreal surface of such hot spots (*arrowheads*), suggesting a relationship between the attachment of macrophages and glial cell activation. (B) Microglia at the vitreal surface of a control rabbit retina (left) and a retina obtained 8 days after a 1-h transient retinal ischemia (right). Note the proliferation of microglial cells. (C)

Microglia migration in the porcine retina after experimental local retinal detachment. Retinal slices were derived from a control retina, a detached retina 7 days after surgery, and a peridetached retinal area that surrounded the detached retina in situ. The slices were labeled with isolectin to stain blood vessels and microglial/immune cells (green). Cell nuclei are blue.

*Arrows and arrowheads*: microglial cell bodies and processes, respectively. Note the migration of microglia from the inner to the outer retina after detachment and the thinner outer nuclear layer (*ONL*) in the detached retina compared to the control retina which reflects the degeneration of photoreceptor cells. *GCL*, ganglion cell layer; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *PRS*, photoreceptor segments.

Scale bars: 20  $\mu\text{m}$ .

## Retinal Microglia

Microglial cells are blood-borne mononuclear phagocytes and antigen-presenting cells. Microglia enter the retina via the ciliary body and hyaloid vasculatures, and later via the optic nerve head, during embryonic and postnatal development (see reference 2 and references therein). Resting microglia are located in the plexiform

and nerve fiber/ganglion cell layers, and around the vessels (Figs. 19.1A and 19.2B–C). Resting microglia display a ramified morphology (Figs. 19.2A and 19.3C) and act as highly motile patrolling cells that constantly survey their microenvironment to clear metabolic products and cellular debris. Microglial process motility is dependent on neuronal activity; it is increased during glutamatergic neurotransmission and decreased during  $\gamma$ -aminobutyric acid (GABA)ergic neurotransmission.<sup>3</sup> Once a pathogenic stimulus is detected, microglia become activated, proliferate (Figs. 19.2A and 19.3C), and migrate towards the region of damage (Figs. 19.2A, C) where the cells kill bacteria, release cytotoxic agents, and phagocytize cellular debris. While activated microglia initially contribute to neuronal protection and tissue regeneration, excessive or prolonged activation of the cells by alarm signals from exogenous and endogenous sources can lead to chronic overactivation and loss of autoregulatory mechanisms which contribute to retinal inflammation and degeneration.<sup>4,5</sup>

**FIG. 19.3** Propagation of retinal gliosis in response to experimental focal detachment of the porcine retina.

The tissues and cells were obtained from control retinas, from retinal areas that were detached for 3 and 7 days, respectively, and from nondetached retinal tissues that were localized around the focally detached retinal areas in situ (peridetachment). (A) Müller cell gliosis is reflected by the upregulation of the intermediate filament glial fibrillary acidic protein (GFAP; above) and the downregulation of Kir4.1 (middle) in the detached and peridetached retinal areas compared to the control retina. In contrast, the localization of the aquaporin-4 water channel remained unaltered after detachment (below). Retinal slices were obtained 7 days after surgery. Cell nuclei are blue. *Arrowheads*: perivascular staining. Note that GFAP expression is restricted to astrocytes in the nerve fiber (*NFL*)/ganglion cell layers (*GCL*) in the control retina

(above). (B) The distribution of Kir2.1 protein does not alter after detachment compared to control. (C) Staining of microglia (red) in the NFL/GCL in wholemounts of retinas 3 days after surgery. (D) Retinal detachment increases the ATP-induced calcium responsiveness in the endfeet of Müller cells. The calcium imaging records were obtained from the NFL/GCL of retinal wholemounts before (*control*) and during administration of ATP (*ATP*) (200  $\mu$ M). The wholemounts were derived from a control retina and a 7-days-detached retina. In the control retina, single endfeet of Müller cells showed a calcium response (green) while in the detached retina, the majority of Müller cell endfeet displayed a response. (E) Kir currents (left) and resting membrane potential (*RMP*; right) of Müller cells derived from control (unoperated and vitrectomized), 3-days-detached, 7-days-detached, and attached retinal areas. Note the time-dependent decrease of the Kir currents in the cells of the attached retinal area. (F) Focal retinal detachment causes an alteration in the osmotic swelling properties of Müller cells in the detached and peridetached retinal areas. The cross-sectional area of Müller cell somata was measured in retinal slices. Acute exposure of retinal slices to a hypoosmotic extracellular solution (60% osmolarity) induced a time-dependent swelling of Müller cell bodies in detached and peridetached retinal areas, and had no effect on the size of Müller cell bodies in control retinas. The images display original records of a Müller cell body in a slice of a detached retina, obtained before (left) and during (right) hypoosmotic exposure. (G) Relation between the amplitude of the Kir currents and the severity of osmotic cell swelling in Müller cells derived from control, 7-days-detached, and peridetached retinas. *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *ONL*, outer nuclear layer. Scale bars: (A–D) 20  $\mu$ m; (F) 5  $\mu$ m.

## Resting Microglia

Resting microglia are programmed for immunologic tolerance and

display an antiinflammatory phenotype characterized, for example, by low nitric oxide (NO) and superoxide anion production.<sup>6</sup> The quiescence of microglia requires the presence of antiinflammatory cytokines such as thrombospondin-1, transforming growth factor (TGF)- $\beta$ , and interleukin (IL)-10 which downregulate antigen-presenting molecules like major histocompatibility (MHC) class II, block inflammatory gene expression, and inhibit microglial migration and phagocytic activity.<sup>7</sup> Thrombospondin-1 is essential for the immune privilege of the retina.<sup>8</sup> Further soluble and cell-contact factors such as CD200 and fractalkine (CX3CL1) contribute to microglia quiescence.<sup>2</sup>

## Microglia Activation

Microglial cells become activated early under pathologic conditions (Figs. 19.2A–C and 19.3C). Microgliosis is associated with and often precedes retinal degeneration (see reference 2 and references therein). Many retinopathies, like retinal detachment and proliferative vitreoretinopathy (PVR) (Fig. 19.2A), are characterized by a tripartite process involving inflammation, immune response, and coagulation/fibrinolysis, which is mediated by activation of immune cells (microglia in the retinal parenchyma, blood-derived monocytes/macrophages and neutrophils in the subretinal space and/or vitreous, and leukostasis in blood vessels).<sup>9</sup>

Microglia activation is associated with a morphologic transition from a stellate, ramified morphology to an ameboid cell shape; activated microglia display enlarged somata and shortened and thickened processes (Fig. 19.3C). Microgliosis is triggered by various molecules, including bacterial lipopolysaccharide, complement components, thrombin, inflammatory cytokines and chemokines such as IL-1 $\beta$ , IL-6, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), vascular endothelial growth factor (VEGF), fractalkine, macrophage colony-stimulating factor, and monocyte chemoattractant protein-1 (MCP-1; Ccl2), advanced glycation endproducts, glycated albumin, and adenosine 5'-triphosphate (ATP) released from damaged neurons (see reference 2 and references therein). MCP-1 also recruits bone marrow-derived monocytic precursor cells into the retina that replace resident microglia.<sup>10</sup>

## Microglial Contribution to Neuronal Degeneration

Although inflammation normally protects from dangerous stimuli and restores tissue homeostasis, chronic, overstimulated, and dysregulated inflammation is a major cause of secondary tissue damage.<sup>4,5</sup> Activated microglia generate reactive oxygen and nitrogen species, produce prostaglandins and matrix metalloproteinases (MMPs), and secrete Fas-ligand and proinflammatory cytokines like TNF- $\alpha$  and IL-1 $\beta$ .<sup>2</sup> The majority of these microglia-secreted molecules can cause progressive neurodegeneration upon chronic exposure.<sup>4</sup> Damage-associated molecular patterns released from degenerating neurons trigger Toll-like receptor (TLR)-dependent microglia activation which may lead to attacks against healthy neurons by the release of cytotoxic cytokines like TNF- $\alpha$ , the production of reactive oxygen and nitrogen species, and the initiation of immune responses against retinal antigens.<sup>4</sup> Activated microglia may also exacerbate photoreceptor and neuronal degeneration by the production of chemotactic factors such as MCP-1 that recruits monocytes/macrophages and polymorphonuclear leukocytes to the retinal tissue.<sup>11</sup> Activated microglia produce endothelin-2 which induces astrogliosis, retinal ganglion cell death, and vasoconstriction; microglia-induced vascular dysfunction is a pathogenic factor of glaucoma, for example.<sup>12</sup> Activated microglia also exacerbate retinal pathologies after systemic viral, bacterial, and fungal infections.<sup>2</sup> The spread of retinal gliosis and retinal degeneration from a local retinal injury to the surrounding noninjured tissue (Figs. 19.3A, D–F) is mediated by the diffusion of growth and inflammatory factors, and by migrating activated microglia (Fig. 19.3C). Inhibition of microglia activation was shown to slow hereditary and light-induced retinal degeneration, and to have protective effects in glaucomatous eyes, and in the ischemic-hypoxic and diabetic retina.<sup>2</sup>

## Microglial Contribution to Neuronal Survival

Microglia activation can also promote neuroprotection and

regeneration. Resting and activated microglia produce neurotrophic factors such as brain-derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF), glial cell line-derived neurotrophic factor (GDNF), and basic fibroblast growth factor (bFGF), as well as antiinflammatory cytokines that facilitate neuronal and photoreceptor survival (see reference 2 and references therein).<sup>4</sup> Activated microglia also benefit surviving cells by removing toxic byproducts, pathogens, extravasated serum proteins, and cell debris. Photoreceptor degeneration in mice was shown to be promoted by activated resident microglia, but inhibited by bone marrow-derived microglial precursors.<sup>13,14</sup> Activated microglia may also limit retinal inflammation by directing T cells toward the Th2 pathway and the release of immunosuppressive cytokines like TGF- $\beta$ .<sup>15</sup> Astrocytes and Müller cells may limit the magnitude of retinal inflammation by facilitating the quiescence of microglia.<sup>16</sup> At present, it is unclear why microglia are sometimes damaging and other times protective.

## Microglia in the Aging Retina

With advancing age, micro- and macroglial cells display increased signs of gliosis. Microglia undergo age-related changes in gene expression which give rise to pathogenic phenotypes and to a dysregulation of immune responses.<sup>17</sup> Breakdown of the blood–retinal barrier, MHC class II expression, microglia activation, and trafficking of activated T cells are characteristics of physiologic aging.<sup>18</sup> In the young adult retina, the outer retina is devoid of microglia (Fig. 19.2C). In the aging retina, a subretinal accumulation of microglia is triggered by the inefficient clearance of oxidized photoreceptor lipoproteins by the retinal pigment epithelium (RPE).<sup>5</sup> Microglia migrate from the inner retina to the subretinal space to clear oxidized lipoproteins.<sup>2,5</sup> The subretinal microglia was suggested to activate the RPE and to form “crystallization” points for cellular deposits and complement-containing immune complexes.<sup>19</sup> Infiltrating macrophages and resident microglia are major sources of the complement factors C3 and CFB, complement activators associated with retinal light damage and the pathogenesis of age-related macular degeneration (AMD).<sup>2</sup>

Activated microglia containing photoreceptor debris may actively exit the retina, and may reach the spleen, where they act as antigen-presenting cells and elicit systemic immune responses against retinal antigens.<sup>20</sup> Autoantibodies against retinal antigens play pathogenic roles in various retinopathies including AMD, diabetic retinopathy, light-induced retinal degeneration, and glaucoma (see reference 2 and references therein).

Activated microglia also contribute to the progression of AMD to the neovascular stage. In experimental choroidal neovascularization, infiltrating monocytes/macrophages and resident microglia express VEGF, the major angiogenic factor implicated in wet AMD, prior to the increased VEGF expression in the RPE.<sup>2</sup> By the release of blood–retinal barrier-dissolving factors like VEGF, NO, and MMPs, activated microglia also contribute to the breakdown of the barrier resulting in retinal edema, a characteristic of wet AMD and diabetic retinopathy. In human subjects with diabetic macular edema, assumed to be primarily caused by vascular leakage, oral administration of the microglia-inhibitory agent minocycline improves visual function, macular edema, and vascular leakage.<sup>21</sup>

## Retinal Astrocytes

Astrocytes are localized in the nerve fiber/ganglion cells layers (Figs. 19.1A and 19.3A); their processes contact the retinal ganglion cell somata and axons, and the superficial blood vessels (Figs. 19.4A–B). Both astrocytes and microglia play crucial roles in retinal vascularization (see reference 2 and references therein). Astrocytes, vascular endothelial cells, and pericytes are immigrants from the brain. In the mature retina, astrocytes, microglia, pericytes, and Müller cells normally inhibit vascular endothelial cell proliferation, maintain vascular stability, and contribute to the formation of the inner blood–retinal barrier which is constituted by tight junctions between vascular endothelial cells.<sup>2</sup> In the developing retina, astrocytes promote the capability of retinal ganglion cells to receive synaptic input and the growth of ganglion cell axons.<sup>22,23</sup> In the mature retina, the growth of ganglion cell axons is inhibited by astrocytes.<sup>24</sup> Retinal astrocytes contribute to various glial

homeostatic functions which are also carried out by Müller cells, e.g., removal of carbon dioxide (CO<sub>2</sub>), regulation of extracellular pH, and clearance of the extracellular fluid from neurotransmitters and excess potassium (see below). The gap junctional coupling of astrocytes creates a functional syncytium which allows the intercellular propagation of intracellular signals, the control of the ionic and metabolic homeostasis of retinal ganglion cell somata and axons, the neurovascular coupling, and the propagation of intercellular glial calcium waves.<sup>2</sup>

**FIG. 19.4** Astrocytes in the murine retina. (A) In the central retina, the processes of many astrocytes run parallel to the bundles of ganglion cell axons and form (together with Müller cell endfeet, *MCE*) perivascular endfeet. (B) In the periphery of the same retina, the density of nerve fibers is low; accordingly, the pattern of astrocytic processes is rather irregular but still these processes form endfeet at the blood vessels (*asterisks*).

## Astrocytes in the Aging Retina

Decreases in astrocyte number and gliotic changes of astrocytes were observed in the aged human retina and in AMD.<sup>25</sup> These changes will impair the capacity of astrocytes to maintain tissue homeostasis and the support of neuronal function in old age, and

will predispose the retina to age-related diseases such as glaucoma and AMD.<sup>26</sup> The age-related degeneration of astrocytes is associated with a breakdown of the blood–retinal barrier and inflammation.<sup>18</sup> On the other hand, inflammatory astrogliosis was also suggested to be required for the survival of retinal ganglion cells in the aged and diseased retina.<sup>27</sup>

## Astrocytes in the Diseased Retina

After retinal injury, astrocytes become activated, proliferate, migrate, exhibit enlarged somata and processes, and upregulate intermediate filaments such as glial fibrillary acidic protein (GFAP), but often to a lesser extent than Müller cells (see reference 2 and references therein). Elevation of the intraocular pressure results in deleterious changes of astrocytes in the optic nerve head and the retina.<sup>28</sup> Activation of astrocytes initially represents a cellular attempt to limit the extent of neuronal injury, but reactive astrocytes also have noxious effects on retinal ganglion cell axons by creating mechanical injury and changing the neuronal microenvironment, resulting in activation of the autonomous self-destruction of ganglion cells.<sup>29</sup> Astrocytes are suggested to contribute to the secondary death of retinal ganglion cells in glaucoma via a spread of oxidative stress through the astrocytic network from the injured axons to the ganglion cell somata.<sup>30</sup> The inflammatory response of astrocytes in experimental glaucoma, which involves the upregulation of soluble inflammatory and neurotoxic factors like TNF- $\alpha$ , prostaglandins, reactive oxygen and nitrogen species, and MMPs, is thought to mediate the glial toxicity in retinal ganglion cells.<sup>2,31</sup>

Malfunction and degeneration of astrocytes may also play a key role in vascular degeneration and retinal dysfunction in diabetic retinopathy.<sup>2</sup> The hyperplasia and malfunction of astrocytes in experimental diabetes coincides with the inner retinal hypoxia and ganglion cell dysfunction.<sup>32</sup> Under ischemic–hypoxic conditions, upregulation of VEGF and TGF- $\beta$  in astrocytes and Müller cells, and downregulation of antipermeability factors like atrial natriuretic peptide (ANP) in astrocytes, contribute to the breakdown of the blood–retinal barrier and the development of

retinal edema.<sup>2,33,34</sup> A malfunction of astrocytes in glaucoma and diabetic retinopathy may lead to an impaired neurovascular coupling (the hyperemia in response to neuronal activity; see below) and may thus contribute to hypoxic conditions. Upregulation of proangiogenic factors and enzymes like VEGF, platelet-derived growth factor, placental growth factor, NO synthases, and cyclooxygenase-2, and downregulation of antiangiogenic factors like ANP contribute to the development of retinal neovascularization (see reference 2 and references therein).

Bacterial and viral infections are important cofactors of autoimmune uveitis. In addition to infiltrating and resident microglia/macrophages, activated astrocytes have the potential to act as antigen-presenting cells.<sup>35</sup> Various pathogenic conditions like oxidative stress, hypoxia, and elevated intraocular pressure, as well as inflammatory factors stimulate the antigen presentation by astrocytes, via upregulation of MHC class I and II molecules.<sup>2</sup> Pathogen-associated molecular patterns which activate microbial recognition receptors like TLRs trigger alterations in retinal astrocytes required to activate T cells.<sup>36</sup> T-cell-derived IL-17 induces increased production of inflammatory cytokines and chemokines in retinal astrocytes which stimulate the migration of granulocytes.<sup>37</sup>

Activation of astrocytes also has neuroprotective and regenerative effects. Astrocytes protect retinal ganglion cells from injury by various mechanisms including the uptake of excess glutamate, the production of neurotrophic factors like bFGF, BDNF, and CNTF, the restoration of the blood–retinal barrier, and the inhibition of retinal neovascularization.<sup>2</sup> Astrocyte-derived BDNF and CNTF also stimulate the regeneration of retinal ganglion cell axons after injury.<sup>2,38</sup>

## Müller Glial Cells

Müller cells are specialized radial glial cells which span the entire thickness of the neural retina, from the vitreal surface to the subretinal space (Figs. 19.1A–B). Their somata are localized in the inner nuclear layer; two stem processes radiate from the soma in opposite directions. The outer stem process draws towards the subretinal space; here, microvilli of Müller cells surround the

photoreceptor inner segments (Figs. 19.5A–B). Zonulae adherentes between Müller and photoreceptor cells form the outer limiting membrane of the retina. The inner stem process projects towards the vitreous chamber; the end of this process is expanded into a funnel-shaped endfoot (Fig. 19.5A). The basement membrane at the inner retinal surface and Müller cell endfoot membranes (Fig. 19.1D) constitute the inner limiting membrane. Lateral processes expand into the plexiform layers where they form sheaths around the synapses, as well as into the nuclear layers where they embed neuronal perikarya (Fig. 19.5A). In the macula, Müller cells display a “Z-shaped” morphology because the outer processes accompany the centrifugally running cone axons in the Henle fiber layer (Figs. 19.6A–B).

**FIG. 19.5** Müller cells form the cores of radial units of retinal neurons. Every Müller cell is surrounded by a distinct group of retinal neurons (A) with which it interacts specifically during development, mature functioning, and injury of the retina. These repetitive radial units are almost identical throughout most regions of the retina (B) but differ in the (peri-)fovea (C) by the lack of rods, an increased number of neurons of

the inner nuclear and ganglion cell layers, and by an elongation and a Z-shaped course of the outer processes of Müller cells (cf. Fig. 19.6). Blue, Müller cells; yellow, retinal neurons; orange, cones; brown, rods.

**FIG. 19.6** Müller cells of the primate macula are elongated and run in parallel with the Henle fibers. (A) Scanning electron microphotograph of the fovea of a macaque. The extremely high packing density of cone inner and outer segments in the photoreceptor segment layer (*PSL*), the complex centrifugal course of their axons crowded in the Henle fiber layer (*HFL*), and the absence of the ganglion cell (*GCL*), inner plexiform layer (*IPL*), inner nuclear layer (*INL*) and outer plexiform layer (*OPL*) are illustrated. The outer processes of Müller cells run among the Henle fibers but can not be reliably identified. (B) When the Müller cell processes

are visualized by vimentin immunohistochemistry (brown; cell nuclei are blue-stained; siamang retina), they can be traced along their path from the outer margin of the outer nuclear layer (*ONL*) up to their endfeet; it becomes obvious that they run in parallel to the Henle fibers.

The human retina contains 4–5 million regularly arranged Müller cells (Figs. 19.1C and 19.7C). Each Müller cell constitutes the core of a column of retinal neurons which represents the smallest functional unit for the “forward information processing.”<sup>39</sup> Such a column contains one cone per Müller cell (Figs. 19.5A–C and 19.7C–D) and up to 10 rods, as well as 6 (fovea) and 4 (periphery) inner nuclear layer neurons, and 2.5 (fovea) and 0.3 (periphery) ganglion cell layer neurons, respectively.<sup>1</sup>

**FIG. 19.7** Müller cells are “optical fibers” guiding the incoming light to the photoreceptor cells. (A) Artist's view of the optical path through the retina. Light arrives at the inner retinal surface where it hits the Müller cell endfeet. Then it propagates through the Müller cell stem processes (thus bypassing the light-scattering retinal structures, particularly the synapses in the two plexiform layers) until it arrives at the photoreceptor cells. (B,C) Vertical (B) and horizontal (C) sections

through the guinea pig retina. Müller cells were immunolabeled for vimentin (green), and cones were red-stained. (B) The cone inner segments in the photoreceptor segment layer (*RSL*) appear as “continuous” with the outer processes of Müller cells which envelop the cone perikarya in the outer nuclear layer (*ONL*). (C) The focus of the image is on the outer plexiform layer. The number of cone pedicles (red) roughly equals that of Müller cell processes (green); often the two elements appear as pairs. Thus, each cone receives its part of the image of the outside world by its “individual” light-guiding Müller cell. (D) Every Müller cell illuminates a distinct group of photoreceptors, about 10 rods and 1 cone, in the guinea pig retina.

Müller cells provide crucial homeostatic, metabolic, and functional support to the neurons of their columns. They constitute an anatomical and functional link between neurons and the compartments with which they need to exchange molecules (blood vessels, vitreous chamber, subretinal space). Most nutrients, “waste” products, ions, water, and other molecules are transported through Müller cells between the vessels and neurons. Müller cells play crucial roles in the regulation of the extracellular space volume, ion and water homeostasis, and the maintenance of the inner blood–retinal barrier. They release gliotransmitters and other neuroactive molecules, and impact synaptic activity by neurotransmitter recycling which involves the supply of neurons with the precursor of the transmitters. All of these functions directly or indirectly modify the neuronal activity. The Müller cell-mediated homeostasis of the extracellular space composition and volume has a great impact for the setting of the signal-to-noise ratio of the synaptic transmission and the spatial distribution of light-induced signaling. Müller cells support the survival of photoreceptors and neurons, are responsible for the structural stabilization of the retina, and are modulators of immune and inflammatory responses. They guide the light to the photoreceptors and buffer mechanical tissue deformations. Müller cells become activated upon virtually all pathogenic stimuli. Reactive Müller cells are neuroprotective but may also quit supporting the neurons,

and rather contribute to neuronal degeneration. Currently, the many roles of Müller cells in the regulation of retinal function are still not resolved, and are the subject of ongoing intensive research. Noteworthy, much of the current knowledge about Müller cell (dys-)functions was obtained in animal models and thus awaits confirmation on human cells.

## Light Guidance

Because the retina is inverted, light has to pass the entire depth of the neuroretina before it arrives at the photoreceptors. In the retina as in any other organ, cells and their processes and organelles are phase objects which scatter the incoming light. In particular, the synapses in the plexiform layers have dimensions close to 500 nm, i.e., within the wavelength range of visible light; this makes them light-scattering structures.<sup>40</sup> The backscattering of light from the retinal cell structures is clinically used by optical coherence tomography. However, light scattering will reduce visual sensitivity and acuity, particularly outside the fovea (where the inner layers are shifted aside, and the light directly hits the cones; [Figs. 19.6A–B](#)).

To reduce light scattering, nonfoveal Müller cells act as living optical fibers that guide the light through the inner retinal layers toward the photoreceptors ([Fig. 19.7A](#)).<sup>40</sup> The funnel-shaped endfeet of Müller cells act as light collectors at the vitreal surface of the retina. The refractory index of Müller cells is slightly lower than that of photoreceptor segments (which are also light-guiding structures) but higher than that of the surrounding retinal tissue.<sup>40</sup> The refractory index of the Müller cell endfeet is about halfway between that of Müller cell stem processes and that of the vitreous.<sup>40</sup> This allows a “soft coupling” of the light path between the vitreous and the retina, and reduces light reflection at the inner retinal surface. By light guidance, Müller cells transport an image (like a fiberoptic plate) with minimal loss of light intensity from the inner retinal surface to the photoreceptors; this image is resolved in “pixels” corresponding to individual Müller cells ([Fig. 19.7A](#)). Because the local densities of cones and Müller cells are roughly equal ([Figs. 19.7B–C](#)), every cone has its “private” Müller cell which

delivers its part of the image, while several (up to 10) rods are illuminated by 1 Müller cell (Fig. 19.7D).

## Glial Support to Photoreceptor Function

There exist two metabolic cycles in the retina that regenerate photopigments, the rod and the cone visual cycle.<sup>41</sup> In the photoreceptor outer segments, all-*trans* retinal is reduced to all-*trans* retinol. Rod-derived all-*trans* retinol is regenerated to 11-*cis*-retinal in the RPE while cone-derived all-*trans* retinol is processed by Müller cells. Müller cells convert all-*trans* retinol to 11-*cis* retinal, which is released for the uptake by cone photoreceptors. Müller cells phagocytose outer-segment discs shed from cones and contribute to the assembly and renewal of photoreceptor outer segments by the delivery of lactose, pigment epithelium-derived factor (PEDF), and docosahexaenoic acid.<sup>2,42,43</sup>

## Regulation of Synaptic Activity by Neurotransmitter Uptake

Precise “shaping” (i.e., control in time and space) of synaptic activity depends on the kinetics of the presynaptic neurotransmitter release and the reuptake of transmitter molecules into the cells. In the neuroretina, photoreceptor cells, neurons, and glial cells express high-affinity transporters for neurotransmitters. Müller cells possess uptake and exchange systems for various neurotransmitters, including glutamate and GABA (Fig. 19.8). By the uptake of neurotransmitters, Müller cells are involved in the regulation of the synaptic activity in the inner retina.

**FIG. 19.8** Recycling of amino acid neurotransmitters in the outer plexiform (synaptic) layer. The ribbon synapse of a photoreceptor cell (PC) synthesizes glutamate which is continuously released in the dark. The postsynaptic elements are dendrites of bipolar (BC) and horizontal cells (HC). Horizontal cells release GABA which is formed from glutamate. The synaptic complexes are surrounded by Müller cell sheets. The right side of the figure shows neurotransmitter uptake systems and some metabolic pathways of Müller cells.

Glutamate, GABA, and ammonia ( $\text{NH}_4^+$ ) are transported into Müller cells and transformed to glutamine, alanine, and  $\alpha$ -ketoglutarate ( $\alpha$ -KG). Glutamine is released from Müller cells and serves as precursor for the transmitter synthesis in neurons (glutamate–glutamine cycle). Lactate, alanine, pyruvate,  $\alpha$ -ketoglutarate, and glutamine are utilized by neurons as substrates for their energy metabolism.

The mitochondrial enzyme GABA transaminase (GABA-T) catalyzes the formation of glutamate from 2-oxoglutarate (2OG), coupled to a conversion of GABA to succinate semialdehyde (SSA). Glutamate is also used for the production of reduced glutathione (GSH) which is an antioxidant, released from Müller cells and taken up by neurons under oxidative stress conditions.

Abbreviations: AcCoA, acetyl coenzyme A; AGC, aspartate-glutamate carrier; ALAT, alanine aminotransferase; AAT, aspartate aminotransferase; CGA, cystine-glutamate antiporter; CyT, cystine

transporter; EAAC1, excitatory amino acid carrier 1; EAAT5, excitatory amino acid transporter 5; GAD, glutamic acid decarboxylase; GAT, GABA transporter; GDH, glutamate dehydrogenase; GLAST, glutamate-aspartate transporter; GLT-1, glutamate transporter-1; GlyT, glycine transporter; GP, glutathione peroxidase; GR, glutathione reductase; GS, glutamine synthetase; GSSG, glutathione disulfide; LDH, lactate dehydrogenase; MAS, malate–aspartate shuttle; OAA, oxaloacetate; PAG, phosphate-activated glutaminase; R•, free radicals; TCA, tricarboxylic acid cycle.

The major glutamate uptake carrier of Müller cells is the glutamate-aspartate transporter (GLAST, or excitatory amino acid transporter-1, EAAT1).<sup>44,45</sup> In addition, EAAT2 (GLT1) and EAAT3 were found in human Müller cells.<sup>46,47</sup> EAATs mediate a cotransport of three sodium ions and one proton, and the countertransport of one potassium ion, with each glutamate anion.<sup>48</sup> The transport of an excess of sodium into the cell generates an inward current (Figs. 19.9A–B, E, G) and cellular depolarization. The amplitude of the glutamate transporter currents is voltage-dependent (Fig. 19.9A); a very negative membrane potential is essential for the efficient uptake of glutamate.<sup>49</sup> Sodium-dependent carriers allow uphill transport of substrates into the cells against a concentration gradient. The driving force for the transport is the electrochemical sodium gradient across the plasma membrane generated by the Na<sup>+</sup>, K<sup>+</sup>-ATPase. Other transporters, e.g., for GABA, are also electrogenic (Figs. 19.9C–D). The subcellular distribution of the GABA transporter currents (Fig. 19.9C) corresponds with the observation that GABA is taken up by amacrine and Müller cells in the inner retina but exclusively by Müller cells in the outer retina.<sup>50</sup>

**FIG. 19.9** Glutamate and GABA receptors and transporters of Müller cells. (A) Administration of glutamate (1 mM) to a rabbit Müller cell induces inward currents at negative membrane potentials (left). The current-voltage relation of the glutamate transporter currents in guinea pig Müller cells (right) shows that the efficiency of the glutamate transport increases with increasing (i.e., more negative) membrane potentials. (B) Activation of ionotropic P2X<sub>7</sub> receptors (which mediate cation currents and thus induce a depolarization of the cells) decreases the electrogenic uptake of glutamate in human Müller cells. The glutamate transporter currents induced by glutamate (Glu; 100 μM) were diminished in the presence of the P2X<sub>7</sub> receptor agonist BzATP (10 μM). Inhibition of P2X<sub>7</sub> activation by KN-62 (1 μM) suppressed the BzATP-induced current (and cell depolarization), resulting in glutamate transporter currents similar in amplitude as under control conditions. (C) Subcellular distribution of the GABA transporter currents in a guinea pig Müller cell. The distribution of the currents was determined by focal ejections of GABA (1 mM)

onto the following cell membrane domains: endfoot, inner stem process, soma, and inner and outer parts of the outer stem process. (D) GABA (100  $\mu\text{M}$ ) induces two kinds of inward currents in human Müller cells: a transient, rapidly inactivating chloride current mediated by GABA<sub>A</sub> receptors (*arrow*) and a sustained current mediated by electrogenic GABA transporters (*asterisk*). (E) In a rat Müller cell, glutamate (100  $\mu\text{M}$ ) induces inward currents through electrogenic glutamate transporters while the glutamate receptor agonists kainate (500  $\mu\text{M}$ ) and NMDA (100  $\mu\text{M}$ , in the presence of 10  $\mu\text{M}$  glycine and the absence of magnesium) do not induce membrane currents. (F) Administration of glutamate (100  $\mu\text{M}$ ) and ATP (500  $\mu\text{M}$ ) to a human Müller cell induces intracellular calcium responses, suggesting the presence of metabotropic glutamate receptors. The calcium imaging record was done in a cell from a patient with PVR. (G) (Above) A subpopulation of human Müller cells express GABA<sub>A</sub> receptors. GABA (500  $\mu\text{M}$ ) induced a transient increase of the inward and outward membrane currents (*arrows*). ATP (500  $\mu\text{M}$ ) induced a transient increase of the BK channel-mediated potassium currents (at +120 mV). (Below) In human Müller cells, glutamate (500  $\mu\text{M}$ ) induces a delayed transient increase of the BK currents. The increase in the currents at -60 and -100 mV during the exposure of glutamate (*arrow*) reflects the activation of electrogenic glutamate transporters. P2Y receptor activation by ATP (500  $\mu\text{M}$ ) induces an immediate transient activation of BK channels and of calcium-induced cation channels (*arrowhead*). (H,I) Agonists of metabotropic glutamate receptors (200  $\mu\text{M}$  glutamate; H) and P2Y receptors (100  $\mu\text{M}$  UTP and ATP, respectively; I) induce activation of single BK channels in human Müller cells. The diagrams show the time-dependent open probability of single BK channels. c, closed state; 1, open state of the channels.

In the outer plexiform layer, photoreceptor-derived glutamate is mainly removed by photoreceptor, horizontal, and bipolar cells<sup>44,51</sup> while Müller cells prevent the lateral spread of glutamate beyond the synapses, thus ensuring visual resolution (Fig. 19.8). In the inner

plexiform layer, Müller cell-provided glutamate uptake takes a more active part in shaping the synaptic responses. The rapid termination of the synaptic glutamate action in nonspiking inner retinal neurons and in retinal ganglion cells is predominantly mediated by the uptake of glutamate into Müller cells.<sup>52,53</sup>

Generally, Müller cells remove the bulk of extracellular glutamate in the inner retina.<sup>45,54</sup>

## **Malfunction of Glial Glutamate Uptake Contributes to Retinal Degeneration**

Glutamate toxicity is a major cause of neuronal loss in many retinal disorders including glaucoma, ischemia, diabetes, and inherited photoreceptor degeneration. A malfunction and/or downregulation of GLAST may cause, or contribute to, a rise in extracellular glutamate toward excitotoxic levels.<sup>55-57</sup> Hypoxia facilitates the formation of free radicals in mitochondria; the resulting lipid peroxidation disrupts the glutamate transport into Müller cells.<sup>58</sup>

This mechanism is one cause of neuronal dysfunction and degeneration in various retinopathies including diabetic retinopathy and Leber hereditary optic neuropathy.<sup>59,60</sup>

Inflammatory lipids like arachidonic acid and a reduction of the extracellular pH as occurs in ischemia also inhibit the glial glutamate uptake.<sup>61</sup>

Because the glutamate transport is voltage-dependent (**Fig. 19.9A**), depolarization decreases the efficiency of the glial glutamate uptake.<sup>49,62</sup> Depolarization of Müller cells occurs in response to pathologic rises in extracellular potassium (as in ischemia and glaucoma), to the opening of cation channels in Müller cells, e.g., of P2X<sub>7</sub> receptor channels (**Fig. 19.10C**), and to a decrease in the potassium permeability of glial membranes which results from an inactivation and/or downregulation of inwardly rectifying potassium (Kir) channels (**Figs. 19.3A, E, G, 19.10A, 19.11B-D and 19.12D, G**). An inactivation of Kir channels was observed in animal models of various retinopathies (see below). Cellular depolarization can also be induced by inflammatory lipids like arachidonic acid and prostaglandins that potently inhibit the Na<sup>+</sup>, K<sup>+</sup>-ATPase. Depolarization of Müller cells may even result in a reversal of the

glutamate transport.<sup>63</sup> A nonvesicular release of glutamate and aspartate via reversed operation of glial glutamate transporters was suggested to be implicated in the excitotoxic damage of retinal ganglion cells.<sup>64,65</sup> A release of glial glutamate might also be mediated by the cysteine glutamate antiporter (which is activated under oxidative stress conditions when an elevated production of glutathione requires an increased uptake of cystine; Fig. 19.8) and by exocytosis of glutamate-containing secretory vesicles.<sup>66–68</sup> Under various pathologic conditions including ischemia, glaucoma, retinal detachment, and proliferative retinopathies, an enhanced expression or activity of GLAST was observed.<sup>69,70</sup> This may counterbalance the depolarization-induced malfunction of the glial glutamate uptake.

**FIG. 19.10** Purinergic signaling in Müller cell gliosis. (A,B) Upregulation of glial calcium responsiveness in response to P2Y receptor activation in animal models of different retinopathies. (A) The incidence of rabbit Müller cells that respond to exogenous ATP (200  $\mu$ M) with a rise in the cytosolic free calcium level (bar chart, below) is inversely related to the density of Kir potassium currents (bar chart, above). This relation was observed after experimental retinal detachment and in moderate and massive proliferative vitreoretinopathy (PVR). The traces shown above represent examples of potassium current records in single Müller cells. The images below show examples of peak calcium responses (green areas) to ATP (200  $\mu$ M) at the inner surface of the retinas. While nearly all Müller cell endfeet displayed a calcium response in the retinas of rabbits with retinal detachment and PVR,

only some Müller cell endfeet responded in the retina of the control animal. (B) Ischemia–reperfusion increases the P2Y-induced calcium responsiveness in Müller cell endfeet recorded in wholemounts of the porcine retina. The calcium responses were recorded 1 min after beginning of the administration of ATP (200  $\mu\text{M}$ ). Tissues of a control retina and a retina 3 days after a 1-h transient retinal ischemia were investigated. (C) Activation of P2Y and P2X<sub>7</sub> receptors alters the membrane conductance of a human Müller cell. Activation of P2Y receptors by extracellular ATP (100  $\mu\text{M}$ ) induced repetitive transient calcium-induced activation of BK currents while activation of P2X<sub>7</sub> receptors by BzATP (50  $\mu\text{M}$ ) induced a sustained calcium-induced activation of BK currents and cation currents through P2X<sub>7</sub> receptor channels. (D) Müller cells of human subjects with PVR exhibit a greater density of P2X<sub>7</sub>-mediated cation currents than cells from healthy donor eyes. The density of the BzATP (50  $\mu\text{M}$ )-induced P2X<sub>7</sub>-mediated currents in cells of each subject is plotted against the density of the BK currents activated by calcium ions which flow through P2X<sub>7</sub> receptor channels. (E) Peak calcium responses in Müller cell endfeet on the vitreal surface of a control rat retinal wholemount induced by ATP (500  $\mu\text{M}$ ). Note the constriction of the arteriole in response to ATP. Müller cell endfeet fill the spaces between the arteriole and nerve fiber bundles (*asterisk*). Scale bars: 20  $\mu\text{m}$ .

**FIG. 19.11** Müller cell gliosis is associated with alterations of Kir channel expression and osmotic cell swelling. (A) The subcellular localization of Kir channel subtypes determines the direction of the spatial buffering potassium currents through Müller cells. Left:

Current–voltage (I–V) relations of different potassium channels. Kir4.1 channels mediate inward and outward potassium currents with similar amplitudes, whereas Kir2.1 channels mediate inward currents but almost no outward currents. Two-pore domain (TASK) channels mediate outward potassium currents. Right: Schematic drawing of the potassium buffering currents flowing through Müller cells during neuronal activity. Activated neurons release potassium which is absorbed by Müller cells through Kir2.1 and Kir5.1/4.1 channels, and distributed into the blood vessels, the vitreous, and the subretinal space through Kir4.1 channels. Kir4.1 channels mediate in- and outward currents and thus contribute to the osmohomeostasis between the neuroretina and extraretinal fluid-filled spaces. (B) Immunolocalization of glial Kir channels in slices of the normal and postischemic rat retina. The Kir4.1 protein is predominantly localized at the limiting membranes of the neuroretina (*arrowheads*) and around the vessels (*arrow*). Kir2.1 protein is localized in glial membrane domains that abut neuronal compartments of the inner retina such as processes that traverse the inner plexiform layer (IPL) (*arrowheads*). Seven days after a 1-h transient retinal ischemia, the Kir4.1 protein is largely downregulated whereas the localization of the Kir2.1 protein remains unaltered. Note the decrease in the thickness of the inner retina which is a characteristic of retinal ischemia–reperfusion injury. (C) Examples of whole-cell potassium currents of single Müller cells isolated from a control retina, and from retinas 3 and 7 days after a 1-h transient retinal ischemia. (D) The amplitude of the Kir currents decreases time-dependently after transient retinal ischemia. Simultaneously, the resting membrane potential (RMP) of the cells decreases and the whole-cell capacitance (that is proportional to the cell membrane area) increases, indicating cellular hypertrophy. The parameters were measured at different periods (3 hours to 3 days) after transient ischemia. (E) Under hypoosmotic stress, Müller cells in slices of 3-days-postischemic retinas display a rapid swelling which is not observed in Müller cells in slices of control retinas. Administration of triamcinolone acetonide (*Triam*; 100  $\mu$ M) simultaneously with the

hypoosmotic solution fully inhibited the Müller cell swelling. The time-dependent alterations in the cross-sectional area of Müller cell somata are shown. The images on the right display Müller cell somata in a postischemic retina before (above) and after (below) hypoosmotic swelling. *GCL*, ganglion cell layer; *INL*, inner nuclear layer; *ONL*, outer nuclear layer; *OPL*, outer plexiform layer. Scale bars: (B) 20  $\mu\text{m}$  and (E) 5  $\mu\text{m}$ .

**FIG. 19.12** Age- and disease-related Müller cell reactivity. (A–C) Müller cell reactivity in experimental proliferative vitreoretinopathy (PVR). (A) Ophthalmoscopic image of an experimentally induced PVR in the rabbit eye. Note the large, folded cellular masses on the vitreal surface of the retina (*arrows*). (B) Schematic drawing of increasing degrees of Müller cell reactivity in PVR (from left to right). Müller cells reenter the proliferation cycle, migrate out of the neural retina,

and participate in the formation of periretinal fibrocellular membranes. (C) Transmission electron micrograph of a reactive Müller cell (*MC*) of the rabbit retina which migrates through a hole in the inner limiting membrane (*arrowheads*) into the vitreous body (*asterisk*). The nucleus (*N*) of the Müller cell is translocated to the innermost retinal layer. (D) Alterations in the membrane conductance of human Müller cells in proliferative retinopathies. Four different types of potassium currents can be recorded in Müller cells of postmortem donors without apparent eye diseases: *BK*, currents mediated by big-conductance potassium channels; *K<sub>A</sub>*, fast transient (A-type) potassium currents; *K<sub>DR</sub>*, delayed rectifying potassium currents; *K<sub>ir</sub>*, inwardly rectifying potassium currents. Müller cells obtained from patients with proliferative vitreo- (*PVR*) and diabetic retinopathies (*PDR*) display an almost complete absence of *K<sub>ir</sub>* currents. The *arrow* indicates transient inward currents through voltage-gated sodium channels. (E) Age-dependent alterations in the densities of *K<sub>ir</sub>* and L-type voltage-gated calcium channel (*VGCC*) currents in human Müller cells. While the *K<sub>ir</sub>* currents display an age-dependent decrease, the currents through L-type calcium channels increase in the course of aging. (F) Immunolabeling of isolated human Müller cells for the  $\alpha_{1C}$ - and  $\alpha_{1D}$ -subunits of voltage-gated calcium channels (*red-orange*). Right: Müller cell endfeet at higher magnification. *Arrow*, cell soma. *Arrowhead*, cell endfoot. Scale bars: 20  $\mu\text{m}$ . (G) Relation between the *K<sub>ir</sub>* current density and the resting membrane potential of Müller cells from human donors of different age. The cells were derived from donors without apparent retinal disease (*Healthy*) and from patients with *PVR*. Note the great variability of the membrane potential in the cells of the patients. (H) Single action potential-like discharges (*arrow*) can be induced in the current-clamp mode by large depolarizing current steps in a Müller cell of a patient with *PVR*. Depolarizing currents from 40 to 200 pA (increment, 20 pA) were applied after administration of a hyperpolarizing current of 250 pA (resulting in a membrane potential between -100 and -125 mV).

## Glutamate–Glutamine Cycle

To ensure synaptic transmitter recycling, Müller cells are endowed with specific enzymes. After GABA is taken up by Müller cells, it is readily converted to glutamate by GABA transaminase; glutamate is converted to glutamine by glutamine synthetase (Fig. 19.8).

Glutamine synthetase is exclusively localized to glial cells.<sup>71</sup>

Glutamine is released from Müller cells and taken up by neurons as a precursor for the resynthesis of glutamate and GABA (Fig. 19.8).<sup>72</sup>

While photoreceptor cells produce only a part of glutamate from glia-derived glutamine (and also take up glutamate from the synaptic cleft and produce glutamate from other substrates), the production of glutamate in bipolar and ganglion cells depends almost entirely on glia-derived glutamine.<sup>51,73</sup> Pharmacologic blockade of glutamine synthetase in Müller cells causes a loss of the glutamate content of bipolar and ganglion cells, and the animals become functionally blind.<sup>73</sup> Likewise, a significant amount of GABA in amacrine cells is synthesized from glia-derived glutamine.<sup>73</sup>

Downregulation of glial glutamine synthetase contributes to neuronal dysfunction and glutamate toxicity, for example in inherited photoreceptor degeneration and after retinal detachment.<sup>74,75</sup> bFGF is one factor that induces a downregulation of glutamine synthetase.<sup>76</sup> bFGF is rapidly released in the retina after detachment, and it is increasingly expressed under ischemic conditions, after light and mechanical injuries, and in inherited photoreceptor degeneration (see reference 2 and references therein). Although bFGF is a neurotrophic factor that supports the survival of photoreceptors and neurons,<sup>77–79</sup> the bFGF-induced downregulation of glutamine synthetase may aggravate neuronal degeneration.

## Trophic and Antioxidative Support to Photoreceptors and Neurons

The uptake of glutamate by Müller cells links neuronal excitation with the release of metabolic substrates and the defense against oxidative stress. Müller cells produce various substrates of

oxidative neuronal metabolism such as glutamine, lactate, alanine, and  $\alpha$ -ketoglutarate (Fig. 19.8),<sup>80</sup> these substrates are used by photoreceptors and neurons in periods of metabolic stress in the dark. The metabolic support is regulated by neuron-derived glutamate (which stimulates the uptake of glucose and the production of lactate) and potassium (which induces hydrolyzation of glycogen in Müller cells).<sup>2,81</sup>

Glutamate in Müller cells is also utilized for the production of the antioxidant, glutathione (Fig. 19.8).<sup>82</sup> The retina has a high need of antioxidant protection; this results from the light exposure together with the high oxygen consumption and the high level of polyunsaturated fatty acids in photoreceptors. The outer retina underlies circadian periods of hypoxia (dark) and hyperoxia (light);<sup>83</sup> both increase the oxidative stress level. Usually, retinal glutathione is confined to glial and horizontal cells.<sup>82,84</sup> In response to oxidative stress, for instance during ischemia, glutathione is rapidly released from Müller cells and provided to neurons<sup>84</sup> where it acts as cofactor of reducing enzymes, the glutathione peroxidases. The glial release of antioxidants like glutathione, and of neuroprotective factors like bFGF and adenosine, protects the photoreceptors from the harmful effects of circadian light exposure.

Müller cells from aged animals contain reduced levels of glutathione; this is associated with mitochondrial damage, membrane depolarization, and reduced cell viability.<sup>85</sup> The decrease in retinal glutathione may accelerate the development of age-related retinopathies. In diabetic retinopathy, the decreased glutamate uptake of Müller cells results in a reduced glutathione synthesis and in an upregulation of glutaredoxin which catalyzes the deglutathionylation of proteins; this leads to an increased expression of inflammatory factors.<sup>86,87</sup>

## Removal of CO<sub>2</sub> and Regulation of pH

Photoreceptor cells have the highest rate of oxidative metabolism of all cells in the body.<sup>88</sup> This high metabolic activity is associated with high oxygen and glucose demands. The glucose metabolism generates CO<sub>2</sub> and water which are redistributed into the blood and vitreous by a transcellular transport through Müller cells. CO<sub>2</sub> is

rapidly hydrated to bicarbonate and protons by carbonic anhydrases<sup>89</sup> which are localized to Müller and amacrine cells, and the vascular endothelia.<sup>90-92</sup> Bicarbonate is transported to the blood and vitreous by sodium-bicarbonate cotransporters and anion exchangers; both are enriched in glial endfoot membranes.<sup>92</sup>

By the removal of CO<sub>2</sub>, Müller cells also regulate the extracellular pH. Light-induced neuronal activity is associated with extracellular alkalinization.<sup>93</sup> The pH shift is balanced by an efflux of protons from photoreceptors and the consecutive action of carbonic anhydrases and glial sodium-bicarbonate cotransporters.<sup>94,95</sup> Because sodium-bicarbonate transporters are electrogenic, depolarization of Müller cells by potassium released from active neurons causes an influx of bicarbonate into the cells.<sup>95</sup> The carbonic anhydrase-generated protons remain outside the cells and cause an extracellular acidification.<sup>95</sup> Because extracellular acidification inhibits synaptic transmission,<sup>96</sup> Müller cell-mediated pH regulation may protect neurons from overexcitation. A subpopulation of human Müller cells express ionotropic GABA<sub>A</sub> receptors (Figs. 19.9D, G).<sup>2</sup> Because GABA<sub>A</sub> receptors are permeable for bicarbonate, they may be implicated in the regulation of the extracellular pH. In addition, GABA<sub>A</sub> receptor activation may compensate the decrease in the extracellular chloride level caused by the chloride influx into activated neurons.

## Spatial Potassium Buffering

Neuronal activity is associated with rapid ion shifts between the intra- and extracellular spaces. Sodium, chloride, and calcium ions flow into active neurons, and potassium ions are released from neurons. Light onset causes increases in the extracellular potassium level within the plexiform layers, and a decrease in the subretinal space.<sup>97</sup> If not corrected, excess extracellular potassium will cause neuronal hyperexcitation. Müller cells buffer imbalances in the local extracellular potassium level via permission of transcellular potassium currents, a process termed “spatial potassium buffering” or “potassium siphoning.”<sup>98</sup> Müller cells take up excess potassium from the extracellular fluid, and release equal amounts of potassium into fluid-filled spaces outside the neuroretina where the

potassium concentration is constant or decreased, i.e., blood vessels, vitreous, and subretinal space (Fig. 19.11A).

Because Müller cell membranes are highly permeable to potassium, Müller cells have a very negative resting membrane potential close to the potassium equilibrium potential, around  $-80$  mV.<sup>99</sup> The potassium permeability is mainly mediated by potassium channels of the Kir channel subfamily.<sup>100</sup> In particular, Kir4.1 (which mediate bidirectional potassium currents; Fig. 19.11A) and Kir2.1 channels (which mediate inward potassium currents) are implicated in potassium siphoning.<sup>101,102</sup> The channel proteins are localized in a polarized fashion in the Müller cell membrane (Fig. 19.11A). Homomeric Kir4.1 channels are mainly localized in membrane domains across which the cells extrude potassium into spaces outside the neuroretina, i.e., in perivascular and vitreal endfoot membranes, and in the microvilli that extend into the subretinal space (Figs. 19.3A, 19.11B and 19.13).<sup>101,103</sup> Membranes that abut neuronal cell structures contain predominantly Kir channels which mediate inward potassium currents, i.e., Kir2.1 (Figs. 19.3B and 19.11B) and heterotetrameric Kir4.1/Kir5.1 channels.<sup>102,104</sup> Thus, the direction of the transcellular potassium currents is determined by the subcellular localization of different Kir channel subtypes, while the local increases in extracellular potassium cause the driving force for the passive currents through the channels. Müller cells also express other types of potassium channels which may contribute to potassium buffering, including voltage-gated potassium ( $K_A$ ,  $K_{DR}$ ) channels, calcium-activated big-conductance potassium (BK) channels (Figs. 19.9G–I, 19.10C and 19.12D), and tandem-pore domain potassium channels. In addition, the  $Na^+$ ,  $K^+$ -ATPase, and transporter molecules, e.g., the K/Na/2Cl cotransporter, contribute to the Müller cell-mediated potassium homeostasis (see reference 2 and references therein).

**FIG. 19.13** Disruption of the Müller cell-mediated fluid clearance and (under conditions of osmotic imbalances) Müller cell swelling may contribute to the development of diabetic retinal edema. Retinal edema develops from an imbalance between the fluid influx into the retina mainly caused by vascular leakage and the fluid clearance from the retinal tissue mainly mediated by the water transport through Müller cells coupled to the potassium transport. In diabetic retinopathy, the major potassium channel of Müller cells (*Kir4.1*), which is predominantly expressed around the retinal vessels and at the inner limiting membrane, is downregulated. This disrupts the water transport through the cells which is facilitated by water channels (*AQP4*) and normally coupled to potassium currents through potassium channels (*Kir2.1*, *Kir4.1*). Accumulation of potassium within the cells increases the intracellular osmotic pressure, resulting in a water flux into the cells and cellular swelling.

Many of the homeostatic functions of Müller cells, including potassium siphoning and neurotransmitter uptake, depend on the very negative membrane potential constituted by *Kir4.1* channels.<sup>101</sup> *Kir4.1* channels are also involved in the cell volume regulation that compensates for changes in the osmotic conditions (see below). Under various pathologic conditions, *Kir4.1* channels of Müller cells are downregulated and/or dislocated (Figs. 19.3A, 19.11B and 19.13)

resulting in a decrease of the potassium currents through Müller cells. Such alterations have been observed in animal models of various ischemic–hypoxic and inflammatory diseases including ischemia–reperfusion (Figs. 19.11C–D), ocular inflammation, diabetic retinopathy, blue light injury, retinal detachment (Figs. 19.3E and 19.10A), retinal vein occlusion, and proliferative vitreoretinopathy (Fig. 19.10A), as well as in Müller cells from patients with proliferative retinopathies (Figs. 19.12D, G).<sup>2,105</sup> The impaired transcellular potassium transport and the depolarization of the cells (Figs. 19.3E, 19.11D and 19.12G), which impairs the glutamate uptake, contribute to neuronal hyperexcitation and glutamate toxicity.<sup>62</sup> Human Müller cells display an age-dependent decrease of the Kir currents, on average by 50% between the ages of 40 and 80 years (Fig. 19.12E). This may enhance the susceptibility for age-related retinopathies.

## Water Clearance

Water accumulates in the retinal tissue resulting from a water influx from the blood coupled to the glucose uptake, a water influx from the vitreous, and the metabolic water production by the oxidative degradation of glucose. The accumulation of metabolic water is especially abundant in the macular tissue which displays a high metabolic activity and a high density of cells. This generates the necessity of a substantial constitutive efflux of water out of the retina into the blood. In addition, the transmembrane ion shifts associated with neuronal activity (in particular, with ionotropic glutamatergic signaling) needs, for osmotical reasons, to be buffered by a rapid water transport across glial membranes.

The retinal water clearance is mediated by an osmotically driven transcellular water transport coupled to a transport of osmolytes, in particular, to potassium currents.<sup>2,103</sup> The Müller cell-mediated clearance of the retinal tissue from excess potassium will simultaneously redistribute metabolic water out of the neuroretina. The transmembrane water transport is facilitated by aquaporin-4 water channels which are mainly localized in glial membranes in the inner retina and the outer plexiform layer (Fig. 19.3A).<sup>2,103</sup> In Müller cell membranes that contact fluid-filled spaces outside the

neuroretina, aquaporin-4 and Kir4.1 channels are colocalized (Fig. 19.3A).<sup>103</sup> This suggests that osmotic gradients between the neuroretina on the one hand and the blood, vitreal fluid, and subretinal fluid on the other hand are compensated by a bidirectional potassium and water flux across Müller cell membranes. Müller cells also express aquaporin-4 in the perisynaptic membranes within the plexiform layers (Fig. 19.3A). Because the plexiform layers are high-resistance barriers for the paracellular fluid movement,<sup>106</sup> any water flowing into neurons (associated with the ion flux) will be delivered from Müller cells through aquaporin-4.<sup>2</sup> Aquaporin-4 knockout mice display reduced electroretinogram b-waves,<sup>107</sup> suggesting that the Müller cell-mediated water transport is implicated in the maintenance of the regular neuronal activity. Ischemia-reperfusion results in a decreased thickness of the inner retina (Fig. 19.11B) due to a neuronal degeneration mainly caused by reactive oxygen radicals and glutamate toxicity.<sup>108</sup> Deletion of aquaporin-4 in mice protects against ischemic injury of the retina,<sup>109</sup> suggesting that Müller cell-mediated water transport is implicated in the pathomechanisms of neuronal cell death after ischemia.

## Contribution to Edema Development and Resolution

Dysfunctional Müller cells may contribute to the development of retinal edema. Edema is characterized by a thickening of the retinal tissue due to extra- and/or intracellular water accumulation.

Extracellular edema is caused by vascular leakage in association with a dysfunctional glial water clearance. Retinal capillaries are closely ensheathed by glial processes. Usually, Müller cells enhance the barrier function of vascular endothelia by the secretion of factors such as PEDF, thrombospondin-1, and GDNF.<sup>110-112</sup>

However, in response to hypoxia, inflammation, or glucose-deprivation, Müller cells produce factors such as VEGF and TNF that increase the vascular permeability.<sup>111,113,114</sup> Müller cells are also a source of MMPs<sup>33,114</sup> which degrade the tight junction protein, occludin.<sup>115</sup>

Intracellular water accumulation may result in cellular swelling.

While neuronal cell swelling is observed early after ischemia–hypoxia, and is mainly caused by overexcitation of ionotropic receptors (Figs. 19.14A–B),<sup>108</sup> Müller cell edema occurs within days after hypoxia.<sup>116</sup> Müller cells release glutamate<sup>67,68</sup> and ATP,<sup>117</sup> e.g., during mechanical stress; Müller cell-derived glutamate (acting at ionotropic glutamate receptors) and ATP (acting at ionotropic P2X<sub>7</sub> receptors) may contribute to the swelling and degeneration of retinal ganglion cells, e.g., in glaucoma.<sup>2,118,119</sup> Because the water transport through Müller cells is coupled to potassium currents,<sup>103</sup> the downregulation or functional inactivation of Kir4.1 channels observed under pathologic conditions (Figs. 19.3A, E, 19.10A, 19.11B, 19.12D, G and 19.13) will also disturb the transcellular water transport. Indeed, Müller cell bodies in slices of diseased retinas swell upon hypoosmotic challenge which is not observed in control tissues (Figs. 19.3F–G and 19.11E). In the absence of functional Kir4.1 channels, the cells are not capable of rapidly releasing potassium and thus to compensate the osmotic gradient between the Müller cell interior and the hypoosmotic environment. This results in a water influx and cellular swelling. Because Müller cells are still capable of taking up excess potassium from the extracellular space through Kir2.1 channels which are not altered in their expression (Figs. 19.3B and 19.11B), the impairment in the release of potassium from Müller cells will result in a potassium accumulation within the cells which increases the intracellular osmotic pressure.<sup>105</sup> The increased osmotic pressure draws water from fluid-filled spaces outside the neuroretina (blood, vitreous) into the perivascular and endfeet regions of Müller cells, resulting in Müller cell edema. The water influx from the blood and vitreous is supported by aquaporin-4 water channels which are not altered, or even increased, in their expression (Fig. 19.3A).<sup>116</sup> Thus, dysfunctional glial water clearance and possibly Müller cell swelling, may contribute to the development of edema (Fig. 19.13).

**FIG. 19.14** Glutamate and ischemia induce morphological alterations of neurons and Müller cells in the guinea pig retina. (A) The retinal slice displays Müller cells and the optical planes in the ganglion cell layer (*GCL*) and inner plexiform layer (*IPL*) which were used to record the morphological alterations of the cells. Müller cells are selectively green stained, while neuronal structures are dark. (B) The retinal wholemount was exposed to glutamate (1 mM) for 10 min. Above: Glutamate exposure results in a swelling of the neuronal cell bodies in the GCL (red). The elongated structures are nerve fiber bundles. Below: Glutamate causes a reduction in the thickness of

Müller cell stem processes that traverse the IPL (green) resulting from a swelling of the synapses between the Müller cell processes (red). (C) A decrease of the thickness of Müller cell processes (and an increase in the size of neuronal cell bodies; not shown) was also observed shortly after a 1-h ischemia of the retina. (D) Glutamate (1 mM) induces a decrease of the extracellular space volume in the IPL. This is associated with a decrease of the cross-sectional area of Müller cell processes that traverse the IPL. *INL*, inner nuclear layer; *ONL*, outer nuclear layer; *OPL*, outer plexiform layer. Scale bars: 20  $\mu\text{m}$ .

## Neurovascular Coupling

In order to meet the extremely high metabolic demands and oxygen consumption of the retina,<sup>88</sup> the ability to regulate the local blood flow is critical for retinal function.<sup>120</sup> Light stimulation induces functional hyperemia via dilation of retinal arterioles.<sup>120</sup> Purinergic neuron-to-glia signaling and glial calcium waves are involved in the activity-dependent regulation of the blood flow rate in the superficial vascular plexus in dependence on the synaptic activity in the inner plexiform layer.<sup>120</sup> In response to light, retinal neurons release ATP in the inner plexiform layer which induces calcium responses in Müller cells (Figs. 19.3D and 19.9F).<sup>121</sup> The blood flow-regulatory signals transmit to the inner surface of the retina (where arterioles are localized) via propagation of ATP-mediated<sup>117</sup> calcium waves in Müller cells and astrocytes.<sup>121,122</sup> Calcium responses activate phospholipases A<sub>2</sub> in glial cells resulting in the production of arachidonic acid metabolites that cause dilation (epoxyeicosatrienoic acids and prostaglandins) or constriction (20-hydroxyeicosatetraenoic acid) of arterioles.<sup>121</sup> Whether vasodilating or vasoconstricting responses are produced by glial cells is dependent on the production of NO; increased NO reduces vasodilation.<sup>121,123</sup> ATP and adenosine released from neurons and/or glial cells<sup>124</sup> induce constriction (Fig. 19.10E) and relaxation, respectively, of arteriolar vascular smooth muscle cells and capillary-surrounding pericytes.<sup>125,126</sup> It was shown that the functional hyperemia is dramatically reduced in the retina of

diabetic patients, possibly resulting in retinal hypoxia that contributes to the development of diabetic retinopathy.<sup>127</sup> The glia-induced vasodilation is reduced early in experimental diabetic retinopathy, likely resulting from an overproduction of NO which alters the glia-to-vessel signaling.<sup>123</sup> Because activation of purinergic receptors on retinal glial cells induces glial calcium waves that lead to vasodilation,<sup>120</sup> it is conceivable but remains to be proven that the increase in the glial calcium responsiveness observed under pathologic conditions (Figs. 19.3D and 19.10A–B, D) may contribute to the impaired neurovascular coupling in the diabetic retina.

## Regulation of the Extracellular Space Volume

The ion flux into activated neurons is (for osmotic reasons) coupled to a water flux which may result in a swelling of neuronal cell bodies and synapses (Fig. 19.14B), and thus in a decrease of the extracellular space volume (Fig. 19.14D).<sup>2</sup> The ion flux into neurons also decreases the osmolarity of the extracellular fluid.<sup>128</sup> In order to avoid detrimental decreases in the extracellular space volume (which otherwise will cause neuronal hyperexcitation), Müller cells inhibit a swelling of their cell bodies even when the extracellular fluid becomes hypoosmotic, which normally favors a water influx (Figs. 19.3F and 19.11E). In addition, Müller cells elongate and reduce the thickness of their inner stem processes (Figs. 19.14B–D).<sup>2</sup> The rapid, activity-dependent alterations in cell shape are supported by the viscoelastic properties of Müller cells (see below).

To regulate the cellular volume, Müller cells possess a purinergic signaling mechanism that is triggered by glutamate released from neurons or Müller cells.<sup>2</sup> The final step of this autocrine cascade is the release of adenosine from Müller cells, which activates adenosine A<sub>1</sub> receptors resulting in the opening of potassium and chloride channels. The ion efflux compensates the osmotic gradient across the Müller cell membrane and thus prevents cellular swelling. This mechanism may also accelerate the clearance of excess fluid from the retina through Müller cells.<sup>2</sup> The antiinflammatory corticosteroid triamcinolone acetonide, which is clinically used to rapidly clear retinal edema, was shown to inhibit

the osmotic swelling of Müller cells (Fig. 19.11E), via inducing a release of endogenous adenosine.<sup>129</sup> The adenosine-induced opening of ion channels may reestablish the ion and water transport through Müller cells under conditions when the Kir4.1 channels are inactivated, and may thus support the resolution of extra- and intracellular edema.

## Responses to Mechanical Stress

The activity-dependent reshaping of Müller cell processes (Figs. 19.14B–D) is supported by the viscoelastic properties of the cells. Müller cells are softer than neurons; in particular, the processes within the plexiform layers are very soft.<sup>130</sup> Because growing neurites prefer soft substrates,<sup>131</sup> soft glial processes may support the growth of neuronal processes implicated in the synaptic plasticity.<sup>130</sup> Müller cell gliosis is associated with an increase of the cell stiffness mainly resulting from the upregulation of intermediate filaments like GFAP (Figs. 19.2A and 19.3A); this will inhibit the neurite growth and might be one reason for the aberrant tissue repair after retinal injury.<sup>132</sup> The increased stiffness of gliotic Müller cells may also be responsible for the fact that, in retinal neovascularization, new blood vessels grow towards the vitreous rather than within the retinal tissue.<sup>133</sup>

Müller cells sense mechanical deformations of the retina by calcium-dependent mechanisms. Stretching of the retinal tissue induces calcium responses and upregulation of bFGF in Müller cells.<sup>134</sup> This may have implications for postnatal eye growth. Because bFGF counteracts the development of form deprivation-induced axial myopia,<sup>135</sup> Müller cell-derived bFGF may prevent retinal overstretching and the development of myopia during ocular growth.<sup>134</sup> Stretch-induced Müller cell responses may also be implicated in epiretinal membrane formation. Vitreous fibers, which adhere to Müller cell endfeet at sites of vitreoretinal attachments, exert tractional forces onto the cells; this activates Müller cells and results in cellular hypertrophy and proliferation, as well as vascular leakage.<sup>136</sup> Mechanically stressed Müller cells release growth factors (e.g., bFGF) and ATP.<sup>117,134</sup> Calcium influx (through stretch-activated and/or voltage-gated channels;

Figs.19.12E–F) and activation of BK channels (Figs. 19.9G, I and 19.10C–D) are required for the growth factor- and ATP-induced proliferation of Müller cells.<sup>2,137</sup> An increased expression of calcium-permeable P2X<sub>7</sub> receptors (Fig. 19.10D), which induce upon activation opening of BK channels (Fig. 19.10C), are a characteristic of proliferating Müller cells in PVR.<sup>2</sup>

## Müller Cell Gliosis

Müller cells become activated in response to virtually every pathologic stimulus (see reference 2 and references therein). Reactive gliosis is thought to represent a cellular attempt to protect the tissue from further damage, to promote tissue repair, and to limit tissue remodeling. An upregulation of intermediate filaments like GFAP in glial cells (Fig. 19.3A) is a very sensitive and early “retinal stress” indicator.<sup>2,138</sup> Müller cell gliosis has both neuroprotective and neurotoxic effects (see reference 2 and references therein). Particularly under conditions of massive (proliferative) gliosis (Fig. 19.12A), the regular glial-neuronal interactions are disrupted and the retina degenerates (Figs. 19.12B–C). An inverse relation between Müller cell proliferation and the expression of neuron-glia symbiosis-mediating proteins has been observed. However, also in the case of “conservative” gliosis (associated with short-term, or low-level, Müller cell proliferation), a dysfunction of Müller cells may contribute to neurodegeneration. After retinal detachment, for example, the downregulation of cellular retinal binding protein and glutamine synthetase<sup>139</sup> disrupts glioneuronal interactions involved in photopigment and neurotransmitter recycling. The downregulation of carbonic anhydrases<sup>139</sup> and Kir channels (Figs. 19.3A, E, 19.10A, 19.11B–D and 19.12D, G)<sup>2</sup> results in disturbances of the retinal acid–base, potassium, and water homeostasis. Because the electrogenic uptake carriers are voltage-dependent (Fig. 19.9A), membrane depolarization (Figs. 19.3E, 19.11D and 19.12G) reduces the efficiency of the glial neurotransmitter recycling which, together with an increase in extracellular potassium, will aggravate neurotoxicity. Because the potassium currents of Müller cells are also a major driving force for the water transport through the cells,

downregulation of functional Kir channels also impairs retinal water homeostasis, contributing to the development of edema (Fig. 19.13).

Inflammatory responses of reactive Müller cells may contribute to retinal degeneration. After retinal detachment, Müller cells upregulate inflammatory factors like MCP-1 which recruit phagocytotic monocytes/macrophages and microglial cells to the injured area (Fig. 19.2A).<sup>9,140</sup> Blood-derived monocytes/macrophages and neutrophils release oxygen-free radicals and cytotoxic cytokines which play critical roles in photoreceptor apoptosis after retinal detachment and neuronal degeneration after ischemia–reperfusion, for example.<sup>141,142</sup> Mice deficient in vimentin and GFAP display attenuated detachment-induced glial cell responses (e.g., a lowered expression of MCP-1) and, as a consequence, a decrease in monocyte infiltration and photoreceptor apoptosis.<sup>143</sup>

Contrariwise, reactive Müller cells may also protect photoreceptors and neurons from cell death by various mechanisms, including the secretion of neurotrophic factors, in particular bFGF, which enhance the neuronal survival.<sup>2,79,144</sup> GDNF produced by photoreceptor and glial cells protects photoreceptors and ganglion cells from apoptosis through upregulation of the glial glutamate transporter GLAST.<sup>145,146</sup> Retinal preconditioning with bright light or mechanical stress protects photoreceptors from apoptosis because these stimuli induce an upregulation of bFGF and CNTF in Müller cells.<sup>78,144</sup> Likewise, argon laser photocoagulation slows photoreceptor degeneration by the induction of bFGF in Müller cells.<sup>147</sup>

## Müller Stem Cells

As a precondition for proliferation and migration, Müller cells reactivate distinct cellular programs normally used during ontogenetic development. In the injured retina, a subpopulation of Müller cells dedifferentiates to cells with properties similar to pluripotent retinal progenitor/stem cells, and may even express distinct neuronal and photoreceptor markers.<sup>148,149</sup> The decrease of the Kir currents (Figs. 19.12D, G) and the increase of voltage-gated

sodium currents (Figs. 19.12D, H) observed in Müller cells from patients with proliferative retinopathies<sup>70</sup> may reflect such a transdifferentiation of the cells. However, the neuron-regenerating capability of mammalian Müller cells in situ is very restricted. Attempts to facilitate the neurogenic program of Müller cells, e.g., by transdifferentiation of cultured Müller cells, are ongoing.<sup>149,150</sup> The tedious progress of this approach underlines the general issue that a better understanding of the gliotic mechanisms is essential for the development of efficient therapeutic strategies which increase the protective and regenerative, and decrease the destructive, roles of reactive Müller cells.

## Introduction

Oxygen is necessary for the existence of mammals because it is required to generate adenosine triphosphate (ATP) oxidatively. Although the partial pressure of oxygen ( $PO_2$ ) is 149 mmHg (21% of atmospheric oxygen) at sea level, arterial oxygen content is as low as 75–100 mmHg (10–14%) and tissue  $PO_2$  is much lower. The oxygen level in inner segments of photoreceptors (mitochondria-rich) after dark adaptation plunges to zero but measures up to 20 mmHg in the light. Inner retinal oxygen is normally 10–20 mmHg, thus normoxia depends on the area of retina and dark/light state.<sup>1,2</sup> Hypoxia is an oxygen level below normoxia, while hyperoxia is achieved by inhaling high levels of oxygen as in the isolette of the

neonatal intensive care unit.

The retina, one of the most metabolically active tissues in the body, has two unique zones of oxygenation.<sup>1</sup> The inner retina is supplied with oxygen by the retinal vasculature. The retinal vasculature is autoregulated because it is responsive to changes in systemic oxygen levels, keeping the inner retina at a relatively constant level. If the retinal vasculature is compromised, as in ischemic retinopathies, the retina becomes hypoxic in that area. The outer retina is supplied solely by the choroidal vasculature. Unlike retina, choroidal vessels are not autoregulated, so systemic levels of oxygen control the level of oxygen in choroid. Blood flow in the choroidal vasculature, at least in bird and rat, is parasympathetically baroregulated.<sup>3</sup> Supply of oxygen to choroid is diminished by stenosis of the ophthalmic artery, which is the branch off the internal carotid that is most likely to be stenosed because it arises as a right-angled branch.

## Comparison of Retinal and Choroidal Vasculatures

Although less than 300  $\mu\text{m}$  apart in distance, the retinal and choroidal vasculatures are vastly different in many attributes in addition to autoregulation. The initial superficial retinal vasculature in human starts forming around 14 weeks' gestation (WG) by vasculogenesis, development by differentiation and assembly of vascular precursors, angioblasts.<sup>4-6</sup> The deep capillary network forms after 20 WG by angiogenesis, development by migration, and proliferation of endothelial cells from existing blood vessels. The driving force for vascular development is physiologic hypoxia; metabolic requirements of developing neurons are met only by stimulating the development of a retinal vasculature.<sup>7,8</sup> It is mostly a bilayered system, a superficial network, and a deep capillary plexus; however, there are multiple layers of capillaries in the peripapillary region, the radial peripapillary capillaries. There is only one layer of blood vessels in the periphery at the ora serrata where the retina thins to 100  $\mu\text{m}$ . The retinal vasculature is supplied with blood directly by the central retinal artery in humans.

The retinal vasculature has a traditional end-arterial hierarchy:

arteries branch to arterioles, which supply a capillary network that is drained by venules, and then veins remove the blood from the retina (Fig. 20.1). The retinal vasculature forms the inner blood–retinal barrier (BRB), restricting passage of molecules that do not have receptors or transporters on the luminal surface of the endothelial cells. Capillaries have a luminal diameter of 3.5–6  $\mu\text{m}$ , permitting passage of red blood cells only after deformation of their disc shape. The retinal capillaries and venules have perivascular pericytes, and the retina has the highest endothelial cell-to-pericyte ratio in the body, 1 : 1.<sup>9</sup>

**FIG. 20.1** Comparison of retinal (A–C) and choroidal

(D–F) vasculatures. (A) The retinal vasculature, stained here with adenosine diphosphatase (ADPase) enzyme histochemistry, has an end-arterial hierarchy: arteries (*arrow*) have a capillary-free zone, and arterioles and then capillaries, which are drained by venules, and then veins (*arrowhead*). (B) A capillary in the deep capillary network has a pericyte and endothelial cell. (C) Transmission electron microscopy (TEM) of a retinal capillary shows a pericyte (*p*) within the shared basement membrane (*arrow*) with an endothelial cell (*e*). (D) The choriocapillaris, stained by alkaline phosphatase (APase) enzyme histochemistry, has a lobular hierarchy. (E) When sectioned, the endothelial cell APase activity in choriocapillaris (*c*) shows the broad flat lumens of the choriocapillaris, which are positioned under retinal pigment epithelial cells (top), and Bruch's membrane between them. (F) With TEM the thin processes of the choriocapillaris endothelial cells (*arrow*) are apparent and, at higher magnification (inset), the fenestrations in these endothelial cells are visible. (Panel C courtesy of DB Archer, TA Gardiner, and AW Stitt.)

The choroidal vasculature forms well before the retinal vessels (6–9 WG), although its maturation is only completed after 20 WG.<sup>10</sup> It develops by hemovasculogenesis, formation of blood cells and blood vessel cells from a common progenitor, the hemangioblast.<sup>11</sup> The choroidal vasculature provides oxygen and nutrients to the photoreceptors. The capillary system, the choriocapillaris, lies directly under the Bruch's membrane, while intermediate and large blood vessels of the system lie posterior to the capillaries. The short and long ciliary arteries supply blood to the choroidal vasculature while 4–6 vortex veins remove blood from this vast system. Unlike the retina, the hierarchy in choroid is lobular, similar to kidney glomeruli (Fig. 20.1). The lobules change in shape, vascular density, and size depending upon area; the location of feeding arterioles and draining venules also varies by geographic location of the lobule.<sup>12</sup> The capillaries are broad and flat, having luminal diameters ranging from 10 to 38  $\mu\text{m}$  in diameter. Another major difference from retina is that the capillaries are fenestrated, allowing the passage of small molecules and solutes through these 60–70-nm

pores. The choriocapillaris is sided in that the majority of the fenestrations are on the retinal side as well as all three types of vascular endothelial growth factor (VEGF) receptors.<sup>13</sup> Pericytes, however, are mostly on the scleral side of these capillaries. Control of vascular tone in choroid may be accomplished by mast cells, which lie abluminal to arteries and arterioles,<sup>14,15</sup> or choroidal ganglion cells.<sup>16</sup>

## History of Retinal Ischemia

Ischemia is the restriction in oxygen supply without considering actual levels of oxygen. Michaelson<sup>17,18</sup> and Wise<sup>19</sup> hypothesized that areas of vascular loss in retina must be hypoxic because the high metabolic rate requires a continuous supply of oxygen. They observed that neovascularization always formed adjacent to these nonperfused areas and, therefore, an angiogenic factor must be produced by the hypoxic retina. They hypothesized that this factor X must be hypoxia-inducible and diffusible. Subsequently, oxygen was measured directly in retinas of several species and it demonstrated that nonperfused areas were indeed hypoxic.<sup>1,2</sup> It was not until 1989 that factor X was discovered, purified, and characterized as VEGF.<sup>20</sup> This factor was first shown to be responsible for the increased vascular permeability seen in some retinopathies.<sup>21</sup>

## Normoxia

The studies of Wangsa-Wirawan and Linsenmeier<sup>1</sup> and Yu and Cringle<sup>2</sup> using oxygen electrodes directly assessed oxygen levels from choroid to vitreous in various species. The oxygen tension is approximately 70 mmHg in choroid and plummets to zero at the inner segments in the dark (Fig. 20.2). Inner retina is around 10–20 mmHg. There are regional variations in oxygen concentration within the retina. Yu et al.<sup>22</sup> showed that oxygen consumption in outer retina is highest in the parafoveal region while inner retinal oxygen in the fovea (approximately 5 mmHg) reflected the lack of a retinal vasculature and the predominantly choroidal source of oxygen.

**FIG. 20.2** Oxygen profile measured with microelectrodes in cat retina during light and dark adaptations. The schematic at the top shows where, anatomically, the measurements were taken from choriocapillaris (left, retinal depth = 100) to the internal limiting membrane (right, retinal depth = 0). (Reproduced with permission from Wangsa-Wirawan ND, Linsenmeier RA. Retinal oxygen. Arch Ophthalmol 2003;121:547–55.)

## Hyperoxia

Life in utero is hypoxic, so when a child is born prematurely, the normoxic environment is actually hyperoxic. Prematurely born children are placed in 40% oxygen, making their tissue further hyperoxic, which yields vaso-obliteration (endothelial cells die and pericytes and progenitors survive).<sup>23</sup> The only direct measurements of oxygen in a model of retinopathy of prematurity (ROP) were performed by Ernest and Goldstick.<sup>24</sup> They found in kittens after 80–90% O<sub>2</sub> that preretinal  $P_{O_2}$  over avascular retina was close to zero but was normal over vascularized retina. Vaso-obliteration

from hyperoxia does not occur in the choroid of humans and dogs<sup>23</sup> but does occur when rats are exposed to hyperoxia.<sup>25</sup> Loss of vasculature in vaso-obliteration makes the retina hypoxic when the child is returned to room air. Exposure of the adult vasculature to hyperoxia causes constriction but not vaso-obliteration. During hyperoxia breathing (100% oxygen), the inner retinal  $PO_2$  remains unchanged due to autoregulation while the choroidal  $PO_2$  rises to 250 mmHg in cat<sup>26</sup> and 220 mmHg in the minipig, due to a lack of metabolic control of the choroidal vasculature.<sup>27</sup>

## Hypoxia

Complex homeostatic mechanisms are designed to maintain  $O_2$  concentration in each cell within a narrow range. While  $O_2$  consumption increases with the metabolic activity of the organism, exposure to  $O_2$  must be limited due to the potentially damaging effects of reactive oxygen species (ROS). Hypoxia, the state of low oxygen concentration, promotes the formation of blood vessels and is important for the formation of a vascular system in embryos.<sup>28</sup> Disease occurs when the retina and choroid are deprived of adequate oxygen supply; this can also be described as a mismatch of oxygen supply versus demand at the cellular level within ocular tissues.

The blood  $O_2$ -carrying capacity is maintained by the  $O_2$ -regulated production of erythropoietin (EPO), which stimulates the proliferation and survival of red blood cell progenitors. In 1991, Semenza and coworkers<sup>29,30</sup> performed seminal studies to identify hypoxia-inducible factor 1 (HIF-1). HIF-1 orchestrates a pleiotropic adaptive response to hypoxia by inducing the expression of more than 100 genes encoding glycolytic enzymes and glucose transporters (thereby facilitating the glycolytic switch in energy metabolism typically observed under hypoxic conditions), matrix metalloproteinases, and angiogenic, mitogenic, and survival factors, including EPO.<sup>31,32</sup> Other molecules upregulated by HIF-1 that have profound effects on vasculature include 5' nucleotidase, an enzyme that is the major source of the potent vasodilator adenosine in the body, VEGF, and angiopoietin-like 4 (ANGPTL4).<sup>33</sup> HIFs are vital to

development and, in mammals, deletion of the HIF-1 genes results in perinatal death. HIF-1 is expressed in all cell types and functions as a master regulator of oxygen homeostasis by playing critical roles in embryonic development and postnatal physiology.

## Hypoxia-Inducible Factor

HIF is a highly conserved transcriptional complex that is a heterodimer composed of an alpha and a beta subunit. HIF-1 belongs to the PER-ARNT-SIM (PAS) subfamily of the basic helix–loop–helix (bHLH) family of transcription factors. The alpha- and beta-subunit both contain an N-terminus bHLH domain for DNA binding, a central region with PAS domain, which facilitates heterodimerization, and a C-terminus, which recruits transcriptional coregulatory proteins.

The activity of HIF depends on the intracellular levels of its inducible alpha-subunit. In the presence of oxygen, HIF-1 $\alpha$  is hydroxylated on two critical proline residues (Pro<sub>402</sub> and Pro<sub>564</sub>) in the so-called oxygen-dependent degradation domain. Three prolyl hydroxylases have been identified in mammalian cells and use O<sub>2</sub> as a substrate to generate 4-hydroxyproline at residues 402 and/or 564 of HIF-1 $\alpha$ . The hydroxylation reaction also requires 2-oxoglutarate ( $\alpha$ -ketoglutarate) as a substrate and generates succinate as a side product. These prolyl hydroxylases have a high K<sub>m</sub> for O<sub>2</sub> that is slightly above atmospheric concentration; thus O<sub>2</sub> is rate-limiting for enzymatic activity under physiologic conditions, and any change in cellular O<sub>2</sub> concentration is directly transduced into changes in the rate of HIF-1 $\alpha$  hydroxylation.<sup>34</sup>

Factor-inhibiting HIF-1 (FIH-1), which was identified in a yeast two-hybrid screen as a protein that interacts with, and inhibits the activity of, the HIF-1 $\alpha$  transactivation domain,<sup>35</sup> functions as an asparaginyl hydroxylase.<sup>36</sup> As in the case of the prolyl hydroxylases, FIH-1 appears to use O<sub>2</sub> and 2-oxoglutarate,<sup>37</sup> although it has a K<sub>m</sub> for O<sub>2</sub> that is three times lower than the prolyl hydroxylases.<sup>38</sup> Hydroxylation provides a mechanism for regulating protein–protein interactions, similar to the effect of phosphorylation and other posttranslational modifications. However, this

hydroxylation occurs in an O<sub>2</sub>-dependent manner, thus establishing a direct link between cellular oxygenation and HIF-1 activity. Following HIF-1 $\alpha$  hydroxylation, the protein becomes targeted for ubiquitination by an E3 ligase complex (including the von Hippel–Lindau [VHL] tumor suppressor protein) and subsequent proteasomal degradation.

Under hypoxic conditions, the HIF prolyl hydroxylases are inhibited, because these HIF prolyl hydroxylases utilize oxygen as a cosubstrate. Hypoxia results in an increase in succinate, due to inhibition of the electron transport chain in the mitochondria, which serves to inhibit further HIF prolyl-hydroxylase activity. When stabilized by hypoxic conditions, HIF increases the expression of critical genes that promote survival in low-oxygen conditions, including glycolytic enzymes, which allow ATP synthesis in an oxygen-independent manner. HIF activates the transcription of genes encoding secreted signaling molecules, including angiogenic growth factors and survival factors, cell surface receptors, extracellular matrix proteins and modifying enzymes, transcription factors, cytoskeletal proteins, proapoptotic proteins, and glucose transporters and glycolytic enzymes (Fig. 20.3).<sup>34</sup>

**FIG. 20.3** Hypoxia-inducible factor 1 (Hif-1 $\alpha$ ) in hypoxia and hyperoxia. ARNT, aryl hydrocarbon receptor nuclear translocator.

HIF-induced VEGF, stromal-derived factor 1 (SDF-1), and EPO promote neovascularization. HIF-1 acts by binding to HIF-responsive elements in promoters that contain the sequence NCGTG, which is present in the promoters for VEGF, SDF-1, EPO, and many other genes. In addition to hypoxia, other factors such as nuclear factor  $\kappa$ B (NF- $\kappa$ B) modulate HIF-1 $\alpha$  expression in the presence of normal oxygen pressure. Thus, conditions such as tissue inflammation can lead to local HIF-1 $\alpha$  expression.<sup>39</sup> HIF-1 DNA-binding activity and target gene expression are induced in cells exposed not only to hypoxia but also to the iron chelator desferrioxamine or to cobalt chloride.<sup>40</sup>

A structurally and functionally related protein to HIF-1 $\alpha$ , designated HIF-2 $\alpha$ , is the product of the *EPAS1* gene. HIF-2 $\alpha$  can also heterodimerize with HIF-1 $\beta$ .<sup>41</sup> HIF-1 $\alpha$ :HIF-1 $\beta$  and HIF-2 $\alpha$ :HIF-1 $\beta$  heterodimers have overlapping yet distinct target gene specificities.<sup>42</sup> HIF-2 $\alpha$ , unlike HIF-1 $\alpha$ , is not expressed in all cell types, and HIF-2 $\alpha$  can be inactivated by cytoplasmic sequestration.

This “compartmentalization” of oxygen-sensitive signaling components also influences the hypoxic response.<sup>43,44</sup>

Interestingly, recent studies by Shelby et al. demonstrate another novel function of HIF-1 $\alpha$ . HIF-1 $\alpha$ , but not HIF-2 $\alpha$ , was shown to be required in regulating photoreceptor autophagy and that silencing of HIF-1 $\alpha$  in rat retinas resulted in increased photoreceptor cell death.<sup>45</sup> Their data support that HIF-1 $\alpha$  serves as an early response signal to induce autophagy and reduce photoreceptor cell death.

High throughput screening of a drug library with a reporter cell line for HIF-1 transcriptional activity has identified digoxin and doxorubicin as strong inhibitors of HIF-1 activity.<sup>46,47</sup> Subcutaneous injections or intraocular injections of digoxin reduce levels of VEGF, PDGF-B, SDF-1 and their receptors in ischemic retina and resulted in a dose-dependent reduction in retinal neovascularization.<sup>48</sup>

## HIF Deficiency and Its Resultant Pathology

O<sub>2</sub> delivery to cells of the developing embryo becomes limited by diffusion such that establishment of a functioning circulatory system is required for embryonic survival by embryonic day 9 (E9) in the mouse. In wild-type mouse embryos, HIF-1 $\alpha$  expression increases dramatically between E8.5 and E9.5, whereas embryos that lack HIF-1 $\alpha$  expression die between E9.5 and E10.5 and show cardiac malformations, vascular regression, and massive cell death.<sup>49</sup> Complete HIF-2 $\alpha$  deficiency is also associated with embryonic lethality,<sup>50</sup> and because the embryos survive longer than HIF-1 $\alpha$ <sup>-/-</sup> mice, effects on multiple organ systems can be demonstrated.<sup>51</sup>

Complete HIF-1 $\alpha$  deficiency results in developmental defects; however, partial HIF-1 $\alpha$  deficiency is sufficient to result in impaired responses to physiologic stimuli. A particularly dramatic example is the loss of O<sub>2</sub> sensing in the carotid body of HIF-1 $\alpha$ <sup>+/-</sup> mice.<sup>52</sup> Although the carotid bodies are anatomically and histologically normal and depolarize normally in response to cyanide application, they show essentially no response to hypoxia. Thus partial HIF-1 $\alpha$  deficiency in the carotid body results in a complete loss of the ability to sense and/or respond to changes in the arterial *P*O<sub>2</sub> by stimulation of the central nervous system

cardiorespiratory centers. The HIF-1 target genes that are critical for O<sub>2</sub> sensing and/or efferent responses by the carotid body have not been identified.

Mice with HIF-1 $\alpha$  conditionally knocked out using PAX6-Cre have delayed development of the outer retinal plexus but not the superficial or deep plexus.<sup>53</sup> However, when HIF-1 $\alpha$  was knocked down only in Müller cells using a Cre-LOX system, and the animals were made diabetic with streptozotocin, vascular permeability in retina was reduced and leukostasis and overproduction of VEGF and intercellular adhesion molecule (ICAM)-1 were attenuated in adult mice.<sup>54</sup> Xin et al. suggested that expression of hypoxia-inducible ANGPTL4 by Müller cells promoted increased vascular permeability.<sup>33</sup> Sears and associates prevented OIR by inhibiting prolyl hydroxylases during the hyperoxia.<sup>55,56</sup> Furthermore, they demonstrated that stabilizing hepatic HIF-1 $\alpha$  prevented OIR as well, so stabilizing HIF-1 $\alpha$  in visceral organs may be a simple strategy to protect capillary beds in retina.<sup>57</sup>

Another dramatic phenotype is the complete inability of HIF-1 $\alpha$ <sup>-/-</sup> myeloid cells (granulocytes and macrophages) to respond to inflammatory stimuli.<sup>58</sup> Myeloid cells are dependent on glycolysis for ATP generation, perhaps reflecting the hypoxic microenvironment that is often associated with inflammation and infection. HIF-1 $\alpha$  deficiency results in ATP deficiency, which impairs critical myeloid cell functions such as aggregation, motility, invasion, and bacterial killing. HIF-1 also plays critical roles in B-lymphocyte development<sup>59</sup> and T-lymphocyte activation.<sup>60</sup> Hoppe and associates demonstrated a twofold increase in circulating bone marrow-derived endothelial precursors when hepatic HIF-1 $\alpha$  was stabilized with dimethyloxalylglycine (DMOG).<sup>57</sup>

## HIF-Activated Genes Relevant to Physiologic and Pathologic Ocular Angiogenesis

The paragraphs above provide a brief summary of the critical role of HIF-1 $\alpha$  in oxygen sensing, development, and physiology. HIF-1 $\alpha$  plays an equally important role in disease pathophysiology, including retinal diseases. As a result, there is considerable interest in HIF-1 $\alpha$  as a therapeutic target.<sup>61</sup> In cardiovascular diseases,

increased HIF-1 $\alpha$  activity induced as a result of HIF-1 $\alpha$  gene therapy,<sup>62</sup> small-molecule inhibitors of prolyl hydroxylase activity,<sup>63</sup> or inhibitors of HIF-1 $\alpha$ –VHL interaction<sup>64</sup> may provide a means to stimulate neovascularization in ischemic tissue. Sears and Hoppe have found novel hypoxia mimetics that stabilize HIF-1 $\alpha$  and may provide new strategies in protecting the retinal vasculature from hyperoxia.<sup>65</sup> In contrast, small-molecule inhibitors of HIF-1 $\alpha$  activity may be useful as antiangiogenic agents. However, because HIF-1 $\alpha$  functions as a global regulator of oxygen homeostasis, it may not be a useful therapeutic target if the treatment results in unintended and undesirable side-effects.

An alternative therapeutic approach that may be particularly relevant to the treatment of ocular pathology is to focus on modulation of HIF-1 $\alpha$  target genes. However, the protein products of these target genes must also be delivered in a precise and perfectly timed manner. EPO is an oxygen-regulated hormone stimulating erythrocyte production and is critical for retinal angiogenesis. Increasing EPO expression in phase 1 of the murine ROP model (postnatal days 7–12) is protective and results in less neovascularization during phase 2 (postnatal days 12–17).<sup>66</sup> In contrast, EPO mRNA expression levels in retina are highly elevated during the hypoxia-induced proliferation phase of retinopathy (phase 2) and inhibition of retinal EPO mRNA expression with RNA interference results in suppressed retinal neovascularization.<sup>66</sup>

The best-known gene activated by HIF-1 $\alpha$  is *Vegfa*, first identified as a potent promoter of vascular permeability<sup>21</sup> and endothelial cell proliferation.<sup>19</sup> VEGF has become known as a master regulator of angiogenesis.<sup>67</sup> Tight control of physiologic VEGF levels is required for proper embryologic development.<sup>68</sup> Although it was initially thought that the postembryonic role of VEGF was restricted to a few processes, it is now quite clear that VEGF acts as a pluripotent growth factor essential for a wide variety of physiologic processes,<sup>69</sup> including maintenance of the adult microvasculature,<sup>70</sup> neuronal survival,<sup>71</sup> and trophic maintenance of ocular tissues.

## VEGF in Health and in Ocular Disease

VEGF is produced by many cell types in the retina, including

retinal pigment epithelium (RPE),<sup>72</sup> vascular endothelial cells,<sup>73</sup> pericytes,<sup>73</sup> retinal neurons,<sup>74</sup> Müller cells,<sup>74</sup> and astrocytes,<sup>75</sup> suggesting that VEGF has important functions in ocular homeostasis. RPE-secreted VEGF plays an important role in maintaining the choriocapillaris.<sup>13,76,77</sup> VEGF secretion by retinal cells and the RPE is stimulated in response to hypoxia.<sup>73</sup> VEGF administration protects retinal neurons from apoptosis.<sup>78</sup> Moreover, chronic VEGF inhibition can lead to a significant loss of retinal ganglion cells in normal adult animals.<sup>78</sup>

While VEGF is critical to maintaining normal ocular function, overproduction of VEGF is deleterious. Elevated levels of VEGF have been strongly implicated in the pathogenesis of ocular neovascular diseases such as neovascular age-related macular degeneration (NV in AMD)<sup>79</sup> and proliferative diabetic retinopathy<sup>80</sup> as well as diabetic macular edema.<sup>81</sup> Elevated VEGF levels are observed in central and branch retinal vein occlusion (CRVO and BRVO),<sup>82</sup> neovascular glaucoma,<sup>83</sup> and ROP.<sup>84</sup> Blocking VEGF action is now an established strategy for the treatment of NV in AMD, with three agents (VEGF trap or Eylea, Avastin, and the humanized murine monoclonal antibody antigen-binding fragment ranibizumab<sup>85</sup>) having received regulatory approval for the intravitreal treatment of NV in AMD.

While current standard of care for NV in AMD uses intravitreal delivery of an anti-VEGF agent on a repeated basis, this routine clinical practice does not address all the nuances of VEGF biology. The biology of the VEGF proteins is extremely complex. The VEGF family members are part of a superfamily of cysteine knot proteins and include VEGF-B, -C, -D, and placental growth factor (PlGF). Alternative splicing events for VEGFA give rise to at least 14 subtypes of VEGF, namely, VEGF<sub>111</sub>, VEGF<sub>121</sub>, VEGF<sub>121b</sub>, VEGF<sub>145</sub>, VEGF<sub>145b</sub>, VEGF<sub>148</sub>, VEGF<sub>162</sub>, VEGF<sub>165</sub>, VEGF<sub>165b</sub>, VEGF<sub>183</sub>, VEGF<sub>183b</sub>, VEGF<sub>189</sub>, VEGF<sub>189b</sub>,<sup>86</sup> and VEGF<sub>206</sub>.<sup>87,88</sup> Following the discovery of the antiangiogenic isoform of VEGF, VEGF<sub>165b</sub>, and its associated family of isoforms, a further layer of complexity was added to understanding the regulation of VEGF.<sup>89</sup>

All VEGF isoforms are essential regulators of angiogenesis and vascular permeability. VEGFs elicit their intracellular activities via the activation of two receptor tyrosine kinases (RTKs): VEGFR-1

and -2. VEGFR-1, a high-affinity fms-like tyrosine kinase-1,<sup>90</sup> and VEGFR-2, a kinase insert domain-containing receptor,<sup>91</sup> are transmembrane glycoproteins consisting of a seven-tandem immunoglobulin-like domains, which serves as the extracellular ligand-binding region, a single-transmembrane domain, and a cytoplasmic domain consisting of two tyrosine kinase catalytic domains. Moreover, it has also been reported that a family of cell surface glycoproteins, particularly neuropilin-1(NP-1), act as isoform-specific coreceptors for VEGF-A.<sup>92</sup> The VEGF family and their respective receptors are outlined in Fig. 20.4.

**FIG. 20.4** Vascular endothelial growth factor (VEGF) family and its receptors. IGF, insulin-like growth factor; PIGF, placental growth factor; SDF, stromal-derived factor.

Ligand binding to the extracellular domain of VEGFR-2 results in a maximal increase of kinase activity following the induction of receptor dimerization and subsequent phosphorylation of tyrosine residues on the intracellular domain of the receptor.<sup>93</sup> This event is crucial for the recruitment of additional signaling molecules that contain Src homology 2 or phosphotyrosine binding domains, which mediate further downstream signaling cascades.<sup>94</sup> The association of RTKs with coreceptors, such as NP-1, in the case of VEGFR-2:VEGF<sub>165</sub> signaling/interaction, can enhance the functional signal transduction and facilitate diverse cellular responses.<sup>93</sup> VEGFR-1/R2 signaling activates RAS, raf1, MEK1, and ERK1/ERK2 and stimulates PI3K/AKT/PKCz/MAPK pathways to mediate proliferation, migration, and cell survival (Fig. 20.4).

VEGFR-2 is the major mediator of angiogenic signaling in endothelial cells and is required for de novo vessel formation, vasculogenesis, and for angiogenesis, the formation of vessels from preexisting vasculature.<sup>95</sup> The pathways leading to VEGFR internalization and the role of receptor degradation in VEGF signaling remain controversial and differ for VEGFR-1 and -2. VEGFRs generate signal output at the plasma membrane and on their way to degradation through endocytic vesicles,<sup>96</sup> whereas, in unstimulated cells, VEGFR-2 is predominantly located in recycling endosomes identified by Rab4 and/or Rab5.<sup>97</sup> VEGFR internalization is clathrin-mediated, and transport is further directed by the endosomal sorting complex required for transport proteins.<sup>98</sup> VEGFR signaling is also regulated by ubiquitination, not only of the receptor itself, but also of receptor-associated signaling molecules.<sup>99</sup> Specific VEGFR trafficking regulates bio output, as shown for arterial morphogenesis, for example.<sup>100</sup>

The molecular basis for ligand specificity of VEGFR signaling is poorly understood. It is well accepted, however, that VEGF receptors can associate with distinct coreceptors such as neuropilins, integrins, semaphorins, or heparan sulfate glycosaminoglycans, and engage distinct signaling molecules giving rise to specific signal output. Ligand-specific signaling may also result from receptor trafficking to specific cellular compartments, including the nucleus,<sup>101</sup> where receptors encounter distinct signaling molecules.<sup>102</sup>

Do et al. have recently identified a conserved binding site for estrogen-related receptor  $\gamma$  (ERR $\gamma$ ) on the promoter of the *Vegfa* gene. ERR $\gamma$  is a constitutively active orphan nuclear receptor, and its expression is increased by hypoxic stimuli in metabolically active tissues. Using the oxygen-induced retinopathy (OIR) mouse model, they show by immunohistochemistry increased ERR $\gamma$  expression in the ganglion cell layer at postnatal day (P) 17. They also use a novel pharmacologic suppressor of ERR $\gamma$ , GSK5182, to reduce hypoxia-induced VEGF expression, supporting that ERR $\gamma$  could be a treatment target for ischemic retinopathies.<sup>103</sup>

In addition to EPO and VEGF, SDF-1 is hypoxia-regulated and ischemic tissues express high levels of SDF-1 to recruit reparative cells to the injured region. SDF-1 activation of either CXCR-4 or CXCR-7 results in stimulation of the Ras/Raf/Mek/ERK pathway and the PI3K/Akt pathway to promote endothelial cell proliferation and neovascularization. Thus ligand–receptor interaction of VEGF to VEGFR-1 and VEGFR-2 and SDF-1 to CXCR4/CXCR-7 and their subsequent internalization sets in motion the cascade of cellular effects of VEGF and SDF-1 (Fig. 20.4). The VEGF and SDF-1 signaling pathways appear to be intimately connected with HIF-1 activation (see Fig. 20.3), as the promoters of each of these factors contain a HIF response element. Because hypoxic tissue releases SDF-1 and VEGF, varying O<sub>2</sub> concentrations would be expected to also influence the expression of the receptors for these ligands, CXCR-4 and VEGFR.

## Bone Marrow-Derived Progenitor Cells (BMPC) and Vascular Repair

In conditions like diabetic retinopathy and ROP, areas of retinal vasodegeneration occur and ultimately lead to retinal ischemia, which in turn induces the expression of hypoxia-regulated angiogenic factors. Typically, BMPCs robustly respond to these factors, including VEGF and SDF-1.<sup>104</sup>

Importantly, all hypoxia-regulated angiogenic factors are modulators of bone marrow-derived stem cells. Specifically, hematopoietic stem cells and other BMPCs reside in the bone marrow and are mobilized into the peripheral circulation by

increased levels of EPO, SDF-1, and VEGF released by the ischemic tissue. Hematopoietic stem cell/BMPC mobilization occurs in response to vascular injury throughout the body and, when functioning properly, leads to revascularization of injured areas.<sup>105</sup> In healthy individuals, bone marrow-derived CD34<sup>+</sup> endothelial progenitor cells as well as other BMPC successfully orchestrate the reparative process. BMPC do not demonstrate an ability to differentiate directly into endothelial cells and form components of new blood vessels by vasculogenesis, but show marked ability to provide paracrine support for the resident vasculature. This paracrine support facilitates resident endothelial cell recovery.

D'Amico et al. have recently demonstrated the protective role of pituitary adenylate cyclase-activating peptide (PACAP) in early diabetes, after 3 weeks of hyperglycemia.<sup>106</sup> They found that the expression of HIF-1 $\alpha$  and HIF-2 $\alpha$  was significantly increased in diabetic rats as compared to controls and that expression levels were significantly decreased after PACAP intraocular administration. The results suggest that the protective effect of the peptide in diabetic retina are mediated through modulation of HIFs' expression.

## Disease-Associated BMPC Dysfunction

In diabetes, for example, BMPC are dramatically altered and cannot facilitate the repair process. Diabetic individuals have fewer circulating CD34<sup>+</sup> cells and an increased number of inflammatory BMPC such as CD14<sup>+</sup> cells compared to nondiabetics.<sup>107-109</sup> This diabetes-related bone marrow dysfunction is closely linked to the impaired healing response experienced by many diabetic individuals and to the vasodegenerative aspect of diabetic macro- and microvascular complications.<sup>109-111</sup> Diabetes-induced BMPC defects occur in part due to uncoupling of nitric oxide synthases, enhanced NADPH oxidase activity, and increased generation of ROS such as superoxide and peroxynitrite (ONOO<sup>-</sup>)<sup>112</sup> within BMPC. While stem and progenitor cells are deemed more resistant to oxidative stress,<sup>113</sup> the highly oxidative diabetic milieu has a clearly detrimental effect on the function of these cells.<sup>114</sup> Prolonged oxidant exposure reduces reparative function<sup>115</sup> by impairing

antioxidant defense enzymes. Previously, we and others have shown that diabetic CD34<sup>+</sup> cells exhibit decreased migration and adhesion activities in vitro and consequently reduce recruitment to areas of injury.<sup>111</sup> In addition to oxidative stress, other key mechanisms implicated in diabetes-induced BMPC dysfunction include a reduction of cathepsin L activity<sup>116</sup> and an upregulation of thrombospondin-1.<sup>115,117</sup> While these functional defects are profound, strategies that successfully reverse BMPC defects in diabetics have included (1) enhancement of angiogenic stimulus by increasing BMPC mobilization using granulocyte colony-stimulating factor and targeting SDF-1;<sup>118</sup> (2) use of nitric oxide donors to correct migration and promote cell deformability;<sup>119</sup> (3) enhancing cell interactions with substrate proteins to increase attachment to basement membranes;<sup>120</sup> (4) reducing high levels of endogenous transforming growth factor- $\beta$  to normal levels;<sup>121</sup> and (5) treatment with rosiglitazone<sup>122</sup> or atorvastatin.<sup>123</sup>

In addition to CD34<sup>+</sup> cells, other populations of bone marrow cells may attempt vascular repair, such as CD14<sup>+</sup> cells, discussed above, which can, under select circumstances, form endothelial-like cells;<sup>124</sup> however, the blood vessels formed by the endothelial cells of CD14<sup>+</sup> origin eventually generate pathological blood vessels with increased permeability and contribute to the pathology of diabetic retinopathy.

We and others have been particularly interested in a novel factor expressed in increased concentrations in hypoxic tissue, insulin-like growth factor-binding protein 3 (IGFBP-3). While the standard IGF-dependent actions of the family of IGF-binding proteins have been well described, recently several IGF-independent actions have been discovered for IGFBPs, including IGFBP-3. These IGF-1-independent actions have been characterized as regulating cell fate and apoptosis.<sup>125-128</sup> The role of IGFBP-3 in the control of cell growth remains an area under intense study, since IGFBP-3 may enhance or suppress cell growth, depending on specific conditions.<sup>127,129</sup> In the retina, multiple forms of IGFBP (2-5) are secreted by retinal endothelial cells.<sup>128</sup> IGFBP-3 has been shown to enhance cell proliferation in retinal endothelial cells and to decrease the formation of neovascular tufts in a murine model of oxygen-induced retinopathy.<sup>130,131</sup> These studies suggest that IGFBP-3 may

be vascular-protective in the retina. Recently, we also have demonstrated that IGFBP-3 is neuroprotective in the retina and reduces injury-induced retinal inflammation.<sup>132</sup>

## Key Factors That Modulate VEGF Function in the Retina

The retina is one of the last organs to become vascularized in the fetus. The vasculogenic part of the process of human retinal vascularization begins at about gestational week 14 and appears to depend on a physiologic hypoxia<sup>8,133</sup> brought about by an increase in metabolic demand within the developing retina.<sup>4-6</sup> This physiologic hypoxia induces the local release of VEGF which, together with IGF-1, regulates angiogenesis and therefore normal vascularization of the retina.<sup>133,134</sup> Retinal vascularization is complete by 36–40 WG.

ROP is a two-phase disease in which the phases are mirror images; the controlling growth factors are deficient in phase 1 and in excess in phase 2. Phase 2 involves uncontrolled proliferative growth of retinal blood vessels in response to hypoxia. The therapeutic intention would be to prevent the first phase of cessation of vessel and neural retinal development and then the second destructive phase would be prevented. This has been successfully performed using exogenous EPO, VEGF, and IGFBP-3 during phase 1 to prevent phase 2. These two phases, seen in premature infants, can be duplicated in animal models of ROP. Hyperoxia causes vaso-obliteration and cessation of normal retinal blood vessel development, which mimics phase 1 of ROP. IGF-1 levels rise in the third trimester of pregnancy but not in the preterm infant. The low IGF-1 in the preterm infant is due to the infant no longer being exposed to the support of the maternal environment, including maternal sources of IGF-1. IGF-1 levels rise slowly after preterm birth, as these babies are unable to produce adequate IGF-1 compared to term infants.<sup>135</sup> In these premature infants, IGF-1 is further reduced by poor nutrition,<sup>136</sup> acidosis, hypothyroxinemia, and sepsis.<sup>137</sup> IGF-1 appears important for retinal and brain growth.<sup>134</sup> Low levels of IGF-1 appear to play an important role in the early cessation of retinal growth that precipitates ROP.

IGF-1 mediates its effects through activation of the IGF-1 receptor (IGF-1R) (see Fig. 20.3). IGF-1R is a receptor tyrosine kinase and is well established as a key regulator of cell growth and survival with activation of Ras-ERK pathway, the PI3K/Akt pathway, and PKC (see Fig. 20.4). Insulin and IGF-2 can also signal using the IGF-R. There is also a growing body of data to support a role for the structurally and functionally related insulin receptor (IR) in cell survival, even though its major function has been to modulate metabolism. Bidirectional cross-talk between IGF-1R and IR is observed, where specific inhibition of either receptor confers a compensatory increase in activity for the reciprocal receptor.

Although fluctuating oxygen has long been associated with the development of ROP, oxygen-regulated factors like VEGF appear to be directly modulated by IGF-1. IGF-1 is a key growth factor in early retinal development. IGF-1 controls maximum VEGF activation of the Akt endothelial cell survival pathway (see Fig. 20.3). Thus loss of IGF-1 leads to loss of VEGF signaling and retinal vaso-obliteration. This vaso-obliteration leads to phase 2 of ROP which is the proliferative phase. At this point, suppression of IGF-1 and VEGF can reduce neovascularization. Thus IGF-1 is critical to normal retinal vascular development, and a lack of IGF-1 in the early neonatal period is associated with lack of vascular growth and with subsequent proliferative ROP. In IGF-1-null mice, the retinal blood vessels grow more slowly than in those of normal mice, a pattern very similar to that seen in premature babies with ROP.

## Adult Retinal Hypoxia and Etiology

### Diabetic Retinopathy

Much like ROP, diabetic retinopathy has a vaso-obliteration phase that leads to a proliferative phase. The vaso-obliteration is not due to hyperoxia but rather to vaso-occlusion and vasodegeneration of the microvasculature, setting up the ischemic environment that leads to the vasoproliferative end-stage condition. Clinically the early pathology has been classified as nonproliferative (microaneurysms, exudates, leakage, capillary nonperfusion) resulting in hypoxia and the endstage pathology as proliferative

(preretinal neovascularization). The purely vasodegenerative, nonproliferative form of the disease is by far the most common and represents a disease of the neurovascular unit, resulting in dysfunction and eventual death of several of the key cells that maintain the BRB: pericytes, vascular endothelial cells, Müller glia, and neurons. Kohner and Henkind elegantly demonstrated that, in diabetic individuals, areas of nonperfusion on fluorescein angiography are associated with acellular capillaries in trypsin digests.<sup>138</sup> Direct measurement of oxygen in diabetic cat retinas demonstrated that even small aneurysms can result in a decrease in retinal interstitial oxygen.<sup>139</sup>

There are many mechanisms implicated in the pathogenesis of diabetic retinopathy but one that has gained considerable attention in the last decade is inflammation. The environment of hyperglycemia, abnormal lipids, increased oxidative stress, elevated serum and tissue advanced glycation endproducts (AGE)/receptor for AGE, increased serum/tissue cytokines, elevated blood pressure, and endoplasmic reticulum stress are the likely initiators of inflammation.<sup>140</sup> Pathways of inflammation converge with pathways of endothelial dysfunction and coagulation to accelerate the pathogenesis of this disease.<sup>141</sup> Initially, nonspecific indicators of inflammation such as white-cell count and fibrinogen were found to be predictive of incident diabetes.<sup>142</sup> Subsequently, plasminogen activator inhibitor-1 (PAI-1), C-reactive protein, and fibrinogen were shown to be independent predictors.<sup>143</sup> These observations are supported by several other prospective studies, in which tissue plasminogen activator, another marker of reduced fibrinolysis,<sup>144</sup> and von Willebrand factor, a marker of endothelial injury, were predictive.<sup>145</sup> In one clinical study of type 2 diabetics, adhesion molecules were higher in subjects with retinopathy than those without,<sup>146</sup> and in another population-based cohort, composite scores of both inflammatory and endothelial function markers were strongly associated with the presence of diabetic retinopathy.<sup>147</sup> Similarly, E-selectin values were found to be increased in a group with type 1 diabetes and retinopathy.<sup>148</sup> Adiponectin was increased in the advanced stages of retinopathy.<sup>149</sup> These results should be interpreted cautiously, however, as serum markers are not necessarily indicators of tissue events. However, P-

selectin, ICAM-1, and polymorphonuclear leukocyte numbers are all elevated in human diabetic retina.<sup>150</sup> Experimental work in diabetic rat retinas later demonstrated that inflammatory cytokine-mediated leukostasis occurs early in diabetic retina and neutralizing ICAM-1 and CD-18 prevents it.<sup>151-153</sup> From these studies it appears that inflammation-mediated EC injury and vaso-occlusion may cause nonperfusion and subsequent hypoxia in diabetic retina.<sup>154,155</sup>

The hypothesis that inflammation is critical to the development of diabetic retinopathy arose from initial reports that diabetic patients taking salicylates to treat rheumatoid arthritis had a lower-than-expected incidence of diabetic retinopathy.<sup>156</sup> The subsequent decades demonstrated an increase in inflammatory markers and growth factors in the diabetic vitreous and retina. Recently microarray analyses substantiated a marked inflammatory response in the retinas of diabetic rodents.<sup>157</sup> Confirmation of the importance of inflammatory factors and growth factors is supported by additional rodent studies that show that blocking these factors prevents the development of lesions characteristic of the retinopathy in animals. Specific inflammatory molecules that have been shown to contribute to structural or functional alterations that are characteristic of the retinopathy include NF- $\kappa$ B;<sup>158</sup> inducible nitric oxide synthase;<sup>159</sup> cytochrome c oxidase;<sup>159</sup> ICAM;<sup>155</sup> 5-lipoxygenase;<sup>159</sup> interleukin-1 $\beta$ ;<sup>160</sup> tumor necrosis factor (TNF)- $\alpha$ ;<sup>161</sup> and VEGF.<sup>80,162</sup> Inflammation can intensify the generation of AGEs that are produced in response to hyperglycemia and increased oxidative stress.

## Retinal Vein Occlusion (RVO)

Occlusion of large retinal blood vessels is a common occurrence, which results in retinal hypoxia. RVO is the second most common sight-threatening retinal vascular disorder after diabetic retinopathy.<sup>163</sup> RVO represents an obstruction of the retinal venous system that involves either the central retinal vein or a branch retinal vein. RVO is typically due to external compression or disease of the vein wall, such as is seen in vasculitis.<sup>164</sup> Central retinal artery occlusion (CRAO) results in sudden, catastrophic

visual loss, and branch retinal arteriolar occlusion (BRAO) causes sudden segmental visual loss and may recur to involve other branch retinal arterioles. CRAO studies have shown that the ischemic retinal whitish opacity and swelling are essentially located in the perifoveolar region of the macula. Oxygen supply and nutrition from the choroidal vascular bed to the thinner peripheral retina help in its much longer survival and the maintenance of peripheral visual fields. The diagnosis is clinical and based on the observation of the ocular fundus: venous dilation and tortuosity, flame-shaped retinal hemorrhages, retinal edema, and cotton-wool exudates affecting all the retinal sectors (in CRVO) or the sector of the retina drained by the affected vein in BRVO. Open angle glaucoma is the most frequent local alteration predisposing to RVO as it compromises venous outflow by increasing intraocular pressure. Raised intraocular pressure causes external compression of the central retinal vein as it passes through the lamina cribrosa, resulting in turbulent blood flow distal to the compression leading to thrombus formation.

The natural history of RVO is highly variable; in some cases the retinal findings progressively disappear and there is a good visual outcome, while in other cases severe complications like ocular neovascularization (proliferative retinopathy), vitreous hemorrhage, neovascular glaucoma, and macular edema develop. Using retinal oximetry in BRVO, venular saturation was found to be highly variable between patients (12–93%);<sup>165</sup> this was attributed to variable severity of the disease, recanalization, degree of occlusion, collateral vasculature, or tissue atrophy. The majority of patients with CRVO have signs of macular edema at presentation whereas only 5–15% of eyes with BRVO develop macular edema over the first year. Venous collateral channels represent tortuous vessels that develop locally, mainly around the optic disc, and are usually associated with a long-standing vascular obstruction. Vitreous hemorrhage develops in 10% of eyes with CRVO within 9 months of presentation and in about 40% of eyes with BRVO.<sup>163</sup> If there is restoration of circulation in the central retinal artery, the retinal capillaries in the central, thickest part of the macular region do not refill because of compression by the surrounding swollen superficial retinal tissue, resulting in the “no-reflow

phenomenon,"<sup>166</sup> and consequently in permanent ganglion cell death in the nonperfused retina; the area of central retinal capillary nonfilling may vary from eye to eye depending upon the severity of retinal swelling in the macular region. This results in the variable size of the permanent central scotoma. In considering the outcome of CRAO, it is important to consider retinal tolerance time to acute retinal ischemia. The chance of recovery of vision only exists as long as the retina has reversible ischemic damage. The retina suffers no detectable damage with CRAO of up to 97 minutes, but after that, the longer the CRAO, the more extensive the irreversible ischemic retinal damage.

It is generally believed that the CRAO is always either embolic or thrombotic in origin. Embolism is far more common than thrombosis,<sup>167</sup> as was pointed out almost a century ago by Coats.<sup>168,169</sup> If diagnosis is made within 15 days from onset of clinical manifestations, low molecular weight heparins at anticoagulant doses are typically used 10–15 days followed by half dose for a total of 90 days.<sup>170</sup> An inflammatory etiology is also postulated in RVO, as RVO is associated with immunologic diseases in young patients. To support this contention, patients can experience prompt resolution of symptoms with the use of periocular steroids.<sup>171</sup>

Giant cell arteritis is an important and well-known cause of CRAO and is an ophthalmic emergency because of the high risk of bilateral visual loss, which is preventable.

Elevated levels of PAI-1, lipoprotein(a), and hyperhomocysteinemia and low circulating levels of folic acid, vitamin B<sub>12</sub> and vitamin B<sub>6</sub> have been implicated in the pathogenesis of this disease.<sup>172</sup> While the pathogenesis is complex and largely unknown, medical treatment includes identification and correction of vascular risk factors. The use of fluorescein fundus angiography before (showing occlusion of the central retinal artery) and immediately after thrombolysis may show improvement in and/or restoration of retinal circulation and retinal function. It is also important to consider that fibrinolytic agents can dissolve only platelet fibrin emboli.<sup>173</sup> Retinal emboli are made of 74% cholesterol, 10.5% calcific material, and only 15.5% of platelet fibrin. Fibrinolytic agents cannot dissolve cholesterol or calcified material. Therefore, there is no scientific rationale for the use of

fibrinolytic agents in at least 85% of CRAO cases. Of Virchow's three classical factors that play a role in thrombogenesis – stasis, vessel wall damage, and hypercoagulability – the first two have long been reported in patients with RVO, whereas the third has not been sufficiently investigated until recently.

## Sickle-Cell Disease (SCD)

The pathologic processes involved in SCD can affect virtually every vascular bed in the body including the retina, and in its advanced stages, SCD has the potential to cause blindness.<sup>174</sup> Classification of ophthalmic manifestations of SCD in the retina is based on the presence or absence of vascular proliferation, which is the most important precursor of blinding complications and precedes development of a vitreous hemorrhage or retinal detachment. Ischemia occurs due to obstruction of capillaries with sickle red blood cells and subsequent thrombus formation. The subsequent scenario for disease pathogenesis is similar to that for ROP, diabetic retinopathy, and RVO, described above, except that there is no retinal leakage of retinal blood vessels only from preretinal neovascularization, even though there is loss of peripheral vasculature and elevation of VEGF.<sup>175</sup> Neovascularization that occurs can lead to fibrosis that can then result in retinal detachment. See [Chapter 60](#) (Hemoglobinopathies) for a complete discussion of sickle-cell retinopathy.

## Ocular Ischemic Syndrome (OIS)

OIS occurs at a mean age of 65 years and is rare before the age of 50. Men are affected twice as often as women,<sup>176</sup> reflecting their higher incidence of atherosclerotic disease; however, no racial predilection exists. Bilateral involvement may occur in up to 22% of cases.<sup>177,178</sup> Sturrock and Mueller estimated 7.5 cases per million persons every year,<sup>179</sup> but this is likely an underestimation as OIS can be easily misdiagnosed. Kearns<sup>180</sup> reported that, of patients with occlusion of the internal carotid artery undergoing surgical anastomosis between the superficial temporal artery and the middle cerebral artery, 18% presented with OIS. Up to 29% of patients with a symptomatic carotid artery occlusion manifest retinal vascular

changes that are usually asymptomatic; however, 1.5% of them progress per year to symptomatic OIS.<sup>181</sup> OIS develops especially in patients with poor collateral circulation between the internal and external carotid arterial systems. Insufficient collateral vascular flow in OIS patients explains the frequent association with cerebral infarctions and the poor neurologic outcomes.<sup>182</sup> Degree of internal carotid artery stenosis, presence of collateral vessels, and compensation by collaterals are important in assessing OIS disease severity. Also if the OIS is bilateral or there are associated systemic vascular diseases, this tends to worsen the prognosis.

## Retinal Detachment

Retinal detachment causes the sensory retina to be distant from choriocapillaris, thus reducing its oxygen supply and resulting in photoreceptor degeneration. Linsenmeier and Padnick-Silver<sup>183</sup> demonstrated in cat that retinal detachment resulted in a significant decrease in outer retinal oxygen, having a serious metabolic effect on photoreceptors. In subsequent work, Linsenmeier demonstrated that hyperoxia may have clinical benefit after retinal detachment because it normalized photoreceptor oxygen consumption and prevented photoreceptor dysfunction.<sup>184</sup> Furthermore, hyperoxia prevents proliferation and reactivity of retinal Müller cells in the detached feline retina, limiting retinal injury.<sup>185</sup>

## Consequences of Retinal Ischemia

In 1971, Judah Folkman reported in the *New England Journal of Medicine* that all cancer tumors are angiogenesis-dependent.<sup>186</sup> If a tumor could be stopped from growing its own blood supply, he surmised, it would wither and die. Though his hypothesis was initially disregarded by most experts in the field, Folkman persisted with his research. After more than a decade, his theory became widely accepted and is now at the center of our understanding of ocular angiogenesis. Retinal neovascularization is defined as a state where new pathologic vessels originate from the existing retinal veins and extend along the inner surface of the retina.

## Vascular Permeability

Growth factors such as VEGF have been implicated in both retinal neovascularization and vascular hyperpermeability.<sup>187</sup> Antibodies to VEGF improve visual function in patients with diabetic macular edema.<sup>188</sup> In experimental diabetes and in VEGF-induced permeability, alterations of the tight junction (TJ) complex of microvascular endothelial cells alters the BRB.<sup>189</sup> A role of classical PKC isoforms (cPKCs) but especially PKC $\beta$  in regulating VEGF-induced vascular permeability is well accepted.<sup>190</sup> VEGF activation of PKC $\beta$  leads to phosphorylation and reorganization of the TJ complex, increasing vessel wall permeability.<sup>191</sup> VEGF increases the phosphorylation of the TJ protein, occludin, at multiple sites,<sup>192</sup> including Ser490.<sup>193</sup> Phosphorylation at Ser490 allows subsequent ubiquitination and endocytosis of occludin and fosters breaks in the TJ.<sup>194</sup> Despite this well-supported mechanism, the PKC $\beta$  inhibitor ruboxistaurin failed to achieve Food and Drug Administration approval for diabetic retinopathy. cPKC inhibition also failed to prevent TNF- $\alpha$ -induced permeability,<sup>195</sup> a proinflammatory cytokine also implicated in diabetic retinopathy. Thus targeting permeability in the retina continues to be a difficult clinical problem.

## Adult Choroidal Ischemia

The choroidal vasculature is an expansive vascular plexus that handles 90% of the blood from the ophthalmic artery. It was often assumed that the choriocapillaris was so vast that generation of choroidal ischemia rarely occurred. However, there are several diseases in which the loss of choroidal vasculature is extensive, resulting in apparent choroidal ischemia.

Diabetic choroidopathy was first described by Hidiyat and Fine.<sup>196</sup> The use of alkaline phosphatase enzyme histochemistry on human choroid permitted quantification of vascular loss in choroid. Viable vessels were positive for alkaline phosphatase while acellular, dysfunctional capillaries lacked it, and choroidal neovascularization had the greatest activity.<sup>12</sup> This technique demonstrated that there was four times greater loss in

choriocapillaris in diabetic subjects than in aged control subjects.<sup>197</sup> Loss of alkaline phosphatase activity was associated with the presence of polymorphonuclear leukocytes.<sup>198</sup> Areas of choriocapillaris loss were also associated with choroidal neovascularization and Bruch's membrane deposits. A consequence of choriocapillaris dropout is loss of outer retinal oxygenation. This may be the reason for loss of blue cones and other cones in diabetic retina when there is no retinopathy present.<sup>199,200</sup>

Decreased choroidal blood flow has been measured in AMD.<sup>201-204</sup> Using alkaline phosphatase activity and quantification of RPE in AMD, the loss of choriocapillaris has been demonstrated in exudative or wet AMD as well as geographic atrophy (Fig. 20.5). RPE loss occurs first in geographic atrophy and then choriocapillaris degeneration occurs. Although some capillaries survive in the area of RPE atrophy, a 50% loss of vasculature occurs and the surviving capillaries are highly constricted.<sup>205,206</sup> This undoubtedly contributes to photoreceptor loss in the area of degeneration. Capillary loss occurs in exudative AMD as well, but in the presence of a complete RPE monolayer (Fig. 20.5). This suggests that the RPE in this area are hypoxic and VEGF production may be increased, causing choroidal neovascularization. Large-vessel stenosis is also often observed in AMD choroid, suggesting that the choriocapillaris blood supply may be limited as well. Unfortunately, we have no way of measuring oxygen directly in the choroid, so we can only assume ischemia occurs when there is loss of viable choriocapillaris and stenosis of large and intermediate choroidal blood vessel.

**FIG. 20.5** The choroid and retinal pigment epithelium (RPE) in geographic atrophy (A–F) and wet (neovascular) age-related macular degeneration (AMD) (G–I). (A) Alkaline phosphatase (APase)-stained choroidal blood vessels in a nonatrophic region of geographic atrophy (GA) choroid. (B) When sectioned, this area has normal-appearing RPE cells (*arrowhead*) and viable choriocapillaris lumens filled with serum APase. (C) Higher magnification shows the intimate relationship between RPE, Bruch's membrane, and choriocapillaris (c). (D) The atrophic region of this GA choroid has no RPE and an attenuated choriocapillaris with narrow lumens. (E) Cross-sections of this area demonstrate the APase reaction product in a few remaining choriocapillaris lumens and the endothelial cells of artery (bottom). (F) At higher magnification it is apparent that the APase<sup>-</sup> capillaries (c) are only collagenous tubes between intercapillary septa. (G) In a flat choroid preparation of a wet AMD subject, a large fan-shaped choroidal neovascular formation is present and the RPE monolayer to the left appears normal. (H) A section of this subject immediately in advance of the choroidal neovascularization demonstrates viable hypertrophic RPE (*arrowhead*) over an attenuated choriocapillaris. (I) At higher magnification, the remnants of atrophic choriocapillaris lumens (c) are present between intercapillary septa and a single APase<sup>+</sup> lumen

remains, yet RPE are still present.

## Conclusions

Both too little and too much oxygen can be damaging to the retina. Retina cannot function properly nor survive without the support of two vasculatures: retinal and choroidal. If either vasculature is dysfunctional, retinal hypoxia occurs and HIF-1 $\alpha$  becomes stable and induces expression of key factors to assist in retinal cell survival. Reduced retinal oxygenation causes impaired neuroretinal activity in young healthy persons.<sup>207</sup> One key factor upregulated by HIF-1 $\alpha$  is VEGF, which stimulates new angiogenesis and increased vascular permeability. These pathol events can be controlled by destroying ischemic retina (photocoagulation), inhibiting VEGF, or reducing levels of HIF-1 $\alpha$ .

**Pathophysiology of Serous Detachment**

**Conclusions and General Implications**

In some cases of retinal detachment, the reasons for retinal separation are obvious, such as penetrating trauma that snags the retina or gross vitreous traction bands that pull the retina from the retinal pigment epithelium (RPE). Any physiologic mechanism of adhesion would be overwhelmed by such forces. However, detachment is also caused by less dramatic forces and under

conditions in which stronger adhesion might prevent, or at least delay, the separation and its spread. The physiology of attachment is especially important with respect to nonrhegmatogenous detachments that cannot develop unless local mechanisms for keeping the subretinal space dry are overwhelmed.

Independent of its clinical relevance, the study of retinal adhesion is also of considerable physiologic interest. No anatomic junctions bridge the mammalian subretinal space,<sup>1</sup> yet this primordial dural cavity remains collapsed and, indeed, tightly closed throughout a lifetime of ocular movement and tugging from the vitreous. Our current knowledge of this system is still incomplete, but evidence suggests that adhesion depends on a mixture of anatomic, physical, and metabolic factors.<sup>2</sup> This chapter reviews these factors and considers clinical and therapeutic implications.

## Models for Measuring Retinal Adhesion

The strength of the adhesion between the sensory retina and the RPE can be measured with *in vitro* and *in vivo* methods.

### In Vitro Methods

Adhesive force falls rapidly after enucleation or death,<sup>3,4</sup> as is discussed later, and this puts a constraint of time on techniques for measuring adhesiveness *in vitro*.<sup>5,6</sup> One approach is to peel the retina within a fluid bath while recording the required force with a transducer.<sup>3</sup> A faster method is to measure the amount of RPE pigment that remains attached to the retina after separation as the index of adhesiveness.<sup>7</sup> An eye can be enucleated and small strips of the eyecup prepared within 30 seconds, after which the retina is gently peeled by hand from the RPE. The stronger the adhesive force, the more pigment adheres to the peeled retina.

### In Vivo Methods

Kita et al.<sup>8</sup> developed the most direct technique for quantifying adhesiveness within the living eye. A small detachment is made in

the eye by injecting fluid into the subretinal space through a micropipette, and a second micropipette is inserted simultaneously into the detachment cavity to measure fluid pressure. The pressure that is required to expand the detachment can be converted mathematically, by Laplace's law, into a value for adhesive force at the margin of the detachment (where the separation is taking place). This technique allows the evaluation in living animals of the effects of drugs and other agents that modify retinal adhesion.<sup>9,10</sup>

## Adhesive Force and Environmental Factors

A substantial force maintains attachment of the sensory retina to the underlying RPE. This force can be altered by environmental factors.

### Magnitude of Adhesive Force

In vitro measurements, 5–20 minutes after enucleation, have shown that about 25 mg of force is required to peel a 5-mm strip of rabbit retina from the RPE.<sup>3,11,12</sup> Pressure measurements in living eyes have shown an adhesive force in the rabbit of 100–180 dyn/cm.<sup>8,9</sup> Adhesion is stronger in cats and monkeys, which show mean values for adhesive force that are 180% (for cats) and 140% (for monkeys) of that in the rabbits.<sup>9</sup>

### Sensitivity to Temperature and Ionic Environment

Retinal adhesiveness drops rapidly postmortem at 37°C, but remains near control levels for hours at 4°C<sup>7,13–15</sup> (Fig. 21.1A). These effects of temperature are reversible. Fig. 21.1B shows that changing the temperature from 37°C to 4°C or vice versa causes retinal adherence in the rabbit<sup>16</sup> to rise or fall, respectively, and repeatedly. This reversibility has also been documented in primate and human tissue.<sup>14,15,17</sup> The mechanism of these reversible temperature effects is still obscure. Temperature could act directly on physicochemical

components of adhesion or modulate metabolic systems. Some of the adhesion-enhancing effect of cold temperature may result from sodium pump inhibition and secondary tissue swelling, which would make the interdigitated outer segments and RPE microvilli harder to separate.<sup>3,13</sup> Because cellular swelling is a pathologic event, the actions of cold temperature may not be entirely relevant to normal adhesive processes.

**FIG. 21.1** Relationship between retinal adhesiveness and temperature in the rabbit. (A) Cold temperatures slow down the postmortem failure in adhesiveness to the point that firm adhesion is maintained at 4°C for many hours. (B) The effects of temperature on retinal adhesion are reversible within minutes, and adhesiveness can be repeatedly strengthened or weakened by cooling or warming the same piece of tissue. (Panel A modified with permission from Endo EG, Yao XY, Marmor MF.

Pigment adherence as a measure of retinal adhesion: dependence on temperature. Invest Ophthalmol Vis Sci 1988;29:1390–6. Panel B modified with permission from Yao XY, Endo EG, Marmor MF. Reversibility of retinal adhesion in the rabbit. Invest Ophthalmol Vis Sci 1989;30:220–4.)

The ionic environment appears to be critical to adhesive strength. In *in vitro* experiments using tissue from rabbits, humans, and other primates, lowering the pH from 7.4 to 5.5, or removing calcium and magnesium ions from the bathing solution, weakened adhesive force and accelerated the rate at which adhesion falls postmortem<sup>11,13,15,17</sup> (Fig. 21.2A). These changes can be rapidly reversible<sup>16</sup> (Fig. 21.2B), although cold temperature will block or mask the effects of pH and calcium ions. *In vivo*, the removal of calcium ions from the subretinal space weakens retinal adhesion in rabbits to about 30% of normal.<sup>18</sup> In other words, calcium appears to be a necessary element for the maintenance of normal adhesiveness in the living eye.

**FIG. 21.2** Effects of pH and calcium/magnesium ion concentration on retinal adhesiveness in the rabbit. (A) The force required to peel retina from retinal pigment epithelium (RPE) drops within seconds after lowering pH (by injecting 1 mL of 1 mol/L HCl near the tissue) or lowering external Ca/Mg-free solution. The tracings represent a continuous measurement of the peeling force; chemical changes were made at time 0. (B) The effects of changing pH or Ca/Mg concentration are rapidly reversible. Pigment adherence was used as an index of adhesiveness. *Dotted line*, tissue maintained in Hanks balanced salt solution; *dashed line*, pH changed from 7.4 to 6.0 and back again; *solid line*, Hanks solution changed to Ca/Mg-free solution and back again. (Panel A modified with permission from Marmor MF, Maack T. Local environmental factors and retinal adhesion in the rabbit. *Exp Eye Res* 1982;34:727–33. Panel B modified with permission from Yao XY, Endo EG, Marmor MF. Reversibility of retinal adhesion in the rabbit. *Invest Ophthalmol Vis Sci* 1989;30:220–4.)

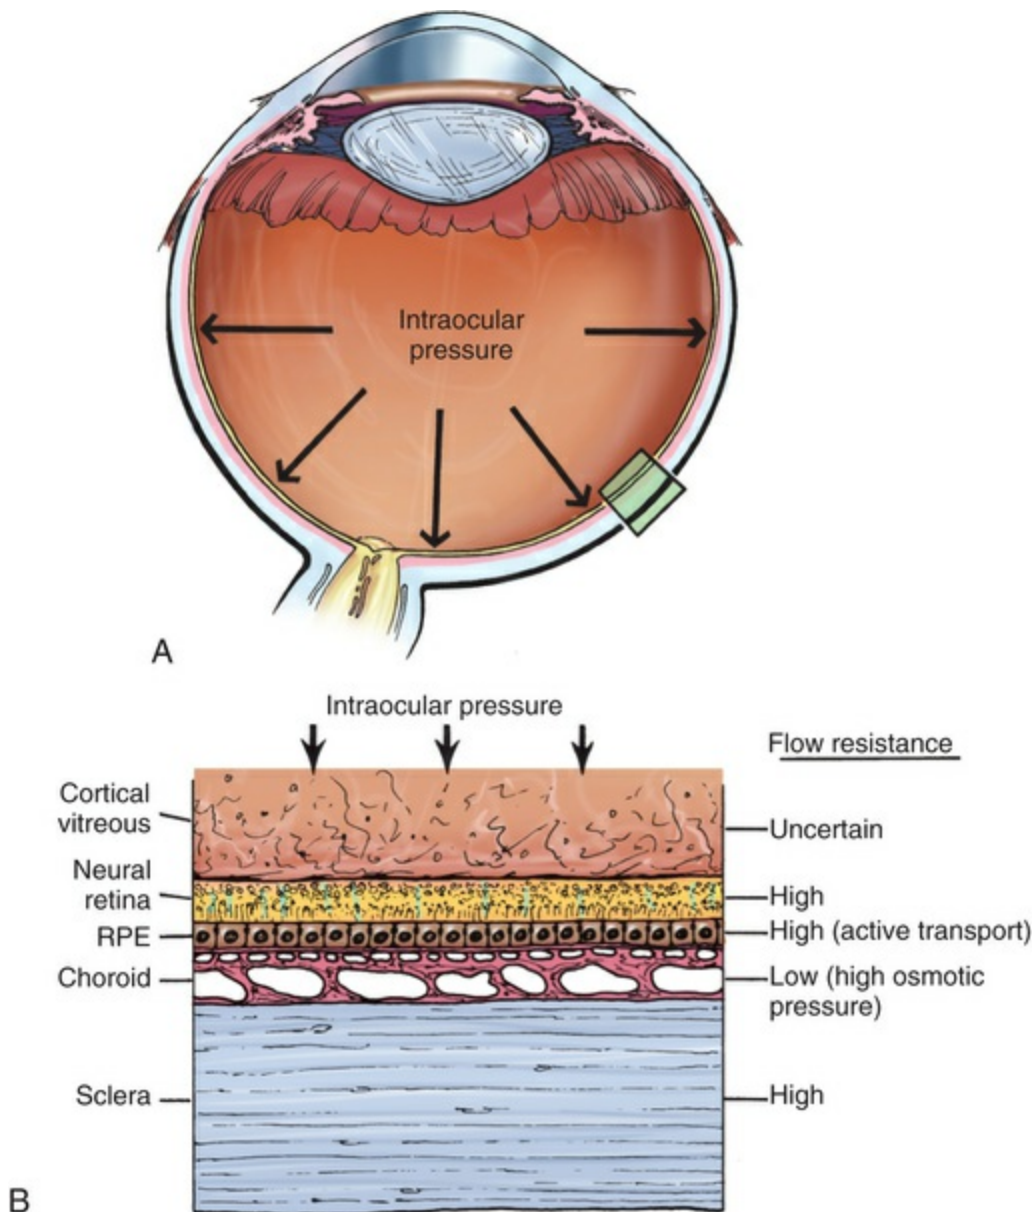

## Mechanical Forces Outside the Subretinal Space

A number of forces play upon the retina from outside the subretinal space, strengthening or weakening retinal adhesion. Most important are fluid and vitreous pressure, not only because they contribute to adhesion, but also because they may cause detachment when altered by pathologic conditions.

### Fluid Pressure: Hydrostatic and Osmotic

Fluid is driven passively from vitreous to choroid by both intraocular pressure and the osmotic pressure of the extracellular fluid in the choroid (estimated to be about 12 mmHg in the rabbit,<sup>19</sup> but possibly lower in humans<sup>20</sup>). However, under normal conditions there appears to be relatively little posterior flow, and most of the fluid that enters the eye as aqueous leaves the eye through anterior drainage channels.<sup>19,21</sup> The posterior route is limited because the retina and RPE<sup>22,23</sup> provide a substantial resistance to water movement, and little fluid can cross these layers under the available heads of pressure. A side-effect of this retinal flow resistance is that the outward movement of fluid acts to push the retina against the RPE (Fig. 21.3). This is one mechanism contributing to normal retinal attachment. The actual pressure difference across retina or RPE is probably small because intraocular pressure is ultimately contained by the sclera, and tissue pressures will therefore equalize to a large degree between the vitreous and choroid. However, Fatt and Shantinath<sup>22</sup> have calculated that even a very small pressure difference (only  $0.52 \times 10^{-3}$  mmHg) across the retina would generate a force sufficient to keep the retina firmly fixed against the wall of the eye. This low value may explain the fact that no one<sup>14,19</sup> has been able to measure a pressure difference between the vitreous cavity and subretinal space.

**FIG. 21.3** Intraocular pressure and retinal flow resistance as a factor in retinal adhesion. (A) Intraocular pressure is evenly distributed within the vitreous cavity so that fluid is continually being pushed through the coats of the eye. (B) Magnified view of the tissue layers in the posterior of the eye, including cortical vitreous. The flow resistance of each layer is indicated on the right; note that the retinal pigment epithelium (*RPE*) and choroid can also modify fluid movement by active transport and osmotic pressure, respectively.

These physical forces can also work in the other direction and cause retinal detachment. For example, if hyperosmotic fluid is

introduced into the vitreous cavity, fluid moving from the choroid into the vitreous will elevate the retina<sup>24,25</sup> (Fig. 21.4). This is an important concern in the evaluation or use of intravitreal drugs that may damage the retina osmotically independently of pharmacologic effects.

**FIG. 21.4** Effects of injecting hyperosmolar solution into the vitreous. (A) Monkey eye enucleated after a midvitreal hyperosmolar injection. Bullous detachment was present in the posterior pole and peripapillary region. (B) Degree of serous retinal detachment in rabbit eyes 15 minutes after injecting 0.05 mL of different solutions and osmolarities into the vitreous: incipient detachment, the vitreoretinal interface glistened but did not visibly separate; low detachment, separation occurred without bullous elevation; moderate detachment, the bullae were confined to the posterior pole; large detachment, there was extension near or beyond the equator. (Reproduced with permission from Marmor MF. Retinal detachment from hyperosmotic intravitreal injection. *Invest Ophthalmol Vis Sci* 1979;18:1237–44.)

It may seem puzzling that, although most intraocular fluid leaves the eye anteriorly rather than posteriorly, ample animal data<sup>26–30</sup> indicated that the RPE can pump fluid from the subretinal space to choroid at a very high rate (about 0.3  $\mu\text{L}/\text{h}/\text{mm}^2$  of RPE) comparable with that of aqueous secretion. How can the RPE have such enormous power for fluid removal, yet very little fluid leaves the normal eye by a posterior route? The answer probably lies in

the flow resistance of the retina. Under normal conditions, given the flow resistance of the tissue and the tiny pressure differential across it,<sup>22,23</sup> water will cross the retina only at a very slow rate. In other words, the tissue resistance is rate-limiting, and most aqueous fluid must leave by the anterior route. Under pathologic conditions of retinal detachment (whether rhegmatogenous or nonrhegmatogenous), fluid is present within the subretinal space and is thus available for transport at a maximal rate. Measurements in humans for the resorption of detachments showed a rate of 0.11  $\mu\text{L}/\text{h}/\text{mm}^2$  of RPE, and the rate may well be higher in eyes without pathology.<sup>31</sup> This translates into roughly 3.5 mL of fluid per day, which explains why a rhegmatogenous detachment can settle within 24 hours, and emphasizes the power of RPE fluid transport.

The clinical importance of fluid pressure as a factor in preventing retinal detachment is uncertain. It undoubtedly helps to keep the retina in place when the retina is intact, but raising intraocular pressure in rabbits to 38 mmHg or lowering it to 0 mmHg had only a modest effect on the rate of subretinal fluid absorption.<sup>32</sup> Furthermore, clinical retinal (as opposed to choroidal) detachment is uncommon in hypotonus eyes, and even a small hole in the retina would theoretically allow fluid to reach the subretinal space and circumvent fluid pressure mechanisms of adhesion. Retinal holes are, in fact, found in about 10% of autopsy eyes without detachment,<sup>33</sup> but many of these holes may not be functionally open because of surrounding pigmentation or because of “tamponade” by the cortical vitreous gel.<sup>34</sup>

Once the retina has detached and adhesion mechanisms that depend on retina–RPE contact can no longer work, fluid dynamics become much more important, even in the presence of a hole. Hammer<sup>35</sup> has calculated that fluid entering a retinal hole over a scleral buckle will, by its flow pattern, create a suction force that pulls the retina backward against the buckle.

Osmotic pressure can be manipulated more easily and may turn out to have therapeutic applications. Both in vitro and in vivo experiments, using rabbits and primates,<sup>9,36,37</sup> have shown that an intravenous injection of mannitol will increase retinal adhesiveness by roughly 50% within 1–2 hours of injection (Fig. 21.5). The magnitude of the effect correlates rather closely with blood

osmolality. Mannitol is known to enhance the absorption of fluid out of the subretinal space.<sup>38</sup> Some of the adhesive effect may come from fluid absorption “pulling” the retina against the RPE; however, most of the effect probably comes from dehydration of the subretinal space (which enhances the binding properties of the interphotoreceptor matrix [IPM]), because the mannitol effect is still evident in excised tissue where there is no flow toward the choriocapillaris.

**FIG. 21.5** Time course of change in retinal adhesive force after intravenous injection of mannitol in rabbits (*broken line*, 2.5 g/kg) and monkeys (*solid lines*, 2.0 g/kg). (Reproduced with permission from Kita M, Marmor MF. Retinal adhesive force in living rabbit, cat, and monkey eyes: normative data and enhancement by mannitol and acetazolamide. *Invest Ophthalmol Vis Sci* 1992;33:1879–82.)

## Vitreous Support and Other Physical Aspects of Adhesion

The role of the vitreous in creating retinal detachments through traction and contraction is well known. The role of the vitreous in maintaining retinal attachment is less clear. Vitreous gel has a physical structure that may help to keep the retina in place,<sup>34,39</sup> although retinas do not just come off when vitreous detachment or

syneresis occurs. A thin cortical layer of vitreous might remain after vitreous detachment or syneresis and serve as a seal or tamponade for retinal holes,<sup>34</sup> thus aiding the action of fluid pressure in keeping the retina apposed (Fig. 21.3).

There is other, indirect, evidence for a vitreous role in adhesion. It is very difficult to produce and maintain an experimental rhegmatogenous detachment if the vitreous body remains intact.<sup>24,40</sup> Vitreous removal (either mechanical or with hyaluronidase) presumably weakens the tamponade and the structural qualities of the gel, but it also allows liquid vitreous to reach the subretinal space. The status of the gel may help account for the vastly different incidence of retinal detachment among young individuals, in whom the gel is largely intact, and among older individuals, in whom syneresis and vitreous detachment have occurred. A retinal hole in a young eye is blocked by gel pressure and can seal uneventfully; a hole in an old eye is more likely to allow fluid to enter the subretinal space and cause detachment. On the other hand, the integrity of the vitreous gel seems of little consequence to the formation or persistence of experimental nonrhegmatogenous detachments<sup>32</sup> or to the retinal adhesive force measured by peeling,<sup>11</sup> so the role of the vitreous gel in attachment may be more one of preventing pathologic fluid access to the subretinal space than one of providing a direct adhesive support or force.

The weight of retina is potentially a factor in attachment and detachment, as influenced by gravity and ocular movement. Once a detachment has occurred, the influence of gravity is well known, because appropriate positioning of the patient can be enormously effective in inducing retina to settle. However, it is hard to envision retinal weight as a major factor in retinal attachment under normal conditions<sup>27,32</sup> because our upright posture and eye movements would dictate that benefits and adverse effects be simultaneously present in different parts of the eye.

## Mechanical Forces Inside the Subretinal Space

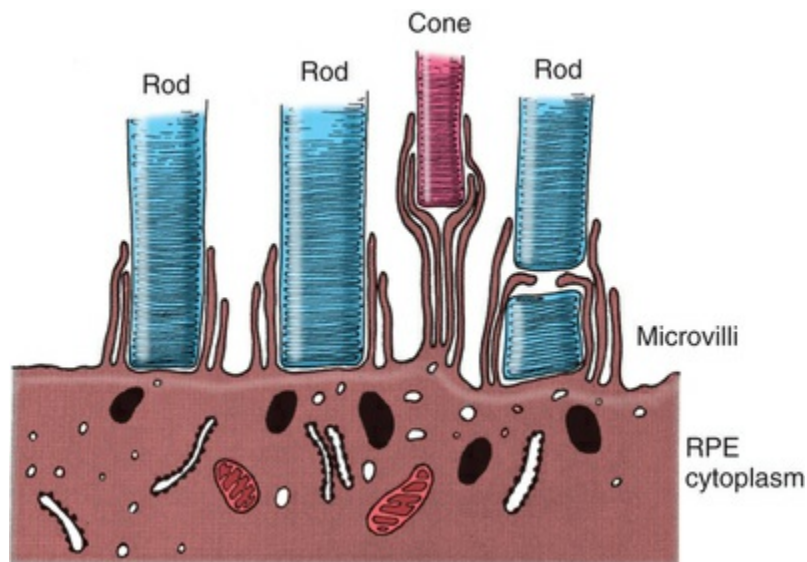

Anatomic bridges do not exist between retina and RPE,<sup>1</sup> but it is

reasonable to ask to what extent matrix material between the layers serves as “glue” and to what extent the physical interdigitation of photoreceptor outer segments and RPE microvilli serves to hold the tissues together.

## Mechanical Interdigitation

RPE microvilli wrap closely around the tips of the outer segments (Fig. 21.6), and this connection is strong enough to allow for daily phagocytosis of outer-segment fragments as the photoreceptors renew their disc material.<sup>1,41,42</sup> However, as a factor in adhesion, interdigitation seems of variable importance. The RPE microvilli are subject to continuous cellular remodeling during the outer-segment renewal cycle. After surgical repair of a retinal detachment, reattachment takes place rather promptly, before the outer segments have regenerated and microvillous connections have been reestablished.<sup>43,44</sup> Interdigitation begins to develop within 3 days of reattachment, but retinal adhesiveness does not return to normal until 5–6 weeks after reapposition of experimentally detached retina in the rabbit<sup>45</sup> (Fig. 21.7).

**FIG. 21.6** Interdigitation between photoreceptor outer segments and the microvilli of the retinal pigment epithelium (RPE). Note that the microvilli actually indent the outer segments during phagocytosis of “outdated” discs. The cone outer segments are shorter,

and the microvilli form long pedicles in order to reach them.

**FIG. 21.7** Time course of the recovery of adhesive strength after separated retina becomes reattached. Experimental detachments were made in rabbit eyes by injecting a balanced salt solution into the subretinal space; the fluid absorbed within several hours, and at intervals after settling of the detachment, a comparison was made between the force required to peel the retina from normal and reattached areas of retinal pigment epithelium. (Reproduced with permission from Yoon YH, Marmor MF. Rapid enhancement of retinal adhesion by laser photocoagulation. *Ophthalmology* 1988;95:1385–8. Copyright © 1988, with permission from the American Academy of Ophthalmology.)

The mechanisms by which interdigitation could produce adhesion are not known. During outer-segment phagocytosis, the microvilli indent the outer segments and must physically impede attempts to withdraw them. Close ensheathment might also provide a frictional resistance to withdrawal, just as a finger is hard to pull from a narrow tube. There may be electrostatic forces that oppose separation of the membranes.<sup>46</sup> The magnitude of all of these effects will also depend on other factors, such as the composition of the intervening matrix and capability of the RPE microvilli for motility and remodeling.

## Interphotoreceptor Matrix Properties

The IPM is a viscous material composed largely of proteins, glycoproteins, and proteoglycans<sup>47,48</sup> but containing a substantial concentration of glycosaminoglycans.<sup>49</sup> The idea that IPM might serve as a viscous glue was proposed many years ago by Berman,<sup>50</sup> but current evidence indicates the IPM is not just a layer of glue but has component structures that play a role in the adhesive process. For example, the cones are surrounded by a specialized sheath of matrix<sup>51,52</sup> that can be recognized histochemically by the binding of peanut agglutinin (PNA) (Fig. 21.8A). These cone matrix sheaths remain attached to both RPE and photoreceptor cells when the neural retina is peeled from the RPE.<sup>48,51,53</sup> If fresh primate or human retina is peeled from the RPE, the matrix material will stretch markedly before breaking (Fig. 21.8B), suggesting a rather strong bonding at both the outer-segment and RPE interfaces.<sup>17,54</sup> The evidence for a bonding function of the IPM is strongest with respect to the cone matrix sheaths, but the structural material that surrounds the rods may play a similar role. It can be recognized histochemically by staining with wheatgerm agglutinin (WGA) or other lectins,<sup>55,56</sup> and stretching of WGA-staining material may be observed on peeling freshly enucleated eyecup material.<sup>17,54,57</sup> The role of newly recognized matrix components such as galectins and IPM proteoglycans remains to be determined.<sup>58,59</sup>

**FIG. 21.8** Fluorescence micrographs of monkey retina showing cone sheaths of the interphotoreceptor matrix (IPM) stained with peanut agglutinin. Photoreceptors are above and retinal pigment epithelium (RPE) below. (A) Normal retina. The cone sheaths are short and thick. (B) Partially peeled retina. The cone sheaths have been stretched markedly between the photoreceptors and the RPE surface, showing the strength of IPM bonding to both sides. (Original magnification  $\times 130$ ). (Reproduced with permission from Hageman GS, Marmor MF, Yao XY, et al. The interphotoreceptor matrix mediates primate retinal adhesion. *Arch Ophthalmol* 1995;113:655–60. Copyright © 1995 American Medical Association. All rights reserved.)

The ability of cone or rod matrix sheaths to serve as a structural bond between retina and RPE may well depend on the presence of specific receptors that bind IPM components to the cell membranes. (“Cell adhesion molecules” represent a group of substances that mediate adhesion between individual cells or between cells and substrates.<sup>60</sup>) Experiments have shown that extracted IPM material does not automatically stick cells to one another,<sup>61</sup> but adhesion is unlikely unless specific receptors are present to bind the macromolecular substances. Several receptor systems, including sites for fibronectin, integrins, and mannose, have been proposed and disputed as being involved with retinal adhesion.<sup>48,62–66</sup> There is

functional evidence that inhibition of chondroitin sulfate proteoglycan synthesis with xylosides causes spontaneous detachments in primates.<sup>48,67</sup> Fibulin 2, an extracellular matrix protein, is upregulated in RPE after retinal detachment.<sup>68</sup>

Other types of evidence support the concept that IPM contributes significantly to retinal adhesion. Physical factors that affect adhesiveness, such as temperature, pH, and calcium concentration, are known to be modulators of the physicochemical properties of IPM macromolecules and may also affect the bonding of large-molecular species at receptor sites.<sup>69,70</sup> There is also a marked loss of retinal adhesiveness when the subretinal space is exposed to enzymes that degrade matrix components,<sup>15,71</sup> such as chondroitinase ABC (which degrades chondroitin sulfate<sup>72</sup>) or neuraminidase (which breaks sialic acid bonds<sup>73</sup>). These enzymes, given intravitreally or into the subretinal space itself, weaken adhesiveness markedly in correlation with cytochemical evidence of damage to the IPM (Figs. 21.9 and 21.10). It is unknown whether the effects of these enzymes on adhesiveness are a result of changes in viscosity or damage to the structural elements of the IPM. However, adhesiveness returns to normal roughly 3 weeks after exposure of an eye to neuraminidase or chondroitinase ABC, and the recovery of adhesiveness correlates closely with the recovery of normal PNA-binding properties in the IPM.<sup>74</sup>

**FIG. 21.9** Fluorescence light micrographs depicting binding of peanut agglutinin (PNA) to rabbit retinas in the region between the retinal pigment epithelium (RPE) and outer plexiform layer (OPL). (A) In a normal eye, PNA bound intensely and specifically to cone matrix sheaths (*arrows*). (B) After injection of neuraminidase, PNA binds throughout the interphotoreceptor matrix, with binding in the region of cones being diminished (note gaps indicated by *arrows*). (C) After intravitreal injection of testicular hyaluronidase, cone matrix sheaths were disrupted, especially at their apices (*asterisks*), and shallow separations between the photoreceptors and RPE were commonly observed. (Reproduced with permission from Yao XY, Hageman GS, Marmor MF. Retinal adhesiveness is weakened by enzymatic modification of the interphotoreceptor matrix in vivo. *Invest Ophthalmol Vis Sci* 1990;31:2051–8.)

**FIG. 21.10** Peeled whole-mount retinas after subretinal injection of enzymes. The areas of strong adhesion show retinal pigment epithelium pigment adherent to the retina after peeling; the areas of weak adhesion are clear of pigment. (A) Three days after injection of control (Hanks) solution, adhesion is normal (strong) except at the injection site. At (B) 1 day, (C) 2 days,

and (D) 3 days after testicular hyaluronidase, there was a progressive increase in the area of weakened adhesion beyond the injection site. A similar progression of adhesive loss was observed after neuraminidase. (Reproduced with permission from Yao XY, Hageman GS, Marmor MF. Retinal adhesiveness is weakened by enzymatic modification of the interphotoreceptor matrix in vivo. *Invest Ophthalmol Vis Sci* 1990;31:2051–8.)

Experiments have shown that the chemical nature of the IPM may change with light and dark adaptation.<sup>75</sup> To the extent that photic effects might modify the viscosity or bonding properties of the IPM, light could be a modulating factor of retinal adhesion. However, experimental data on adhesion in the light and dark have been contradictory and of uncertain significance.<sup>11,76,77</sup>

## Subcellular Components and Mobility

Subcellular components of the RPE, such as microtubules and microfilaments, will be relevant to retinal adhesion to the extent that they influence remodeling and movement of the RPE microvilli.<sup>78</sup> Actin filaments control melanin movement in the amphibian RPE<sup>11</sup> and are present in mammalian RPE,<sup>79,80</sup> but a movement of melanin granules has never been observed in mammals. A few attempts have been made to alter adhesion by inhibiting subcellular components of the RPE. Cytochalasin B, which blocks microfilaments, was found to have no effect on adhesion when the drug was presented to excised tissue briefly after enucleation.<sup>12</sup> However, injecting cytochalasin into the vitreous 4–72 hours before enucleation caused a 70–90% reduction in pigment adherence as a measure of adhesiveness.<sup>81</sup>

When retina detaches, the surface morphology of the RPE changes literally within minutes.<sup>23</sup> The evolution of these changes can be altered by both colchicine (which disassembles microtubules) and cytochalasin,<sup>82</sup> suggesting that microtubules and microfilaments are important to apical RPE morphology. Actin filament contraction and subcellular motility are known to require calcium,<sup>83</sup> the absence of which is severely detrimental to retinal adhesion. However, we do not know whether the action of calcium in weakening adhesiveness relates to this mechanism or to effects

that calcium may have on transport systems and matrix-binding properties.

## Metabolic Factors

The question of whether or why metabolic activity is necessary or even contributory to retinal adhesion is extremely important. From a physiologic standpoint, we would like to know the interaction between RPE transport, IPM properties, and the passive physical forces that impinge on the subretinal space. From a clinical standpoint, if adhesion is purely passive (i.e., dependent on pressure, or “glue”), therapy for clinical detachments would be primarily mechanical, whereas if active metabolism is necessary for adhesion, physicians may have a very different range of therapeutic options.

## Critical Dependence on Oxygen

It was noted previously that adhesiveness in living rabbit eyes falls severely within a few minutes of death<sup>5</sup> (see Fig. 21.1A).

Furthermore, just 1 minute of ocular ischemia in living rabbits weakens adhesion dramatically, whereas restoration of circulation restores adhesiveness.<sup>84,85</sup> The postmortem adhesive loss appears to be slower in primates and humans, and under similar in vitro conditions, at least a moderate adhesive force was measurable for 30 minutes or more after enucleation of primate and human tissue<sup>15,17,85</sup> (Fig. 21.11A).

**FIG. 21.11** Dependence of retinal adhesion on

metabolic activity. (A) Scanning electron micrograph of the photoreceptor surface of human retina peeled from the retinal pigment epithelium (RPE) within 4 minutes of enucleation. The outer segments are largely covered by apical fragments of RPE cells, indicating that the strength of retinal adhesion in living or fresh tissue is greater than that of the RPE cell membrane. Retinas peeled 1 hour after enucleation showed little or no adherence of RPE fragments. Bar = 10  $\mu$ m. (B) Effect of oxygenation on the adhesiveness of rabbit retina in vitro. Left, Postmortem adhesive failure was delayed markedly by the incubation of tissue in an oxygenated rather than static bath. Right, Switching tissue from a static bath to an oxygenated one caused a prompt recovery of adhesive strength. (Panel A reproduced with permission from Marmor MF, Yao XY. The metabolic dependency of retinal adhesion in rabbit and primate. *Arch Ophthalmol* 1995;113:232–8. Panel B modified with permission from Marmor MF, Yao XY. The metabolic dependency of retinal adhesion in rabbit and primate. *Arch Ophthalmol* 1995;113:232–8.)

One possible explanation for the post-enucleation loss of adhesion is that the rapid release of lysosomal enzymes by injured RPE alters the IPM.<sup>86</sup> Enzyme release can occur quickly after injury,<sup>86,87</sup> and lysosomal enzyme activity is generally enhanced by warm temperature, low pH, and low calcium levels, all of which reduce retinal adhesiveness. However, the loss of adhesion under warm temperature, low pH, and low calcium conditions is rapidly reversible by restoring normal environmental conditions,<sup>16</sup> which would seem unlikely if irreversible degradation of the IPM had taken place. We have also been unable to find any cytochemical or morphologic changes in the IPM that correlate with the postmortem period loss of adhesion.

The postmortem failure can be retarded or even reversed simply by improving or restoring oxygenation.<sup>84</sup> With enhanced oxygenation, retinal adhesion in excised rabbit tissue can be maintained for 15–30 minutes (instead of 1–2 minutes) without postmortem failure (Fig. 21.11B); adhesive failure that occurred after a few minutes without oxygen was rapidly reversed by oxygenating the bath. In monkeys, adhesiveness may persist in oxygenated Ames solution for 1 hour or more.<sup>85</sup>

These results are extremely important with respect to the

mechanisms of adhesion because they show that, although IPM may account for much of the mechanical bond between retina and RPE, continuous oxygenation and active metabolic activity by RPE and photoreceptors are vital to the maintenance of adhesive strength. The critical activity might be subretinal fluid transport, which dehydrates the subretinal space, or it might be the metabolic control of membrane systems that modulate local pH, calcium concentration, or other factors that influence the bonding properties of the IPM. Metabolic failure could also affect the synthesis of IPM components and the function of subcellular organelles that influence microvillous motility.

## Metabolic Inhibitors and Other Agents

A number of experiments have shown that general metabolic inhibitors have a deleterious effect on the process of retinal adhesion. For example, the introduction of cyanide into the experimental bath reduces the measured adhesive force and hastens the postmortem failure of adhesion.<sup>3</sup> In vivo experiments with dinitrophenol placed in the subretinal space showed that retinal adhesiveness was rapidly reduced to an unmeasurable level<sup>10</sup> (Fig. 21.12). Sodium iodate and hemicholinium-3 also cause retinal adhesiveness to fall rapidly to a low level,<sup>88-91</sup> but these effects may involve a variety of mechanisms because these agents affect not only metabolic functions of the RPE (and, more slowly, the photoreceptors) but also the physical integrity of the RPE cells and blood–retinal barrier.<sup>89,92</sup>

**FIG. 21.12** The retinal adhesive force after injection of active agents into the subretinal space. Columns show mean value; bars show standard error; the numbers of experiments are in parentheses; asterisks indicate a significant difference from control ( $p \leq 0.05$ ). *cAMP*, cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; *DNP*, dinitrophenol. (Reproduced with permission from Kita M, Marmor MF. Retinal adhesive force in living rabbit, cat, and monkey eyes: normative data and enhancement by mannitol and acetazolamide. *Invest Ophthalmol Vis Sci* 1992;33:1879–82.)

Specific transport inhibitors, in contrast, may act very selectively on different aspects of the adhesive process. For example, ouabain, which blocks the electrogenic sodium pump, will ultimately kill photoreceptor and RPE cells. However, in the short term its effect is to strengthen adhesiveness<sup>3,10</sup> (Fig. 21.12) because sodium entry causes cellular swelling that tightens (presumably) the interdigitation between RPE microvilli and outer segments.<sup>13</sup> This is a pathologic effect, of course, and is probably of little relevance to normal mechanisms of adhesion. Acetazolamide, which inhibits carbonic anhydrase, causes an increase in retinal adhesiveness, measured in vitro in rabbits<sup>93</sup> and in vivo in rabbit and monkey<sup>9</sup> (Fig. 21.13). The drug is effective only when given systemically and does not enhance adhesion if placed in the subretinal space or in an

experimental bath.<sup>3,93</sup> Acetazolamide enhances the apical-to-basal transport of fluid across the RPE,<sup>93</sup> and its effects on adhesion may well be a result of fluid movement, since the enhancement of outward fluid movement by other means such as mannitol<sup>36</sup> also increases adhesiveness.<sup>36,37</sup>

**FIG. 21.13** Effects of acetazolamide on retinal adhesiveness. (A) Retinal adhesion in the rabbit is increased by systemically administered acetazolamide. The graph shows the force required to peel retina from the retinal pigment epithelium at four time intervals after enucleation, with and without acetazolamide. (B)

The time course of change in retinal adhesive force in three monkeys after intravenous injection of a clinical dose (15 mg/kg) of acetazolamide. A control value (100%) was derived from each eye before administration of the drug. (Panel A modified with permission from Marmor MF, Maack T. Enhancement of retinal adhesion and subretinal fluid resorption by acetazolamide. *Invest Ophthalmol Vis Sci* 1982;23:121–4. Panel B reproduced with permission from Kita M, Marmor MF. Retinal adhesive force in living rabbit, cat, and monkey eyes: normative data and enhancement by mannitol and acetazolamide. *Invest Ophthalmol Vis Sci* 1992;33:1879–82.)

Cyclic adenosine monophosphate (cAMP), which has been shown by several groups to inhibit the outward transport of fluid from the subretinal space,<sup>94–96</sup> reversibly weakens retinal adhesive force in vitro<sup>12</sup> (Fig. 21.14). cAMP is present in the RPE, but it is not known whether it actively modulates adhesive force in the living eye. In rabbits with experimental detachments, cyclic guanosine monophosphate (cGMP) has the opposite effect of cAMP on RPE fluid transport (i.e., it facilitates outward movement),<sup>95,97</sup> but it has not been shown to have an effect on retinal adhesiveness.

**FIG. 21.14** Retinal adhesive force is weakened by exposure to cyclic adenosine monophosphate (cAMP). The graph shows the force required to peel rabbit retina from the retinal pigment epithelium (RPE) at various times after enucleation. For each strip of eyecup, three measurements of peeling force were made: one in control solution, one after cAMP was

added to the bath, and one after the tissue was returned to control solution. The addition of cAMP always weakened adhesion, but the effect was reversible on removing it from the bath. (Modified with permission from Yoon YH, Marmor MF. Effects on retinal adhesion of temperature, cyclic AMP, cytochalasin B, and enzymes. *Invest Ophthalmol Vis Sci* 1988;29:910–14.)

Retinal adhesiveness in vivo in the rabbit was also decreased, relative to normal, to 86% with furosemide and 81% with amiloride<sup>10</sup> (Fig. 21.12). Both these agents reduce apical–basal fluid transport across epithelial cells.<sup>98,99</sup>

## Relationship of Adhesion to Subretinal Fluid Transport and Subretinal Protein

The RPE actively transports water from the subretinal space to the choroid<sup>23,94,100</sup> and experiments on the control of subretinal fluid transport<sup>3,27,28,32,93,95,97,101</sup> show that many of the factors affecting adhesion also influence transport in a similar direction. This concurrence may, in part, be fortuitous, since both physiologic processes involve the RPE; thus, conditions that nonspecifically stimulate or inhibit the RPE will have a similar effect on adhesion and fluid absorption. However, there may also be a more direct connection insofar as conditions that dehydrate the subretinal space should serve to keep the retina closely apposed, the matrix viscous, and the matrix molecules tightly interactive at ionic or receptor-binding sites. Conversely, conditions that block subretinal fluid transport and allow the subretinal space to become hydrated would seem intuitively to weaken adhesiveness. Thus, part of the metabolic requirement for retinal adhesion is almost certainly a direct result of the fact that subretinal fluid transport under normal conditions takes place primarily by active metabolic transport across the RPE. Adhesiveness is also increased by raising systemic osmolality with mannitol,<sup>9,36,37</sup> which passively enhances the absorption of subretinal fluid.<sup>38</sup>

In certain conditions the efficacy of subretinal fluid transport is clearly a critical factor in maintaining adhesion. For example, under conditions where defects occur in the RPE barrier and choroidal

pressure is relatively elevated (e.g., through venous obstruction, ocular hypotony, systemic hypertension, or other causes), there will be a risk of fluid following the pressure gradient to enter the subretinal space and cause a nonrhegmatogenous (serous) detachment. Passive adhesive systems are important to minimize the spread of fluid laterally, but the critical determinant of whether a detachment forms and how large it grows will be the ability of the RPE surrounding the “leak” to remove fluid as quickly as it enters the subretinal space. This concept of serous detachment<sup>2</sup> is discussed later.

Since the subretinal fluid of both serous and rhegmatogenous detachments has a high concentration of protein, the question may be asked whether oncotic pressure from this protein contributes to the formation or persistence of detachments by drawing in fluid. However, in experiments that introduced albumin (serum) or larger molecules into the subretinal space of rabbits (Fig. 21.15), fluid was absorbed within a few hours regardless of whether protein or other larger molecules remained in the subretinal space.<sup>102-104</sup> Furthermore, retina is sufficiently permeable to ions and water that the osmotic pressure of the subretinal space is continuously equilibrating with that of the vitreous to neutralize gradients<sup>104,105</sup> (Fig. 21.15B). In fact, albumin can also diffuse slowly across the retina. When serum is injected into the subretinal space, the subretinal fluid loses roughly 5% of its protein concentration per hour into the vitreous (Figs. 21.15A, C). Thus, the high protein content of subretinal fluid is not self-maintaining and is not the cause of detachment; rather it is the result of continued protein influx from the RPE or vitreous. Faulty RPE transport may also contribute to the retention of fluid within the retina, i.e., macular edema.<sup>106</sup>

**FIG. 21.15** Changes in protein concentration and osmolality after injecting highly proteinaceous fluid into the subretinal space of rabbit eyes. (A) Protein concentration of subretinal fluid. There is a steady decrease despite simultaneous water absorption. (B) Osmolality of the subretinal fluid. The osmolality of the injected fluid was initially low, but it equilibrated to vitreous levels (293 mosmol/kg) within 2 minutes and then remained steady despite the changing subretinal protein concentration. (C) Protein concentration of vitreous. There was a steady increase as protein diffused from the subretinal space. (Modified with permission from Takeuchi A, Kricorian G, Marmor MF. Albumin movement out of the subretinal space after experimental retinal detachment. *Invest Ophthalmol Vis Sci* 1995;36:1298–305.)

## Pharmacologic Modification of Adhesion

Pharmacologic agents that modify retinal adhesive force could be useful clinically in several ways. Agents that enhance adhesion

could help reduce the risk of retinal detachment in high-risk eyes. They might minimize the spread of an existing detachment while awaiting surgical repair. They could improve or hasten the healing process after surgical repair of a detachment. To the extent that they enhance the absorption of subretinal fluid, they would speed the recovery of nonrhegmatogenous, as well as rhegmatogenous, detachments and minimize the risk of redetachment. If drugs can compensate in part for metabolic factors that fail in older eyes (which are more susceptible to detachment than younger ones) or in specific diseases that are predisposed to detachment, the risk of detachment might be decreased in these selected populations. Agents that reduce adhesion could facilitate an atraumatic separation of the retina in surgical procedures such as the removal of subretinal lesions, macular translocation, RPE transplantation, and injections of therapeutic agents such as a viral vector for gene transfer or stem cells for retinal regeneration.<sup>107,108</sup>

## Mannitol

Mannitol is an accepted therapeutic agent in humans for glaucoma and cerebral edema. In systemic doses that are used clinically, it causes a 50% increase in retinal adhesiveness, measured both in excised tissue *in vitro*<sup>37</sup> and in the living eyes of primates and rabbits<sup>9,36</sup> (Fig. 21.5). The magnitude and duration (2–3 hours) of the mannitol effect are directly related to the increase in blood osmolality. However, the effect is not simply a result of fluid movement “pulling” the retina against the RPE, because it is measurable *in vitro* (where there is no transretinal flow). More likely, it depends on dehydration of the IPM, which strengthens bonding characteristics.

Intravenous mannitol might be useful preoperatively for short-term stabilization of retinal attachment (in a case with partial detachment) or postoperatively to enhance the absorption of fluid and increase the initial strength of bonding of retina to RPE. The drug might even be given intraoperatively to help minimize retinal separation during vitrectomy. The benefits are limited, however, because the drug cannot be given repeatedly over long periods. This would seem to reduce its value in the management of serous

nonrhegmatogenous detachments, although it might help to clear the accumulated fluid in cases where the source of leakage is no longer active.

When hyperosmotic solutions are injected into the vitreous cavity,<sup>25</sup> the gradient is in the opposite direction and retinal detachment can be induced (Fig. 21.4). This is a risk with certain drugs, but could in theory be used to produce or facilitate retinal separation in conjunction with procedures that require surgical elevation of the macula. Limitations are the minutes required for detachment to develop and the associated cellular damage if the osmotic load is too great.

## Acetazolamide

The acetazolamide effect is slightly weaker than mannitol in the clinical doses we have used, causing a 30–45% increase in retinal adhesiveness in primates and rabbits<sup>9,17</sup> (Fig. 21.13). The acetazolamide effect lasts for 3–4 hours after a single injection, but acetazolamide can be given safely over long periods (although currently it is unknown whether the positive effects on adhesion would persist). Acetazolamide increases subretinal fluid transport<sup>93</sup> and thus could theoretically help to absorb fluid postoperatively or in cases of serous detachment. However, judging by anecdotal reports, researchers have not found acetazolamide to be dramatically effective in the management of central serous retinopathy. The problem may be that the effect of acetazolamide on subretinal fluid transport is not very strong and can only occur when the RPE is basically healthy and receptive to metabolic stimulation.<sup>109</sup> In a disorder such as central serous retinopathy, where RPE transport is probably compromised as a part of the disease, there may not be a normal substrate of RPE on which the acetazolamide can work.

Although acetazolamide and related carbonic anhydrase inhibitors have not been clinically useful for detachment disorders, they have proved quite useful for the removal of foveal cystic fluid in a number of disorders. They have not been of great use in postcataract cystoid edema and diabetic macular edema, where fluid continuously enters from vascular sources, but they can clear

intraretinal cysts dramatically where the fluid is relatively static in disorders such as retinitis pigmentosa, X-linked juvenile retinoschisis, enhanced S-cone syndrome, and sometimes macular epiretinal membrane formation.<sup>106,109–113</sup> The effectiveness probably depends on reasonable preservation of RPE metabolic function under the fovea, so that the drug can augment transport. One limitation to its use for retinal edema is the systemic side-effects, which may relate in part to its action on intracellular carbonic anhydrase throughout the body. Agents like benzolamide, which affect only the membrane-bound enzymes that are relevant to RPE transport, may have fewer side-effects.<sup>114</sup> Recent work has shown that enough drug may enter from topical carbonic anhydrase drops to produce a clinical effect, although the onset may take months instead of days.<sup>115,116</sup> The action of both oral and topical carbonic anhydrase inhibitors seems subject to tachyphylaxis (rebound of cystic edema), and cysts may return after roughly a year of usage; however, the effects will usually return after several months off treatment.<sup>117,118</sup>

## Cold Temperature and Ouabain

Both cold temperature and ouabain increase retinal adhesiveness,<sup>3,7</sup> but their action depends on pathologic changes (cellular swelling) rather than a true enhancement of the mechanisms of adhesion.<sup>13</sup> Neither cold nor ouabain therefore can be used for any long-term clinical applications, but they may be valuable in special situations. For example, cooling the irrigating solution during vitrectomy might reduce the risk of retinal separation during the manipulation of surgery.

## Ionic Changes

The removal of local calcium and magnesium ions, or lowering the pH, causes a dramatic fall in retinal adhesive force. Thus transient irrigation of the retina with calcium-free solution, or a solution of low pH, might facilitate the production of atraumatic surgical separation in association with submacular surgery. Alternatively a small amount of such solution might be injected into the subretinal space to weaken adhesion and make enlargement of the surgical

detachment easier. Preliminary studies on this approach have been reported,<sup>75,107</sup> but RPE or retinal toxicity is a risk, and guidelines for safe administration still need to be established.

## Implications for Vitreoretinal Surgery

Understanding mechanisms of retinal adhesion, both positive and negative, is relevant to vitreoretinal surgery. During procedures of repair, or whenever retinal detachment would be a complication, it may be useful to create conditions that maximize adhesiveness. Conversely, when detachment is created surgically such as during macular translocation, it may be useful to create conditions that weaken adhesiveness to make the procedure as atraumatic as possible.

Two agents have already been documented to enhance retinal adhesiveness to a significant degree – mannitol and acetazolamide. cGMP might theoretically be of use, and a study of related agents may reveal some that are clinically beneficial. Other options for the future include agents that modify local pH or calcium concentration, strengthen the binding properties of adhesion molecules within the IPM, or stimulate microvillous growth and ensheathment of outer segments. Even a “pathologic” effect of cold temperature in strengthening adhesion through cellular edema might prove useful in temporary clinical situations such as vitreous surgery.

Conversely, conditions that reduce adhesiveness, such as intravitreal hyperosmolarity, metabolic inhibition, low  $\text{Ca}^{2+}$ , and low pH, might prove useful in subretinal surgery where retinal separation needs to be produced transiently and with little cellular damage. Low- $\text{Ca}^{2+}$ , low- $\text{Mg}^{2+}$  solutions have already been shown to weaken adhesion and facilitate experimental detachment in rabbits.<sup>75,107,119</sup> Metabolic inhibitors, such as dinitrophenol, should in theory also be effective if their effects could be made transient and nontoxic. Another agent that might reduce adhesiveness is cAMP. Some of these approaches are likely to reach clinical practice within the next few years.

## Recovery After Rhegmatogenous Retinal Detachment

Retinal reattachment forces return following reapproximation of the sensory retina and RPE. This is observed both without retinopexy and following such therapy, which augments the adhesion.

## Recovery of Adhesiveness Without Retinopexy

Recovery after retinal detachment depends on a variety of factors, including the length of detachment (which may affect the survival of cells) and effectiveness with which adhesive mechanisms can be reestablished. We have measured in rabbits the retinal peeling force *in vitro*<sup>45</sup> after making small experimental detachments that spontaneously settled within hours to a few days. The results show that restoration of normal adhesive strength requires 4–6 weeks (Fig. 21.7). Keep in mind that these experiments involved the injection of a small amount of balanced salt solution into the subretinal space; in clinical detachments, where the fluid is serous and the retina is separated for longer periods, there could well be more trauma to the RPE or outer segments and thus an even more prolonged recovery period. It remains to be shown which adhesive factors are rate-limiting for the recovery process, considering that full recovery involves the restoration of anatomic interdigitation, RPE synthetic capabilities, IPM structure and binding, and subretinal fluid transport. These data show how clinical recovery after retinal detachment is possible without retinopexy,<sup>120-122</sup> although it is slow and would only be advisable when mechanical (vitreous) traction forces have been fully relieved.

## Effects of Retinopexy

Retinal surgeons frequently use retinopexy (i.e., scarification of the retina and RPE with laser photocoagulation, diathermy, or cryotherapy) as a means of creating an extra-strong adhesion between retina and RPE that will strengthen attachment and prevent the lateral movement of subretinal fluid. Experiments on

the in vitro peeling force<sup>45</sup> and the in vivo adhesive force<sup>122</sup> show that laser photocoagulation produces a bond that approaches normal adhesive strength within 24 hours, possibly from local effects such as fibrin formation (Fig. 21.16). The adhesive strength continues to increase gradually and reaches levels roughly twice normal by 2–3 weeks after the photocoagulation.<sup>45,123,124</sup> Diathermy effects, measured in vivo, have a similar time course. Cryotherapy, however, weakens adhesion for the first week, after which the adhesive force rises to the same levels as with other forms of retinopexy. The initial weakening after cryotherapy probably relates to local inflammation or edema. Thus, all forms of retinopexy appear to be effective in the long run, presumably by inducing scar formation; however, if a rapid bond is required, laser photocoagulation or diathermy is preferable.

**FIG. 21.16** Laser photocoagulation of freshly reattached retina can rapidly enhance the strength of retinal adhesion. Two experimental detachments were made in each eye (Fig. 19.7), and after the subretinal fluid had spontaneously absorbed, the base of one detachment was covered with laser photocoagulation. The force required to peel retina from the reattached areas, with or without photocoagulation, was compared to the force required in the intervening normal areas. The adhesive force in the photocoagulated regions exceeded normal within hours and reached an

apparent maximum after about 2 weeks (although at these levels of force the retina frequently tore rather than separated, and the “true” adhesive strength may be even greater). (Reproduced from Yoon YH, Marmor MF. Rapid enhancement of retinal adhesion by laser photocoagulation. *Ophthalmology* 1988;95:1385–8. ## Effects of Vitreous in the Subretinal Space

One of the factors contributing to many rhegmatogenous detachments is vitreous syneresis and liquefaction, which allow fluid to percolate through the retinal tear and expand or maintain the elevation of retina. Although there is some evidence that hyaluronic acid may be toxic in high concentrations to RPE,<sup>125</sup> clinical data indicate that liquid vitreous is tolerated insofar as a reasonable recovery of retinal function generally occurs if detachments are repaired within a few days or weeks. The presence of liquefied vitreous in the subretinal space has no immediate effect on the rate of fluid transport across the RPE.<sup>126</sup> The concentration of protein in normal vitreous is only about 1% of that in serum, but when vitreous enters the subretinal space, the concentration of subretinal protein rises slowly.<sup>126</sup> This occurs because water is pumped out faster than the protein can be removed, whereas the continued entry of liquid vitreous brings in more protein. This mechanism may contribute to the high protein concentration of subretinal fluid in chronic rhegmatogenous detachments. Serum and protein may also leak in from the choroid to the extent that the RPE has been damaged under the conditions of detachment.

## Pathophysiology of Serous Detachment

For detachment to occur there must be forces that cause the retina to separate and also conditions that allow subretinal fluid to persist. The clinical condition of serous detachment (considered in detail in [Chapter 32](#), Pathogenesis of serous detachment of the retina and

pigment epithelium) provides a case in point. In central serous chorioretinopathy (CSC), fluorescein angiography demonstrates apparent “leaks” through the RPE, defects through which fluid enters the subretinal space from the choroid. However, experimental work has clearly shown that subretinal fluid overlying an intact RPE is removed very actively by active metabolic transport and that damage to the RPE barrier in general makes the absorption of fluid faster rather than slower (Fig. 21.17). For example, damaging the RPE focally by mechanical micropipette injury or laser burns or diffusely by the systemic administration of sodium iodate hastens the absorption of subretinal fluid.<sup>127,128</sup> This occurs because intraocular pressure and the osmotic absorption of the choroid both move fluid in an outward direction, and their effectiveness is increased when the RPE flow barrier is removed. Even serous fluid is absorbed at least as fast over damaged as over intact RPE.<sup>103,105</sup> Furthermore, to cause detachment the entering fluid must overcome the retinal adhesive forces at the margin of the leak. Thus the mere presence of a focal defect in the RPE does not “cause” serous detachment.<sup>129</sup>

**FIG. 21.17** Conditions that control the movement of fluid across the retinal pigment epithelium (RPE). Left, When the tight junctions are intact between normal RPE cells, fluid is transported across by active transport. Middle, If the tight junctions are damaged, fluid can cross passively under the influence of hydrostatic and osmotic pressure. Right, If the tight junctions are intact and the metabolic transport capability of the RPE has been compromised, then fluid is unable to cross. *ATP*, adenosine triphosphate.

How then do serous detachments form?<sup>2,130,131</sup> The question is not whether the leaks are the source of fluid – they must be – but why the fluid accumulates when entry is slow and one would expect subretinal fluid to be cleared rapidly by active transport (across a normal RPE) or by passive mechanisms (across damaged RPE). On reflection, the one condition that would allow fluid to accumulate is when the RPE barrier function remains intact around the leak, whereas active fluid transport is impaired (Fig. 21.18). In this situation fluid cannot leave passively or actively. The present author's conjecture is that many serous detachments form because there is widespread functional damage to the process of transport across the RPE (either from RPE disease directly or from disease of the underlying choroid and choriocapillaris). For example, the absorption of subretinal fluid in rabbits is slowed by the ligation of vortex veins,<sup>132</sup> and the choroid is typically thickened in CSC, which may signify increased hydrostatic pressure.<sup>108</sup> When fluid absorption is compromised, fluid that enters from a focal leak may persist and accumulate within the subretinal space (Fig. 21.19). One may ask whether the persistence of serous detachment can be accounted for simply by oncotic pressure when protein-rich fluid leaks into the subretinal space. However, as noted earlier, protein in the subretinal space does not prevent fluid absorption: it is osmotically neutralized by the diffusion of water and ions from the vitreous, and it will not persist unless there is a continual influx of new proteinaceous fluid.

**FIG. 21.18** Transport capabilities of the retinal pigment epithelium (RPE) can determine whether or not a serous detachment will form in the presence of fluid leakage through an RPE defect. Left, When the active systems are working at normal efficiency, fluid can be pumped out as fast as it enters the subretinal space, and little or no detachment will develop. Right, When RPE transport has been compromised, then a serous detachment will form until a large enough area of RPE is exposed to subretinal fluid to allow outward transport to balance the inward leakage of fluid.

**FIG. 21.19** Fluorescein angiograms from different fundus regions of the same cat, showing the effects of diffuse retinal pigment epithelium (RPE) damage on the accumulation of serous fluid. (A) Control region. Weak laser burns were applied after the animal was given intravenous rose Bengal to photosensitize the choriocapillaris. Fluorescein leaks from the burn sites but spreads very little. (B) RPE-damaged region. This area was pretreated with intense white light to injure the RPE diffusely before giving the rose Bengal and laser burns. The dye leakage extends much farther beyond the burn sites and slowly fills an overlying detachment. (Unpublished data reproduced with permission from Marmor MF, Yao XY. Conditions necessary for the formation of serous detachment: experimental evidence from the cat. *Arch Ophthalmol* 1994;112:830–8.)

Three conditions appear to be necessary for serous fluid to accumulate.<sup>131,132</sup> (1) a defect in the RPE barrier that allows access to

the subretinal space; (2) a source of fluid pressure, to move fluid in; and (3) an impairment of outward fluid transport (or a broad area of leakage), so fluid spreads and persists in the subretinal space. Weakness of retinal adhesion or retinal tension may be an additional facilitating factor. Unless all three basic conditions are present, detachment will not occur, and the balance of these forces has been modeled mathematically.<sup>133</sup> For example, attempts to induce serous detachment in rabbits by damaging the RPE focally while altering intraocular pressure (conditions 1 and 2 only) have been largely unsuccessful.<sup>120</sup> However, diffuse injury to the RPE and underlying choriocapillaris (by photosensitization with rose Bengal dye<sup>134</sup> or by toxic effects of *N*-ethylmaleimide<sup>135</sup>) leads to the formation of bullae (Fig. 21.20), since the damaged capillaries not only serve as a source of fluid, but also compromise RPE transport and barrier functions. In clinical practice, choroidal vascular damage is probably the most frequent primary cause of serous detachments and may underlie even the focal RPE defects of CSC.<sup>108,130</sup>

**FIG. 21.20** Histology from the margin of an experimental serous detachment in the rabbit, induced by illumination of the fundus after injection of the photosensitizing dye, rose Bengal. This treatment causes vascular injury, and the animal was cooled to prevent choroidal thrombosis. There was diffuse fluorescein leakage across the base of the detachment, and the detached area (right) shows

retinal pigment epithelium damage over patent (but presumably injured) choriocapillaris. (Reproduced with

permission from Yao XY, Marmor MF. Induction of serous retinal detachment in rabbit eyes by pigment epithelial and choriocapillary injury. Arch Ophthalmol 1992;110:541–6. Copyright © 1982 American Medical Association. All rights reserved.)

If CSC is more a disease of diffuse transport dysfunction than a result of the focal “leak” seen on angiography,<sup>2</sup> why does laser photocoagulation of the leak help to clear the fluid? Because the laser seals a leak so that the existing fluid can slowly absorb. However, recurrences will be common as long as the underlying transport dysfunction persists, and this is indeed the clinical course of the disease. In further support of the concept of diffuse dysfunction, serous retinopathy is often associated with systemic disease, including vascular disorders, inflammatory disease, abnormal blood protein, corticosteroid usage, and emotional stress (chronic administration of epinephrine can produce serous detachments in experimental animals<sup>136</sup>). And the serous fluid accumulations are often bilateral and multifocal. Unfortunately, treatment with carbonic anhydrase inhibitors that enhance RPE transport has not shown great value in most serous detachment, presumably because the RPE transport system is already compromised by disease. However, as noted earlier, these agents can be very effective in clearing cystic intraretinal fluid, especially in retinal dystrophies including retinitis pigmentosa, X-linked retinoschisis, and enhanced S-cone syndrome.

## Conclusions and General Implications

One important conclusion to be derived from the evidence reviewed in this chapter is that retina “wants” to adhere. A variety of systems, including passive hydrostatic forces, the interdigitation of outer segments and RPE microvilli, the active transport of subretinal fluid, and the complex structure and binding properties of the IPM, all work to keep the retina properly apposed to the wall of the eye. Thus retinas do not detach simply because there is a hole or a tear or even a leak in the RPE; there must be positive traction pulling it off or a positive force pushing fluid into the subretinal

space (often in conjunction with underlying pathologic conditions of the RPE or choriocapillaris that block the normal transport processes that remove subretinal fluid). Retinal detachment is not simply a disease of physical separation but is the result of a vital battle between a destructive influence and the collection of forces routinely at work constructively to maintain attachment.

This multifactorial nature of retinal adhesiveness is important clinically, as well as physiologically. To function optimally, adhesive systems require proper anatomic relations, healthy metabolic activity, and an appropriate local environment (pH, temperature,  $\text{Ca}^{2+}$  concentration) in the subretinal space. This means that adhesion may be weakened by diseases with various sites and modes of action; at the same time, the complementary mechanisms for attachment undoubtedly provide safety coverage for one another, so injury or illness of one adhesive system does not necessarily doom the eye to total detachment. The multiplicity of factors also allows us to consider a variety of therapeutic options that might otherwise not be available. For example, the presence of holes in the retina obviates the use of fluid pressure to aid retinal apposition but leaves open options for encouraging fluid transport pharmacologically or for creating scars as a means of restoring local adhesion. As the different mechanisms of adhesion become better understood, more specific medical and surgical approaches to the prevention, as well as the management, of detachments should become available.

The importance of metabolic activity in maintaining retinal adhesion cannot be emphasized too strongly. If retinal attachment were solely a passive process, then detachment would be solely at the mercy of passive forces and physical means of repair. To the extent that the metabolic health of the RPE appears to be critical to adhesion, we can better understand the failure of adhesion in certain disease states or ocular locations, and we may ultimately realize more effective means of treatment. The propensity of aged eyes to suffer detachment much more than younger ones, for example, may in part lie in the gradual metabolic failure of the RPE. The retinal periphery has a less effective vascular supply than the posterior pole, and this, too, is where most detachments begin. This discussion is not intended to minimize the well-documented role of

vitreous syneresis and vitreous traction in creating detachments. However, by improving the metabolic status of peripheral retina and RPE, we might be able to reduce the incidence of detachment and improve the success rate of surgical repair. Cutting vitreous bands and sealing holes manage only one aspect of the disease; we will treat the whole disease only when we can also treat the pathologic conditions within the subretinal space.

## **Conclusion**

## **Introduction, History, Embryology**

Bruch's membrane is a thin (2–4  $\mu\text{m}$ ), acellular, five-layered

extracellular matrix located between the retina and choroid.<sup>1,2</sup> It extends anteriorly to the ora serrata, interrupted only by the optic nerve. Tissue resembling Bruch's membrane is visible anterior to the ora serrata extending forward to the pigmented epithelium of the ciliary body. Bruch's membrane lies between the metabolically active retinal pigment epithelium (RPE) and a capillary bed (choriocapillaris) and thus serves two major functions as the substratum of the RPE and a vessel wall. It has major clinical significance because of its involvement in age-related macular degeneration (AMD) and other chorioretinal diseases.

## Early History

Carl Ludwig Wilhelm Bruch (1819–1884) ([Fig. 22.1 online](#)) first isolated the “lamina vitrea” that we now know as Bruch's membrane and described it in his 1844 doctoral thesis<sup>3,4</sup> where he also first described the tapetum found in many mammals. By light microscopy, Bruch's membrane appeared transparent, with little internal structure. Later studies by A.E. Smirnow<sup>5</sup> divided this membrane into an outer elastic layer (first described by Sattler in 1877) and an inner cuticular layer, separated by a dense plexus of very fine elastic fibers.<sup>6,7</sup>

**FIG. 22.1** Carl Bruch (1819–1884). (With permission from the Archives of the University of Heidelberg. <http://www.ub.uni-heidelberg.de/helios/digi/anatomie/bruch.html>.)

## Development of Bruch's Membrane

The bipartite character of Bruch's membrane arises from the embryology of its tissue. When the optic cup invaginates and folds, its inner layer forms the neural retina, and its outer layer, the RPE. The RPE lies in contact with mesenchyme. At this apposition, Bruch's membrane forms by 6–7 weeks' gestation. Thus, its inner layer is composed of ectodermal tissue and its outer, mesodermal. At the border of two layers, the elastic layer forms last, becoming histologically visible by 11–12 weeks.<sup>8–10</sup>

The collagen that fills the extracellular space, and the later appearing elastin, appear to be made by invading fibroblasts and the filopodia of endothelial cells lining the adjacent choriocapillaris. The two basal laminae are produced by their associated cell layers.<sup>11</sup> In addition to collagen IV subunits specific to specialized basal lamina, RPE expresses genes for structural collagen III and angiostatic collagen XVIII in a developmentally regulated manner

linked to photoreceptor maturation.<sup>12</sup>

By week 13, fenestrations are apparent in the endothelium facing Bruch's membrane,<sup>10</sup> indicating that at this stage, transport across this tissue may be functional. Choroidal endothelial cells originate from paraocular mesenchyme. Development of the choroidal vasculature, and Bruch's as part of it, depends on differentiated RPE and its production of inductive signals, including basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF).<sup>13</sup>

## Structure of Bruch's Membrane in the Young Adult Eye

Hogan's five-layer nomenclature for Bruch's membrane<sup>14,15</sup> is commonly used. Gass proposed a three-layer system that did not include the cellular basal laminas as part of Bruch's proper.<sup>16</sup> These layers are shown in Fig. 22.2 and their constituents in Table 22.1. Important components in specific layers are structural collagens, elastin, and proteoglycans with negatively charged glycosaminoglycan side-chains.

**FIG. 22.2** Macular Bruch's membrane throughout the lifespan. Retinal pigment epithelium (RPE) is at the top of all panels. RPE basal lamina (*arrowheads*) and

elastic layer (EL, *yellow arrows*, discontinuous in macula) are shown. (A) 17 years: Electron-dense amorphous debris and lipoproteins are absent. Scale bar: 1  $\mu$ m. (B) 46 years: Electron-dense amorphous debris and lipoproteins are present. A coated membrane bounded body (*green arrow*) contains lipoproteins. L, lipofuscin. (C) 65 years: Electron-dense amorphous debris and lipoproteins are abundant. Membranous debris, also called lipoprotein-derived debris (*red arrow*) has electron-dense exteriors within BLamD (\*). Within OCL, banded material is type VI collagen, often found in BLamD.

**TABLE 22.1**

**Structural and Molecular Components of Bruch's Membrane**

Layer (Common Abbreviation)	Component; Age Change	References
Basal laminar deposit (BlamD)	+ <b>Fibronectin, laminin, IV <math>\alpha</math>4-5, VI, endostatin, EFEMP1</b>	220, 223, 277–280

Table shows definitely localized components. Most determinations were made in macula. Studies showing histochemical/ immunohistochemical verification of biochemistry and ultrastructural validation of structures identified by light microscopy

techniques were given greater weight. Localizations were assigned to specific layers if immunogold-electron microscopy or high magnification confocal microscopy images were available. Roman numerals denote collagens. Components are ordered within each layer: structural components, lipoproteins, extracellular matrix and its regulation, modified lipids and proteins, complement/immunity, cellular response/activity, metals. Known changes with advancing age are **bold** with an arrow indicating direction of change. New additions with age are shown with a plus (+). Plain text means no change or not tested.

Abbreviations: 7-KCh, 7 keto-cholesterol;<sup>301</sup> CML, carboxymethyl-lysine;<sup>298</sup> DHP-Lys, dihydropyridine lysine;<sup>78</sup> GA-AGE, glycolaldehyde derived AGE;<sup>293</sup> HHE, 4-hydroxyhexenal;<sup>78</sup> MDA, malondialdehyde.<sup>78,290</sup>

## RPE Basal Lamina (RPE-BL)

This ~0.15- $\mu\text{m}$  thick layer is a meshwork of fine fibers like other basal laminas in the body.<sup>17,18</sup> The RPE-BL resembles that of the choriocapillaris endothelium (ChC-BL) in containing heparan sulfate proteoglycans with several sulfation motifs.<sup>19–21</sup> Unlike ChC-BL, RPE-BL does not contain collagen VI. The RPE-BL contains collagen IV  $\alpha 3-5$ ,<sup>22</sup> like that of kidney glomerulus, another organ with specialized filtration and transport functions. The RPE synthesizes specific laminins that preferentially adhere Bruch's membrane to the RPE through interaction with integrins.<sup>23</sup>

## Inner Collagenous Layer (ICL)

The ICL is ~1.4  $\mu\text{m}$  thick and contains 70-nm-diameter fibers of collagens I, III, and V in a multilayered crisscross, parallel to the plane of Bruch's membrane.<sup>1</sup> The collagen grid is associated with interacting molecules, particularly chondroitin sulfate and dermatan sulfate proteoglycans.<sup>19,21,24</sup>

## Elastic Layer (EL)

The EL consists of stacked layers of linear elastin fibers, crisscrossing to form a 0.8- $\mu\text{m}$  thick sheet with interfibrillary spaces of ~1  $\mu\text{m}$ . This sheet extends from the edge of the optic nerve to the ciliary body pars plana.<sup>1</sup> In addition to elastin fibers, the EL contains collagen VI, fibronectin, and other proteins, and collagen fibers from the two collagenous layers can cross the EL. Some EL

elastin fibers cross the tissue space between the choriocapillaris and join bundles of choroidal elastic tissue.<sup>25</sup> The EL confers biomechanical properties, vascular compliance, and antiangiogenic barrier functions. It is discontinuous in the macula, perhaps explaining why choroidal neovascularization is more prominent there.<sup>26</sup> This concept is supported by the extensive laser-induced neovascularization in mice deficient in lysyl oxidase-like 1, an enzyme required for elastin polymerization.<sup>27</sup>

## Outer Collagenous Layer (OCL)

The OCL contains many of the same molecular components as the ICL, and the collagen fibrils running parallel to the choriocapillaris additionally form prominent bundles. This layer, unlike the ICL, has periodic outward extensions between individual choriocapillary lumens called intercapillary pillars, where thickness cannot be determined due to the lack of a boundary. Between pillars, OCL thickness can range from 1 to 5  $\mu\text{m}$ .<sup>28</sup>

## Choriocapillaris Basal Lamina (ChC-BL)

This 0.07- $\mu\text{m}$ -thick layer is discontinuous with respect to Bruch's membrane due to the interruptions of the intercapillary pillars of the choroid. It is continuous with respect to the complex network of spaces defined by the choriocapillary lumens because the basal lamina envelops the complete circumference of the endothelium. A remarkable structural feature of the adjacent choriocapillary endothelium is fenestrations that are permeable to macromolecules (Fig. 22.3).<sup>29</sup> This basal lamina may inhibit endothelial cell migration into Bruch's membrane, as do basal laminas associated with retinal capillaries.<sup>30</sup>

**FIG. 22.3** Surface of the endothelium of the choriocapillaris showing fenestrations with a bicycle-spoke pattern (*yellow arrow*) and presumed artifactual openings arising from tissue preparation (*cyan arrow*); quick-freeze/deep-etch, 64-year-old eye, macula.

Scale bar: 100 nm. (Reproduced with permission from Johnson M, Huang J-D, Presley JB, et al. Comparison of morphology of human macular and peripheral Bruch's membrane in older eyes. *Curr Eye Res* 2007;32:791-9.)

## Bruch's Membrane in an Aged Eye

Aging is the largest risk factor for developing AMD,<sup>31</sup> and Bruch's membrane undergoes significant age-related changes. Identification of factors predisposing to disease progression is a priority. This task has been challenged by difficulty imposed by the thinness of the tissue, and the closely integrated functions of RPE, Bruch's membrane, and choriocapillaris. Current opinion holds that RPE and Bruch's membrane age in concert, and normal Bruch's membrane aging transforms insidiously into AMD pathology.<sup>1,17,18,32</sup> This section covers aging, to inform the following section on function.

## Lipid Accumulation: Bruch's Membrane Lipoproteins

Early electron microscopists described aged Bruch's membrane as being filled with debris, including amorphous electron dense material, membrane fragments, vesicles, and calcification.<sup>33,34</sup> Debris deposition in ICL and OCL begins in the second decade of life in the macula and is delayed in equatorial regions.<sup>35</sup> Verhoeff speculated that calcification of aging Bruch's membrane might follow lipoidal deposition<sup>36</sup> as it does in atherosclerosis. Later investigators described aged Bruch's membrane as sudanophilic (i.e., histochemically detectable lipid).<sup>37,38</sup> Histochemical, ultrastructural, biochemical, gene expression, cell biologic, and epidemiologic evidence have converged to indicate that the lipid-rich material accumulating with age in Bruch's membrane is cholesterol-rich lipoprotein particles containing apolipoproteins B and E that are assembled and secreted by the RPE.<sup>39</sup> This process, ongoing throughout life yet first revealed by aging, has implications for formation of AMD-specific lesions, RPE physiology, nutrient and waste product transport to and from the outer retina, and maintenance of photoreceptor health. The physicochemical properties, physiologic roles, and distribution of cholesterol in relation to AMD pathology has been reviewed.<sup>40</sup>

Clinical observations on fluid-filled RPE detachments in older adults led to Bird and Marshall's hypothesis that a lipophilic barrier in Bruch's membrane blocked a normal, outwardly directed fluid efflux from the RPE<sup>41</sup> (as opposed to leakage from neovascularization). This hypothesis motivated a seminal histochemical study by Pauliekhoff<sup>42</sup> that demonstrated oil red O-binding material (EC, esterified cholesterol; TG, triglyceride; FA, fatty acid) localized exclusively to Bruch's membrane, unlike other stains. This lipid was absent <30 years, variably present at 31–60 years, and abundant at ≥61 years.<sup>43,44</sup> Biochemical studies confirmed the strongly age-related nature of the deposition.<sup>45,46</sup>

The oil red O-binding material proved to be EC, which with unesterified cholesterol (UC) accumulates markedly in Bruch's membrane, in sevenfold higher quantities in macula than periphery.<sup>44,47</sup> Key techniques were use of the fluorescent marker

filipin, which binds the 3- $\beta$ -hydroxy group of sterols to reveal unesterified (free) cholesterol (UC) or EC depending on tissue pretreatment<sup>47</sup> and hot stage polarizing microscopy,<sup>44</sup> which showed very few birefringent crystals signifying the neutral lipid TG. Among lipids, EC is confined exclusively to Bruch's membrane,<sup>48</sup> focusing attention on lipoproteins, the only means by which EC is released by cells. Human RPE expresses apoB gene and protein, along with microsomal triglyceride transfer protein, required for apoB lipidation and secretion.<sup>49</sup> This suggests that RPE is a constitutive lipoprotein secretor. Indeed, human- and rat-derived RPE cell lines secrete full-length apoB.<sup>50,51</sup>

Lipid-preserving ultrastructure and analytic biochemistry support this concept. Ultrastructural studies described, in Bruch's membrane of older eyes,<sup>39</sup> numerous small (<100 nm), round, electron-lucent vesicular profiles, implying aqueous interiors. These so-called vesicles are actually solid, lipid-containing particles (Fig. 22.4B) when prepared by lipid-preserving methods including postfixation in osmium paraphenylenediamine (OTAP)<sup>47</sup> and, strikingly, quick-freeze/deep-etch (QFDE), a freeze fracture method with etching to remove frozen water.<sup>52-54</sup> Particles vary in size from 60 to 100 nm and occasionally appeared to coalesce (Fig. 22.4). Particles of comparable diameter with lipoprotein-like flotation properties and spherical shapes indicating neutral lipid cores are isolable from normal human Bruch's membrane<sup>50,55</sup> (Fig. 22.5). These fractions include apolipoproteins B, A-I, and E. Bruch's membrane cholesterol is EC-enriched (EC/total cholesterol = 0.56)<sup>47,50,55,56</sup> and there is little triglyceride (EC/TG = 4-11), unlike hepatic very-low-density lipoprotein (VLDL), of similar diameter. An early report of TG-enriched Bruch's membrane<sup>46</sup> was not replicated. Thus, Bruch's membrane apoB-lipoproteins are unusual because they are large like VLDL yet EC-rich like atherogenic LDL (Fig. 22.5).

**FIG. 22.4** Lipid Wall, a layer of lipoproteins on the inner surface of Bruch's membrane. (A) Lipoproteins (spherical vesicles of uniform diameter) accumulate 3–4 deep between the RPE basal lamina (*black arrowheads*) and Bruch's membrane ICL (*white arrowheads*). Thin section transmission electron micrograph following osmium postfixation. *RPE*, retinal pigment epithelium; *BrM*, Bruch's membrane; *L*, lipofuscin. Sectioning plane is vertical; scale bar: 1  $\mu\text{m}$ . (B) Quick-freeze deep-etch shows tightly packed Bruch's membrane lipoproteins in the Lipid Wall, and that lipoproteins have classic core and surface morphology.<sup>53</sup> Fracture plane is oblique; scale bar: 200 nm.

**FIG. 22.5** Bruch's membrane lipoprotein composition. (A) Lipoprotein particles isolated from Bruch's membrane are large and spherical; negative stain.<sup>190</sup> Scale bar: 50 nm. (B) Bruch's membrane lipoprotein composition inferred from direct assay,<sup>190,285</sup> druse composition, and RPE gene expression.<sup>174,191</sup> *TG*, triglyceride; *EC*, esterified cholesterol; *UC*, unesterified cholesterol; *PL*, phospholipid; *Apo*, apolipoproteins. The question mark signifies that not all apolipoproteins are known.

A natural history of Bruch's membrane lipid deposition obtained with quick-freeze deep etch showed lipoprotein particles first gathering among fibrils of the elastic layer in early adulthood.<sup>57,58</sup> This accumulation then extends toward RPE to fill the ICL by the seventh decade of life,<sup>54,57</sup> consistent with an RPE origin. In many older eyes, a new layer, the Lipid Wall,<sup>52</sup> forms between RPE basal lamina and OCL, and this is considered a precursor to basal linear deposits, a specific lesion of AMD (see below). With solid lipoprotein particles occupying nearly 100% of this sub-RPE space, the Lipid Wall displaces ICL collagen fibrils that anchor the RPE basal lamina (Fig. 22.4).

The fatty acid composition of Bruch's membrane lipids implicates diet as a driving force in RPE lipoprotein secretion. A longstanding hypothesis that debris in aging Bruch's membrane originates as outer segment membranes phagocytosed by RPE<sup>59</sup> was tested through fatty acid profiling of Bruch's membrane lipoproteins and lipid extracts.<sup>50,56</sup> Outer segment membranes have characteristically high concentrations of docosahexaenoate.<sup>60</sup> In contrast, all lipid classes in Bruch's membrane were dominated by linoleate, the most abundant fatty acid in plasma, with little (<2%) docosahexaenoate. Bruch's membrane lipid deposition is thus proposed as a recycling system whereby plasma lipoproteins delivering dietary essentials (vitamins A, E, lutein, UC) are taken up by RPE, stripped of cargo destined for photoreceptors, and excess fatty acids and UC repackaged as lipoproteins for basolateral secretion and choroidal clearance.<sup>61</sup>

If the proposed primacy of diet is true, then cells in culture medium should be able to create deposits without supplementation

by outer segments. A landmark study by Johnson et al. confirmed these predictions,<sup>62</sup> demonstrating that highly differentiated and polarized human fetal RPE, supplemented only by culture medium, secreted apoE-immunoreactive particles resembling native Bruch's membrane lipoproteins. While the source of cholesterol in Bruch's membrane lipoproteins has not been determined to date, endogenous synthesis, taken-up plasma lipoproteins, and phagocytosed outer segments are obvious choices (see below).

It is informative to contrast Bruch's membrane lipid deposition with the systemic process whereby extracellular oil red O-binding lipids increase with age in normal human connective tissues. In arterial intima, tendons, sclera, and cornea, perifibrous lipid provides the background to atherosclerosis, xanthomas, and lipid keratopathy.<sup>44,63–66</sup> The source of extracellular EC in these locations is LDL translocated from plasma and trapped via binding to proteoglycans.<sup>67,68</sup> After apolipoproteins degrade, the remaining lipid components fuse.<sup>67</sup> The evidence that lipid deposition in aging Bruch's membrane is a distinct process dictated by photoreceptor physiology and not simply an ocular manifestation of this systemic process is compelling<sup>40</sup> (see below, [AMD lesions](#)). Indirect evidence also emerges from epidemiology. If EC deposition in Bruch's membrane and AMD-associated lesions were a manifestation of systemic perifibrous lipid and atherosclerosis, then a strong positive correlation between disease status and plasma lipoprotein levels, like that in cardiovascular disease,<sup>69</sup> might be expected. Such an association has not emerged despite many studies.<sup>70</sup> Nevertheless, the commonality of cholesterol-rich lipoproteins in a vessel wall is a rationale for seeking guidance in cardiovascular disease for AMD pathogenesis and treatments.

## Other Aging Changes

Bruch's membrane thickens throughout adulthood (20–100 years), two- to threefold under the macula and becoming more variable between individuals at older ages.<sup>28,71,72</sup> Equatorial Bruch's membrane changes little while Bruch's membrane near the ora serrata increases twofold during this time.<sup>28</sup> In the macula, the OCL thickens more prominently than the ICL.<sup>73</sup> A large ultrastructural

study of 121 human donor eyes demonstrated that the macular EL is three to six times thinner than peripheral EL at all ages.<sup>26</sup>

Unbalanced regulation of extracellular matrix molecules and their modulators are thought to result in Bruch's membrane thickening. Increased histochemical reactivity for glycoconjugates, glycosaminoglycans, collagen, and elastin is seen in the macula relative to equator and near the ora serrata.<sup>28</sup> Collagen solubility declines with age.<sup>74</sup> Metalloproteinases MMP-2 and MMP-3 increase with age as does a potent inhibitor of metalloproteinases, TIMP-3. TIMP-3 immunoreactivity reaches mature levels at 30 years of age near vasculature in lung, kidney, and in Bruch's membrane, signifying the end of developmental organogenesis.<sup>75</sup> The reduction or absence of TIMP-3 is proangiogenic, as this protein not only regulates metalloproteinases during the normal turnover of Bruch's membrane matrix components but it also binds to VEGF.<sup>76,77</sup>

The EL thickens with age but decreases relative to overall thickening of Bruch's membrane.<sup>26</sup> Thus elastin referenced to other Bruch's constituents, as detected by Raman spectroscopy, decreases with age.<sup>78</sup> Similar arguments can be made for collagen III and IV. A prominent age-change,<sup>79</sup> noted early,<sup>36</sup> is calcification and ensuing brittleness. This process involves deposition of fine electron-dense particulate matter<sup>80</sup> confirmed as calcium phosphate<sup>81</sup> on individual elastin fibrils.

Long-lived proteins like collagens are modified *in vivo* by nonenzymatic Maillard and free radical reactions to yield advanced glycation end products (AGEs) and the formation of lipid-derived reactive carbonyl species like malondialdehyde (MDA), and 4-hydroxyhexenal (HHE), collectively called age-related lipoperoxidation end products (ALEs). Accumulation of AGEs and ALEs, characteristic of diabetes and atherosclerosis, also occurs in aging Bruch's membrane (Table 22.1). Finally, other components prominent in aged eyes include complement components C3d, C5b-9, and pentraxin-3, a homolog of the acute phase respondent C-reactive protein. Thus, at the molecular level, aging Bruch's membrane contains evidence of many biologic activities including remodeling, oxidative damage, and inflammation, in addition to lipoprotein accumulation.

New evidence from Clark, Bishop, Day, and associates indicates

that variations in proteoglycan sulfation in Bruch's membrane have potential pathogenic significance for AMD.<sup>21,82-86</sup> Bruch's membrane has many heparan sulfate (HS) proteoglycan structures and motifs, as determined with antibodies to specific full-length and enzymatically truncated forms.<sup>21</sup> Sequence variants in the gene encoding the fluid phase regulator of complement factor H (CFH) are highly associated with risk for AMD.<sup>87</sup> Key in innate immunity, CFH can discriminate self from nonself for clearing by recognizing polyanionic structures such GAG chains of proteoglycans (e.g., HS and dermatan sulfate), thereby inhibiting complement activation on host cell surfaces. CFH of molecular weight 155 kD comprises 20 complement control protein (CCP) domains and contains main GAG-binding regions in CCP7 and CCP20. The Y402H polymorphism, in CCP7, alters CFH binding to sulfated GAGs. This polymorphism also affects factor H-like protein-1 (FHL-1), a 43 kD protein containing the CCP7 module that is generated by a splice variant of the CFH gene. The disease-associated 402H polymorphic variant of CFH was found to require 2-O- and/or 6-O-sulfation for binding to HS and dermatan sulfate in human Bruch's membrane tissue slices. In contrast, the non-disease-associated 402Y form binds to a broader range of proteoglycans, suggesting that it is overall more tightly bound and thus potentially more effective as an inhibitor. Importantly, in aged human Bruch's membrane, HS is reduced 50% overall and in the macula.<sup>86</sup> This change, attributed to either decreased production or increased turnover of HS core proteins, is one way in which disease-associated sequence variants could promote complement activation, lipoprotein binding to extracellular matrix,<sup>88</sup> and AMD progression in Bruch's membrane.

## Function of Bruch's Membrane

As a vessel wall of the choroid, Bruch's membrane primary function is structural, like other vessel walls. Its architecture is similar to vascular intima, with a sub-endothelial extracellular matrix and elastic layer corresponding to the internal elastic lamina. The abluminal surface of Bruch's membrane differs from other vessel walls in that it abuts a basal lamina, that of the RPE. Essentially, Bruch's membrane is comprised of two epithelial membranes in

apposition, consistent with its embryologic origin. The luminal surface faces a fenestrated vascular endothelium and basal lamina, making Bruch's membrane structurally analogous to the renal glomerulus and providing a basis for commonality between retinal and kidney disease.<sup>89-91</sup> The importance of fluid and macromolecular transport across the renal glomerulus is well known.<sup>92</sup> Transport is a second important function of Bruch's membrane.

## Structural Role of Bruch's Membrane

Bruch's membrane encircles more than half the eye and stretches with the corneoscleral envelope as intraocular pressure (IOP) increases. It withstands this stretch and return to its original shape when IOP decreases. This tissue also stretches to accommodate changes in choroidal blood volume. Finally, the choroid (and Bruch's membrane with it) may act as a spring that pulls the lens during accommodation.<sup>93,94</sup> For these reasons, then, Bruch's membrane requires elasticity.

Marshall and Hussain's group estimated the modulus of elasticity in Bruch's membrane-choroid preparations to be 7–19 MPa.<sup>95</sup> These values are similar to those of sclera (although sclera is much thicker and thus can support more load) consistent with the notion that Bruch's membrane contributes to load bearing. After early adulthood, the modulus of elasticity of human Bruch's membrane-choroid complex increases ( $p < .001$ ) at a rate of ~1% per year. Bruch's membrane stiffness in AMD eyes does not differ from age-matched normals.<sup>96</sup>

## Transport Role of Bruch's Membrane

The choroid services the metabolic needs of the outer retina, facilitated in part by fenestrated endothelium (Fig. 22.3). Oxygen, electrolytes, nutrients, and cytokines destined for the RPE and photoreceptors pass from the choriocapillaris and through Bruch's membrane, and waste products travel back in the opposite direction for elimination. Vitamins, signaling molecules, and other factors needed for photoreceptor function are carried to the RPE by lipoprotein particles passing through Bruch's membrane, as do the

RPE-produced lipoproteins that are eliminated in the opposite direction. The RPE pumps water from the subretinal space to counter the swelling of the interphotoreceptor matrix glycosaminoglycans (GAGs). This fluid flows across Bruch's membrane to reach the circulation. Thus, many transport processes involve Bruch's membrane, as reviewed here.

## Hydraulic Conductivity of Bruch's Membrane

GAGs are concentrated in the interphotoreceptor matrix<sup>97,98</sup> and corneal stroma.<sup>99</sup> In both locations, these highly charged macromolecules maintain geometric fidelity essential for vision (periodic collagen spacing for corneal transparency, orderly photoreceptor spacing for visual sampling).<sup>98,100,101</sup> GAGs generate significant swelling pressure (up to 50 mm Hg in cornea).<sup>102,103</sup> Without a mechanism to maintain tissue deturgescence, GAGs would imbibe fluid, swell, destroy tissue geometry, and interfere with visual function. Corneal endothelium forestalls swelling by continuously pumping fluid out. This function is accomplished for retina by the RPE, and its failure can lead to retinal detachment.

The fluid pumped by the RPE must then flow from the basal surface of the RPE, across Bruch's membrane, and through the endothelial lining of the choriocapillaris to be adsorbed by the vasculature. A driving force adequate to overcome the collective flow resistance of these tissues is provided by a gradient in fluid pressure and oncotic pressure (the osmotic pressure generated by plasma proteins). This balance is embodied by Starling's Law that characterizes the relationship between fluid flux ( $q$ : flow per unit area; positive when flow is out of the blood vessel) across a capillary vessel wall and the forces driving this flow:

$$q = L_p * (\Delta P - \sigma \Delta \Pi) \quad [22.1]$$

$L_p$  is hydraulic conductivity, which characterizes the ease with which fluids flow cross the vessel wall. If the surface area of the blood vessel is  $A$ , then  $1/(L_p A)$  is the flow resistance of the vessel wall.  $\Delta P$  is the difference between the fluid pressure within the blood vessel ( $P_{cc}$ ) and the pressure at the basal surface of the RPE

( $P_{\text{RPE}}$ ).  $\Delta\Pi$  is the difference between the oncotic pressure within the blood vessel ( $\Pi_{\text{cc}}$ ) and that at the basal surface of the RPE ( $\Pi_{\text{RPE}}$ ).  $\sigma$  is the reflection coefficient that characterizes the extent to which the vessel wall rejects the plasma proteins species generating  $\Delta\Pi$ .  $\sigma$  ranges from 0 for a freely permeable species to 1 when a species is completely rejected by the membrane.

We can estimate the magnitude of  $\Delta P - \sigma \Delta\Pi$  using measured value of  $q$  and  $L_p$ . The fluid pumping rate by human RPE has been measured as  $q=11 \mu\text{L h}^{-1} \text{cm}^{-2}$ , similar to that in other animals (Table 22.2). The hydraulic conductivity of macular Bruch's membrane/choroid of healthy young humans ranges from 20 to  $100 \times 10^{-10} \text{ m s}^{-1} \text{Pa}^{-1}$ .<sup>104</sup> Then, using  $q=11 \mu\text{L h}^{-1} \text{cm}^{-2}$  and  $L_p=50 \times 10^{-10} \text{ m s}^{-1} \text{Pa}^{-1}$ ,<sup>a</sup> we can calculate that the magnitude of  $(\Delta P - \sigma \Delta\Pi)$  necessary to drive this flow through Bruch's membrane is roughly 0.05 mm Hg.

**TABLE 22.2**  
**Retinal Pigment Epithelium Fluid Pumping Rates**

Species	Fluid Transport Rate Across RPE ( $\mu\text{L h}^{-1} \text{cm}^{-2}$ )	References
Frog	4.8-7.6	303, 304
Rabbit	12±4	305, 306
Canine	6.4	307
Primate <sup>a</sup>	14±3	308, 309
Human	11	310

<sup>a</sup>Cantrell and Pederson measured a much higher transport rate than that reported here,<sup>308</sup> but used fluorescein as a tracer which likely does not track fluid flow due to its high diffusion coefficient.

Retinal pigment epithelium (RPE) pumping rates were measured by reabsorption of subretinal fluid or by direct measurement in culture.

$\sigma$  can be roughly estimated by assuming that the fluid in the suprachoroidal space is in equilibrium with blood in the choroid. Using measurements in monkeys of plasma protein concentration inside and outside of choriocapillaries (82.1 and 23.7 mg/ml, respectively),<sup>107</sup> and the Landis Pappenheimer equation<sup>108</sup> for osmotic pressure, the osmotic pressure difference, in this species, across the choroid can be estimated to be 33 mmHg – 6 mmHg=27 mmHg. The pressure in suprachoroidal fluid was measured by Emi<sup>107</sup> to be 4.7 mmHg below IOP while that in the choriocapillaris

was measured at 8 mmHg higher than IOP<sup>109</sup> giving a pressure difference across this wall of 12.7 mmHg. Then, Eq. 22.1 is used to estimate that  $\sigma=0.5$ , assuming equilibrium conditions.

Using  $\Pi_{cc}=33$  mmHg,  $P_{cc}=IOP+8$  mmHg,  $\Pi_{RPE}=0$  mmHg (fluid pumped by the RPE is assumed protein-free), and we take  $P_{RPE}=IOP$  (assuming no pressure is generated by the RPE above that necessary for crossing Bruch's), we find that  $\Delta P - \sigma \Delta \Pi$  is approximately 8.5 mmHg pulling fluid into the choroid. Thus, in normal young adults, oncotic pressure within the choroid is more than sufficient to adsorb all the fluid pumped by the RPE. We can also use Eq. 22.1 to calculate that the lowest value of  $L_p$  that still adsorbs fluid pumped by the RPE without generating an elevated pressure at the RPE basal surface is  $L_p > 0.3 \times 10^{-10} \text{ m s}^{-1} \text{ Pa}^{-1}$ .

Experiments using laser ablation of Bruch's membrane/choroid explants allowed Starita et al.<sup>110</sup> to conclude that the ICL was responsible for most of the flow resistance in Bruch's membrane. Attempts to further localize the flow resistance using morphometric methods are complicated by (i) stereologic issues<sup>111</sup> and (ii) the loss of ultrastructural fidelity from connective tissue conventionally processed for electron microscopy.<sup>52</sup> Failure to appreciate the former difficulty can lead to unphysiologically low estimates for tissue porosity and thereby hydraulic conductivity.<sup>1</sup>

## Age-Related Changes in Hydraulic Conductivity and Disease

Fisher was the first to measure  $L_p$  of human Bruch's membrane,<sup>112</sup> finding that  $L_p$  decreased significantly with age. However, his values for  $L_p$  of Bruch's membrane and other tissues are much lower than those found by later investigators.<sup>106,113,114</sup> Marshall and Hussain carefully revisited these measurements using Bruch's membrane/choroid with RPE removed, a preparation that was simpler to create. They showed using laser ablation that the flow resistance of these preparations was entirely due to Bruch's membrane.<sup>110</sup> They also found that flow rate increased linearly with driving pressure, indicating that  $L_p$  of Bruch's membrane is relatively insensitive to pressure up to 25 mmHg.

They reported that  $L_p$  of macular Bruch's membrane exhibited a dramatic, exponential decline throughout life (Fig. 22.6), dropping from  $130 \times 10^{-10} \text{ m s}^{-1} \text{ Pa}^{-1}$  in young children to  $0.52 \times 10^{-10} \text{ m s}^{-1} \text{ Pa}^{-1}$  in old age.  $L_p$  of macular Bruch's membrane dropped more rapidly with age than did that of the periphery, consistent with an accelerated process occurring in the macula.<sup>1,104,105,115,116</sup> Note that the lowest value measured for  $L_p$  of Bruch's membrane in normal eyes is similar to the calculated minimum value of  $L_p$  ( $0.4 \times 10^{-10} \text{ m s}^{-1} \text{ Pa}^{-1}$ , see above) that allows complete resorption of fluid pumped by the RPE without need of an elevated pressure at the basal surface of the RPE. Marshall and Hussain reached similar conclusions regarding this process.<sup>115</sup>

**FIG. 22.6** Hydraulic conductivity ( $L_p$ ) of Bruch's

membrane as a function of age. Dotted lines are exponential fits to data from macular and peripheral regions, respectively. Note that all of the data from eyes with AMD (taken only in peripheral region) have lower values of  $L_p$  than the best fit to data taken from peripheral Bruch's membrane of nondiseased eyes.<sup>115</sup>

Determining  $L_p$  of Bruch's membrane in isolated macular samples of AMD eyes is difficult due to scar formation and other changes.<sup>115</sup> However, Marshall and Hussein's group showed that in the periphery,  $L_p$  of Bruch's membrane is decreased in AMD eyes as compared to age-matched normal eyes (Fig. 22.6).<sup>115</sup> Assuming that similar processes occur in macular Bruch's membrane due to the profound lipid accumulation in this region, then in diseased eyes, the RPE must generate higher pressures at its basal surface to drive fluid into the choriocapillaris, with further pathologic consequences.<sup>41</sup> Above an unknown threshold level, higher pressure will cause the RPE-EL to separate from the ICL, leading to RPE detachment and fluid accumulation, as seen in 12–20% of AMD patients.<sup>115</sup>

What causes the dramatic age-related decrease in  $L_p$  of Bruch's membrane? It is natural to suspect the age-related lipid accumulation. In fact, McCarty et al.<sup>117</sup> showed that lipid particles trapped in an extracellular matrix can generate very significant flow resistance, more than would be expected based simply on their size and number. However, Marshall and Hussain observed that most of the marked change in  $L_p$  occurred before age 40 (Fig. 22.7A) while the increase in Bruch's membrane lipid content occurred largely after this age. They thus concluded that other age-related changes must be responsible for changes in  $L_p$ .<sup>1,104</sup>

**FIG. 22.7** (A) Hydraulic conductivity of human macular Bruch's membrane/choroidal preparations as a function of age, as compared to lipid accumulation in human macular Bruch's membrane; lines as exponential fits to the data. (B) Hydraulic resistivity of human macular Bruch's membrane/choroidal preparations as a function of age,<sup>1</sup> as compared to esterified cholesterol accumulation in human macular Bruch's membrane,<sup>47</sup> lines are exponential fits to the data (the fits nearly overlie one another). (Panel A modified from Marshall J, Hussain AA, Starita C, et al. Aging and Bruch's membrane. In:

A different conclusion can be reached from examining age-effects on flow *resistivity*, the *inverse* of  $L_p$ . Resistivity increases from a low of roughly  $R=10^8 \text{ Pa m}^{-1} \text{ s}^{-1}$  for young individuals to  $R=10^{10} \text{ Pa m}^{-1} \text{ s}^{-1}$  for aged persons. Thus, when hydraulic conductivity  $L_p$  drops from roughly  $100 \times 10^{-10} \text{ m s}^{-1} \text{ Pa}^{-1}$  to  $25 \times 10^{-10} \text{ m s}^{-1} \text{ Pa}^{-1}$  between the ages of birth and 40 years of age, 75% of its total possible decrease, resistivity  $R$  increases from  $1 \times 10^8 \text{ Pa m}^{-1} \text{ s}^{-1}$  to  $4 \times 10^8 \text{ Pa m}^{-1} \text{ s}^{-1}$ , only 4% of the ultimate increase. Simply put, hydraulic conductivity drops more rapidly with age at young ages because its value is high to start with. Fig. 22.7B plots resistivity and histochemically detected EC against age for Bruch's membrane.<sup>118</sup> The agreement between the trends and the fits to the data are striking. This is strong evidence that the increasing lipid content and progressively hydrophobic character of Bruch's membrane are responsible for impairing fluid transfer with age, as postulated.<sup>41</sup> The strong correlation between flow *resistivity* of Bruch's membrane and lipid content was likewise found by Marshall and Hussain.<sup>1,104,116</sup> Laser ablation studies localizing flow resistance to the ICL<sup>110</sup> further supports this conclusion, because lipids accumulate prominently in the ICL with aging.<sup>53</sup> Further, more laser pulses were required to abolish flow resistance in the oldest eyes, consistent with presence of a Lipid Wall, requiring prior removal.

Thus, it appears that decreased  $L_p$  and increased resistivity of Bruch's membrane with aging is closely related to the age-related accumulation of lipids, primarily EC. Lipids accumulate more rapidly in the macular Bruch's membrane than in the periphery.<sup>47,119</sup> Thus,  $L_p$  of the macula decreases more rapidly with age than it does in the periphery.

## **$L_p$ in Other Species**

$L_p$  of dog Bruch's membrane was measured as  $3.7 \times 10^{-10} \text{ m s}^{-1} \text{ Pa}^{-1}$ ,<sup>120,121</sup> similar to the value found in an older human. Hillenkamp et al.<sup>122</sup> reported a very low value of  $L_p=0.345 \times 10^{-10} \text{ m s}^{-1} \text{ Pa}^{-1}$  in cow eyes, lower than that found in any human eyes. Cankova et al.<sup>123</sup>

examined calf eyes and found a much higher value of  $L_p$  ( $14.2 \times 10^{-10}$  m s<sup>-1</sup> Pa<sup>-1</sup>) that was threefold lower in the cow eyes that they examined ( $4.9 \times 10^{-10}$  m s<sup>-1</sup> Pa<sup>-1</sup>), although not as low as measured by Hillenkamp et al. Cankova et al.<sup>123</sup> concluded that, as in humans,  $L_p$  decreases with age.

## Permeability of Bruch's Membrane to Solute Transport

Along with bulk fluid flow, there is significant transport of individual molecular species across Bruch's membrane, including dissolved gases, nutrients, cytokines, and waste products driven by passive diffusion. Flow crossing Bruch's membrane is too slow to influence this process. This can be seen through calculation of the Peclet number, the relative magnitude of convection of a species due to bulk flow to that of diffusion:<sup>124</sup>

$$\frac{VL}{D_0} \quad [22.2]$$

where  $V$  is the velocity of the flow,  $L$  is the transport path length, and  $D_0$  the free diffusion coefficient of the species being transported. (The free diffusion coefficient in saline is used rather than its value in tissue, since the species carried by flow is constrained to the same extent by the tissue as is its diffusion). Using the RPE pumping rate (Table 22.2) for  $V$ , Bruch's membrane thickness (average of  $3 \mu\text{m}$ <sup>71</sup>) for  $L$ , and a range of diffusion coefficients of species crossing Bruch's membrane ( $2 \times 10^{-7}$  cm<sup>2</sup>/sec for LDL to  $2 \times 10^{-5}$  cm<sup>2</sup>/sec for oxygen)<sup>124,125</sup> we find that the Peclet number ranges in value from  $5 \times 10^{-5}$  to  $5 \times 10^{-3}$ . Thus, convection is negligible in transporting species across Bruch's membrane under physiologic conditions.

Diffusion follows Fick's law whereby the diffusive flux per unit area ( $j$ ) is proportional to the diffusion coefficient ( $D$ ) of that species in the medium through which it passes and to the concentration difference across the medium ( $\Delta C$ ), and inversely proportional to the diffusion length:

$$j = D \Delta C / L$$

[22.3]

The *permeability* of a tissue to a given species is defined as  $P = j / \Delta C$ . We see then that  $P = D / L$ . For example, the permeability of Bruch's membrane to oxygen is  $\sim 0.067$  cm/sec. Note that since diffusion moves down a concentration gradient, one species might be diffusing across Bruch's membrane toward the RPE (e.g., oxygen) while another species (e.g., carbon dioxide) diffuses simultaneously in the other direction.

With high diffusion coefficient and little interaction with extracellular matrix, small molecules (e.g., oxygen, cytosine, RNAaseA) diffuse quickly across Bruch's membrane with diffusion coefficients nearly the same as in free solution.<sup>126</sup> However, macromolecules have much smaller free solution diffusion coefficients due to their larger size. Their diffusion coefficients are further reduced by interactions with extracellular matrix and/or lipoproteins that accumulate with age. For example, the diffusion coefficients of albumin and ferritin are an order of magnitude smaller in Bruch's membrane than their values in free solution.<sup>126</sup>

The transport of amino acids,<sup>127</sup> serum proteins,<sup>128</sup> drugs,<sup>129</sup> and LDL<sup>123,130</sup> across Bruch's membrane has been examined. Transport experiments by Clark and associates<sup>85</sup> suggest that FHL-1 (43 kDa) crosses Bruch's membrane more readily than CFH (155 kDa) and is in fact the major CHF form in native aged Bruch's membrane.

There are technical challenges to these transport experiments. First, as indicated in Eq. 22.3, diffusional flux depends on the length of the tissue. Since the diffusion coefficient of the transported species is likely different in Bruch's membrane than in the choroid in a combined preparation, but the path lengths of both tissue components are usually not determined, it is difficult to use the measured values to determine absolute values of permeability. Instead the more easily measured flux rate ( $j$ ; see Eq. 22.3) is usually presented. Second, an unstirred layer can develop near the membrane thereby complicating the results, and this can occur even in cases when the solutions are stirred.<sup>131</sup> Nonetheless, useful comparative results can be generated.

The transport rate across human Bruch's membrane declines linearly with age for all molecules measured. Amino acids exhibited permeabilities of  $0.6 \times 10^{-4}$  cm/sec (phenylalanine) to  $1.2 \times 10^{-4}$  cm/sec

(glycine) for young Bruch's membrane and exhibited a modest decline (twofold or less) with aging.<sup>127</sup> Serum proteins decrease more markedly, dropping from  $3.5 \times 10^{-6}$  cm/sec in the first decade to  $0.2 \times 10^{-6}$  cm/sec in the ninth decade, a >10-fold decrease.<sup>128</sup> In particular, proteins larger than 100 kDa have significantly decreased flux through Bruch's membrane of older individuals. Macular Bruch's membrane showed a steeper decrease with age than did the periphery.<sup>132</sup> Permeability was reduced in eyes with AMD relative to age-matched normal eyes.<sup>132</sup>

Decreased permeability of Bruch's membrane to transport is likely due to a decrease in diffusion coefficients, especially for the larger species affected by interaction with extracellular matrix and lipoproteins. As indicated in Eq. 22.3, increased path length due to age-related thickening of Bruch's membrane<sup>71</sup> could also have a significant effect.

An original proposal of a molecular weight (MW) exclusion limit to Bruch's membrane macromolecule transport of 66–200 kD<sup>127,128</sup> has been questioned by more recent work suggesting that if such a limit exists, it is much higher.<sup>132</sup> Because of the importance of lipoproteins in transporting lipophilic nutrients to the RPE for ultimate use by the photoreceptors, and also because lipoproteins accumulate with age in Bruch's membrane, Cankova et al.<sup>123</sup> specifically examined the reflection coefficient of bovine Bruch's membrane to plasma LDL. They measured a reflection coefficient of 0.62 (compared to a reflection coefficient of arterial endothelium to LDL of 0.998 and arterial intima to LDL of 0.827<sup>133</sup>). Thus, while LDL did not pass freely through Bruch's membrane, it could nonetheless pass. Hussain et al.<sup>132</sup> also concluded that particles as large as LDL could cross Bruch's membrane. Accordingly, RPE cells have been shown to internalize plasma LDL from the choroid.<sup>134–136</sup>

These considerations are relevant not only to understanding mass transfer between the choriocapillaris and the RPE, but also for transcleral drug delivery strategies including antiangiogenic agents for treating AMD and steroids for treating diabetic retinopathy.<sup>137,138</sup> Cheruvu and Kompella<sup>129</sup> reported that the choroid–Bruch's layer is a more significant barrier to drug transport than is sclera. It hindered the transport of lipophilic solutes more than hydrophilic solutes and in a more dramatic way than does sclera. Importantly,

the reduction in transport across this layer directly correlated with solute binding to the tissue. Pitakänen et al. found significant lag times associated with transport of lipophilic beta blockers across the RPE-choroid, consistent with binding of these drug to the tissues; however, they found that the permeability of the lipophilic drugs across this tissue was greater than that of hydrophilic compounds or macromolecules.<sup>139</sup> Lipophilic substances are known to have both different transport characteristics in connective tissues and also bind to extracellular matrix.<sup>140</sup>

## Summary and Implications

Bruch's membrane's physiologic roles are structural and facilitating transport. Transport across Bruch's membrane is increasingly hindered with age, due at least partly to the marked age-related accumulation of EC-rich lipoproteins in this tissue, impeding pumping of fluid from RPE.<sup>115</sup> A  $\geq 90\%$  decrease in transport of some species from the choroid<sup>128,132</sup> may include lipophilic essentials delivered by lipoproteins. This decline in transport capability is thought to have functional consequences for photoreceptors.<sup>141</sup> A well-characterized change occurring through the lifespan of individuals with healthy maculas is slowed dark adaptation,<sup>142</sup> attributed to impaired translocation of retinoids across the RPE-Bruch's interface. This slowing, worse in AMD patients,<sup>143,144</sup> can be partly ameliorated by short-term administration of high-dose vitamin A,<sup>145</sup> presumably overcoming the translocation deficit via mass action.

However, it is important to recognize that except for the studies on tissue from individuals with AMD, all of the results in human summarized here were from eyes that did not have retinal disease. As such, while the age-related decline in the transport capability of Bruch's membrane has functional consequences on photoreceptor function it is not likely that this represents disease, but instead, is part of the aging process. Accordingly, a prospective study has shown that slowed dark adaptation is detectable in 22% of older adults with maculas considered normal by color fundus photography and that these persons are two times more likely to have incident early AMD 3 years later.<sup>146,147</sup> Thus the overall model of photoreceptor nutritional insufficiency, due to impaired

transport, at the interface of aging and disease has strong *in vivo* validation.

## Pathology of Bruch's Membrane

### AMD Lesions

In aging and AMD, characteristic extracellular lesions accumulate in tissue compartments between the RPE-BL and ICL (Fig. 22.8). Known as drusen and basal linear deposits (BLinD),<sup>32,148</sup> these lipid-containing aggregations ultimately impact RPE and photoreceptor health by impairing transport, causing inflammation, and predisposing to choroidal neovascularization. Basal laminar deposit (BLamD), a stereotypic thickening of RPE basal lamina, forms in parallel with lipid deposition in Bruch's and may indicate RPE stressed by it. Since 2010, clinical optical coherence tomography (OCT) has revealed that AMD lesions include a major new component, called subretinal drusenoid deposits (SDD) by cross-sectional OCT and histology<sup>149</sup> and reticular pseudodrusen by en face imaging such as color fundus photography.<sup>150</sup> These solid space-filling lesions located between the photoreceptors and RPE (Fig. 22.8) are common in AMD but are not unique to AMD. In the section below, we refer to retinal regions as foveal (central 1 mm), perifoveal (0.5–3 mm from the foveal center), and extramacular (>3 mm).

**FIG. 22.8** Bruch's membrane and characteristic AMD lesions. (A) Bruch's membrane has five layers in a normal eye: 1, basal lamina of the retinal pigment epithelium (RPE); 2, inner collagenous layer; 3, elastic layer; 4, outer collagenous layer; 5, basal lamina of the

choriocapillary endothelium (fenestrated cells, pink). L, lipofuscin. (B) Older eyes have basal laminar deposit (BlamD) and the Lipid Wall, precursor to basal linear deposit and soft drusen. (C) Drusen, basal linear deposit, and the Lipid Wall occupy the same tissue compartment. Basal mounds are soft druse material within BlamD. (D) Subretinal drusenoid deposit is an extracellular lesion compositionally distinct from drusen, located between the photoreceptors (not shown) and the RPE. (Modified from Curcio CA, Johnson M, Huang J-D, et al. Apolipoprotein B-containing lipoproteins in retinal aging and age-related maculopathy. *J Lipid Res.* 2010;51(3):451-67.)

## Drusen

In a fundus view, drusen are 30–300  $\mu\text{m}$ -diameter yellow–white deposits posterior to the RPE. By OCT, they appear as variably hyporeflective spaces in the same location.<sup>151–153</sup> Found in most older adults,<sup>79,154</sup> drusen are more numerous in extramacular retina than in macula.<sup>155–157</sup> Drusen are typically classified as “hard” and “soft” by the appearance of their borders. Other rare druse types exist and are less well characterized.<sup>158</sup> Soft drusen confer high risk of advanced disease.<sup>159–162</sup> Histologically, drusen are focal, domed lesions between the RPE basal lamina and the ICL (Fig. 22.8), as illustrated<sup>163</sup> and established<sup>148,164</sup> using transmission electron microscopy.

In separate 1854 publications, Donders (a Dutch ophthalmologist) and Wedl (an Austrian pathologist) described “colloid bodies” (*Colloidkugeln*) or “hyaline deposits” on the inner surface of the choroid in older or diseased human eyes<sup>3,165,166</sup> (translated by Busk). Both authors interpreted droplets filling these deposits as “fat-globules.” The term drusen originated with Müller in 1856, from the German word for geode (not to be confused with *drüse*, meaning gland).<sup>167</sup> The name drusen was adopted by English writers early in the 20th century<sup>168</sup> yet “colloid body” was used by Verhoeff into the 1920s.<sup>169</sup> Lauber<sup>170</sup> (cited in reference 171) noted that deposits between the lamina vitrea and the RPE were sudanophilic in 1924. Wolter and Falls<sup>38</sup> stated that “hyaline bodies [drusen] ... stain reddish with ... oil red O” in 1962. Soft drusen

were termed serogranular and hard druse hyaline (glassy) by S. Sarks,<sup>159</sup> implying different composition. Soft drusen are oily, difficult to isolate individually, biomechanically more fragile than hard drusen, and found only in the macula.<sup>157</sup> Friability upon processing for conventional paraffin histology was noted early.<sup>172</sup> Due to this and other technical challenges, few recent drusen compositional studies (Table 22.3 online) included true macular soft drusen.<sup>173–177</sup> Many studies analyzed peripheral drusen, combined macular and peripheral drusen, or did not specify location.

**TABLE 22.3**  
**Localized Components of Drusen**

Component	Phase	Direct Assay	Abundance	References
Lipoproteins (EC, UC, phospholipid)	P	✓	All drusen; >40% of hard druse volume; EC pools in soft drusen	157,194,311
Modified lipids (7-ketocholesterol, isolevuglandin)	D	✓	All drusen	185,312
Apolipoproteins (apoB, A-I, C-I, E)	P	apoE ✓	60–100% of hard drusen; higher rates in periphery than macula	189,191,311
Melanin/lipofuscin granules	P		6% of hard and soft drusen	157
Cells (dendritic, others)	P		3–6% of hard drusen only	157, 313
Amyloid vesicles (0.25–10 μm)	P		2% of hard drusen, 40% of compound drusen, frequent in eyes with many drusen, some AMD eyes	157, 173, 194, 200
Hydroxyapatite (calcium phosphate)	P	✓	43% of macular hard drusen, 1.6% of soft drusen, 2% of peripheral hard drusen by light microscopy; all drusen by specific label	157, 215
Clusterin, TIMP3, vitronectin, apolipoprotein E, complement factor H, membrane attack complex (complement components 8, 9), C-reactive protein	D	✓	Reliably detected; abundance inferred	186, 198, 314–317
Components of classic, lectin, alternative, terminal complement pathways; C3 fragments indicating activation	D	Some ✓	Many pathway components evidence key role of complement	318
RGR-d	D		All drusen	319
αA- and αB-crystallin	D	✓	N.A.; higher in BrM, more in AMD drusen	201, 202
Ubiquitin	D		Most drusen in most eyes	196, 320

Carbohydrates	D		All drusen	181
Zinc	D	✓	Many drusen	18, 321
Iron	D	✓	Many drusen	321
Exosome markers CD63, CD81, and LAMP2	P		N.A.	322
Bestrophin, membrane-bound	P		N.A.	323

P, particulate; D, dispersed; BrM, Bruch's membrane; Localization methods: immunohistochemistry, histochemistry, immunogold transmission electron microscopy; Direct assays: proteomics, Western blot, microprobe synchrotron X-ray fluorescence for zinc; N.A. not available. Varying estimates of particulate druse components are due to differences in location of samples and druse types examined. "All drusen" means "all drusen sampled." Many studies did not specify the location of drusen studied or pooled macula and periphery.

Extant theories for druse formation, extending back to their discovery,<sup>167</sup> fit into two general categories: transformation of the overlying RPE and deposition of materials onto Bruch's membrane. The latter is now accepted.<sup>166</sup> The RPE has been implicated as a source of many druse components, via budding of membrane-bound packets of cytoplasm or secretion of lipoproteins with retention by aged Bruch's membrane,<sup>39</sup> as experimentally confirmed.<sup>178</sup> BLinD and soft drusen are two physical forms (layer and lump) of the same AMD-specific lesion, located only in the macula. BLinD forms consequent to lipoprotein accumulation in Bruch's membrane and formation of the Lipid Wall, likely involving lipoprotein aggregation, oxidation of individual lipid classes, and local inflammation. Soft drusen involves these and other processes that cause the distinctive dome shape of these lesions. RPE expresses genes for many druse components, including lipoproteins.<sup>18,179,180</sup> The contribution of plasma-derived components, in contrast, has not been well characterized. The existence of druse subregions additionally suggest remodeling in the extracellular compartment, such as cellular invasion and enzymatic activity<sup>181–183</sup> and uplifting of the Lipid Wall.<sup>174</sup>

Most prominent among druse constituents are lipids (Table 22.3 online<sup>Ⓞ</sup>), as noted early. All drusen contain EC and UC, in addition to phosphatidylcholine, other phospholipids, ceramides, and 7-ketocholesterol, an oxidation product of UC that is angiogenic and proinflammatory.<sup>44,47,163,174,182,184,185</sup> Extractable lipids account for ≥40% of hard druse volume<sup>186</sup> and likely more for macular soft drusen.<sup>174</sup> This includes large EC-rich lakes in soft drusen (Figs. 22.9A–B), as in atherosclerotic plaques.<sup>187</sup> Apolipoprotein

immunoreactivity appears in drusen with high frequency (100%, apoE; >80% apoB; 60%, A-I).<sup>174,188-191</sup> Importantly, hard drusen contain many solid, Folch-extractable electron-dense particles of the same diameter as the lipoproteins in Bruch's membrane. These observations together with the appearance of membranous debris in soft drusen (below) make an RPE-secreted apoB,E-containing lipoprotein particle an efficient mechanism to place multiple lipids and apolipoproteins within lesion compartments. Only half of macular drusen take up hydrophilic fluorescein in angiography,<sup>192</sup> possibly reflecting differing proportions of lipid classes in individual lesions.<sup>184</sup>

**FIG. 22.9** Esterified cholesterol (EC) forms lakes in macular soft drusen. (A) EC lakes in a macular soft druse revealed by filipin fluorescence (*arrow*). Scale bar: 25  $\mu\text{m}$ . (B) Macular soft druse from an AMD eye has lakes of homogeneous electron-dense lipid (*arrow*) among partially preserved lipoprotein-like material. Basal laminar deposit (*asterisk*) overlying the druse has similar material, called membranous- or lipoprotein-derived debris (to the right of the asterisk). Scale bar: 1  $\mu\text{m}$ . (Panel A modified from Malek G, Li C-M, Guidry C, et al. Apolipoprotein B in cholesterol-containing drusen and basal deposits in eyes with age-related maculopathy. *Am J Pathol.* 2003;162(2):413-25.)

Discrete nonlipid components in some drusen granules of lipofuscin or melanin indicate cellular origin (Table 22.3 online). Spherical  $\beta$ -amyloid assemblies<sup>173,193,194</sup> now appear to be due to nonspecific binding of proteins to hydroxyapatite spherules (see below), consistent with immunohistochemistry.<sup>195,196</sup> Other

constituents present in all drusen include vitronectin, TIMP-3, complement factor H, complement components C3 and C8, crystallins, ubiquitin, and zinc.<sup>26,183,193,197-201</sup> Many druse components are found also in retina IL-1<sup>177</sup> and/or choroid (carboxypyrrhole adducts<sup>202</sup>) of the same eyes and thus are less specific for these lesions than other components.

The principal lipid-containing component of soft drusen and BLinD was called “membranous debris” by the Sarks<sup>159,203,204</sup> and “lipoprotein-derived debris” was suggested as an alternative, for two reasons.<sup>39</sup> First, these lesions are richer in histochemically detectable UC than surrounding cellular membranes.<sup>184,205</sup> By transmission electron microscopy following osmium tetroxide postfixation, membranous debris appears as variably sized, contiguous coils of uncoated membranes consisting of uni- or multilamellar electron dense lines, that are denser than cellular membranes and surround an electron-lucent center (Fig. 22.2). Since conventional ultrastructural preparation methods can remove lipids, the building blocks of membranous debris are likely the UC-rich exteriors of lipoproteins (native and fused) whose neutral lipid interiors are not well preserved in postmortem tissue.<sup>53,190,206</sup> Second, all drusen have abundant EC that can only be explained by lipoprotein particles in addition to cellular membranes.

By ophthalmoscopy, refractile or glistening deposits thought to be calcified drusen<sup>172</sup> regularly appear in areas where drusen regress, before the onset of geographic atrophy.<sup>207,208</sup> Recent investigation has confirmed that glistening drusen in fact contain calcium phosphate in the form of hydroxyapatite spherules, culminating a five-decade quest. Studies included detection of refractile nodules by light microscopy,<sup>32,209-212</sup> phosphate detection via von Kossa histochemistry,<sup>172,208</sup> confirmation of calcium and phosphate signals in nodules by energy dispersive X-ray analysis,<sup>213,214</sup> and identification of hydroxyapatite mineral by synchrotron micro-X-ray diffraction.<sup>215</sup> Most drusen contain 0.5–20 µm diameter spherules that become clinically visible when the RPE degenerates.<sup>208</sup> Concentric shells within the spherules account for the refractility.<sup>208</sup> Spherules also have UC within them.<sup>215</sup> As hydroxyapatite binds proteins well and is widely used as a stationary phase for chromatography, these nodules are strong

candidates for nucleation sites for further protein deposition and druse enlargement.<sup>215</sup> Calcification in drusen differs from that within Bruch's membrane itself by not requiring the presence of elastin fibers. The source and mechanism of high calcium and phosphate concentration in the sub-RPE space, likely reflecting RPE physiology, are important areas for future research.

### **Basal Linear Deposit**

BLinD is a thin (0.4–2  $\mu\text{m}$ ) layer located in the same sub-RPE compartment as soft drusen (Fig. 22.8). BLinD is not visible clinically except as associated with other pathology. By lipid-preserving ultrastructural techniques, BLinD is rich in solid lipoprotein particles and lipid pools (Figs. 22.10A,C) and can contain hydroxyapatite.<sup>203</sup> BLinD and soft drusen are considered alternate forms of the same entity.<sup>216</sup> ApoE and apoB are present in BLinD and its precursor, the Lipid Wall.<sup>174,188,189</sup> Transitional morphologies between Lipid Wall and BLinD have been reported.<sup>217</sup> BLinD is thicker in the fovea than in the perifovea, unlike SDD, consistent with these lesions reflecting differential aspects of cone and rod physiology<sup>61</sup> (see below).

### **Basal Laminar Deposit**

BLamD forms small pockets between the RPE and the RPE-BL in many older normal eyes or a continuous layer as thick as 15  $\mu\text{m}$  in AMD eyes<sup>204,205,218</sup> (Fig. 22.8). The presence and abundance of BLamD has been used to stage AMD.<sup>32,219</sup> Ultrastructurally, BLamD resembles basement membrane material (Fig. 22.10B), containing laminin, fibronectin, type IV, and type VI collagen.<sup>220–223</sup> The latter is a distinctive banded material with 120 nm periodicity, called wide- or long-spacing collagen, which also appears in other ocular locations like epiretinal membranes. Thick BlamD, associated with advanced AMD risk,<sup>204</sup> contains histochemically detectable lipid including UC and EC<sup>184,205</sup> and is a classically described site for membranous debris (Fig. 22.2). By lipid-preserving methods, solid particles are seen in BLamD (Figs. 22.10A–B). Especially enriched in basal mounds<sup>204</sup> (Fig. 22.8C), lipoprotein-derived debris in BLamD may be considered as retained in transit from the RPE to BLinD and/or drusen.<sup>174,184,205</sup> Morphologically heterogeneous BLamD also

contains vitronectin, MMP-7, TIMP-3, C3, and C5b-9,<sup>218</sup> EC, and UC.<sup>205</sup> Evoked in numerous mouse models of aging, stress, and genetic manipulation, BLamD is a reliable marker of RPE stress.<sup>224,225</sup>

**FIG. 22.10** Lipoprotein-derived debris and lipid pools in AMD lesions are solid rather than vesicular material. (A) Above retinal pigment epithelium (RPE) basal lamina (*arrowheads*) is basal lamina deposit (BlamD) with individual particles indicated (*arrow*). Below RPE basal lamina are numerous solid particles in basal linear deposit (BlinD). Transmission electron microscopy, OTAP fixation; scale bar: 500 nm. (B) BlamD appears as a solid column of basal lamina-like material, with solid particles embedded within (*arrow*). Scale bar = 500 nm. (C) BlinD has lipoproteins of

heterogeneous sizes and shapes as well as pooled lipid, consistent with a model of surface degradation and particle fusion. Scale bar = 200 nm. (Panel A Curcio CA, Presley JB, Millican CL, Medeiros NE. Basal deposits and drusen in eyes with age-related maculopathy: evidence for solid lipid particles. *Exp Eye Res* 2005;80(6):761–75. Panel B image courtesy of J.-D. Huang, PhD. Panel C Curcio CA, Johnson M, Rudolf M, Huang J-D. The oil spill in ageing Bruch's membrane. *Br J Ophthalmol* 2011;95(12):1638–45.)

## Subretinal Drusenoid Deposit

Hypotheses of druse formation must eventually also account for SDD, the extracellular deposits between RPE and photoreceptors (Fig. 22.8). These lesions were first illustrated histologically in AMD by the Sarks<sup>203</sup> and independently described as drusen “visible en lumière bleu” by Mimoun et al.<sup>226</sup> Conferring risk for late AMD,<sup>227</sup> SDD appear in 60% or more of eyes with geographic atrophy,<sup>227,228</sup> 49% of early AMD eyes, and 23% of older eyes considered normal by color fundus photography.<sup>229</sup> SDD are also detectable in several Mendelian inherited disorders affecting the RPE–Bruch's membrane complex.<sup>230–232</sup> Comprehensive histology, clinicopathologic correlation, and adaptive optics scanning laser ophthalmoscopy<sup>61,233–235</sup> have definitively localized these lesions in the subretinal space, after some early debate. SDD lack markers for cells bounding this space (photoreceptors, Müller cells, RPE).<sup>175,205</sup> SDD share protein components with drusen,<sup>175</sup> and importantly, SDD lipid composition differs from drusen (UC only vs. UC and EC, respectively<sup>236</sup>). SDD are abundant in the perifovea and peripapillary area<sup>149,150,229,237–239</sup> and sparse in central macula, whereas BLinD is thickest under the fovea.<sup>61</sup> Cones are numerous in the fovea, and rods are numerous in the perifoveal region and just beyond.<sup>240</sup> Thus drusen and SDD have been linked in a system of outer retinal lipid recycling serving the differential lipid requirements of rod and cone photoreceptor outer segment membranes.<sup>61,241</sup> The low content of EC relative to drusen has been explained by invoking a hypothetical high-density lipoprotein particle, rich in UC, that shuttles UC from and docosahexanoate to rod outer segments selectively.<sup>61</sup> If this hypothesis is true, SDD might be also rich in docosahexanoate and its derivatives, an

important question to address experimentally.

## Summary

Levels of significance ascribed to molecules sequestered in drusen (Table 22.3 online), and by inference, BLinD, include toxicity to the overlying RPE, stigmata of formative processes (extrusion of cellular materials, secretion, extracellular enzymatic processing, cellular activity), and markers of a diffusely distributed disease process affecting RPE and Bruch's membrane. Additional significance can be ascribed to these lesions as physical objects that increase path length between choriocapillaries and retina and provide a biomechanically unstable cleavage plane between RPE-BL and ICL. Many of these processes likely also occur in the subretinal space in relation to SDD.<sup>149</sup>

## Response-to-Retention Hypothesis of AMD

The parallels between the pathology of arterial intima of large arteries in atherosclerosis and that of Bruch's membrane in AMD are striking. Both diseases feature cholesterol-rich lesions in subendothelial compartments within the systemic circulation, involving many of the same molecules and biologic processes at multiple steps, as long anticipated.<sup>242,243</sup> According to the Response-to-Retention theory of atherosclerosis, plasma lipoproteins cross the vascular endothelium of large arteries, and bind to extracellular matrix. By itself, this process is not pathologic. However, lipoprotein components become modified via oxidative and nonoxidative processes and launch numerous downstream deleterious events, including inflammation, macrophage recruitment, and neovascularization leading to disease.<sup>244,245</sup> Parallel with apoB-lipoprotein-instigated disease in arterial intima, an intraocular Response-to-Retention involving the RPE and Bruch's membrane in aging and AMD would begin with age-related accumulation of lipoproteins, but of *local origin*. Oxidation, perhaps driven by reactive oxygen species from adjacent RPE mitochondria, would then initiate a pathologic process resembling that in the vascular system with inflammation-driven downstream events including complement activation and structurally unstable

lesions.<sup>39</sup> New model systems such as highly differentiated and polarized cultured RPE<sup>178</sup> and mice with genetically modified lipoprotein pathways<sup>246</sup> will allow rigorous experimental test of these concepts.

## Neovascular AMD

Choroidal neovascularization (CNV), the major sight-threatening complication of AMD, involves angiogenesis along vertical and horizontal vectors: vertically across Bruch's membrane, and either laterally external to the RPE (type 1 CNV,<sup>247</sup>), laterally within the subretinal space (type 2 CNV), or further anteriorly into the retina (type 3 CNV).<sup>247-249</sup> Of 40+ conditions involving CNV, AMD is the most prevalent, followed by ocular histoplasmosis,<sup>247</sup> and including angioid streaks (below). CNV is a multifactorial nonspecific wound healing response to various specific stimuli, involving VEGF stimulation of choriocapillaris endothelium, compromise to Bruch's membrane, and participation of macrophages.<sup>247</sup> Impaired transport across Bruch's membrane in AMD increasingly isolates the RPE from its metabolic source in the choriocapillaries and enhances the challenge in waste product disposal. VEGF released by RPE as a stress signal initiates an angiogenic response by the endothelium. However, Bruch's membrane compromise is essential for CNV to proceed, as evidenced by intrachoroidal neovascularization without CNV in a mouse overexpressing VEGF in the setting of an intact Bruch's membrane.<sup>250</sup>

Bruch's membrane in a state of compromise can be breached easily by new vessels in AMD. It is notable that the EL is thinner and more interrupted in eyes with neovascular AMD.<sup>26</sup> The length of gaps in the EL is greater in eyes with early AMD and any CNV.<sup>26</sup> In paired donor eyes with and without CNV secondary to AMD, progressed eyes are distinguished by calcification and breaks in Bruch's membrane.<sup>251</sup> In contrast, calcification in a small number of geographic atrophy eyes is unremarkable.<sup>252</sup>

BLinD and soft drusen together further this process by presenting a horizontal cleavage plane for vessel formation to exploit. The lipid-rich composition, relative lack of structural elements like collagen fibrils, lesion biomechanical instability,<sup>157</sup> and

proinflammatory, proangiogenic compounds like 7-ketocholesterol and linoleate hydroperoxide<sup>247,253,254</sup> likely promote vessel growth in this plane.<sup>253</sup> Interestingly, SDD is strongly associated with type 3 neovascularization,<sup>255,256</sup> suggesting that this lesion also plays a similarly important proangiogenic role.

## Angioid Streaks (*ABCC6, MTP* Genes)

Angioid streaks are ruptures in Bruch's membrane associated with multiple disorders, caused by excess calcification of the elastic layer<sup>257</sup> and often accompanied by CNV. They are prominent ocular manifestation of pseudoxanthoma elasticum (PXE), a systemic connective tissue disorder. PXE patients harbor mutations of a hepatically expressed lipid transporter *ABCC6*.<sup>258</sup> Clinical presentation includes, in addition to streaks and CNV, peau d'orange (flat, yellow, drusen-like lesions), optic nerve head drusen, outer retinal tubulations, subretinal fluid, and pigmentary changes.<sup>230</sup> PXE clinical manifestations are believed related to ectopic mineralization of nonhepatic tissues, suggesting a defect in the transport of antimineralization agents.<sup>259</sup>

Angioid streaks are associated with abetalipoproteinemia,<sup>260–263</sup> an extremely rare disorder with low plasma apoB-containing lipoproteins, acanthocytosis of erythrocytes, neuropathy, and pigmentary retinopathy. It is historically attributed to lack of lipophilic vitamins delivered by plasma LDL.<sup>264</sup> The RPE expresses the abetalipoproteinemia gene (microsomal triglyceride transfer protein),<sup>265</sup> which cotranslationally lipidates apoB (see above). How this deficiency leads to angioid streaks is unknown. The finding, however, highlights that *lack* of apoB lipoproteins has negative consequences for Bruch's membrane health, likely by impacting RPE health, just as an *excess* of retained apoB lipoproteins has negative consequences via lesion formation and impaired transport (see above). Good chorioretinal function thus requires an optimal balance between these extremes.

## Thick Basal Laminal Deposits (*TIMP-3, CTRP5, EFEMP1* Genes)

Three autosomal dominant-inherited disorders with adult onset – Sorsby fundus dystrophy, late-onset retinal degeneration (LORD) and Malattia Leventinese–Doyme honeycomb retinal dystrophy (ML–DH) – share phenotypic similarities with AMD and provide mechanistic support for many aspects of Bruch's membrane physiology and pathophysiology discussed above. All three conditions result from mutations in genes encoding extracellular matrix proteins or their regulators (Sorsby – *TIMP3*<sup>266</sup>, LORD – *CTRP5*<sup>267</sup>, and ML–DH – *EFEMP1*<sup>268</sup>). All three can progress to CNV. All three have visual dysfunction, especially rods, attributed to a nutritional night blindness that is responsive to short-term administration of high-dose vitamin A.<sup>269–271</sup> Sorsby and LORD are notable for panretinal thick BLamD and areas of RPE atrophy,<sup>272</sup> while ML–DL is notable for radially distributed drusen and peripapillary deposits. In Sorsby mutant *TIMP-3* localizes to BLamD. In ML–DL, *EFEMP1* localizes to BLamD and not to the pathognomonic drusen themselves, suggesting an important role of BLamD in druse formation. Notably drusen in ML–DL are immunoreactive for fibulin-3 and collagen IV unlike drusen associated with aging and AMD.<sup>273</sup>

BLamD in Sorsby and LORD, like that in AMD, is notably rich in oil red O-binding lipid.<sup>274–276</sup> In LORD eyes<sup>276</sup> deposits contain EC, UC, and apoB, and lipid-preserving ultrastructural methods revealed solid electron-dense particles tracking in intersecting networks across the BLamD. Although not initially apparent, these may represent native lipoproteins in transit from RPE to the choriocapillaris. Lipid particle disposition within these thick deposits has been replicated in a mouse model expressing the R345W *EFEMP1* mutation.<sup>224</sup>

## Conclusion

Bruch's membrane serves essential functions as substrate to the RPE and vessel wall of the outer retina. Its layers and constituent proteins collectively represent a barrier that keeps choroidal vessels at bay, provides a route for water, solutes, and macromolecules that transfer between RPE and choroid while supporting the structural integrity of both. It is unusual among human tissues in

accumulating a high content of EC-rich neutral lipid over the lifespan. A natural history and biochemical model now suggests this lipid is due to apoB lipoprotein secretion by RPE, which may be part of an outer retinal nutrition system with an second component possibly also involving lipoproteins in the subretinal space. This deposition can account for the impaired outward movement of fluid from RPE, increasing risk for RPE detachments more common in older persons, and impaired macromolecular transport also leading to RPE stress. Oxidation of these lipid deposits in Bruch's membrane likely initiates an inflammatory process that leads to lesion formation and choroidal neovascularization in AMD.

---

<sup>a</sup>This does not include the flow resistance of the choriocapillaris endothelium, which is not measured when  $L_p$  of a Bruch's membrane/choroidal preparation is determined. For this highly fenestrated endothelium with fenestra taking up roughly 80% of luminal surface area,<sup>105</sup>  $L_p$  can be estimated as roughly  $25 \times 10^{-10} \text{ m s}^{-1} \text{ Pa}^{-1}$ ,<sup>106</sup> which does not affect our conclusions.

# Vitreous and Vitreoretinal Interface\*

*J. Sebag*

**Biochemistry**

**Anatomy And Histology**

**Physiology**

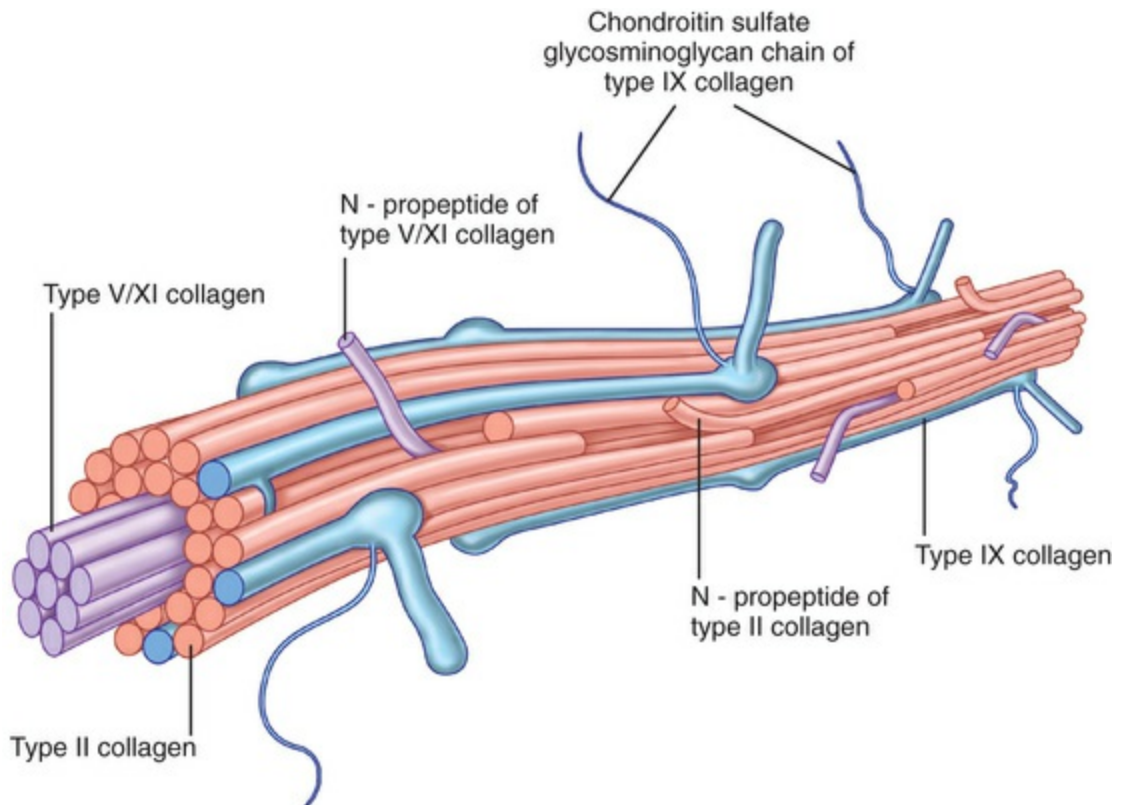

**Pathology**

## Biochemistry

Vitreous is 98% water and 2% structural proteins,<sup>1</sup> extracellular matrix components, and miscellaneous compounds.<sup>2</sup>

## Collagen

Collagen is the major structural protein, consisting of heterotypic fibrils (Fig. 23.1) similar to cartilage.<sup>3,4</sup> Following vitrectomy, a type II procollagen is secreted in humans,<sup>5</sup> but an actual vitreous body is not reformed, since reoperations reveal that the gel state of vitreous is not reestablished.

**FIG. 23.1** Fibrillar structure of human vitreous collagen. Schematic diagram of the major heterotypic collagen fibrils of vitreous based upon the current knowledge of the structure and biophysical attributes of the constituent molecules. (Reproduced with permission from Bishop P. The biochemical structure of mammalian vitreous. *Eye* 1996;10:64.)

Type II collagen<sup>6</sup> comprises 75% of the total collagen content in vitreous. There are considerable similarities between vitreous and cartilage collagens,<sup>7,8</sup> perhaps explaining why inborn errors of type II collagen metabolism result in “arthro-ophthalmopathies,”<sup>9</sup> manifesting similar phenotypic expression in joints and vitreous. Type IX collagen accounts for up to 15% of vitreous collagen,<sup>10</sup> where it always contains a chondroitin sulfate glycosaminoglycan chain<sup>11</sup> covalently linked to the  $\alpha_2$  (IX) chain at the NC3 domain, enabling the molecule to assume a proteoglycan form.

An important function of vitreous is maintaining transparency within the eye (Fig. 23.2).<sup>4</sup> Studies<sup>12</sup> have shown that one of the minor collagens of vitreous is type XVIII, progenitor of endostatin, a potent inhibitor of angiogenesis.<sup>13</sup>

**FIG. 23.2** Dissected human vitreous. Vitreous body dissected of the sclera, choroid, and retina in a 9-month old girl. The vitreous body is attached to the anterior segment, and the specimen is placed on a surgical towel in room air. The exquisite gel state of the vitreous body and the crystal-clear transparency are evident. (Specimen courtesy of the New England Eye Bank; originally published as cover photo in Sebag J. The vitreous: structure, function, and pathobiology. New York: Springer-Verlag; 1989.)

## Hyaluronan

Hyaluronan (HA) was first isolated from bovine vitreous in 1934. HA appears after birth, perhaps synthesized by hyalocytes,<sup>4</sup> the ciliary body, and/or Müller cells. It is a large polyanion, which can influence the diffusion of drugs through vitreous.<sup>14,15</sup> As a result of HA's entanglement within the vitreous collagen fibril matrix, the mechanical force of HA's extension and contraction can be transmitted to the retina, optic disc, and neovascular complexes, inducing untoward effects in conditions that have fluctuations in ionic balance and hydration, such as diabetes.<sup>16</sup>

## Chondroitin Sulfate

Most vitreous chondroitin sulfate is in the form of versican,<sup>17</sup> believed to form complexes with HA as well as with microfibrillar

proteins such as fibulin-1 and fibullin-2 and play a crucial role in maintaining the molecular morphology of vitreous.<sup>18</sup> Mutations that alter the splicing of the central chondroitin sulfate-bearing domains of versican have been implicated in Wagner syndrome, a condition with excess vitreous liquefaction.<sup>19</sup>

## Noncollagenous Structural Proteins

### Fibrillins

In Marfan syndrome, defects in the gene encoding fibrillin-1 (*FBN1* on chromosome 15q21) result in both ectopia lentis and vitreous liquefaction,<sup>20</sup> an important cause of rhegmatogenous retinal detachment (RD) in these patients.

### Opticin

A major noncollagenous protein of vitreous is opticin (formerly called vitrican).<sup>21</sup> It is bound to the surface of the heterotypic collagen fibrils and prevents aggregation of adjacent collagen fibrils into bundles. Opticin binds heparan and chondroitin sulfates, suggesting that it may play a role in vitreoretinal adhesion.<sup>22,23</sup> Similar to its role in articular cartilage,<sup>24</sup> opticin may also stabilize vitreous gel structure by binding chondroitin sulfate proteoglycans.

## Anatomy and Histology

### Vitreous Body

Vitreous is a clear gel-like structure with a volume of about 4.0 mL. During invagination of the optic vesicle, the “primary” vitreous forms between the lens and the inner limiting membrane (ILM) of the retina. It is noteworthy that the ILM is continuous with Bruch's membrane (Fig. 23.3A), demonstrating a common embryologic origin with analogous molecular composition and structure, suggesting important similarities later in life.<sup>25</sup>

**FIG. 23.3** Fetal human vitreous. (A) Human embryo eye stained with immunofluorescent anti-ABA (basement membrane lectin) antibodies revealing the continuity of the inner limiting membrane (*ILM*) and Bruch's membrane (*Bruch's*), demonstrating a common embryologic origin with an analogous molecular composition and structure. This suggests similarities during aging and as participants in various disease processes, especially those that feature cell migration and proliferation: biologic processes that will occur along these interfaces. (B) Photomicrograph of human fetal eye aged 13 gestational weeks. A prominent hyaloid artery and vasa hyaloidea propria can be seen arising from the optic nerve and extending anteriorly towards the lens to anastomose with the tunica vasculosa lentis (hematoxylin and eosin; scale bar: 100  $\mu\text{m}$ ). (Panel A reproduced with permission from Sebag J, Hageman GS. Interfaces. *Eur J Ophthalmol* 2000;10:1. Panel B courtesy of Kenneth MP Yee and Fred Ross-Cisneros, Doheny Eye Institute/UCLA.)

The “secondary” vitreous begins to develop at the 13-mm stage of embryogenesis and is derived from the retina and mesoderm of the hyaloid vascular system (Fig. 23.3B). Recent proteomic studies of human embryonic vitreous have identified changes in protein expression during the second trimester that may play a role in regression of the hyaloid vasculature.<sup>26</sup> Confirmatory studies may thus open new avenues of drug development to prevent or treat pathologic neovascularization in the eye and elsewhere.

Classic depictions of human vitreous structure are shown in Fig. 23.4. Modern concepts proposed membranous (Fig. 23.5A)<sup>27</sup> and

cisternal (Fig. 23.5B)<sup>28</sup> systems. Sebag and Balazs<sup>29</sup> performed dark-field slit microscopy to define the posterior vitreous cortex as a thin, membranous structure continuous from the ora serrata to the posterior pole. Two round holes are present in the prepapillary and premacular areas (Fig. 23.6). Anteroposterior fibers (Fig. 23.7) comprised of parallel collagen fibrils (Fig. 23.8) arise from the vitreous base (Fig. 23.9A), where Gartner<sup>30</sup> found “lateral aggregation” in older individuals. Vitreous base collagen fibers insert anterior to the ora serrata forming the anterior loop (Fig. 23.9B), important in anterior proliferative vitreoretinopathy (PVR).<sup>31</sup> In the posterior pole, fibers extend through the premacular hole (Figs. 23.6 and 23.7A), but a few attach to the rim of the hole. Condensed bundles of fibers insert into the vitreous cortex in the midperiphery and equator (Fig. 23.10).

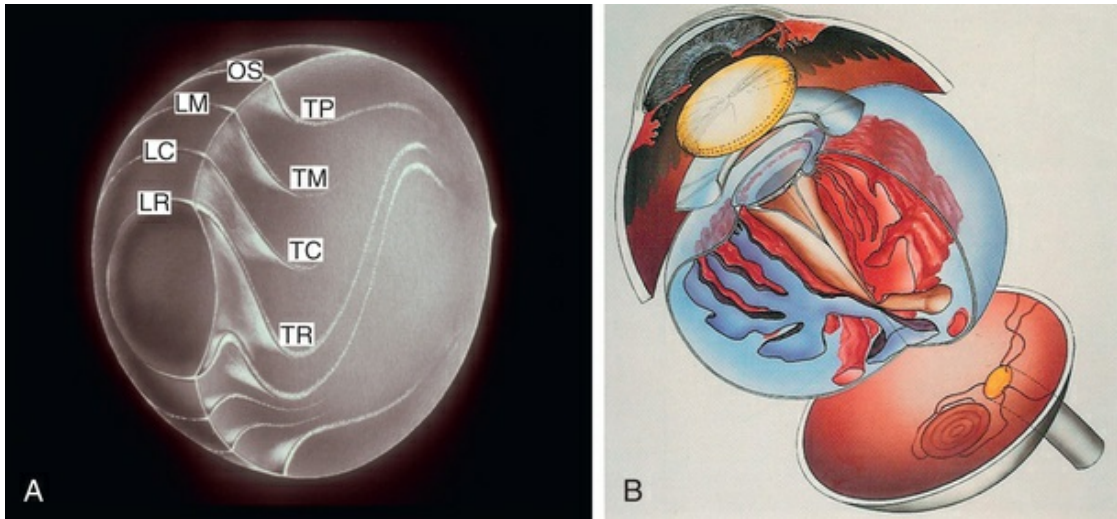

**FIG. 23.4** Classic depictions of vitreous structure. (A)

Schematic representation of vitreous structure. (B)

Schematic diagram of vitreous structure with classic nomenclature of internal and interface structures. (Panel

A redrawn with permission from Green WR. Pathology of the vitreous. In: Frayer WC, editor. Lancaster course in ophthalmic histopathology, unit 8. Philadelphia: FA Davis; 1981. Panel B reproduced with permission from Sang DN. Embryology of the vitreous. Congenital and developmental abnormalities. In: Schepens CL, Neetens A, editors. The vitreous and vitreoretinal interface. New York: Springer-Verlag; 1987. p. 20.)

**FIG. 23.5** Vitreous structure. (A) Membranellae, called tractae, course from the area of the ciliary body to the posterior pole. *LC*, ligamentum coronarium; *LM*, ligamentum medianum; *LR*, ligamentum retrolentalis; *OS*, ora serrata; *TC*, tractus coronarius; *TM*, tractus medianus; *TP*, tractus preretinalis; *TR*, tractus retrolentalis. (B) Cisterns are identified by injecting with colored India ink. Light brown, Cloquet's canal opening into the prepapillary area of Martegiani; light purple, equatorial cistern opening into the bursa premacularis.

(Panel A reproduced with permission from Eisner G. Clinical anatomy of the vitreous. In: Duane TD, Jaeger EA, editors. Biomedical foundations of ophthalmology, vol. 1. Philadelphia: JB Lippincott; 1984. p. 21. Panel B reproduced with permission from Jongbloed WL, Worst JGF. The cisternal anatomy of the vitreous body. *Doc Ophthalmol* 1987;67:183–96.)

**FIG. 23.6** The two “holes” in the posterior vitreous cortex correspond to the prepapillary (smaller, to left) and premacular (larger “hole,” to right) regions. Vitreous can be seen extruding through these holes. The bright pin-point foci of intense light-scattering are hyalocytes embedded in the posterior vitreous cortex.

(Reproduced with permission from Sebag J, Balazs EA. Human vitreous fibres and vitreoretinal disease. *Trans Ophthalmol Soc U K* 1985;104:123–8.)

**FIG. 23.7** Human vitreous morphology. Human vitreous structure visualized by dark-field slit illumination. All photographs are oriented with the anterior segment below and the posterior pole above. (A) Posterior vitreous in the left eye of a 52-year-old man. The vitreous body is enclosed by the vitreous

cortex. There is a hole in the prepapillary (small, to the left) vitreous cortex. Vitreous fibers are oriented toward the premacular region. (B) Posterior vitreous in a 57-year-old man. A large bundle of prominent fibers is seen coursing anteroposteriorly and entering the retrocortical space by way of the premacular vitreous cortex. (C) Same photograph as (B), at higher magnification. (D) Posterior vitreous in the right eye of a 53-year-old woman. There is posterior extrusion of vitreous out of the prepapillary hole (to the right) and premacular (large extrusion to the left) vitreous cortex.

Fibers course anteroposteriorly out into the retrocortical space. (E) Horizontal optical section of the same specimen as (D), at a different level. A large fiber courses posteriorly from the central vitreous and inserts into the premacular vitreous cortex. (F) Same view as (E), at higher magnification. The large fiber has a curvilinear appearance because of traction by the vitreous extruding into the retrocortical space (see D). However, because of its attachment to the posterior vitreous cortex, the fiber arcs back to its point of insertion. (G) Anterior and central vitreous in a 33-year-old woman. Cloquet's canal is seen forming the retrolental space of Berger. (H) Anterior and peripheral vitreous in a 57-year-old man. The specimen is tilted forward to enable visualization of the posterior aspect of the lens and the peripheral anterior vitreous. To the right of the lens there are fibers coursing anteroposteriorly that insert into the vitreous base.

These fibers "splay out" to insert anterior and posterior to the ora serrata. (Panels A, E, and F reproduced with permission from

Sebag J, Balazs EA. Pathogenesis of CME: anatomic consideration of vitreo-retinal adhesions. *Surv Ophthalmol* 1984;28 (Suppl):493. Panels and C from Sebag J, Balazs EA. Morphology and ultrastructure of human vitreous fibers. *Invest Ophthalmol Vis Sci* 1989;30:187. Panels D, G, and H from Sebag J. *The vitreous: structure, function, and pathobiology*. New York: Springer-Verlag; 1989. Specimens were courtesy of the New York Bank for Sight and Restoration, New York, NY.)

**FIG. 23.8** Ultrastructure of human vitreous fiber. The fibers of the human vitreous visible by dark-field microscopy result from bundles of parallel collagen fibrils such as the one shown here in cross-section (*arrow*). (Reproduced with permission from Sebag J, Balazs EA. Morphology and ultrastructure of human vitreous fibers. Invest Ophthalmol Vis Sci 1989;30:187.)

**FIG. 23.9** (A) Vitreous base morphology. In this eye of a 58-year-old woman, postmortem dark-field slit microscopy studies showed vitreous fibers that are continuous from the posterior vitreous cortex (at the top of the photo) to the vitreous base, where they “splay out” to insert into the vitreous base (*arrow*). (B) Anterior loop of the vitreous base. Central, anterior, and peripheral vitreous structure in a 76-year-old man. The posterior aspect of the lens is seen below. Fibers course antero-posteriorly in the central vitreous and

insert into the vitreous base. The “anterior loop” configuration of those fibers inserting into the vitreous base anterior to the ora serrata is seen on the right side of the specimen (*arrow*). (Panel A reproduced with permission from Sebag J, Balazs EA. Pathogenesis of CME: anatomic consideration of vitreoretinal adhesions. *Surv Ophthalmol* 1984;28 (Suppl):493–8.)

**FIG. 23.10** Fibers condense into bundles and insert into the vitreous cortex (*arrows*). Between these insertions are spaces seemingly devoid of structure, but probably filled with liquid vitreous. (Reproduced with permission from Sebag J, Balazs EA. Human vitreous fibres and vitreoretinal disease. *Trans Ophthalmol Soc U K* 1985;104:123–8.)

## Vitreoretinal Interface

The equatorial and posterior vitreoretinal interfaces consist of the posterior vitreous cortex, the ILM of the retina, and an intervening extracellular matrix.<sup>32</sup>

### Posterior Vitreous Cortex

The posterior vitreous cortex is 100–110  $\mu\text{m}$  thick and consists of densely packed collagen fibrils<sup>33</sup> (Fig. 23.11). There is no vitreous cortex over the optic disc (Figs. 23.6 and 23.7A), and the cortex is

thin over the macula. The prepapillary hole can sometimes be visualized clinically following posterior vitreous detachment (PVD). If peripapillary tissue is torn away during PVD and remains attached around the prepapillary hole, it is called a Vogt or Weiss ring. Hageman<sup>34</sup> demonstrated a lamellar organization of the posterior vitreous cortex (Fig. 23.12), confirmed in humans by three-dimensional optical coherence tomography (OCT) (Fig. 23.13).<sup>35</sup> During anomalous PVD (APVD),<sup>36,37</sup> this lamellar structure predisposes to splitting along the potential cleavage planes between the lamellae, resulting in vitreoschisis.<sup>38</sup>

**FIG. 23.11** Ultrastructure of human vitreoretinal interface. Scanning electron microscopy of anterior surface of the human retina (top) and the posterior surface of the posterior vitreous cortex (bottom).

(Reproduced with permission from Sebag J. The vitreous: structure, function, and pathobiology. New York: Springer-Verlag; 1989.)

**FIG. 23.12** Lamellar structure of the posterior vitreous cortex. Immunohistochemistry with anti-ABA lectin antibodies of the monkey vitreoretinal interface demonstrates lamellae in the posterior vitreous cortex just above the inner limiting membrane of the retina (intensely staining yellow line). These lamellae represent potential cleavage planes during anomalous posterior vitreous detachment with vitreoschisis.

**FIG. 23.13** Human posterior vitreous cortex. Three-dimensional spectral domain optical coherence tomography imaging of human posterior vitreous cortex demonstrates the lamellar structure that predisposes to vitreoschisis. (Reproduced with permission from Sebag J. Vitreous – the resplendent enigma. *Br J Ophthalmol* 2009;93:989–91. Image courtesy of Dr. Carl Glittenberg and Prof. Susanne Binder, Vienna.)

### **Hyalocytes.**

Hyalocytes are mononuclear cells embedded in the posterior vitreous cortex 20–50  $\mu\text{m}$  from the ILM posteriorly (Figs. 23.6 and 23.14). The highest density of hyalocytes is in the vitreous base followed by the posterior pole, with the lowest density at the equator.<sup>39,40</sup> Balazs<sup>41</sup> suggested that these cells synthesize vitreous HA,<sup>42–45</sup> but Swann<sup>7</sup> disagreed. Evidence suggests that hyalocytes maintain ongoing synthesis and metabolism of glycoproteins<sup>46,47</sup> and may also synthesize collagen<sup>48</sup> and enzymes.<sup>49</sup>

**FIG. 23.14** Human hyalocytes. (A) Phase contrast microscopy of human hyalocytes in situ. (B) A mononuclear cell is seen embedded within the dense

collagen fibril (*black C*) network of the vitreous cortex. There is a lobulated nucleus (*N*) with a dense marginal chromatin (*white C*). In the cytoplasm there are mitochondria (*M*), dense granules (*arrows*), vacuoles (*V*), and microvilli (*MI*) (magnification =  $\times 11,670$ ). (Panel A reproduced with permission from Sebag J. *The vitreous: structure, function, and pathobiology*. New York: Springer-Verlag; 1989, p. 49. Panel B courtesy of J.L. Craft and D.M. Albert, Harvard Medical School.)

The phagocytic capacity of hyalocytes has been described *in vivo*<sup>50</sup> and demonstrated *in vitro*.<sup>51-53</sup> Hyalocytes become phagocytic in response to inducing stimuli and are important in antigen processing and as initiators of the immune response, making it possible for intravitreal inoculation of antigens to promote systemic immunity.<sup>54</sup> HA may have a regulatory effect on hyalocyte phagocytic activity.<sup>55,56</sup> Various constituents of vitreous<sup>57,58</sup> may be immunogenic and play a role in ocular inflammatory diseases. Sakamoto and Ishibashi have recently published excellent reviews of hyalocytes.<sup>59,60</sup>

Hyalocytes are important in macular pucker when APVD<sup>31</sup> and vitreoschisis<sup>29,33,61</sup> leave these cells on the macula (Fig. 23.15). Under the influence of cytokines, hyalocytes proliferate<sup>62</sup> on the surface of the retina, resulting in hypercellular membranes. Hyalocytes also recruit cells from the circulation and the retina (glial cells) via the release of connective tissue growth factor and induce collagen gel contraction in response to platelet-derived growth factor and other cytokines,<sup>63,64</sup> causing tangential vitreoretinal contraction.<sup>61</sup>

**FIG. 23.15** Vitreoschisis. Transmission electron microscopy of human hyalocyte (same as in Fig. 23.14B) demonstrating two potential levels of splitting during vitreoschisis. Anomalous posterior vitreous detachment that induces vitreoschisis, which splits the posterior vitreous cortex anterior to the level of hyalocytes (*red dashes*) leaves these cells attached to the macula, resulting in a hypercellular membrane. The lack of attachment to the optic disc allows inward (centripetal) tangential traction and macular pucker. If vitreoschisis splits the posterior vitreous cortex posterior to the level of hyalocytes (*blue dashes*), the remaining membrane is thin and hypocellular. If there is also vitreopapillary attachment, the tangential forces will be outward (initially nasally), opening a central dehiscence and inducing a macular hole. *ILM*, inner limiting membrane; *MP*, macular pucker; *VS*, vitreoschisis; for other abbreviations see Fig. 23.14.

## Inner Limiting Membrane of the Retina

The ILM is a multilaminar structure of variable thickness

topographically. Adjacent to Müller cell footplates is the lamina rara externa (0.03–0.06  $\mu\text{m}$ ) with no species variations or changes with topography or age. The lamina densa is thinnest at the fovea (0.01–0.02  $\mu\text{m}$ ) and thicker in the posterior pole (0.5–3.2  $\mu\text{m}$ ) than at the equator or vitreous base, where Foos<sup>65</sup> found the ILM to be uniformly thin (51 nm) and the lamina rara to be 40 nm thick with traversing fibrils that were denser at sites corresponding to attachment plaques in Müller cells. The ILM is very thin over major retinal vessels (Fig. 23.16) where defects allow glial cells to extend on to the inner retina.<sup>66</sup> Acquired ILM defects are in the foveola, retinal pits, retinal tufts, and retinal lattice. The ILM progressively thickens posteriorly to about 306 nm at the equator and about 1887 nm posteriorly. Müller footplates are less numerous at the equator than at the vitreous base. Posteriorly, no Müller footplates were observed and the inner aspect of the ILM remains smooth, while the outer aspect is irregular. Peripherally, both inner and outer surfaces are smooth.<sup>2,58</sup>

**FIG. 23.16** Vitreoretinal vessel interface. A large gap (*between arrows*) in the inner limiting membrane (ILM) over and adjacent to a retinal artery is seen with a thin, fibroglial premacular membrane over the ILM (*arrowheads*) (periodic acid–Schiff;  $\times 470$ ).

The ILM consists of type IV collagen, more abundant on the vitreous side of the ILM, and laminin, which is more abundant on the retinal side of the ILM (Fig. 23.17). These are associated with glycoproteins,<sup>25,67,68</sup> type VI collagen, which may contribute to

vitreoretinal adhesion, and type XVIII,<sup>69</sup> which binds opticin.<sup>70</sup> Opticin binds to heparan sulfate, contributing to vitreoretinal adhesion.<sup>71</sup> Type XVIII collagen also prevents cell migration from the retina into vitreous.<sup>72</sup> Recent studies<sup>32</sup> have also identified agrin, a basement membrane-associated heparan sulfate proteoglycan similar to collagen XVIII that provides proteolytically cleaved bioactive fragments for modulating cellular behavior<sup>73</sup> at the vitreoretinal interface.

**FIG. 23.17** Human inner limiting membrane (ILM) composition. The human ILM composition is detectable by side-specific labeling of a flat-mounted ILM using antibodies to laminin (A,B) or collagen IV (B,C). Laminin is most abundant on the retinal side of the ILM (A,B), whereas an antibody to collagen IV labels the vitread side (B,C, green). The abundance of both proteins on either the retinal or vitread side is best appreciated by double-labeling (B,C). When dissociated Madin-Darby Canine Kidney (MDCK) Epithelial Cells, corneal or retinal cells were plated on flat-mounted and folded ILMs, the cells adhere preferentially to the retinal side of the ILM (D). The vitread side of this preparation was labeled with an

antibody to the 7S domain of collagen IV a3 (red). The adherent cells were labeled green. (Reprinted with permission from Halfter W, Sebag J, Cunningham ET. Vitreoretinal interface and inner limiting membrane. In: Sebag J, editor. Vitreous – in health and disease. New York: Springer; 2014. p. 1792.)

## **Intervening Extracellular Matrix**

The interface between vitreous and adjacent structures consists of a complex formed by the vitreous cortex and basal laminae, which are firmly attached to their cells.<sup>74</sup> The only part of vitreous not adjacent to a basal lamina is the annulus of the anterior vitreous cortex, which is directly exposed to the zonules and the aqueous humor of the posterior chamber, similar to the surface of articular cartilage, which is exposed to synovial fluid.<sup>53</sup> Zimmerman and Straatsma<sup>75</sup> claimed that there are fibrillar attachments between the posterior vitreous cortex and the ILM. The composition of these fibrillar structures is not known, and their presence has never been confirmed.

It is currently believed that an extracellular matrix “glue” of fibronectin, laminin, and other extracellular matrix components<sup>76</sup> exists between vitreous and retina, causing adhesion to be fascial, as opposed to focal.<sup>62,63</sup> Chondroitin sulfate is present at the sites of strong vitreoretinal adhesion such as the vitreous base and optic disc, forming the rationale for pharmacologic vitreolysis using avidin–biotin complex chondroitinase.<sup>77,78</sup>

## **Topographic Variations**

### **Strength of Vitreoretinal Adhesion.**

Vitreous is attached to all contiguous structures, but is most firmly adherent at the vitreous base,<sup>79</sup> which includes the posterior 2 mm of the pars plana and extends 1–4 mm posterior to the ora serrata, varying with age<sup>80</sup> and topography (more posterior temporally). There are also topographic differences posteriorly, with greater adhesion at the posterior pole than the equator<sup>67</sup> (Fig. 23.18).

**FIG. 23.18** Vitreomacular interface in youth. (A) Dark-field microscopy of the posterior vitreous from a 14-year-old boy. The sclera, choroid, and retina were dissected off the vitreous, which remains attached to the anterior segment. In contrast to adults, there is an extra layer of tissue that remained adherent to the posterior vitreous cortex when the retina was dissected off. The *white arrow* indicates the location of the fovea. The circular structure below this is the prepapillary hole in the posterior vitreous cortex. Emanating from this hole are linear, branching structures (*black arrows*) that correspond to the location of the retinal vessels. *p*, Prepapillary hole; *c*, vitreous cortex. (B) Scanning electron microscopy of the tissue shown in (A) demonstrates round structures adherent to the posterior aspect of this tissue (scale bar: 1  $\mu$ m). (C) Higher magnification of structures shown in (B). (D) Transmission electron microscopy of this specimen identified this tissue as the inner limiting membrane (ILM) of the retina (*arrows*) attached to the posterior vitreous cortex (*p*). The round structures shown in (B)

are identified as the inner portion of Müller (*m*) cells that remained adherent to the posterior aspect of the ILM. The hole on the posterior aspect of these round structures is where the anterior portion of the Müller cell was torn away from the rest of the cell body. At the bottom of the photomicrograph are the collagen fibrils of the vitreous (*Coll*) (original magnification ×20,800).

(Reproduced with permission from Sebag J. Age-related differences in the human vitreoretinal interface. *Arch Ophthalmol* 1991;109:966–71.)

### **Peripheral Fundus and Vitreous Base.**

The vitreous base is a three-dimensional structure that straddles the ora serrata. There is a high density of collagen fibrils oriented at right-angles to the inner surface of the ciliary epithelium and peripheral retina. The fibrils attach to the basement membrane of the nonpigmented epithelium of the pars plana and the ILM of the peripheral retina,<sup>81</sup> intimately interwoven with the intervening extracellular matrix. Within the vitreous base, there are several anatomic variations where vitreoretinal adhesion is firm,<sup>82</sup> adhesions that predispose to retinal breaks<sup>83,84</sup> [see below]

### **Interface Along Major Retinal Blood Vessels.**

The ILM thins and is sometimes absent over major retinal vessels<sup>85,86</sup> (Fig. 23.19). At such points, vitreous may be incarcerated into retina, directly continuous with perivascular tissue, attachments called “vitreoretino-vascular bands,”<sup>87</sup> or “spider-like bodies,”<sup>88</sup> purported to be vitreous fibrils that traverse the ILM and coil about retinal blood vessels. It is common for retinal vessels to be associated with paravascular rarefaction (cystic degeneration), retinal pits and tears, and avulsion of retinal vessels.

**FIG. 23.19** Vitreous interface over retinal vessels. There is a large gap in the inner limiting membrane (ILM) over and adjacent to retinal artery. A glial preretinal membrane (*arrowhead*) originates at a defect in the ILM overlying the retinal vessel. *Arrow* indicates one end of the discontinuous ILM (periodic acid–Schiff stain;  $\times 170$ ). (Reproduced with permission from Clarkson JG, Green WR, Massof D. A histopathologic review of 168 cases of preretinal membrane. *Am J Ophthalmol* 1977;84:1–17.)

### Retinal Sheen Dystrophy.<sup>89</sup>

This ILM dystrophy has cystic spaces under the ILM and in the inner nuclear layer, and numerous areas of separation of the ILM from the retina with filamentous material (Fig. 23.20). Endothelial cell swelling and degeneration, pericyte degeneration, and basement membrane thickening of retinal capillaries suggest that this condition is primarily a retinal vasculopathy with edema, swelling, and degeneration of Müller cells. Alternatively, the primary defect could be in Müller cells.

**FIG. 23.20** Retinal sheen dystrophy. Inferior midperipheral area where the inner limiting membrane (*arrow*) is separated from Müller cells (*M*), and filaments (*asterisk*) and cellular debris (*two asterisks*) are interposed. The outer portion of the inner limiting membrane (*arrowhead*) is separated and remains attached to Müller cells with junctional densities (*circles*) ( $\times 15,000$ ).

### Vitreomacular Interface.

Attachment of vitreous to the macula occurs in an irregular, annular zone of 3–4 mm diameter,<sup>4</sup> generally not visible by clinical examination in normal adults but possibly evident in fetal and young adult eyes and in pathologic conditions. The posterior vitreous cortex is thinner over the macula in a disc-shaped area about 4–5 mm in diameter. Discontinuity of the ILM in the fovea may be a site where glial cells extend onto the inner surface of the retina (Fig. 23.21).

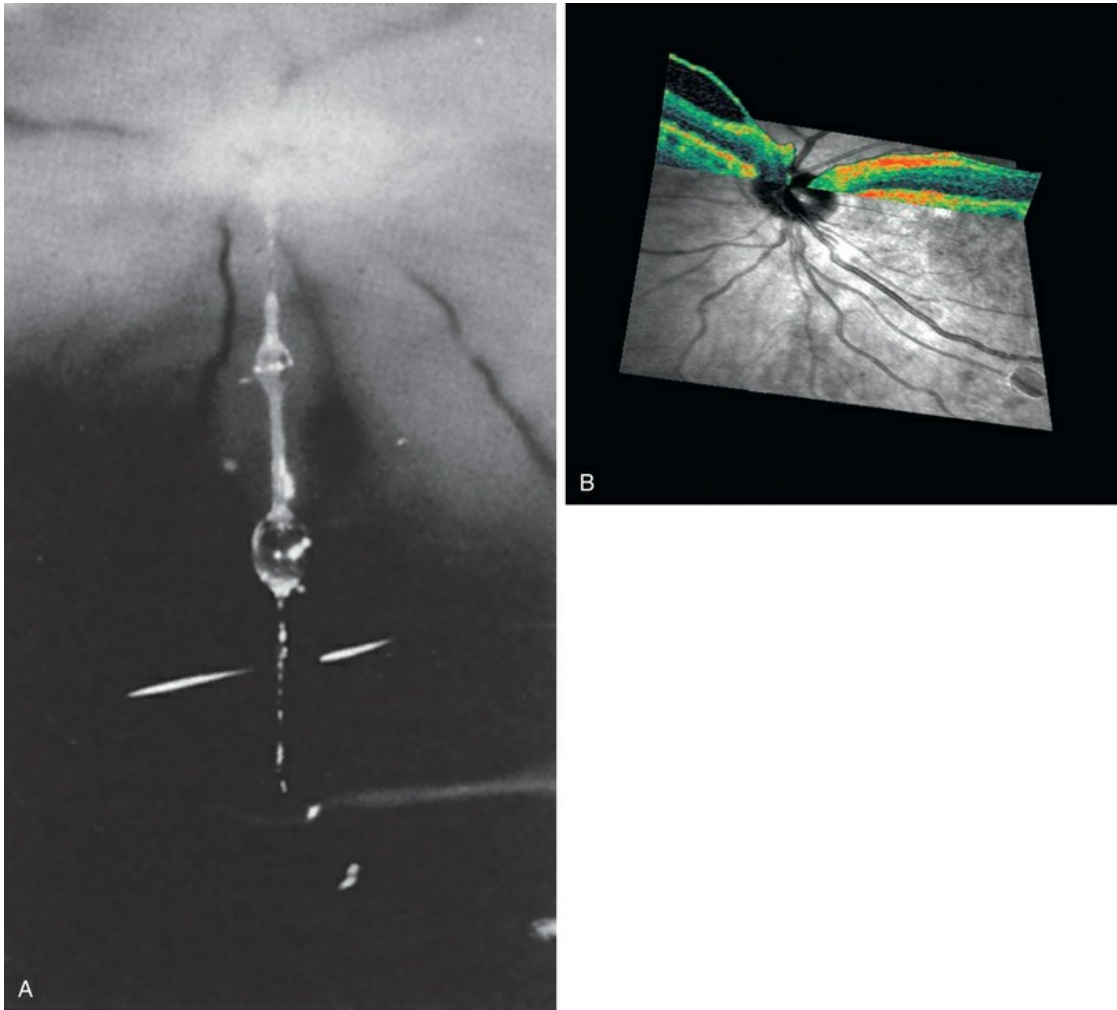

**FIG. 23.21** Vitreomacular interface. The inner limiting

membrane is discontinuous (*between arrows*), at which point glial cells extend on to the inner surface of the retina and form a thin, fibroglial premacular membrane (*arrowheads*) with no apparent contraction (periodic acid–Schiff stain; ×100).

### **Vitreopapillary Interface.**

At the rim of the optic disc the ILM ceases, although the basement membrane continues as the inner limiting membrane of Elschnig.<sup>90</sup> This membrane is 50 nm thick and is believed to be the basal lamina of the astroglia in the optic nerve head. At the centralmost portion of the optic disc the membrane thins to 20 nm, follows the irregularities of the underlying cells of the optic disc, and is composed only of glycosaminoglycans and no collagen (central meniscus of Kuhnt). Given that the ILM prevents the passage of cells,<sup>52</sup> the thinness and chemical composition of the central meniscus of Kuhnt and the membrane of Elschnig may account for frequent cell proliferation from or near the optic disc.

Vitreous attachment to the optic disc may persist even though the vitreous is detached elsewhere<sup>91</sup> (Fig. 23.22). This adhesion may be fortified by epipapillary membranes.<sup>92</sup> The entire complex may subsequently detach, resulting in a ring (Weiss) of tissue composed of fibrous astrocytes and collagen (Fig. 23.23) that flutters in and out of the visual axis, causing “floaters.” Vitreopapillary adhesion contributes to macular holes<sup>93</sup> and any vitreomaculopathy that features intraretinal cystoid spaces,<sup>94</sup> presumably due to the influence of vitreopapillary adhesion upon the vectors of tangential traction at the macula.

**FIG. 23.22** Vitreopapillary adhesion. (A) Gross appearance illustrates partial posterior vitreous detachment with strand of vitreous remaining attached to the optic nerve head. Light reflexes in photograph taken with specimen out of fluid to depict the findings more clearly. (B) Combined optical coherence tomography-scanning laser ophthalmoscopy (OCT-SLO) imaging of vitreopapillary adhesion. The grayscale image is coronal plane imaging by SLO, and the color image is the transverse OCT image through the optic disc.

**FIG. 23.23** Weiss ring. Surgically removed Weiss ring contains fibrous astrocytes that have polarity, basement membrane (*arrowhead*), and large bundles of 10-nm filaments (*arrows*) ( $\times 20,000$ ).

## Physiology

### Biochemical

Vitreous is important in maintaining transparency for maximal photon transmission to the retina. Vitreous may also maintain lens transparency by mitigating the effects of reactive oxygen species on lens proteins and thus preventing cataracts.<sup>95,96</sup> This antioxidant effect is primarily the result of high concentrations of ascorbate in vitreous, an observation originally made in 1944 by Friedenwald and colleagues.<sup>97</sup>

Gisladdottir et al.<sup>98</sup> recently emphasized the influence of vitreous on various physiologic processes and showed that vitrectomy can have considerable effects, both beneficial and harmful.<sup>99</sup> Vitrectomy reduces the risk of retinal neovascularization, but increases the risk of iris neovascularization, reduces macular edema, but stimulates cataract formation. In fact, one approach to mitigating cataract formation following vitrectomy is to leave 3–4 mm of retrolental

vitreous intact.<sup>100,101</sup>

## Biophysical

During ocular saccades, the rotational force of the eye wall is transmitted to the vitreous body via attachments to adjacent structures.<sup>102</sup> During both acceleration and deceleration phases of saccades, vitreous movement lags behind the eye wall, resulting in markedly reduced acceleration.<sup>103</sup> This “slack and lag” results from vitreous viscoelasticity, dampening the force at any given internal vitreous attachment. The inferonasal displacement of the optic disc and the shorter distance between the disc and ora inferiorly and nasally make the relief of torsional strain on equatorial and anterior vitreoretinal attachments greater nasally and inferiorly. Accordingly, the greatest torsional strain on anterior and equatorial vitreous attachments should occur during lateral saccades, with the point of maximum strain located somewhere in the superotemporal quadrant, the site of most frequent retinal tears.<sup>104</sup>

## Pathology

### Age-Related Vitreous Degeneration

#### Liquefaction<sup>105,106</sup>

After age 40 years there is a significant decrease in the gel volume and a concurrent increase in the liquid volume of vitreous, primarily centrally.<sup>107,108</sup> In the posterior vitreous such changes form pockets of liquid vitreous, called “lacunae” (Fig. 23.24). When a single, large pocket forms, the terms “bursa”<sup>27</sup> or “precortical pocket”<sup>109</sup> have been employed. The large posterior lacuna that is present in young individuals is the bursa premacularis, as originally described by Jan Worst and now visualized on Swept Source OCT imaging. Indeed, Balazs and Denlinger<sup>105</sup> found evidence of liquid vitreous after the age of 4 years and observed that, by the time the human eye reaches adult size (ages 14–18 years), 20% of the total volume is liquid vitreous. By the age of 80–90 years more than half the vitreous body is liquid, which can collect in lacunae throughout or a ‘pocket’ posteriorly, a pocket,

sometimes referred to as the posterior precortical vitreous pocket (Fig. 23.24).<sup>109</sup>

**FIG. 23.24** Morphology of human vitreous liquefaction. (A) Gross appearance of central vitreous liquefaction. (B) Dark-field slit microscopy of human vitreous demonstrates the central vitreous has thickened, tortuous fibers. The peripheral vitreous has regions devoid of any structure, which contain liquid vitreous. These regions correspond to so-called lacunae (arrows).

### Pathogenesis of Vitreous Liquefaction.

Changes in collagen<sup>110,111</sup> or the conformation of HA with subsequent crosslinking and aggregation of fibrils into bundles may result in vitreous liquefaction. Free radicals generated by metabolism and/or photons alter vitreous macromolecules and trigger dissociation of collagen from HA, leading to liquefaction.<sup>112</sup> Vitreous liquefaction may also result from changes in the minor glycosaminoglycans and chondroitin sulfate profile of vitreous.<sup>113</sup> Such mechanisms may be at play in myopic vitreopathy<sup>114</sup> where liquefaction occurs unrelated to aging.

Biochemical studies support the age-related rheologic observations described above. Total vitreous collagen content does not change after age 20–30 years. However, collagen concentration in gel vitreous at the ages of 70–90 years (0.1 mg/mL) was significantly greater than at the ages of 15–20 years (0.05 mg/mL;

$p < .05$ ).<sup>105</sup> Since the total collagen content does not change, this is likely due to the decreased volume of gel vitreous that occurs with aging and a consequent increase in the concentration of the collagen in the remaining gel. This concept is supported by the finding that vitreous HA concentration increases until about the age of 20, when adult levels are attained. Thereafter, until 70 years, there are no changes in the HA concentrations of either the liquid or gel compartments. This necessarily means that there is an increase in the HA content of liquid vitreous and a concomitant decrease in the HA content of gel vitreous, since the amount of liquid vitreous increases and the amount of gel vitreous decreases with age.

## **Structural Changes With Aging**

### **Aging of the Vitreous Body.**

The aforementioned rheologic and biochemical alterations induce significant structural changes during aging, consisting of a transition from a clear gel in youth (see [Fig. 23.2](#)) to a fibrous structure in adults (see [Fig. 23.7A](#)). In old age there is advanced liquefaction with thickening and tortuosity of vitreous fibers, and collapse of the vitreous body ([Fig. 23.25](#)). Postmortem studies<sup>115</sup> found such changes in 70% of subjects in the eighth decade. Gel liquefaction occurs earlier and is more extensive in myopic eyes,<sup>114,116</sup> and is accelerated with inflammation, trauma, and arthropathies.<sup>9,117</sup>

**FIG. 23.25** Gross appearance of posterior vitreous detachment in a phakic eye.

### **Aging of the Vitreoretinal Interface.**

With aging there is significant increase in ILM thickness ([Fig. 23.26](#)). This may play a role in weakening of vitreoretinal adhesion with age, although the mechanism of such a phenomenon is presently unclear.

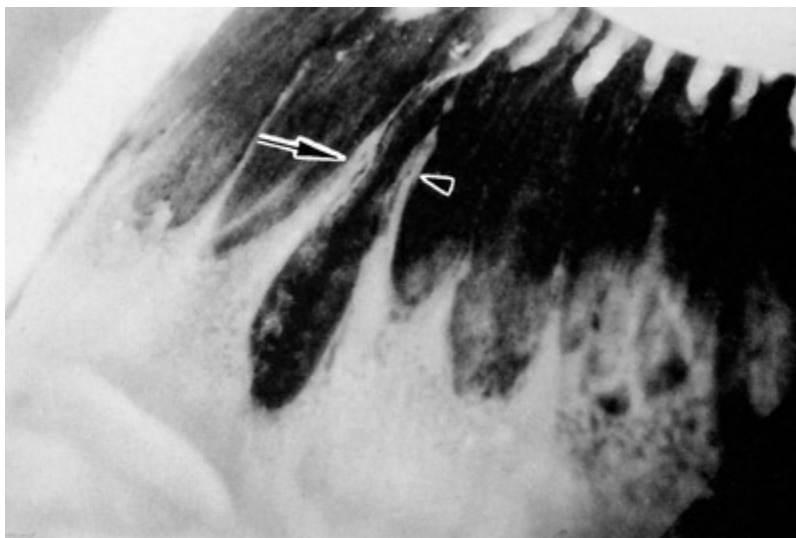

**FIG. 23.26** Age-dependent increase in human internal limiting membrane (ILM) thickness. Transmission electron micrographs show the vitread surface of the retina from a 16-week fetal (A) and from 27-, 54-, and 83-year-old adult human eyes (B–D). The ILM in the fetal eye (A) is 70 nm thick with a typical lamina densa and three-layered ultrastructure. Between 22 and 83 years of age (B–D), the ILM dramatically increases in thickness, becomes highly irregular. The retinal surface no longer contains a distinct lamina densa. The vertical black bars in panels A–D indicate the thickness of the ILM. Panel E shows an adult human retina with the location in the superior posterior pole of the right eye (*boxed*) where the retina was sampled. The graph in panel F shows the age-dependent increase in ILM thickness. Each of the data points represents averages of measurements in one pair of eyes from a single patient. *F*, fovea; *I*, inferior; *N*, nasal; *OP*, optic papilla (disc); *S*, superior; *T*, temporal. Scale bar A–D: 500 nm. (Reprinted with permission from Halfter W, Sebag J, Cunningham ET. Vitreo-retinal interface and inner limiting membrane. In:

### Peripheral Fundus.

Teng and Chi<sup>80</sup> found that the width (in the radial dimension) of the vitreous base posterior to the ora serrata increases with age to over 3.0 mm. There is also posterior migration of the posterior border of the vitreous base with age,<sup>80,118</sup> mostly temporally. In addition, Gartner<sup>119</sup> found “lateral aggregation” of the collagen fibrils in the vitreous base of older individuals. These and the changes listed below play important roles in the pathogenesis of peripheral retinal breaks and rhegmatogenous retinal detachment:

Ora bays<sup>75,82,120</sup> (Fig. 23.27)

**FIG. 23.27** A meridional complex (*arrow*) and dentate process (*arrowhead*) are located at the margin of a non-enclosed ora bay.

Meridional folds<sup>84,121</sup> (Fig. 23.28)

White with pressure, white without pressure<sup>147–154</sup>

Verruca<sup>155</sup> (Fig. 23.39).

**FIG. 23.39** Verruca. Scanning electron microscopy shows cellular elements resembling cells of the inner plexiform layer near the retinal surface. The “trunk” of the verruca extends from the retina to the vitreous cortex. The “branches” of the verruca are intertwined with vitreous collagen fibers. There is local collagen destruction (*arrows*) and interruption of the inner limiting membrane of the retina. (Reproduced with permission from Dunker S, Glinz J, Faulborn J. Morphologic studies of the peripheral vitreoretinal interface in humans reveal structures implicated in the pathogenesis of retinal tears. *Retina* 1997;17:124–30.)

### Posterior Pole – Degenerative Remodeling.

Foos<sup>156</sup> defined a spectrum of changes in the ILM as “degenerative remodeling.” Features include detachment and discontinuity of the ILM with vitreous collagen beneath the ILM (Fig. 23.40), cellular debris with macrophages, and absence of Müller cell attachment plaques. In larger lesions, vitreous may insinuate into degenerative crypts and adhere to the cell membrane of the lining Müller cells that have no basal lamina (Fig. 23.41). In the peripapillary area,

retinal glial cells extend from the optic disc and are continuous with a glial epipapillary membrane that has vitreous fiber incarceration. Roth and Foos<sup>92</sup> observed nasal epipapillary membranes associated with Bergmeister papillae in 27.6% of autopsy eyes.

**FIG. 23.40** Degenerative remodeling. Basal area with vitreous collagen located between detached inner limiting membrane (*arrow*) and glial cell process.

(Courtesy of Tsuyoshi Kimura.)

**FIG. 23.41** Basal zone showing detached and degenerating inner limiting membrane under which the attachment plaques are missing in the surface of Müller cells and vitreous has become incarcerated. Vitreous in degeneration crypt has become firmly adherent to Müller cell (*arrow*) ( $\times 12,600$ ). (Reproduced with permission from Foos RY. Vitreoretinal juncture: topographical variations. Invest Ophthalmol 1972;11:801–8.)

## Posterior Vitreous Detachment (PVD)

Due to inadequate diagnostics,<sup>157</sup> PVD is an inaccurate diagnosis. PVD begins at the posterior pole, perhaps in the perifoveal region.<sup>158</sup> An innocuous PVD is clean separation between the ILM of the retina and the cortical vitreous.<sup>159</sup> Whereas it is widely held that PVD is an “abnormal” event, it is possible that PVD may be a preprogrammed event that mitigates the risks of an attached vitreous, which in patients with diabetic retinopathy or age-related macular degeneration are more dangerous than a PVD.<sup>160</sup> Fortunately, PVD is innocuous in most cases.

### Epidemiology.

The incidence of PVD is 66% between the ages of 66 and 86 years,<sup>161</sup> and 53% after 50 years.<sup>162</sup> Clinical examination,<sup>163</sup> ultrasonography,<sup>164</sup> and monochromatic photography<sup>165</sup> have been standard, but nanotechnologies, such as dynamic light scattering,<sup>166,167</sup> are being developed to improve clinical evaluation.

In a postmortem study<sup>168</sup> of 786 subjects aged  $\geq 20$  years, an upside-down suspension-in-air technique detected a 41% incidence of PVD over 65 years of age. Of 62 aphakic eyes, 94% had partial or complete PVD.

### Symptomatic PVD.

The sudden onset of “floaters” heralds the onset of PVD. A smartphone survey of 603 individuals recently determined that floaters are much more common than previously appreciated, with 76% reporting that they see floaters and 33% claiming visual impairment.<sup>169</sup> Other studies have found that floaters have a significant negative impact on the quality of life.<sup>100,170</sup> It has been

determined that the likely cause is a significant reduction in contrast sensitivity,<sup>101</sup> which is strongly correlated with the degree of vitreous opacification as measured by quantitative ultrasonography.<sup>171</sup> Fortunately, studies<sup>100,101</sup> have shown that within one week of limited vitrectomy contrast sensitivity levels return to normal and remain normal thereafter.

The incidence of retinal tears in patients with acute symptomatic PVD varies from 8 to 15%, to as high as 46%.<sup>172</sup> In a study<sup>173</sup> of 589 patients with “floaters,” diffuse dots, vitreous cells, and hemorrhage were high-risk factors for a retinal tear, since 93 of 176 (52.8%) of eyes with one or more of these risk factors had retinal tears. Novak and Welch<sup>174</sup> reported that, in 172 eyes of 155 patients with acute symptomatic PVD, 31% had complications. Of these 155 patients, PVD developed in the fellow eye in 17 (11%) within 2 years.

## **Anomalous PVD (APVD)**

APVD results from gel liquefaction without concurrent weakening of vitreoretinal adherence, causing various clinical manifestations based upon where vitreous is most liquefied and where the interface is most firmly adherent (Fig. 23.42).

**PATHOPHYSIOLOGY OF ANOMALOUS PVD**

**FIG. 23.42** Schematic of anomalous posterior vitreous detachment (APVD). This diagram demonstrates the various possible manifestations of anomalous PVD. When gel liquefaction and weakening of vitreoretinal adhesion occur concurrently, the vitreous body separates away from the retina without sequelae. If the gel liquefies without concurrent dehiscence at the vitreoretinal interface, there can be various untoward consequences, depending upon where the vitreous is most adherent. If separation of vitreous from retina is full-thickness but topographically incomplete, there can be different forms of partial PVD (right side of diagram). Posterior separation with persistent peripheral vitreoretinal attachment can induce retinal breaks and detachments. Peripheral vitreoretinal separation with persistent full-thickness attachment of vitreous to the retina posteriorly can induce traction

upon the macula, known as the vitreomacular traction syndrome (VMTS). This phenomenon appears to be highly associated with exudative age-related macular degeneration (EXUD AMD). Persistent attachment to the optic disc can induce vitreopapillopathies and also contribute to neovascularization and vitreous hemorrhage in ischemic retinopathies, as well as full-thickness macular hole. If, during PVD, the posterior vitreous cortex splits (vitreoschisis), there can be different effects depending upon the level of the split. Vitreoschisis anterior to the level of the hyalocytes leaves a relatively thick cellular membrane attached to the macula. If there is also separation from the optic disc (present in about 90% of cases), inward (centripetal) contraction of this premacular membrane induces macular pucker. If the split occurs at a level posterior to the hyalocytes, the remaining premacular membrane is relatively thin and hypocellular.

Persistent vitreopapillary adhesion (VPA, present in 87.5% or more of cases) influences the vector of force in the tangential plane, resulting in outward (centrifugal) tangential traction (especially nasally), inducing a macular hole. Some cases of macular hole may develop in the absence of vitreoschisis. (Reproduced

with permission from Sebag J, Niemeyer M, Koss MJ. Anomalous PVD and vitreoschisis. In: Sebag J, editor. Vitreous – in health and disease. New York: Springer; 2014. p. 252.)

## Vitreous Effects of APVD

An important consequence of APVD is vitreoschisis<sup>33,38</sup> (Fig. 23.43) or splitting of the posterior vitreous cortex with forward displacement of the anterior portion of the cortex, leaving the posterior layer attached to the retina. Vitreoschisis has been detected in diabetic retinopathy,<sup>16,175</sup> macular pucker, and macular holes.<sup>37,176,177</sup>

**FIG. 23.43** Vitreoschisis. (A) Ultrasonography of posterior vitreoschisis demonstrates the two layers of the schisis cavity rejoining into full-thickness posterior vitreous cortex (below). (B) Optical coherence tomography-scanning laser ophthalmoscopy imaging of posterior vitreoschisis demonstrates the two walls of the schisis cavity rejoining into full-thickness posterior vitreous cortex (to left). (C) Histopathology of vitreoschisis. Surgical specimen removed from a patient with macular pucker demonstrates the split in the posterior vitreous cortex and rejoining of the two walls into full-thickness posterior vitreous cortex. Hyalocytes (*arrows*) are seen within the posterior vitreous cortex. Note the lack of any additional cellularity on the surfaces of the split posterior vitreous cortex. (Periodic acid–Schiff;  $\times 300$ .) (Panel A reproduced with permission from Green RL, Byrne SF. Diagnostic ophthalmic ultrasound. In: Ryan SJ, editor. Retina. 1st ed. St Louis: Mosby; 1989. Panels B and C reproduced with permission from Gupta P, Yee KMP, Garcia P, et al. Vitreoschisis in macular diseases. Br J Ophthalmol 2011;95:376–80.)

## Peripheral Retinal Effects of APVD

### Retinal Breaks.

Retinal holes unrelated to PVD were observed in 326 (13.9%) of

2334 autopsy cases by Foos et al.<sup>138</sup> Retinal tears (Fig. 23.44) result from fluid movements.<sup>178</sup> Vitreous remains attached to the posterior margin of the retinal flap, which may be avulsed leaving a round or oval hole. The flap of retina remains attached to the posterior surface of the detached vitreous (operculum). Large detached flaps may form a cystic structure (Fig. 23.45).

**FIG. 23.44** Retinal pits and tears. Gross appearance of eye with posterior vitreous detachment, a string of retinal pits along vessels (*arrows*), and three horseshoe-shaped retinal tears (*arrowheads*). (Reproduced with permission from Green WR. Pathology of the vitreous. In: Frayer WC, editor. Lancaster Course in Ophthalmic Histopathology, unit 8. Philadelphia: FA Davis; 1981.)

**FIG. 23.45** Large retinal tear. Microscopic features include rounded anterior (*arrowheads*) and posterior margins of the hole and coiled-up, detached operculum (*arrow*) that remains attached to the posterior surface of the detached vitreous (periodic acid–Schiff stain;

×16). (Reproduced with permission from Green WR. Pathology of the vitreous.  
In: Frayer WC, editor. Lancaster course in ophthalmic histopathology, unit 8.  
Philadelphia: FA Davis; 1981.)

The clinical incidence of retinal tears<sup>179</sup> varies from 7.2%<sup>180</sup> to 5.8%,<sup>181</sup> with a high of 13.75%<sup>121</sup> and a low of 0.59%.<sup>182</sup> Postmortem incidences were 3.9%,<sup>183</sup> 8.6%,<sup>184</sup> 4.7%,<sup>185</sup> 8.8%,<sup>196</sup> 3.7%,<sup>187</sup> and 7.3%.<sup>138</sup> Although the role of retinal tears in causing retinal detachment (RD) is undisputed, management is controversial. Byer<sup>188</sup> concluded that prophylactic treatment is not justified for asymptomatic retinal breaks in phakic eyes. However, in a natural history study of 166 eyes with retinal breaks, Davis<sup>146</sup> observed that 31 (18%) progressed to RD. Neumann and Hyams<sup>189</sup> reported that 2% of 153 eyes with retinal breaks developed RD. The incidence of retinal tears is much greater than RD, which varies between 9 (0.009%)<sup>190</sup> and 24.4 (0.02%) per 100,000 per year.<sup>191</sup> Benson<sup>192</sup> promoted patient education while Combs and Welch<sup>193</sup> concluded that prophylactic treatment of acute horseshoe tears with vitreous traction significantly reduces the incidence of RD. A particularly high-risk group are patients with vitreous hemorrhage that obscures fundus visualization. Ultrasound may be an effective means of identifying retinal tears in such eyes,<sup>194</sup> but misdiagnosis at presentation bodes poorly since there is a 67% incidence of retinal tears.<sup>195</sup>

## Macular Effects of APVD

### Vitreomacular Traction.

For vitreomacular traction syndrome<sup>4,31,36</sup> see Fig. 23.49.

**FIG. 23.49** Vitreomacular traction syndrome. This extreme example of anomalous posterior vitreous detachment with persistent full-thickness adhesion of the posterior vitreous cortex to the macula has induced sufficient traction upon the macula to induce prominent elevation of the central macula. Typically, there is only thickening of the macula without detachment.

### **Exudative Age-Related Macular Degeneration.**

Recent studies<sup>198–200</sup> have determined that vitreomacular adhesion may be a risk factor for exudative age-related macular degeneration. Several subsequent studies have confirmed these findings. It has further been recently discovered that persistent vitreomacular adhesion increases the required number of intravitreal anti-VEGF injections and may limit efficacy.<sup>201</sup>

### **Cystoid Macular Edema.**

For cystoid macular edema,<sup>202–208</sup> see [Figs. 23.50](#) and [23.51](#).

**FIG. 23.50** Cystoid macular edema with cystic spaces in the outer plexiform and inner nuclear layers (hematoxylin and eosin,  $\times 45$ ).

**FIG. 23.51** Irvine–Gass syndrome. Area near posterior pole showing edema and retinal phlebitis (*arrow*) (hematoxylin and eosin,  $\times 185$ ). (Reproduced with permission from

## Macular Cysts.<sup>209</sup>

Macular cysts that result from chronic edema (Fig. 23.52) need to be distinguished from the cystoid spaces created by vitreous traction in macular holes (Figs. 23.53 and 23.54), and macular pucker with vitreopapillary adhesion.<sup>93,94,210</sup>

**FIG. 23.52** Cystic edema (*arrows*) and a large cyst (*asterisk*) are present in the macula (hematoxylin and eosin,  $\times 40$ ). (Reproduced with permission from Green WR. Retina. In: Spencer WH, editor. Ophthalmic pathology: an atlas and textbook, vol. 2. Philadelphia: WB Saunders; 1985.)

**FIG. 23.53** Lamellar macular hole. Combined optical coherence tomography-scanning laser

ophthalmoscopy imaging of a partial-thickness macular hole with adjacent cystoid spaces.

**FIG. 23.54** Full-thickness macular hole. (A) Combined optical coherence tomography-scanning laser ophthalmoscopy imaging of macular hole demonstrating anomalous posterior vitreous detachment, a pseudo-operculum, pericentral intraretinal cystoid spaces, and a thin premacular membrane, particularly visible to the right. (B) Microscopy shows macular hole, detached posterior vitreous cortex (*arrowheads*) with adherent pseudo-operculum (\*), cystoid spaces in outer plexiform and inner nuclear layers, a small area of surrounding retinal detachment, demarcation chorioretinal adhesions on both sides of the elevated retina, and a premacular membrane particularly visible to the right (hematoxylin

and eosin, ×55). (C) Higher-power view of panel B showing a thin hypocellular preretinal membrane (*arrowhead*), prominent cystoid spaces, and demarcation adhesion (*arrow*) (hematoxylin and eosin, ×140). (D) Detached pseudo-operculum demonstrating lack of neural retina elements. (E) Composite low-power view of operculum. Thicker cellular ends are connected by a thinner segment. A thin collagenous layer along this region (cortical vitreous) identified the inner vitreal surface (*arrows*) of the operculum. A short segment of ILM (*circle*) is present in an area of folding (×550). (Panel C reproduced with permission from Frangieh GT, Green WR, Engel HM. A histopathologic study of macular cysts and holes. *Retina* 1981;1:311–36. Panel E reproduced with permission from Madreperla SA, McCuen BW II, Hickingbotham D, et al. Clinicopathologic correlation of surgically removed macular hole opercula. *Am J Ophthalmol* 1995;120:197–207.)

## Macular Holes.

Macular holes are surrounded by a gray ring of cystoid spaces and slightly elevated retina, thinning and depigmentation of the underlying retinal pigment epithelium (RPE), yellow nodular opacities at the level of the RPE, a preretinal membrane in all cases with eccentric retinal pucker in 40%, and an operculum in 25% of patients (see [Fig. 23.54](#)). Macular hole occurred in 8 of 37 (22%) fellow eyes in one study.<sup>211</sup> Avila et al.<sup>212</sup> reported axial traction as the cause, while Morgan and Schatz<sup>213</sup> proposed that involutonal macular thinning predisposes to a macular hole.

## Histopathology and Pseudo-Operculum.

Minor RPE hypertrophy and hyperplasia occur in the area of lamellar and full-thickness macular hole. At the onset of macular hole, there is likely vitreoschisis,<sup>32</sup> leaving a thin hypocellular layer of the posterior vitreous cortex attached to the macula<sup>160,176,214</sup> ([Fig. 23.55](#)). There is little cellular proliferation,<sup>215</sup> suggesting that fluid countercurrents or vitreoschisis ([Fig. 23.56](#)) may be important. Healing of macular hole following surgery<sup>216</sup> does, however, involve glial cell proliferation<sup>217</sup> and Müller cell processes.<sup>218</sup> Macular hole opercula are rarely composed of retinal tissue (see [Fig. 23.54](#)), hence the name “pseudo-operculum.”

**FIG. 23.55** Macular hole with extensive photoreceptor cell atrophy. A thin, tapered layer of cortical vitreous with a hypocellular membrane on its inner surface (*arrowhead*) apparently exerts tangential traction with elevation of the hole margins (periodic acid–Schiff,  $\times 340$ ). (Reproduced with permission from Guyer DR, Green WR. Idiopathic macular holes and precursor lesions. In: Franklin RM, editor. Proceedings of the 1992 New Orleans Academy of Ophthalmology. New York: Kugler; 1993.)

**FIG. 23.56** Membranes removed during macular hole surgery. (A) Tissue removed at surgery for macular hole demonstrates a hypocellular membrane with spindle and stellate-shaped cells (Millipore filter, modified Papanicolaou;  $\times 340$ ). (B) Inner limiting membrane (ILM) of retina. After peeling off the retina, this tissue demonstrates the characteristic “scrolled” configuration of the ILM following chromodissection. This does not occur with preretinal membranes (A), only with the ILM. (Millipore filter, modified Papanicolaou stain;  $\times 340$ .)

## Pathogenesis.

There have been various theories of macular hole pathogenesis: trauma, foveal degeneration, vitreous traction, and involutional thinning with PVD. It is clear from surgical experience<sup>219</sup> that vitreous is the cause of macular hole. Johnson and Gass<sup>220</sup> formulated the tangential traction theory by suggesting that shrinkage of the prefoveal vitreous induces macular hole formation in four stages. There are three possible mechanisms of tangential vitreous traction: (1) fluid vitreous movements and countercurrents; (2) cellular remodeling of cortical vitreous; and (3) contraction of a cellular membrane on the tapered cortical vitreous after vitreoschisis.<sup>30,35,36</sup> Combined OCT-scanning laser ophthalmoscopy (OCT-SLO) imaging found vitreoschisis in half of eyes with macular hole<sup>33,176</sup> (Fig. 23.57). In an ultrastructural study of epiretinal tissue removed during vitrectomy for impending macular holes, Smiddy et al.<sup>206</sup> observed cortical vitreous in all eyes. VPA may be important, as this is present in 88.2% of macular hole eyes.<sup>93,94</sup> VPA influences the vector of tangential forces on the macula and induces outward (centrifugal) traction, opening a central dehiscence. In macular pucker, there is usually no VPA and the vector of tangential traction is inward (centripetal), causing a macular pucker.

**FIG. 23.57** Vitreoschisis in macular hole. Optical coherence tomography-scanning laser ophthalmoscopy imaging of vitreoschisis in a stage III macular hole. The inner wall of the schisis cavity (*white arrow*) is lifted off the retinal surface but remains adherent to the optic disc. The outer wall of the schisis cavity places centrifugal (outward) tangential traction of the macula opening a central dehiscence and inducing the macular hole. This layer must be removed at surgery, often done with chromodissection. *Black*

*arrow* indicates the outer layer of the vitreoschisis split in the posterior vitreous cortex, which is still attached to the retina.

Some surgeons<sup>221</sup> have advocated prophylactic surgery in symptomatic fellow eyes. However, a multicenter trial failed to demonstrate efficacy for vitrectomy in such eyes,<sup>222</sup> and thus surgery is not routinely performed.

## **Optic Disc Effects**

Anomalous PVD with persistent adhesion to the optic disc can cause vitreopapillary traction inducing hemorrhage,<sup>223</sup> exacerbating neovascularization in proliferative diabetic vitreoretinopathy,<sup>224</sup> and even inducing gaze-evoked visual disturbances.<sup>225</sup> Vitreopapillary adhesion also plays a role in the formation of macular holes and cysts.<sup>93,94,210</sup>

## **Vitreoretinal Changes After Lens Extraction**

### **Structural**

Opacification<sup>226</sup>

Vitreous hemorrhage (APVD) with subsequent liquefaction

Vitreous incarceration with vitreoretinal traction<sup>227</sup> (Fig. 23.58).

**FIG. 23.58** Traction retinal detachment in eye of a 23-year-old man with a previous history of traumatic cataract who underwent surgery complicated by vitreous incarceration in the wound. A vitreous strand (*arrow*) is seen attached to the anterior retina that is under traction and “tented” (*arrowhead*) (periodic acid–Schiff,  $\times 60$ ). (Reproduced with permission from Smiddy WE, Green WR. Retinal dialysis: pathology and pathogenesis. *Retina* 1982;2:94–116.)

## Biochemical

Reduction of vitreous HA concentration<sup>228</sup> results in decreased viscosity<sup>229</sup> and shock absorption. This can be prevented by maintaining an intact posterior capsule after lens surgery.

## PVD Following Lens Extraction<sup>230,231</sup>

PVD occurred in 84% following intracapsular cataract extraction, 76% following extracapsular cataract extraction (ECCE) and surgical capsular discission, and in 40% of eyes following ECCE with an intact posterior capsule. The incidence of rhegmatogenous RD increases following YAG capsulotomy.<sup>232</sup>

## Inflammatory

Iridovitreous synechiae have been associated with mild cyclitis, vitritis, retinal phlebitis, and cystoid macular edema.<sup>231</sup>

## Vitreoretinal Effects of Trauma

### Blunt Trauma

Blunt trauma may be transmitted to the retina in a direct and contrecoup fashion, resulting in a variety of rhegmatogenous sequelae (Fig. 23.59).<sup>233</sup> Dialysis at the anterior border of the vitreous base typically occurs inferonasally. Less common are avulsion of the vitreous base and retinal dialysis at the posterior border of the vitreous base. Concussive forces following blunt trauma can induce retinal edema, known as commotio retinae.

A

B

**FIG. 23.59** (A) Retinal lesions caused by blunt trauma transmitted to retina. *A*, Dialysis at anterior border of vitreous base. *B*, Avulsion of vitreous base. *C*, Macular hole. *D*, Horseshoe-shaped tear on posterior margin of vitreous base. *E*, Horseshoe-shaped tear at posterior end of a meridional fold. *F*, Horseshoe-shaped tear at equator. *G*, Tear with operculum in overlying vitreous. *H*, Retinal dialysis at posterior border of vitreous base. (B) Retinal dialysis at posterior aspect of vitreous base with retinal pigment epithelium extending through the dialysis, along the posterior surface of vitreous

(*arrowheads*), and then along the anterior surface of the retina (*arrows*) (hematoxylin and eosin,  $\times 20$ ). (Panel A modified with permission from Cox MS, Schepens CL, Freeman HM. Retinal detachment due to ocular contusion. *Arch Ophthalmol* 1966;76:679–85. Panel B reproduced with permission from Clarkson JG, Green WR, Massof D. A histopathologic review of 168 cases of preretinal membrane. *Am J Ophthalmol* 1977;84:1–17.)

## Shaken-Baby Syndrome (Fig. 23.60B)

Ocular effects are peripapillary hemorrhage, circular macular folds with a sub-ILM schisis cavity containing serosanguinous material<sup>234</sup>, and vitreous detachment with ILM throughout the fundus (Fig. 23.60A), especially at the vitreous base.

**FIG. 23.60** Shaken-baby syndrome. (A) Sub-inner limiting membrane schisis cavity containing serosanguineous material results from severe trauma in a young individual with firm vitreoretinal adherence (hematoxylin and eosin,  $\times 457$ ). (B) Extensive subdural hemorrhage that extends from the adjacent sclera (*arrows*). A peripapillary retinal hemorrhage (*arrowhead*) is present (hematoxylin and eosin,  $\times 183$ ).

## Posterior Penetrating and Perforating Trauma<sup>235</sup>

Wound healing at the perforation site allows fibrocellular proliferation into the eye, inducing traction RD (Fig. 23.61). Histopathologic studies revealed cyclitic and periretinal membranes.<sup>236</sup> Intraocular proliferation starts 2–4 days after injury,<sup>237</sup> PVD develops at 1–2 weeks,<sup>238</sup> and traction RD occurs at 7–11 weeks. Proliferation can be prevented by vitrectomy,<sup>239</sup> less

hazardous after 2 weeks because of the development of PVD<sup>240,241</sup> and more effective if complete.<sup>242</sup> Yet, Miller et al.<sup>243</sup> found that vitreous may play a role in normal healing of retinal wounds.

**FIG. 23.61** Posterior perforation with fibrous tissue ingrowth (*arrow*) and traction retinal detachment (hematoxylin and eosin,  $\times 25$ ).

## Periretinal Cell Proliferation

### Premacular Membranes

Premacular membranes (PMMs) occur in the absence of associated conditions and are most often the result of vitreoschisis,<sup>36</sup> where APVD<sup>35</sup> splits the posterior vitreous cortex leaving the outermost layer attached to the macula. The level of this split can vary, as do the consequences (see Fig. 23.42) from no effects, such as in the case of “cellophane” premacular membranes (Fig. 23.62) that have no contractile features, to contractile premacular (previously called

“epiretinal”) membranes that induce macular pucker.<sup>61,160,176</sup> Smiddy et al.<sup>244</sup> observed the principal cell to be RPE in these cases, although it is likely that many of these cells are actually hyalocytes (see Figs. 23.6 and 23.14) and circulating monocytes recruited from retinal and choroidal circulations.<sup>34,176</sup> Secondary premacular membranes occur in association with inflammation, accidental or surgical trauma, and retinovascular disease. Fibrous astrocytes are the predominant cell in secondary preretinal macular membranes (PMMs).

**FIG. 23.62** Simple premacular membrane. (A) Section illustrates thin, hypocellular epiretinal membrane (*arrow*) and wrinkling of inner limiting membrane (ILM) (hematoxylin and eosin,  $\times 310$ ). (B) The ILM is discontinuous (*arrow*), at which point glial cells extend on to the inner surface of the retina and form a thin, fibroglial epiretinal membrane (*arrowhead*) with no

apparent contraction (periodic acid–Schiff,  $\times 300$ ). (Panel

A reproduced with permission from Clarkson JG, Green WR, Massof D. A histopathologic review of 168 cases of preretinal membrane. *Am J Ophthalmol* 1977;84:1–17.)

Macular pucker (Fig. 23.63) results from PMMs that induce centripetal tangential (inward to the fovea) traction upon the macula. Macular pucker can have as many as four separate centers of retinal contraction<sup>245</sup> (Fig. 23.64). Eyes with three or four contraction centers had significantly more macular thickening and a higher prevalence of intraretinal cysts than eyes with one or two contraction centers.

**FIG. 23.63** Macular pucker. (A) Coronal-plane optical coherence tomography (color) and scanning laser ophthalmoscopy (grayscale) imaging of macular

pucker with prominent retinal striae in a radial configuration centered in the fovea. (B) Thick fibroglial membrane (*arrow*) that apparently contracted and produced wrinkling of the inner limiting membrane (ILM) (*arrowheads*) and a large gap (*asterisk*) in the ILM (periodic acid–Schiff,  $\times 90$ ). (Reproduced with permission from Clarkson JG, Green WR, Massof D. A histopathologic review of 168 cases of preretinal membrane. Am J Ophthalmol 1977;84:1–17.)

**FIG. 23.64** Multifocal macular pucker. Coronal plane optical coherence tomography-scanning laser ophthalmoscopy (OCT-SLO) imaging with superimposition of OCT (color) onto SLO (grayscale) images. (A) Unifocal macular pucker. (B) Bifocal macular pucker with two centers (*arrows*) of retinal

contraction. (C) Trifocal macular pucker with three centers (*arrows*) of retinal contraction. (D) Four distinct centers (*arrows*) of retinal contraction are present.

(Panels A and C are reproduced with permission from Gupta P, Sadun AA, Sebag J. Multifocal retinal contraction in macular pucker analyzed by combined optical coherence tomography/scanning laser ophthalmoscopy. *Retina* 2008;28:447–

52.)

## **Retroretinal Membranes**

These membranes typically occur after RD when RPE grows in sheets over the undersurface of the retina. Strands of fibrous tissue contract and can prevent retinal reattachment.<sup>246</sup>

## **Complex Membranes**

Complex membranes ([Fig. 23.65](#)) develop after RD surgery or after trauma. Most often the result of proliferative vitreoretinopathy (PVR),<sup>247</sup> contraction of this proliferative tissue causes traction RD. Anterior PVR features anterior-loop contraction<sup>248</sup> (see [Fig. 23.9](#)).

**FIG. 23.65** Complex premacular membrane. Fibrous astrocytes in thick epiretinal membrane after anterior-segment surgery and severe intraocular inflammation. Membrane contains new collagen (*asterisk*) and fibrocytes in addition to fibrous astrocytes. Multiple layers of fibrous astrocytes line inner (vitreal) surface (*between arrows*). These cells show polarity with basement membrane (*circles* and bottom right inset), and cells contain numerous cytoplasmic filaments measuring 8–10 nm (*rectangle* and bottom left inset). Blood vessels (*arrowheads*) are also present in membrane (top left and top right insets). (Main figure  $\times 6600$ ; top insets, paraphenylenediamine hydrochloride stain; top left inset  $\times 160$ ; top middle and top right insets  $\times 250$ ; bottom left inset  $\times 50,000$ ; bottom right inset  $\times 41,000$ .) (Reproduced with permission from Michels RG. A

Histopathologically, retinal glial cells gain access to the inner retinal surface via ILM discontinuities, such as at the optic disc, foveola, along major vessels, and at retinal tufts. Acquired sites of ILM discontinuity include retinal tags, pits (lamellar holes), holes, and tears (Fig. 23.66), avulsed retinal vessels, areas of degenerative remodeling, and retinal lattice. Retinal glial cells are the principal cells in membranes at the optic disc, in simple PMMs, in most secondary membranes associated with inflammatory diseases or retinovascular disease, after photocoagulation or RD surgery, and in retinitis pigmentosa. RPE gains access to the vitreous via retinal breaks, the ora serrata, and retinal lattice. RPE can also migrate through intact retina. RPE is the principal cell in PVR (Fig. 23.67), but glial cells are present in about 50% of cases. Myofibrocytes (Fig. 23.68) were observed by electron microscopy in 91% of membranes studied by Kampik et al.,<sup>249</sup> and actin has been observed in cells of PVR membranes.<sup>250</sup>

**FIG. 23.66** Glial cell proliferation. (A) Peripheral retinal hole with glial membrane extending on the inner surface of the retina anteriorly and posteriorly (periodic acid–Schiff,  $\times 65$ ). (B) Higher-power view of anterior margin of retinal tear, showing glial preretinal membrane (*arrow*) extending along the inner surface of the inner limiting membrane (*arrowheads*) (periodic acid–Schiff;  $\times 190$ ). (Reproduced with permission from Clarkson JG, Green WR, Massof D. A histopathologic review of 168 cases of preretinal membrane. Am J Ophthalmol 1977;84:1–17.)

**FIG. 23.67** Retinal pigment epithelium (RPE) cells in proliferative vitreoretinopathy. Pigmented membrane removed from the peripapillary area is composed of RPE arranged in a monolayer. Well-developed basement membrane (*arrows*) and basal laminae infoldings (*circle*, and top right inset) are present along the retinal surface. Extensive villous processes are present on the apical side of cells. Numerous apically located subplasmalemmal microfilaments that measure 4–5 nm and have fusiform densities are present (left insets). Occasional cytoplasmic lipid vacuoles are seen (*arrowhead*). (Main figure,  $\times 4500$ ; top left inset,  $\times 17,000$ ; top right inset,  $\times 17,000$ ; bottom left inset,  $\times 36,000$ .) (Reproduced with permission from Michels RG. A clinical and histopathologic study of epiretinal membranes affecting the macula and removed by vitreous surgery. *Trans Am Ophthalmol Soc* 1982;80:580–656.)

**FIG. 23.68** Myofibrocyte. There is a characteristic spindle shape that contains large aggregates of subplasmalemmal microfilaments measuring 4–5 nm and small fusiform densities (*circle* and inset). (Main figure,  $\times 14,000$ ; inset,  $\times 44,000$ .) (Reproduced with permission from Michels RG. A clinical and histopathologic study of epiretinal membranes affecting the macula and removed by vitreous surgery. *Trans Am Ophthalmol Soc* 1982;80:580–656.)

Incomplete vitrectomy, intraoperative hemorrhage,<sup>237</sup> and excessive cryopexy<sup>251</sup> render most cases of PVR an iatrogenic disease. Fibronectin and platelet-derived growth factor are the chemoattractants that stimulate migration of RPE<sup>252</sup> and glial cells.<sup>253</sup> Incomplete vitrectomy leaves behind hyalocytes (see [Figs. 23.6](#) and [23.14](#)), which are also the first cells to be exposed to these growth factors and other stimuli. When stimulated, these cells become phagocytic ([Fig. 23.69](#)). These resident macrophages play an important role in early PVR pathogenesis. Thus, targeting these cells for pharmacotherapy, similar to what has been done during vitrectomy for RD,<sup>254</sup> may significantly mitigate PVR. Alternatively,

eliminating the role of vitreous via pharmacologic vitreolysis<sup>78,255</sup> will have a great impact on PVR and many of the aforementioned conditions.

**FIG. 23.69** Phagocytic hyalocyte. Macrophage-like cell with multiple pleomorphic inclusions contained in membrane-bound secondary lysosomes (*arrows*) is most likely a hyalocyte embedded within the collagen fibrils of the posterior vitreous cortex. (Main figure,  $\times 12,000$ ; inset,  $\times 22,600$ .) (Reproduced with permission from Michels RG. A clinical and histopathologic study of epiretinal membranes affecting the macula and removed by vitreous surgery. *Trans Am Ophthalmol Soc* 1982;80:580–656.)

Genetic Modification

**Conclusions**

Oxidative stress has been implicated in the development and progression of retinal diseases. This chapter will focus on three forms of retinal pathology that are related to oxidative stress: age-related macular degeneration (AMD), diabetic retinopathy (DR), and inherited retinal degenerations. We will discuss specific mechanisms of oxidative stress that affect the retinal pigment epithelium (RPE), retinal vasculature, photoreceptors, and mitochondria. We will also consider the evidence linking oxidative stress and inflammation in the pathogenesis of retinal disease. Finally, we will explore potential therapies targeting oxidative stress in the retina.

## Overview of Oxidative Stress in the Retina

Reactive oxygen species (ROS) are a major source of retinal oxidative stress. These highly reactive particles include free radicals and nonradical oxidants such as peroxides and singlet oxygen. Free radicals such as the hydroxyl radical ( $\text{OH}\bullet$ ), hydroperoxyl radicals ( $\text{HO}_2\bullet$ ), superoxide anion ( $\text{O}_2^-\bullet$ ), and lipid peroxy radicals, are strong oxidizing agents with an unpaired electron in their outer shells. Peroxides (e.g., hydrogen peroxide [ $\text{H}_2\text{O}_2$ ], lipid peroxides) and singlet oxygen ( $^1\text{O}_2$ ) have a full complement of electrons in an unstable state.<sup>1</sup>

Under physiologic conditions, the body produces ROS through normal metabolic processes such as glycolysis and the Krebs cycle. Aging and disease may disturb the balance between ROS generation and clearance, resulting in oxidative damage to macromolecules.<sup>2</sup> The majority of endogenous ROS are produced

by mitochondria through the electron transport chain, which converts 2–3% of all utilized oxygen into ROS.<sup>3</sup> Stimuli such as aging, inflammation, irradiation, air pollutants, and cigarette smoke lead to increased ROS, and thus increased cellular oxidative injury.<sup>1,4,5</sup>

The body's defenses against increasing oxidative stress consist of small antioxidant molecules including vitamin C, vitamin E, and carotenoids, as well as larger antioxidant enzymes, such as superoxide dismutase (SOD), glutathione peroxidase (GSHPx), and catalase. Most ROS are eliminated immediately by these antioxidant enzymes. For example, the superoxide anion, produced by mitochondria during the electron transport stage of cellular respiration, is converted to the less noxious hydrogen peroxide molecule ( $H_2O_2$ ) by SOD.<sup>1</sup> The smaller antioxidant molecules (e.g., vitamin C [ascorbate], vitamin E [tocopherol], and carotenoids) reduce ROS by acting directly on free radicals.

As most free radical chain reactions are prevented by free radical-scavenging molecules, it appears that free radicals are often not the direct cause of oxidative damage but rather act to initiate further oxidative damage by nonradical oxidants. The redox hypothesis describes radical-free oxidative stress in which disrupted thiol redox circuits interfere with regulation of cellular redox status, affecting cell signaling and homeostasis. Redox-sensitive thiols include the amino acid cysteine (Cys), the Cys-derived disulfide cystine (CySS), the Cys-containing tripeptide glutathione (GSH), and glutathione disulfide (GSSG). Sulfur redox couples act as “on/off” switches regulating gene expression and protein function. Because the Cys/CySS and GSH/GSSG couples are not in equilibrium, it is plausible that abnormal levels of nonradical oxidants could be sufficient to disrupt normal function.<sup>6</sup>

The retina is particularly vulnerable to oxidative stress because of its high oxygen consumption and high proportion of polyunsaturated fatty acids (PUFAs).<sup>1,2</sup> High light exposure and phagocytosis in the RPE contribute to the oxidative burden of the retina. The turnover rate of photoreceptors is high, with these cells shedding about 10% of their outer segment discs each day. The disc membranes, in particular the PUFAs, are subject to peroxidation, which is highly damaging to the RPE. This can be more impactful in

the central retina, the macula, where there is a high level of metabolic activity and where light exposures are higher. There the macular pigment, which protects against ROS in the retina, is composed of two carotenoids: lutein, which exists as a single stereoisomer, and zeaxanthin, which exists in two predominant isomeric forms, zeaxanthin and meso-zeaxanthin. Lutein and zeaxanthin can quench the reactive singlet oxygen and form an optical filter that blocks highly damaging blue light from reaching the photoreceptors.<sup>1</sup>

## Retinal Diseases Related to Oxidative Stress

Oxidative stress contributes to diseases of the retina, including age-related macular degeneration, diabetic retinopathy, and inherited retinal degenerations (Table 24.1). To set the stage for detailed discussion of the underlying mechanisms of oxidative damage to the retina, we will discuss the pathology and evidence for a role of oxidative stress in each of these diseases.

**TABLE 24.1**  
**Oxidative Stress in the Pathophysiology of Common Retinal Diseases**

Disease	Supporting Evidence
AMD	<p>AMD risk factors (e.g., aging, smoking) linked to increased systemic oxidative stress<sup>1,2,4,74,75</sup></p> <p>Oxidative modifications to proteins and DNA in Bruch's membrane, drusen, and RPE cells<sup>23-26</sup></p> <p>Light exposure associated with increased generation of ROS and AGEs<sup>74,75</sup> and increased risk of AMD<sup>1,2</sup></p> <p>Colocalization of RAGE with AGE deposits and macular disease in AMD retinas<sup>77</sup></p> <p>RAGE-induced secretion of VEGF in RPE cells<sup>77</sup></p> <p>Low macular pigment associated with AMD<sup>27-29</sup></p> <p>Dietary or supplemental intake of antioxidants (e.g., vitamins, carotenoids) and zinc linked to lower risk of AMD progression<sup>21,22,30,32</sup></p> <p>Decreased viability and increased proliferation in cultured RPE and choroidal endothelial cells exposed to the oxidant <i>t</i>-BHP<sup>90</sup></p> <p>Increased proliferation and VEGF upregulation in choroidal endothelial cells exposed to AGEs<sup>76,77,91</sup></p>

AGE, advanced glycation endproduct; AMD, age-related macular degeneration; ERGs, electroretinograms; GSH, glutathione; GSHPx, glutathione peroxidase; GST, glutathione-S-transferase; NF-κB, nuclear factor-κB; RPE, retinal pigment epithelium; ROS, reactive oxygen species; RAGE, receptor of AGEs; *t*-BHP, tert-butyl hydroperoxide; VEGF, vascular endothelial growth factor.

## Age-Related Macular Degeneration

AMD, the leading cause of irreversible vision loss in older individuals in the Western world, is a complex disease influenced by factors such as genetics, demographics, and environmental exposures. Approximately 6.5% of individuals in the United States over the age of 40 (7.2 million people) show signs of any AMD, and 0.8% have sight-threatening advanced stages of the disease.<sup>7</sup> With the prevalence of AMD increasing with older age, and the anticipated aging of the American population, cases of advanced AMD are expected to increase to over 3 million by 2050.<sup>8</sup>

AMD can be divided into an early, typically asymptomatic, form and a late form that often results in severe central vision loss. In the early stages of AMD, whitish-yellow waste deposits called drusen accumulate in the macula, usually localized between the RPE and Bruch's membrane. These deposits may be small and discrete (hard drusen) or larger and more confluent (soft drusen). Drusen may also be present between the photoreceptors and RPE or within the photoreceptor cell layer (reticular drusen).<sup>9,10</sup> Histologically, drusen consist of numerous proteins (e.g., complement, immunoglobulins,

amyloid- $\beta$ ) and lipids (e.g., phospholipids, cholesterol, apolipoproteins).<sup>11,12</sup> Early dry AMD may develop into advanced dry or advanced wet AMD. Advanced dry AMD (geographic atrophy) is marked by cell death in the choriocapillaris and overlying RPE. Advanced wet AMD is characterized by choroidal neovascularization, in which abnormal choroidal vessels extend into the subretinal space.

Demographic and environmental risk factors for AMD include older age, smoking, high body mass index (BMI), and high light exposure.<sup>13,14</sup> Smoking, the strongest environmental risk factor for AMD, has been linked to disease onset and progression in multiple large, epidemiologic studies.<sup>15–20</sup> Additionally, high dietary intake of carotenoids and antioxidant supplementation has been associated with lower risk of AMD.<sup>21,22</sup>

Multiple lines of evidence point to the role of oxidative stress in the pathogenesis of AMD. Several AMD risk factors, particularly aging, smoking, and light exposure, have been linked to increased levels of oxidative stress.<sup>1</sup> Additionally, proteomic analysis of human donor eyes revealed oxidative modifications to proteins and DNA in Bruch's membrane, drusen, and RPE.<sup>23</sup> Subsequent proteomic analyses of AMD donor eyes have demonstrated early stage changes in expression of chaperone proteins that aid in microtubule regulation,<sup>24</sup> protect against stress-induced protein unfolding,<sup>24,25</sup> aid in mitochondrial trafficking, and regulate apoptosis.<sup>25</sup> The higher prevalence of these oxidative changes<sup>23</sup> and decreased expression of proteins protective against oxidative stress-induced damage<sup>24–26</sup> in AMD patients versus controls suggest an increased oxidative state in AMD retinas.

Impairment of the retinal antioxidant defense system may also play a role in AMD, as some studies have reported decreased macular pigment in AMD patients.<sup>27–29</sup> Significantly lower levels of macular pigment (lutein and zeaxanthin) were found by direct measurement in AMD versus control eyes at autopsy.<sup>27</sup> The Age-Related Eye Disease Study (AREDS), conducted from 1992 to 2001, demonstrated that supplementation with antioxidants (vitamin C, vitamin E, and  $\beta$ -carotene) and zinc decreased the risk of progression from early to advanced AMD.<sup>30</sup> In past observational studies, high dietary intake of lutein/zeaxanthin and omega-3 fatty

acids such as docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) has corresponded to reduced prevalence and incidence of AMD.<sup>31</sup> These compounds were investigated in AREDS2, conducted from 2006 to 2012, which concluded that the addition of the xanthophylls lutein and zeaxanthin to the original AREDS formula had no additional effect on reducing progression of AMD. However, these compounds were recommended as an alternative to  $\beta$ -carotene in the original formulation due to association of  $\beta$ -carotene supplementation with lung cancer.<sup>32</sup>

## Diabetic Retinopathy

DR, a common microvascular complication of both type 1 and type 2 diabetes mellitus (DM), is the leading cause of vision loss in working-age adults.<sup>33</sup> In the United States, approximately 26 million people have diabetes, and the number of diabetic adults with retinopathy is projected to triple to 16 million by the year 2050.<sup>34</sup> The majority of DM (90–95%) is represented by type 2 diabetes (T2DM), which involves impaired insulin action at target tissues and impaired insulin release. In contrast, the primary cause of type 1 diabetes (T1DM) is the autoimmune destruction of pancreatic  $\beta$ -cells.

Clinically, DR is defined by the presence of specific retinal microvascular signs in an individual with DM. The nonproliferative form is characterized by microaneurysms, hemorrhages, hard exudates, cotton-wool spots, venous dilation and beading, and intraretinal microvascular abnormalities. The more severe proliferative form is characterized by retinal neovascularization, which can lead to vitreous hemorrhage and traction retinal detachment. Intraretinal macular edema, which may be present in either form of retinopathy, can also lead to severe vision loss.

Interestingly, retinal capillary cells in diabetics undergo accelerated apoptosis that precedes the detection of any histopathologic changes characteristic of DR.<sup>35,36</sup> Although the exact mechanism for this accelerated apoptosis remains uncertain, studies have pointed to the involvement of oxidative stress-activated caspases and the activation of the proinflammatory transcription factor NF- $\kappa$ B via Raf-1 kinase in retinal cell death.<sup>37–39</sup> Treatment

with Raf-1 kinase inhibitors resulted in decreased capillary cell death, prevented Raf-1 activation of NF- $\kappa$ B, and reduced the development of DR in rats.<sup>37,39,40</sup> Additional experiments revealed that inhibition of superoxide accumulation in diabetes prevented this early retinal cell death.<sup>41,42</sup>

Oxidative stress appears to be a major risk factor for the onset and progression of diabetes. Many of the common DM risk factors, including obesity and age, foster an oxidative environment that may alter insulin sensitivity by increasing insulin resistance or impairing glucose tolerance. Hyperglycemia, a common result of both types of diabetes, contributes in turn to the progression and maintenance of an overall oxidative environment.<sup>43</sup>

Hyperglycemia may contribute to oxidative stress by generating ROS directly or by disrupting the cellular redox balance. This hyperglycemia-induced oxidative stress can occur via several well-studied mechanisms, including increased polyol pathway flux, increased intracellular formation of advanced glycation endproducts (AGE), activation of protein kinase C (PKC), and disturbance of the hexosamine biosynthesis pathway. The overproduction of superoxide by the mitochondrial transport chain has been proposed as a possible root cause for these metabolic changes.<sup>44,45</sup>

The polyol pathway reduces sugars to their respective sugar alcohols (polyols) via reaction with aldose reductase in an NADPH-dependent manner. Both glucose and the glycolytic metabolites of glucose, such as glyceraldehyde-3-phosphate, serve as substrates for aldose reductase. Hyperglycemia thus leads to increased polyol pathway flux and increased redox stress through consumption of NADPH, an essential cofactor for regenerating the intracellular antioxidant glutathione (GSH). By decreasing the amount of free GSH, the polyol pathway may increase the susceptibility of cells to oxidative injury.<sup>44</sup>

AGEs are modifications of proteins or lipids that become nonenzymatically glycosylated and oxidized after contact with aldose sugars. Early glycation and oxidation of proteins and lipids result in the formation of intermediate Schiff bases and Amadori products, which then undergo further molecular rearrangements that lead to the generation of AGEs.<sup>46</sup> In diabetes, AGEs are found at increased

concentration in the extracellular matrix. AGEs appear to damage cells by modifying intracellular proteins such as transcription factors, extracellular proteins, and matrix molecules. These modified proteins can then bind and activate the receptor of AGEs (RAGE), inducing the production of ROS, which results in upregulation of NF- $\kappa$ B.<sup>44</sup> In endothelial cells, RAGE activation induces the expression of procoagulant genes including thrombomodulin, tissue factor, and vascular cell adhesion molecule (VCAM)-1.<sup>47-50</sup> Recently, additional ligands for RAGE have been identified, including members of the calgranulin and HMGB1 (high-mobility group box 1) families. Hyperglycemia-induced overexpression of these ligands and resultant activation of RAGE induce pro-inflammatory interaction with the innate immune system via TLR-4 (toll-like receptor 4).<sup>51-53</sup>

The activation of PKC leads to multiple characteristics of DR including increased vascular permeability, endothelial cell proliferation and apoptosis, and neovascularization.<sup>54</sup> Hyperglycemia-induced ROS inhibit the key glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase (GAPDH), leading to an increase in glycolytic pathway precursors. Inhibition of GAPDH leads to increased levels of triose phosphate, which results in enhanced de novo synthesis of diacylglycerol (DAG), the primary activator of PKC, from glucose.<sup>54,55</sup> Activated PKC can induce expression of vascular endothelial growth factor (VEGF),<sup>56</sup> a major effector of vessel permeability and a primary stimulator of neovascularization. Activation of PKC induces expression of the protein tyrosine phosphatase SHP-1, which leads to a reduction in downstream signaling of platelet-derived growth factor (PDGF) and resultant pericyte apoptosis.<sup>57</sup> PKC also leads to synthesis of NF- $\kappa$ B and transforming growth factor- $\beta$ 1 (TGF- $\beta$ ), which results in accumulation of microvascular matrix proteins that can contribute to the occlusion of capillaries seen in DR.<sup>44,54,58,59</sup>

The hexosamine biosynthesis pathway may also mediate some of the toxic effects of hyperglycemia. The inhibition of GAPDH by ROS causes diversion of glycolytic metabolites to the hexosamine pathway, producing UDP-N-acetylglucosamine. N-acetylglucosamine is added to serine and threonine residues of transcription factors, often resulting in pathologic changes in gene

expression. Examples include increased expression of TGF- $\beta$  and plasminogen activator inhibitor-1 (PAI-1).<sup>44</sup>

Hyperglycemia-induced alterations in each of these DM-associated pathways can be linked to oxidative stress. Toward that end, Brownlee has proposed a “unifying mechanism” hypothesizing that all of these pathway changes are a result of mitochondrial superoxide overproduction in the endothelial cells of both large and small blood vessels.<sup>45,60</sup> In this model, diabetic hyperglycemia causes increased production of ROS by mitochondria. Greater concentration of ROS in the body induces nuclear DNA strand breaks. This DNA damage activates the DNA repair enzyme poly(ADP-ribose) polymerase (PARP), which reduces GAPDH activity by the addition of ADP-ribose polymers. Decreased GAPDH activity results in a backup of the glycolytic pathway and activation of the polyol, AGE, PKC, and hexosamine pathways discussed above.<sup>44</sup>

## Inherited Retinal Degenerations

Inherited retinal degenerations comprise a group of disorders characterized by primary and progressive loss of photoreceptor cells, leading to irreversible vision loss. Over 230 genes and greater than 270 loci have been associated with inherited retinal degenerations ([www.sph.uth.tmc.edu/retnet](http://www.sph.uth.tmc.edu/retnet)). The proteins encoded by these genes are diverse in function, including not only proteins required for phototransduction but also structural proteins, RNA splicing factors, intracellular trafficking molecules, and proteins involved in phagocytosis and regulation of intracellular pH.<sup>61</sup>

The most common form of these diseases, retinitis pigmentosa (RP), which has an estimated prevalence of around 1 in 4000,<sup>62</sup> involves a primary insult to rods that initiates rod cell death followed by cone cell death (rod–cone dystrophy). Other forms of inherited retinal degeneration include cone dystrophy, cone–rod dystrophy, and macular dystrophy. The most common inherited macular dystrophy is Stargardt macular dystrophy, an autosomal recessive disease with a carrier frequency of approximately 1 in 50.<sup>63</sup>

The first symptom of RP is typically night blindness, followed by

progressive loss of the peripheral visual field. Funduscopy classically demonstrates a pale optic nerve, attenuated retinal vessels, and “bone-spicule” pigmentation in the retinal midperiphery. The widespread retinal degeneration leads to diminution or abolishment of the a-waves and b-waves on electroretinogram (ERG). Various molecular defects have been identified in individuals with RP, including mutations in genes encoding rhodopsin, peripherin, and cGMP phosphodiesterase. These genes are typically rod-specific, but some also code for more general proteins, such as structural proteins in cilia and their associated transport molecules.

The unifying feature in animal models and human cases of RP seems to be the apoptotic cell death of rod photoreceptors, although the mechanisms that lead to photoreceptor cell death in RP remain poorly defined. While most mutations in RP specifically affect rods, both rods and cones die. Several mechanisms have been proposed for the dependence of cone survival on the presence of functioning rods. One theory is that rods produce a survival factor that is required by cones and that modulates the thioredoxin antioxidant defense system in the retina.<sup>64</sup> Several groups have also proposed oxidative stress or alterations in the cellular redox state as a common mediator of photoreceptor cell death.<sup>65,66</sup> Various lines of evidence support this hypothesis, including the induction of apoptosis by oxidants like H<sub>2</sub>O<sub>2</sub><sup>66,67</sup> and the inhibition of apoptosis by antioxidants.<sup>68</sup>

## Oxidative Injury to the Retina

Specific mechanisms of oxidative damage to the retina are unique to the affected retinal cell types. Morphology and function of the RPE, retinal vasculature, and photoreceptors can be severely impaired by the increased oxidative stress associated with disease. Growing evidence suggests that the mitochondria of retinal cells contribute to oxidative stress-related pathology and that inflammatory processes are closely tied to pathologic oxidative stress in the retina.

## Retinal Pigment Epithelium

Oxidative stress can lead to the accumulation of debris and ultimately cell death in the RPE, as manifest by the drusen and geographic atrophy of AMD. Abnormally high concentrations of oxidized products may also interfere with the ability of RPE cells to regulate key angiogenic factors, resulting in retinal neovascularization.

Oxidative damage to the RPE can be induced by oxidizing agents or light. Under normal conditions, phagocytosis of photoreceptor outer segments by the RPE generates ROS via the NADPH oxidase system, leading to increased intracellular  $H_2O_2$  and increased catalase activity.<sup>69</sup> The phosphoinositide 3-kinase (PI3K)-Akt pathway may protect RPE cells from such oxidative stress. The oxidant  $H_2O_2$  was demonstrated to induce PI3K-dependent Akt activation in cultured RPE cells. Akt activation can enhance RPE survival by phosphorylating, and thus inactivating, multiple proapoptotic factors.<sup>70</sup> Cultured human RPE cells exhibited signs of senescence when treated with the oxidizing agents tert-Butyl hydroperoxide (t-BHP)<sup>71</sup> or  $H_2O_2$ ,<sup>72</sup> suggesting that oxidative stress may contribute to the RPE senescence seen in AMD. Oxidative stress induced by hypoxia/reoxygenation in cultured human RPE cells led to the accumulation of extracellular matrix and may be linked to the thickening of Bruch's membrane seen in early AMD.<sup>73</sup> Additionally, animal and laboratory studies have shown that blue light damages the RPE through ROS generation.<sup>74</sup> RPE cells treated with subapoptotic levels of UV light showed increases in both ROS and AGEs.<sup>75</sup>

The AGE-induced activation of RAGE may play a key role in RPE apoptosis. In human donor eyes, RAGE were found to colocalize with AGE deposits and macular disease in AMD retinas, while normal retinas displayed little or no immunolabeling for either AGE or RAGE. This study also showed that AGEs stimulate RAGE-mediated activation in cultured RPE cells in a dose-dependent fashion.<sup>76</sup> RAGE increased secretion of VEGF in cultured RPE cells, suggesting that AGE-mediated activation of the RAGE axis in RPE cells could contribute to neovascular macular disease.<sup>77</sup>

Further evidence supports the idea that oxidative stress in the

RPE has a significant influence on VEGF regulation. Treatment of cultured human RPE cells with the oxidant DL-buthionine-(S,R)-sulfoximine (BSO) caused a significant decrease in intracellular GSH and GSH/GSSG ratios. This change in thiol redox status was associated with increased VEGF-A secretion as well as significant induction of VEGF receptors VEGFR-1 and VEGFR-2.<sup>78</sup> In cultured RPE cells treated with t-BHP, both VEGF-A and VEGF-C were upregulated, with secretion higher to the apical side than to the basal side,<sup>79</sup> suggesting that VEGF may directly affect the photoreceptors. VEGF secretion in RPE cells is regulated, in part, by the mitogen-activated protein kinases (MAPK), including c-Jun-activated kinase (JNK), p38, and extracellular signal-regulated kinases (ERK). Studies in cultured RPE cells demonstrated that constitutive VEGF secretion is regulated by p38, while oxidative stress-induced VEGF secretion is regulated by both p38 and ERK.<sup>80</sup> Finally, it appears that autocrine VEGF-A can enhance RPE cell survival under oxidative stress, utilizing the autocrine VEGF-A/VEGFR-2/PI3K/Akt pathway.<sup>81</sup>

## Retinal Vasculature

Increased oxidative stress can lead to alterations in both the retinal and choroidal vasculature. In diabetes, hyperglycemia-induced ROS may link elevated glucose and multiple metabolic abnormalities associated with the development of retinopathy.<sup>60</sup> Retinal capillary cell cultures containing endothelial cells and pericytes incubated in high-glucose medium exhibited increased oxidative stress markers. In these cells, increased caspase-3 expression and apoptosis were seen after five days in culture.<sup>38</sup>

Oxidative stress has been correlated with the increased production of VEGF and may be involved in the upregulation of endothelial cell VEGF expression seen in diabetes.<sup>82</sup> The increased expression of VEGF in DR may be driven by elevated levels of peroxynitrite,<sup>83</sup> a highly-reactive oxidant formed by the combination of superoxide anion with nitric oxide (NO). In early DR, NF- $\kappa$ B activation and subsequent NO synthesis generate elevated levels of NO that promote peroxynitrite formation.<sup>37,84</sup> Treatment of microvascular endothelial cells with peroxynitrite

demonstrated a dose-dependent increase in VEGF mRNA expression via activation of STAT3.<sup>83</sup> In addition, peroxynitrite mediates a variety of biologic processes including inhibition of key metabolic enzymes, lipid peroxidation, nitration of protein tyrosine residues, and oxidation of thiol pools.<sup>85</sup> The reaction of peroxynitrite with DNA results in the formation of 8-hydroxy deoxyguanosine, a marker of oxidative DNA damage, and high levels of intracellular peroxynitrite deplete glutathione stores, further contributing to oxidative stress and inducing apoptosis.<sup>85</sup>

A hyperglycemic environment may promote the damaging effects of VEGF observed in diabetes. Interestingly, VEGF has been shown to be a potent survival factor for endothelial cells in vitro and in vivo.<sup>86</sup> Despite its antiapoptotic properties, the increased levels of VEGF seen in diabetic retinas<sup>87</sup> are associated with increased retinal endothelial cell death. Cultured endothelial cells subjected to serum withdrawal-induced apoptosis were protected by VEGF in normal glucose but not in high glucose or peroxynitrite media.<sup>85</sup> Further experiments determined that high glucose treatment blocks the pro-survival effect of VEGF and causes accelerated endothelial cell apoptosis via the action of peroxynitrite.<sup>85</sup> Hyperglycemia-induced peroxynitrite accumulation in the retinal vasculature persists even with reversal of poor glycemic control, suggesting that peroxynitrite may contribute to the failure of retinopathy to improve after good glycemic control is attained.<sup>88</sup>

Oxidative stress can also affect retinal endothelial cells' ability to transport glucose into the cell. Exposure of endothelial cells to sustained oxidative stress in the form of H<sub>2</sub>O<sub>2</sub> resulted in decreased glucose transport activity due to increased internalization of GLUT1, the most common retinal glucose transporter.<sup>89</sup> H<sub>2</sub>O<sub>2</sub>-induced oxidative stress was also found to increase the rate of GLUT1 internalization by a proteasome-dependent mechanism involving inactivation of Akt.

Oxidative stress may have direct and indirect effects on the choroidal endothelial cells (CEC), and thus may contribute to the choroidal neovascularization seen in AMD. Treatment of cultured RPE and CEC with the oxidant t-BHP resulted in decreased viability and increased proliferation of both cell types.<sup>90</sup> RPE cells

exposed to t-BHP for 24 hours were found to release basic fibroblast growth factor (bFGF), a prominent proangiogenic factor. This finding suggests that oxidative stress may stimulate choroidal neovascularization via RPE-mediated growth factor release. Interestingly, CECs exposed to oxidative stress-induced AGEs in culture demonstrated increased proliferation as well as upregulation of VEGF, suggesting that AGEs may also promote choroidal neovascularization.<sup>91</sup>

## Photoreceptors

The process of retinal degeneration disrupts the physiologic balance between oxidants and antioxidants in the retinal spaces. As a source of ROS, photoreceptors contribute to the oxidative burden of the retina, particularly in a pathologic oxidative environment. The vitality of rods and cones is directly affected by the redox status of surrounding tissue.

Loss of photoreceptor cells or reduction of energy-demanding activities such as phototransduction can lead to elevated tissue oxygen concentrations because choroidal blood vessels are not autoregulated by local oxygen levels. Accordingly, increases in outer retinal oxygen concentrations have been confirmed in multiple animal models of photoreceptor loss.<sup>92-94</sup> In contrast, the inner retinal arterioles do autoregulate, leading to their attenuation in the presence of high oxygen concentrations.<sup>95</sup> This oxygen imbalance induced by photoreceptor dysfunction and degeneration is manifest by the thinned retinal vessels observed clinically in RP.

Alterations in the cellular redox state appear to mediate photoreceptor cell death. An *in vitro* model of photoreceptor apoptosis demonstrated an early and sustained increase in intracellular ROS accompanied by a rapid depletion of intracellular GSH.<sup>65</sup> Evidence suggests that multiple oxidative-stress related mechanisms underlie the programmed cell death (PCD) of photoreceptors. Classically, caspase-dependent apoptotic pathways have been described.<sup>96,97</sup> More recently, it has been shown that PCD can also be accomplished through caspase-independent apoptosis,<sup>66,98,99</sup> as well as via autophagy.<sup>100</sup> In a photoreceptor cell line treated with the nitric oxide donor sodium nitroprusside,

cytosolic calcium levels increased during photoreceptor apoptosis, leading to activation of caspases as well as the calcium-dependent proteases calpains.<sup>68</sup> Inhibitors of both caspases<sup>68</sup> and calpains,<sup>101</sup> applied independently to the same photoreceptor cell line, failed to prevent apoptosis. These results indicate that, in addition to the classic caspase-dependent pathways of apoptosis, calpain activity may be crucial for apoptosis.

Calpains may lead to retinal oxidative damage by impairing DNA repair mechanisms. Studies in retinal degeneration (*rd1*) mice, which have a mutation in exon 7 of the beta-subunit of the rod photoreceptor *PDE6* gene, have demonstrated downregulation in defensive mechanisms against oxidative stress (e.g., glutathione-S-transferase and glutathione peroxidase), potentially allowing an increase in intracellular ROS.<sup>102,103</sup> Reactions between ROS and DNA can produce the highly mutagenic oxidated nucleotide 8-oxo-guanosine (8-oxoG). Mismatches of 8-oxoG with adenine or cytosine are corrected by the specific DNA repair enzyme 8-oxoG DNA glycosylase (OGG1).<sup>104</sup> OGG1 is regulated by cAMP response element binding protein (CREB), and OGG1 and CREB have both been found to be downregulated in the *rd1* retina. Since OGG1 can be inactivated by calpains, an increase in calpain activity could severely compromise a cell's ability to repair oxidative stress-induced DNA damage.

Cones appear to be sensitive to retinal oxygen concentration. In multiple animal models of RP, increased levels of oxygen in the retina resulted in progressive oxidative damage to cones.<sup>95,105,106</sup> Treatment of *rd1*<sup>-/-</sup> mice with a cocktail of antioxidants resulted in downregulation of markers of oxidative damage in cones, reduced cone cell loss, and preserved the cone ERGs. These results suggest that oxidative damage is important in cone death regardless of the underlying mechanism that kills rods.<sup>107</sup> Most recently, studies in *rd1*<sup>-/-</sup> mice showed that NADPH oxidase plays a critical role in generation of the oxidative stress that leads to cone death in RP.<sup>107</sup>

Initial experiments investigating the progressive death of cones after rod cell death showed that grafting of normal photoreceptors (97% rods) into the eye of the rodless *rd1*<sup>-/-</sup> mouse before the cones degenerated had a positive effect on the host cones, even at some distance from the transplant.<sup>108</sup> Further studies identified a protein

that allowed for cone survival termed Rod-derived Cone Viability Factor (RdCVF).<sup>64</sup> RdCVF, encoded by the exon1 of the nucleoredoxin-like 1 gene (*Nxnl1*), corresponds to a truncated thioredoxin (TRX)-like protein. Because TRX proteins are key to maintaining a reducing intracellular environment (109), disruption of TRXs can lead to conditions of increased oxidative stress. *Nxnl1* knockout mice have been shown to be sensitive to oxidative stress,<sup>109</sup> and the delivery of RdCVF through viral vectors to *Nxnl1*<sup>-/-</sup> mice was protective against light-induced photoreceptor damage,<sup>110</sup> suggesting that RdCVF is part of an endogenous redox-based signaling pathway involved in retinal maintenance.

## Mitochondria

Cumulative oxidative damage to mitochondria appears to play a role in aging and retinal diseases<sup>111</sup> (see also [Chapter 34](#), Mitochondrial genetics of retinal disease). Mitochondria are especially susceptible to oxidative injury due to the high concentration of ROS produced by the electron transport chain and the limited capacity for mitochondrial DNA (mtDNA) repair.<sup>112</sup> RPE cells treated with UV light demonstrated conformational changes in mitochondria,<sup>75</sup> and oxidized photoreceptor outer segments in vitro damaged RPE mtDNA.<sup>113</sup> Additionally, variations in the mitochondrial genome may modulate ROS production and thus susceptibility to disease.

Accumulating evidence, reviewed in [Table 24.2](#), suggests a role for mitochondrial damage in the pathophysiology of both AMD and DR.<sup>111</sup> Abnormalities in the number and structure of mitochondria in the RPE have been reported in studies of AMD donor eyes.<sup>114</sup> Proteomic analyses have suggested that mitochondrial proteins<sup>25</sup> and mtDNA<sup>26</sup> are altered in AMD, and long-extension polymerase chain reaction (PCR) confirmed that mtDNA is increasingly damaged with AMD progression.<sup>115</sup> Characterization of mtDNA from retina and blood of AMD patients and controls demonstrated that AMD mtDNA has an increased number of large deletions, rearrangements, and amino acid-altering single nucleotide polymorphisms (SNPs).<sup>116</sup> Oxidative damage to mitochondria can lead to apoptosis in human RPE cells,<sup>117</sup> and

decreased levels of the mitochondrial antioxidant manganese superoxide dismutase (MnSOD) led to the development of dry AMD-like lesions in mice.<sup>118</sup>

**TABLE 24.2**

**Evidence of Mitochondrial Oxidative Stress in Age-Related Macular Degeneration and Diabetic Retinopathy**

Disease	Supporting Evidence
AMD	Light-induced conformational changes in mitochondria of RPE cells <sup>75</sup> Damage to RPE mtDNA by oxidized photoreceptor outer segments <sup>114</sup> Alterations in mitochondrial proteins <sup>25</sup> and mtDNA <sup>26,115</sup> in AMD Apoptosis in human RPE cells induced by oxidative damage to mitochondria <sup>117</sup> Development of dry AMD-like lesions in mice with decreased levels of MnSOD <sup>118</sup> Association of multiple mitochondrial haplogroups (H, J, U, T) with AMD <sup>121-125</sup>
Diabetic retinopathy	Enhanced permeability of the mitochondrial membrane due to hyperglycemia-induced oxidative stress in retinal endothelial cells and pericytes <sup>119</sup> Protective effects of MnSOD on retinal antioxidant capacity <sup>120</sup> and vascular pathology <sup>41</sup> Association of mtDNA haplogroup T with risk of retinopathy among type 2 diabetics <sup>126</sup> Association of mtDNA haplogroup H with risk of proliferative retinopathy among patients with diabetic retinopathy <sup>127</sup>

AMD, age-related macular degeneration; MnSOD, manganese superoxide dismutase; mtDNA, mitochondrial DNA; RPE, retinal pigment epithelium.

In the case of diabetes, hyperglycemia causes excess production of superoxide by the mitochondrial electron transport chain, inhibiting GAPDH activity.<sup>44</sup> As mentioned previously, Brownlee has proposed that this excess of mitochondrial superoxide in endothelial cells of both large and small blood vessels leads to an array of complications seen in diabetes, including increased activity of the polyol pathway and increased production of AGEs. Specifically, hyperglycemia causes increased oxidation of glucose, leading to an elevation in the voltage gradient across the mitochondrial membrane. Once a critical threshold in voltage gradient is reached, electron transfer inside complex III of the electron transport chain is blocked. The electrons accumulate at coenzyme Q, which donates them to molecular oxygen, creating large amounts of superoxide. Ultimately, the increased number of ROS in diabetes can alter the mitochondrial membrane potential, leading to cell death.<sup>44</sup>

Animal studies have demonstrated the effects of hyperglycemia-induced impairment of the mitochondrial membrane. Increased

levels of cytochrome *c*, a key component of the electron transport chain and the precursor to caspase-9 in the apoptotic cascade, were detected in rats after 8 months of diabetes. These rats also had increased levels of the proapoptotic Bcl-2-associated X protein (BAX) in the mitochondria. In retinal endothelial cells and pericytes, high concentrations of glucose enhanced the permeability of the mitochondrial membrane, increasing levels of cytochrome *c* in the cytosol and BAX in the mitochondria.<sup>119</sup> These glucose-mediated responses were inhibited by the antioxidant MnSOD. A subsequent study by the same group showed that increased expression of MnSOD can prevent the reduction of GSH levels and total antioxidant capacity caused by diabetes.<sup>120</sup> In nontransgenic diabetic mice, upregulation of MnSOD protected against diabetes-related changes in the mitochondria and reduced vascular pathology.<sup>41</sup>

Genetic association studies have indicated that polymorphisms in mtDNA influence the risk of developing AMD and diabetic retinopathy. In the Blue Mountain Eye Study, mitochondrial haplogroup H was associated with a reduced prevalence of any AMD (OR 0.75, 95% CI 0.58–0.97) and early AMD (OR 0.75, 95% CI 0.57–0.98), whereas haplogroups J and U were associated with early AMD only.<sup>121,122</sup> More recent analysis reported a higher frequency of haplogroup J and a lower frequency of haplogroup H in patients with CNV compared to controls without AMD, suggesting that haplogroup H is protective against AMD.<sup>123</sup> A US study determined that individuals with the T2 haplogroup were 2.5 times more likely to have advanced AMD than those without the haplogroup (OR 2.54, 95% CI 1.36–4.80).<sup>124</sup> This finding was supported by studies showing that the mtDNA 4917G polymorphism associated with haplogroup T independently predicted the presence of AMD (OR 2.16, 95% CI 1.21–3.91).<sup>125</sup> Subsequently, PCR analysis of mtDNA from AMD and control donor retinas found that SNPs T16126C and A73G, associated with haplogroups J and T, were more frequent in AMD retinas than in normal retinas.<sup>122</sup> The authors then replicated these associations in blood DNA from 99 cases and 92 controls. The mitochondrial haplogroup T was also associated with risk of retinopathy among type 2 diabetics.<sup>126</sup> As this haplogroup has been associated with multifactorial age-related diseases such as coronary

artery disease<sup>126</sup> and AMD,<sup>125</sup> it seems plausible that carriers of haplogroup T may be exposed to greater oxidative stress or have greater susceptibility to oxidative damage than individuals with other haplogroups. Mitochondrial haplogroups have also been associated with severity of DR. In two independent cohorts of DR patients, those with the haplogroup H were more likely to have proliferative DR, while those with haplogroup Uk were less likely to have proliferative disease.<sup>127</sup>

## Oxidative Stress and Inflammation

Growing evidence from both cell culture and animal studies points to a mechanistic link between oxidative stress and inflammation (Table 24.3). (See detailed discussion of inflammation in Chapter 27, Inflammation and immune responses in retinal health and disease.) Decreased superoxide dismutase 2 (SOD2) and increased superoxide production were associated with mononuclear phagocyte-induced apoptosis of the RPE in *sod2*<sup>+/-</sup> mice.<sup>128</sup> In mice with oxygen-induced retinopathy, injections of the serine proteinase inhibitor SERPINA3K reduced expression of proinflammatory factors (e.g., VEGF, tumor necrosis factor (TNF)- $\alpha$ , and intercellular adhesion molecule (ICAM)-1), decreased ROS production, and increased SOD and GSH levels.<sup>129</sup> The antiinflammatory effect of SERPINA3K was also demonstrated in cultured retinal cells exposed to hypoxia.<sup>129</sup>

**TABLE 24.3**

### Inflammation and Its Relationship With Oxidative Stress in Age-Related Macular Degeneration (AMD) and Diabetic Retinopathy

	Evidence in AMD	Evidence in Diabetic Retinopathy
Inflammation	<p>Presence of complement proteins in drusen<sup>11,12</sup></p> <p>Associations of genetic variants in multiple complement genes (<i>CFH</i>, <i>C2/BF</i>, <i>C3</i>, <i>CFI</i>) with AMD<sup>131-139</sup></p> <p>High blood complement protein levels associated with AMD<sup>143,144</sup></p> <p>Development of retinal deposits similar to AMD drusen in young patients with systemic complement activation<sup>145</sup></p>	<p>Increased vitreous levels of IL-1, IL-6, and IL-8 increased in patients with PDR<sup>156</sup></p> <p>Link between IL-1<math>\beta</math> and retinal capillary cell apoptosis<sup>157</sup></p> <p>Involvement of the inflammatory mediators COX-2 and PGE<sub>2</sub> in the development of diabetic retinopathy via VEGF modulation<sup>158</sup></p>

Link between inflammation and oxidative stress	<p>Decreased <i>CFH</i> mRNA expression in the presence of oxidized photoreceptor outer segments<sup>147</sup></p> <p>Reduced <i>CFH</i> expression in RPE cells in response to H<sub>2</sub>O<sub>2</sub><sup>146</sup></p> <p>Disruption in RPE function in presence of both H<sub>2</sub>O<sub>2</sub> and complement-sufficient serum<sup>154</sup></p> <p>Development of AMD-like lesions in mice treated with CEP adducts<sup>155</sup></p> <p>Association of increased superoxide and decreased SOD2 with mononuclear phagocyte-induced apoptosis of the RPE in <i>sod2</i><sup>+/-</sup> mice<sup>128</sup></p>	<p>Increased superoxide leading to endothelial cell damage, increased microvascular permeability, and recruitment of neutrophils<sup>54</sup></p> <p>Increased ROS leading to activation of the transcription factor NF-κB, which upregulates cytokines, nitric oxide, and prostaglandins<sup>60</sup></p>

CEP, carboxyethylpyrrole; COX-2, cyclooxygenase-2; IL, interleukin; NF-κB, nuclear factor-κB; PDR, proliferative diabetic retinopathy; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; ROS, reactive oxygen species; RPE, retinal pigment epithelium; SOD2, superoxide dismutase 2; VEGF, vascular endothelial growth factor.

Immunologic and inflammatory processes appear to play a major role in AMD, including drusen formation, complement activation, recruitment of tissue-destructive macrophages, and microglial activation and accumulation.<sup>130</sup> The association of multiple complement gene polymorphisms with AMD,<sup>131–139</sup> the presence of complement proteins in drusen,<sup>140–142</sup> and the link between systemic complement activation and AMD<sup>143–145</sup> suggest that innate immunity plays a critical role in AMD pathogenesis. These discoveries have led to experiments designed to define the role of oxidative stress in complement activation in the RPE.

Cell culture studies have linked oxidative stress to reduced expression of the complement factor H (*CFH*) gene in RPE cells.<sup>146</sup> Investigation of constitutive *CFH* production in a stable RPE cell line demonstrated that long-term treatment of RPE cells with oxidized photoreceptor outer segments (POS), but not normal POS, markedly downregulated *CFH* mRNA expression. Furthermore, phagocytosis of both oxidized and normal POS reduced *CFH* protein expression.<sup>147</sup> These results suggest that the phagocytosis of POS, particularly if oxidized, impairs synthesis and secretion of *CFH*, resulting in reduced regulatory control of complement activation and its proinflammatory effects.<sup>147</sup> Additionally, the introduction of H<sub>2</sub>O<sub>2</sub> to RPE cells was shown to reduce the normal interferon (IFN)-γ-induced stimulation of *CFH* expression via acetylation of FOXO3, which interrupts STAT1 binding to the *CFH*

promoter.<sup>146</sup>

Various polymorphisms in the *ARMS2* gene have been associated with increased risk of AMD.<sup>148,149</sup> The presence of risk variants in *ARMS2* has been associated with high serum CRP levels<sup>150,151</sup> and inflammatory markers such as interleukin (IL)-6, IL-8, TNF- $\alpha$ , C3, and C5, suggesting a proinflammatory role for *ARMS2* in the pathogenesis of AMD.<sup>152,153</sup> However, further investigation is necessary to clarify the function of *ARMS2* and its involvement in AMD pathophysiology.

The dynamic interplay between oxidative stress and inflammation may contribute to the abnormalities in RPE function evident in AMD. A combination of H<sub>2</sub>O<sub>2</sub> and complement-sufficient serum was shown to disrupt the barrier function of RPE monolayers in culture and to evoke polarized secretion of VEGF, although introduction of either H<sub>2</sub>O<sub>2</sub> or serum alone did not cause these changes.<sup>154</sup> These results suggest that oxidative stress and complement together impair RPE function. They also point to a common pathway that relates an oxidizing environment and complement activation with VEGF production. Such a pathway could play a role in the neovascularization seen in late AMD.

A close link between oxidative stress and inflammation in AMD is also supported by recent animal work in which mice immunized with mouse serum albumin adducted with the lipid peroxidation product carboxyethylpyrole (CEP) developed AMD-like lesions in the retina.<sup>155</sup> Specifically, these mice produced antibodies to the hapten, fixed complement component 3 in Bruch's membrane, and accumulated drusen below the RPE.<sup>155</sup> Taken together, these studies demonstrate a molecular link between oxidative stress and complement in RPE cells and suggest that the interaction between oxidative stress and inflammatory mediators plays a key role in the development of AMD.

Oxidative stress-related inflammation may also play a key role in the pathogenesis of DR. Increased superoxide can promote inflammation by damaging endothelial cells, increasing microvascular permeability, and recruiting neutrophils.<sup>54</sup> ROS activate the transcription factor NF- $\kappa$ B, which can increase proinflammatory mediators, such as cytokines, nitric oxide, and prostaglandins. The cytokines IL-1 $\beta$ , IL-6, and IL-8 have been

reported to be increased in the vitreous of patients with proliferative DR.<sup>156</sup> Interestingly, it appears that IL-1 $\beta$  increases retinal capillary cell apoptosis.<sup>157</sup> Additionally, IL-1 induces the production of cyclooxygenase-2 (COX-2), a catalyst for prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) formation. The inflammatory mediators COX-2 and PGE<sub>2</sub> are reported to contribute to the development of DR by modulating VEGF-mediated vascular permeability and angiogenesis.<sup>158</sup>

## Retinal Therapies Targeting Oxidative Stress

In this section, we will discuss oxidative stress-related therapies for retinal diseases. We will then explore potential avenues for the development of future treatments that protect against oxidative damage in the retina, including antioxidant therapy, AGE inhibitors, and genetic modification (Fig. 24.1). These potential therapies are outlined in Table 24.4.

**FIG. 24.1** Oxidative stress, brought on by factors such as aging, smoking, light exposure, and hyperglycemia, leads to an oxidized cellular environment that is marked by the accumulation of reactive oxygen species (ROS) and advanced glycation endproducts (AGEs). This oxidized environment triggers stress responses, such as damage to mitochondrial (mt) DNA, vascular changes, inflammatory modulation, and apoptosis. Concurrently, the cellular antioxidant defense system, comprised of both antioxidants and antioxidant enzymes, is activated, mitigating the damage of oxidative stress. The mechanisms of current and potential treatments for retinal diseases are depicted above, with green representing activation and red representing inhibition. *AREDS*, Age-Related Eye Disease Study; *CAT*, catalase; *GPx*, glutathione peroxidase; *GRx*, glutathione reductase; *PON1*, paraoxonase 1; *SOD*, superoxide dismutase.

**TABLE 24.4**

**Retinal Therapies Targeting Oxidative Stress**

Potential Avenues for Retinal Therapy	Specific Treatments Under Investigation
Antiinflammatory agents	Resveratrol to decrease oxidative damage and RPE proliferation via inhibition of the NF- $\kappa$ B pathway <sup>178</sup> Curcumin to decrease expression of inflammatory mediators <sup>173</sup> and inhibit the NF- $\kappa$ B pathway <sup>172</sup>
Boost in antioxidant defense	Vitamin A palmitate supplementation to slow rate of retinal degeneration (e.g., RP) <sup>164</sup> Supplementation with xanthophylls and omega-3 fatty acids for treatment of AMD in AREDS2 clinical trial <sup>31,32</sup> Sulforaphane to protect against retinal oxidative damage via activation of the Nrf2-thioredoxin system <sup>184-186</sup> Curcumin to prevent retinal oxidative damage via activation of the Nrf2-thioredoxin system <sup>1</sup> and increased antioxidant expression (e.g., GST) <sup>174</sup> Lipoic acid to reduce oxidative stress and photoreceptor cell death <sup>95,171</sup>
Genetic modification	Modulation of <i>SOD2</i> and <i>CAT</i> gene expression to protect against oxidative damage to retinal cells <sup>193,194</sup>
Inhibition of AGEs	Pyridoxamine to protect against retinal vascular lesions in diabetics <sup>188</sup> Aminoguanidine to prevent capillary closure, microaneurysm formation, and NOS depletion <sup>190,191</sup>
Inhibition of apoptotic pathways	Quercetin to protect against oxidative damage and senescence in the retina through inhibition of caspase-3 activity <sup>180,181,183</sup>

AGEs, advanced glycation endproducts; AMD, age-related macular degeneration; AREDS2, Age-Related Eye Disease Study 2; CAT, catalase GST, glutathione-S-transferase; NF- $\kappa$ B, nuclear factor- $\kappa$ B; NOS, nitric oxide synthase; RP, retinitis pigmentosa; RPE, retinal pigment epithelium; SOD2, superoxide dismutase 2.

## Supplemental Antioxidants

Currently, care of patients with dry AMD is centered on antioxidant and zinc supplementation, as there are no direct interventions for drusen or geographic atrophy. AREDS, a multicenter, randomized clinical trial sponsored by the National Eye Institute, demonstrated that daily intake of supplemental antioxidants ( $\beta$ -carotene, vitamin C, vitamin E) and zinc reduced the risk of progression to advanced AMD by 25% over 5 years.<sup>159</sup>

Supplemental carotenoids have also been associated with decreased AMD risk. Two smaller studies linked xanthophylls (lutein and zeaxanthin) and/or omega-3 fatty acids with improved visual acuity<sup>160</sup> and central retinal function (as measured by multifocal ERG).<sup>161</sup> In the Rotterdam Study, high dietary intake of zinc, omega-3 fatty acids,  $\beta$ -carotene, and lutein/zeaxanthin corresponded to decreased risk of early AMD onset.<sup>162</sup>

A recent study investigated the relationship between short-term AREDS supplementation and oxidative stress. AMD patients and

controls were placed on a controlled diet supplemented with the AREDS formula for five days. This brief treatment significantly lowered plasma concentrations of the oxidative stress marker cystine, suggesting that the antioxidant and zinc combination directly affects redox status.<sup>163</sup>

The AREDS2 study investigated the effect of oral supplementation of xanthophylls and omega-3 fatty acids (DHA and eicosapentaenoic acid [EPA]) on the risk of AMD progression. In this clinical trial, completed in 2012, AMD patients were randomly assigned to four treatment groups: (1) xanthophylls only (10 mg lutein and 2 mg zeaxanthin); (2) omega-3 fatty acids only (350 mg DHA and 650 mg EPA); (3) xanthophylls and omega-3 fatty acids; and (4) placebo.<sup>32</sup> The addition of xanthophylls, omega-3 fatty acids, or both to the original AREDS formulation did not further reduce the observed risk of progression to advanced AMD. This study also examined the effect of eliminating  $\beta$ -carotene or reducing the zinc doses in the original AREDS formula. There was again no apparent effect of either  $\beta$ -carotene elimination or zinc reduction on progression to advanced AMD. However, a higher incidence of lung cancer was noted in the group receiving  $\beta$ -carotene supplementation, particularly in current and former smokers. Therefore, lutein and zeaxanthin supplementation was recommended as an alternative to  $\beta$ -carotene in the original AREDS formula.<sup>32</sup>

A phase II study investigated topical application of OT-551, a di-substituted hydroxylamine with antioxidant properties for the ability to stop GA progression in AMD. No significant treatment effects were observed, and no further trials were carried out for this agent.

Studies have suggested the benefit of nutritional and drug supplements in preserving photoreceptor function. The most widely recognized supplement for RP patients is vitamin A palmitate, which has been suggested to slow the rate of retinal degeneration by an unknown mechanism.<sup>164</sup> These same studies suggested that vitamin E may be associated with an increase in the deterioration rate of the electroretinogram in RP patients,<sup>164</sup> possibly by reducing the availability of other vitamins in the retina. More recently, studies from the same group investigated the role of

docosahexaenoic acid (DHA)<sup>165</sup> and lutein<sup>166</sup> in the treatment of RP, concluding that these supplements may have positive effects on the disease. However, letters to the journal editor have questioned the clinical conclusions that were drawn based on the experimental data for each of these studies.<sup>167-169</sup> Also, a more recent randomized controlled trial demonstrated no significant difference in the loss of cone cell ERG function with DHA supplementation as compared to placebo.<sup>170</sup>

In preclinical studies, the naturally occurring antioxidant  $\alpha$ -lipoic acid has been demonstrated to reduce oxidative stress and photoreceptor cell death in mouse models of retinitis pigmentosa<sup>95</sup> and light-induced photoreceptor damage.<sup>171</sup> A number of small clinical trials are currently underway to evaluate the ability of  $\alpha$ -lipoic acid to preserve photoreceptor function in retinal diseases.

## Dietary Antioxidants

Naturally occurring compounds found in food may protect against retinal degenerations. Curcumin, from the spice turmeric, has been shown to inhibit the NF- $\kappa$ B pathway, which is involved in immune response,<sup>172</sup> and to decrease expression of inflammatory mediators.<sup>173</sup> Curcumin also increases expression of antioxidants, such as heme oxygenase-1, quinone reductase, and glutathione S-transferase.<sup>174,175</sup> A 2-week diet supplemented with curcumin protected rats from light-induced retinal damage.<sup>176</sup> Similarly, treatment of cultured retinal cells with curcumin protected against H<sub>2</sub>O<sub>2</sub>-induced cell death by increasing production of antioxidant enzymes, such as thioredoxin, and activating the Nrf2 antioxidant pathway.<sup>176</sup> Treatment of diabetic rats with curcumin was protective against Müller cell loss and prevented downregulation of glutamine synthetase compared with untreated rats.<sup>177</sup>

Another member of the plant-derived polyphenol family, resveratrol, a compound in red wine, has been shown to decrease oxidative damage and RPE proliferation in vitro.<sup>178</sup> Evidence suggests that resveratrol may take effect by inhibiting the NF- $\kappa$ B pathway involved in inflammatory response. In diabetic mice, resveratrol prevented diabetes-induced retinal ganglion cell (RGC) apoptosis via downregulation of calmodulin-dependent protein

kinase II.<sup>179</sup>

The flavonoid quercetin, found in green tea and red onion, is a free radical scavenger and a chelating agent that can reduce iron-driven lipid peroxidation.<sup>180</sup> Quercetin has been reported to protect against H<sub>2</sub>O<sub>2</sub>-induced oxidative damage and senescence in cultured RPE cells by inhibiting caspase-3 activity.<sup>181,182</sup> In diabetic rats, retinas treated with quercetin demonstrated significantly lower levels of inflammatory cytokines, NF-κB, and caspase-3 expression compared to untreated rats.<sup>183</sup>

Sulforaphane, an isothiocyanate found in cruciferous vegetables, appears to exert neuroprotective effects through activation of the Nrf2-thioredoxin system. The antioxidant transcription factor Nrf2 binds to the antioxidant response element (ARE), activating the antioxidant defense system in response to oxidative stress.<sup>184</sup> Thioredoxin has been shown to protect against H<sub>2</sub>O<sub>2</sub>-induced damage in photoreceptor cells and light damage in mice.<sup>185</sup> Sulforaphane induces thioredoxin in light-exposed RPE cells via the Nrf2-ARE pathway,<sup>186</sup> thus protecting against photo-oxidative damage to the retina.

## Anti-Advanced Glycation Endproduct Treatment

One possible avenue for treatment of DR targets the accumulation of AGEs, which can disturb retinal vascular cell function. More recently, sulforaphane has been demonstrated to inhibit AGE-induced pericyte damage via downregulation of RAGE, suggesting a protective role for sulforaphane in DR.<sup>187</sup> The AGE inhibitor pyridoxamine protected against diabetes-induced retinal vascular lesions, thickening of the basement membrane, and acellular capillaries in diabetic rats.<sup>188</sup> Treatment of diabetic rats with pyridoxamine decreased the accumulation of AGEs in retinal cells compared to untreated controls.<sup>189</sup> Aminoguanidine, which acts as an inhibitor of inducible nitric oxide synthase and AGE crosslinking, may prevent capillary closure, microaneurysm formation, and nitric oxide synthase (NOS) depletion.<sup>190,191</sup> This inhibition of NOS has been linked to inhibition of apoptosis in mice with oxygen-induced retinopathy.<sup>192</sup> The efficacy of pyridoxamine

and aminoguanidine has yet to be investigated for the treatment of DR in clinical trials.

## Genetic Modification

Gene therapy is being explored for the treatment of retinal degenerations. Toward this end, genes involved in the regulation of cellular oxidative stress are being targeted in animal studies to reduce ROS production, bolster antioxidant defenses, and/or increase cellular repair capacity. In mice with ischemia-induced retinal injury, plasmids encoding the human *SOD2* (MnSOD) or *CAT* (catalase) genes significantly decreased ROS generation and retinal endothelial cell.<sup>193</sup> Another study showed that an adenovirus carrying the *CAT* gene protected against H<sub>2</sub>O<sub>2</sub>-induced damage to RPE cells and light-induced damage to RPE and photoreceptors in mice.<sup>194</sup>

## Conclusions

Oxidative stress plays a significant role in the pathogenesis of multiple retinal diseases, including AMD, DR, and inherited retinal degenerations. ROS, derived primarily from the mitochondria, can adversely affect health and survival of RPE cells, retinal vascular endothelial cells, and photoreceptors. Regardless of a condition's primary insult, oxidative stress often contributes to retinal cell death via instigation of DNA damage, modulation of alternative metabolic pathways, and stimulation of proapoptotic reactions. Because oxidative stress appears to be a common mechanism of retinal cell damage, the development of therapy that protects against retinal oxidative damage has the potential to significantly reduce vision loss from retinal diseases (Fig. 24.1).

## **Summary**

## **Introduction**

Basic science and clinical investigations aimed at understanding mechanisms of retinal disease frequently focus on retinal tissue, specific retinal cell types (such as photoreceptor cells, ganglion cells, Müller cells), and genes/proteins specific to the retina. An emerging approach to understanding retinal disease examines pathogenesis at the level of an intracellular organelle, the endoplasmic reticulum. In this chapter, a brief overview of the field of endoplasmic reticulum stress (ER stress) and the unfolded protein response (UPR) is provided followed by information linking these processes to retinal disease.

## **The Endoplasmic Reticulum**

As its name suggests, the endoplasmic reticulum or ER is a

membrane-bound labyrinth of tubes and sacs, where virtually all plasma membrane and secreted proteins begin their progression to the cellular surface. The ER is the largest membrane compartment within eukaryotic cells, frequently comprising more than half of the total membrane composition. The ER has a number of major physiologic functions.<sup>1</sup> It plays a key role in lipid and protein biosynthesis; it functions as a Ca<sup>2+</sup> storage organelle; and importantly, it is the site where most secretory and transmembrane proteins fold into their native conformation. When proteins enter the ER, they may undergo formation of disulfide bonds through the action of folding enzymes such as protein disulfide isomerase (PDI).<sup>2</sup> Proteins that are processed through the ER frequently undergo glycosylation, a posttranslational modification involving the addition of asparagine-linked oligosaccharides. There are two known chaperone systems in the ER: the calnexin/calreticulin system and binding immunoglobulin protein/78-kDa glucose-regulated protein (BiP/GRP78). The calnexin/calreticulin system is particularly relevant to folding of glycoproteins although some calnexin/calreticulin substrates can also bind BiP/GRP78. Protein folding is essential for protein function; therefore, sophisticated mechanisms have evolved to ensure that proper folding occurs or that irreversibly misfolded proteins are eliminated. Quality control is an ER surveillance mechanism to permit only properly folded proteins to exit the ER en route to other organelles.

When there is perturbation of ER function (such as inhibition of glycosylation or disulfide bond formation, disruption of Ca<sup>2+</sup> homeostasis, hypoxia, infection, etc.), unfolded or misfolded proteins accumulate. This situation, termed ER stress, is defined as an imbalance between the cellular demand for ER function and ER capacity.<sup>2-5</sup> When the influx of nascent unfolded polypeptides exceeds the folding and processing capacity of the ER, the normal physiologic state of the ER is perturbed, activating signaling pathways, termed the ER stress response or the unfolded protein response (UPR), to return the ER to its normal physiologic state.<sup>2-4</sup> The possible fates for a protein in the ER are shown in [Fig. 25.1](#) and include either (1) proper folding and exit through the ER; or in the case of misfolded proteins, (2) translational attenuation whereby protein synthesis halts temporarily to prevent accumulation of

unfolded proteins; (3) transcriptional induction of ER chaperone genes to increase protein folding capacity; (4) transcriptional induction of ER-associated degradation (ERAD) activity. If these strategies fail and protein aggregation is excessive, (5) apoptosis is induced to dispose of cells injured by ER stress thereby ensuring survival of the organism. Recent studies implicate dysregulation of the UPR in neurodegenerative diseases, including retinal diseases.

**FIG. 25.1** Overview of the unfolded protein response (UPR). The ribosome sits at the endoplasmic reticulum

(ER) membrane and the nascent protein is translated. If the protein is folded properly (1), it will typically exit the ER to the Golgi apparatus for further modifications before being secreted or inserted into plasma membrane. If the protein is misfolded, several outcomes are possible that comprise the UPR: (2) Protein translation may be attenuated halting protein synthesis temporarily to prevent further accumulation of unfolded or misfolded proteins; (3) transcriptional induction of ER chaperone genes may occur, which will increase protein folding capacity within the cell; or (4) transcriptional induction of ER-associated degradation (ERAD) activity will dispose of the misfolded protein. If these mechanisms are not successful in managing the misfolded protein, genes that trigger apoptosis (5) may be upregulated leading to cellular death. Excessive accumulation of misfolded proteins is toxic to cells and incompatible with long-term survival.

## **ER Stress and Unfolded Protein Response Signaling**

The UPR is a complex cellular signaling pathway that attempts to restore cellular homeostasis, but in the face of prolonged ER stress, pathways may be activated that lead to cell death.<sup>6</sup> The UPR involves three signaling pathways governed by three integral ER membrane proteins: PERK (protein kinase-like ER kinase, pancreatic ER eukaryotic translation initiation factor (eIF)-2a kinase; official name: EIF2AK3), IRE-1 (inositol-requiring protein 1; official name: ERN1), and ATF6 (activating transcription factor 6). Research related to ER stress and retinal disease has focused on investigations of BiP/GRP78 and these downstream effector proteins.

## **Binding Protein/Glucose-Regulated Protein 78**

BiP/GRP78 is a calcium-dependent resident ER protein that

facilitates the transfer of proteins into the ER through the ER translocator.<sup>2,3,7</sup> It is a heat shock protein with a molecular weight of 78 kD. As a key ER stress regulatory protein, it binds to exposed hydrophobic amino acid sequences of polypeptides that would normally be buried in the interior of correctly folded proteins. Under nonstress conditions, BiP/GRP78 binds to the luminal domains PERK, IRE1, and ATF6, maintaining them in an inactive state (Fig. 25.2). When misfolded proteins accumulate, BiP/GRP78 preferentially binds to these misfolded proteins and dissociates from the UPR sensor proteins allowing their activation. BiP/GRP78 and other UPR gene targets such as GRP94 and calreticulin contain an ER stress response element (ERSE, CCAAT(N<sub>9</sub>)CCACG) that is required and sufficient to activate the UPR. The absolute requirement for BiP/GRP78 for survival is underscored by evidence that absence of BiP/GRP78 results in perimplantation embryonic lethality in mice.<sup>8</sup> Upregulation of *BiP* gene expression is considered by some investigators as a marker for ER stress induction.

**FIG. 25.2** Key regulators of the unfolded protein response. When misfolded proteins aggregate, BiP/GRP78 dissociates from the three ER stress receptors, PERK, ATF6, and IRE1, which permits their

activation. Activation of PERK blocks general protein synthesis by phosphorylating eukaryotic initiation factor 2 $\alpha$  (eIF2 $\alpha$ ), which enables translation of ATF4 (through an eIF2 $\alpha$ -independent translation pathway). ATF4 translocates to the nucleus and induces the transcription of genes required to restore ER homeostasis. When IRE1 is released from BiP/GRP78, it dimerizes and autophosphorylates to activate its RNase activity removing a 26-nucleotide intron from X-box binding protein (XBP1) mRNA. Spliced XBP1 activates many UPR target genes and can activate genes required for ER-associated degradation (ERAD). ATF6 is activated by limited proteolysis after its translocation from the ER to the Golgi apparatus. Active ATF6 can regulate the expression of ER chaperones and XBP1. The combined action of these three ER stress receptors is to attenuate translation to prevent further accumulation of misfolded proteins, to enhance proper protein folding, and to degrade misfolded proteins.

## PERK

The signaling events mediated by PERK represent the most immediate response to ER stress in metazoan cells. PERK is a 125-kDa ER-associated transmembrane serine/threonine protein kinase. When unfolded proteins accumulate in the ER lumen, BiP/GRP78 dissociates from PERK, which then dimerizes and is subsequently autophosphorylated triggering phosphorylation of eukaryotic translation initiation factor 2 on the alpha-subunit (eIF2 $\alpha$ ). Phosphorylation of eIF2 $\alpha$  attenuates mRNA translation, thereby preventing influx of newly synthesized polypeptides into the ER lumen of the stressed cell.<sup>7</sup> This reduces the assembly and folding activities of the ER. Interestingly, although phosphorylation of eIF2 $\alpha$  inhibits translation initiation in general, it is required for selective translation of several mRNAs such as activating transcription factor 4 (ATF4). Activation of ATF4 can increase levels of chaperones, restore cellular redox homeostasis, and help the ER to fold proteins or degrade them. However, it has been reported that excess ATF4 expression can evoke oxidative stress and increase

cell death in mouse embryonic fibroblasts.<sup>9</sup> Besides eIF2 $\alpha$ , PERK can also phosphorylate nuclear erythroid 2 p45-related factor 2 (NRF2), which contributes to dissociation of the NRF2-Keap1 complex and promotes expression of genes containing antioxidant response elements (ARE), preventing oxidative stress by induction of antioxidant genes such as heme oxygenase 1 (HO-1).<sup>10</sup> Lack of the gene encoding PERK is not lethal but does result in increased hypersensitivity to ER stress.<sup>11</sup> Activation of PERK induces transcription of ~1/3 of UPR-dependent genes.<sup>12</sup> Recent data suggest that PERK initially mediates a prosurvival response, which switches into a proapoptotic response under conditions of prolonged ER stress.<sup>13</sup>

## IRE1

IRE1 is a 100-kDa bifunctional transmembrane protein with kinase and endoribonuclease (RNase) activity. It was the first component in the UPR pathway to be identified<sup>14</sup> and is evolutionarily the oldest branch of the UPR. Under nonstress conditions, the protein kinase is maintained in a monomeric form through its interactions with BiP/GRP78. IRE1 can bind members of the tumor necrosis factor (TNF) receptor family and can activate protein kinases that are implicated in immunity, inflammation, and apoptosis. Under conditions of ER stress, when unfolded proteins are accumulating, IRE1 is released from BiP/GRP78, dimerizes, and autophosphorylates to activate its RNase activity.<sup>2-4</sup> Indeed, IRE1 mediates the degradation of many other mRNAs through a pathway referred to as regulated IRE1-dependent decay, or RIDD.<sup>15</sup>

In mammals there are two forms of the protein, IRE1 $\alpha$  and IRE1 $\beta$ . IRE1 $\alpha$  is expressed in most cells and tissues (including retina), while IRE1 $\beta$  is primarily in intestinal epithelial cells. Upon activation of the UPR, IRE1 RNase activity initiates removal of a 26-nucleotide intron from XBP1 (X-box binding protein) mRNA. Spliced XBP1 is a transcriptional activator that activates many UPR target genes through its interaction with ERSE, and it can activate genes required for ER-associated degradation (ERAD). IRE1 may be a focal point for the BCL-2 family of proteins that regulates cell death. BCL-2-associated X protein (BAX) and BCL-2

antagonist/killer (BAK) interact physically with IRE1 $\alpha$  modulating the UPR. If either IRE1 or XBP1 are absent in mouse models, the result is embryonic lethality. Recent studies note that IRE1 can sense ER stress by directly monitoring the concentration of unfolded proteins.<sup>16</sup> Thus, it may be that BiP/GRP78 buffers UPR activity and helps turn IRE1 off, while direct binding to unfolded proteins switches IRE1 on.<sup>17</sup>

## ATF6

ATF6 $\alpha$  and ATF6 $\beta$  are bZIP family transcription factors with calculated molecular weights of ~90 kDa. In the absence of ER stress, BiP/GRP78 binds to the luminal domain of ATF6 tethering it to the ER membrane. When unfolded proteins accumulate, BiP/GRP78 releases ATF6, which then translocates to the Golgi apparatus by vesicular transport.<sup>3,7</sup> Unlike PERK and IRE1 $\alpha$ , ATF6 $\alpha$  and ATF6 $\beta$  do not undergo oligomerization, rather in the Golgi ATF6 is cleaved by proteases and the resultant cytoplasmic portion translocates to the nucleus, where it (like XBP1) binds to an ER stress element (ERSE) to activate transcription of ER chaperone genes such as BiP/GRP78, GRP94, and calreticulin. It is noteworthy that ATF6 transcriptionally upregulates *Xbp1* IRE1 activation. Thus, ATF6 activation can increase ER chaperone activity. If both ATF6 $\alpha$  and ATF6 $\beta$  are deleted in mouse, the result is early embryonic lethality.

## ER-Associated Degradation

The ER employs ERAD to clear aggregated, misfolded, or unassembled proteins. Target proteins are selected through the ER quality control system, are retrotranslocated to the cytosol, and degraded by the ubiquitin-proteasome system. The four steps associated with ERAD are recognition, retrotranslocation, ubiquitination, and degradation.<sup>3</sup> In the recognition step, glycosylated proteins are bound to ER degradation-enhancing  $\alpha$ -mannosidase-like (EDEM) protein that can discriminate folded from unfolded proteins. Misfolded proteins destined for the retrotranslocation machinery associate with PDI and BiP/GRP78 to cleave disulfide bonds and to unfold the partially folded protein.

Proteins are translocated to the cytoplasm where they undergo ubiquitination by the E1–E2–E3 ubiquitin system. The proteins are then deglycosylated and degraded by the proteasome.

## Apoptosis-Inducing Pathways

If PERK, ATF6, and IRE1 pathways cannot suppress ER stress, and if the ERAD pathway does not rectify the unfolded protein accumulation, an apoptotic pathway will be triggered so that the cell will die allowing the organism (or tissue) to survive since accumulation of unfolded proteins is toxic to cells. Apoptosis is signaled through mitochondrial-dependent and -independent pathways. In the ER, apoptosis is signaled through several mechanisms, the most significant of which is the PERK/eIF2 $\alpha$ /ATF4-dependent or ATF6-dependent transcriptional induction of CHOP (CCAAT-enhancer-binding protein homologous protein). CHOP activates transcription of several genes that potentiate apoptosis including *GADD34*, *ER01*, *DR5*, *TRB3*, *carbonic anhydrase VI*. One mechanism of CHOP-induced apoptosis is to suppress the prosurvival protein BCL-2. Additionally, *GADD34* (growth arrest and DNA damage-inducible protein-34) is a particularly important transcriptional target of CHOP as it can dephosphorylate eIF2 $\alpha$ , restoring global protein translation and suppressing ATF4 translation.

## Retinal Diseases Associated With ER Stress

The UPR has been referred to as a “double-edged sword” because it can restore cellular homeostasis, but if unchecked may lead to chronic, overwhelming stress that can cause apoptotic cell death.<sup>18</sup> ER stress and the UPR have been implicated in a number of retinal diseases, including retinitis pigmentosa, achromatopsia, diabetic retinopathy, and macular degeneration.

To investigate the role of ER stress genes and proteins in retina, a number of research tools (antibodies, molecular probes, etc.) are available commercially or have been developed by individual

laboratories. Fig. 25.3 shows immunocytochemical studies performed in freshly isolated mouse retinal Müller cells to detect two ER proteins. Protein disulphide isomerase is a known ER resident protein and hence an excellent marker of this organelle (Fig. 25.3A). In this dual-label experiment, a second antibody was used to detect BiP/GRP78, the key ER stress regulatory protein (Fig. 25.3B). The final panel shows the merged image of PDI and BiP/GRP78; there is considerable overlap in the expression of these two proteins (Fig. 25.3C). Immunodetection methods, gene expression analysis, and elegant genetic manipulation methods have formed the basis of investigations of the ER stress genes/proteins in various retinal diseases.

**FIG. 25.3** Immunocytochemical analysis of PDI and BiP/GRP78 in retinal Müller cells. Primary Müller cells were isolated from neonatal mouse retina using methods established in the author's lab and were subjected to immunocytochemical methods to detect two proteins: protein disulphide isomerase (PDI), a known ER protein, and BiP/GRP78, the major ER stress regulatory protein. The anti-PDI antibody was detected with a secondary antibody that fluoresces red (panel A); the anti-BiP/GRP78 antibody was detected with a secondary antibody that fluoresces green (panel B). When the cells were viewed by epifluorescence using filters to detect green and red fluorescence simultaneously, the areas of colocalization appear yellow in the merged image (panel C). The cells were also labeled with a dye 4'-6-diamidino-2-phenylindole (DAPI), which forms fluorescent complexes with natural double-stranded DNA, hence the nucleus stains blue in the merged image. (Studies performed by Dr. Yonju

Ha in the author's lab.)

## Retinitis Pigmentosa and Other Photoreceptor Dystrophies

Retinitis pigmentosa (RP) is an inherited retinal dystrophy in which loss of photoreceptors leads to progressive vision loss. The prevalence of nonsyndromic RP is ~1/3500–4000. The most common form of RP is a rod–cone dystrophy, characterized initially by night blindness, followed by progressive loss in the peripheral visual field in daylight, eventually leading to blindness after several decades.<sup>19</sup> To date, mutations in over 40 genes have been implicated in RP.<sup>20</sup> In some cases the genes are specific to photoreceptor cells, including rhodopsin, rod cGMP phosphodiesterase, peripherin, and rod outer-segment membrane protein-1, while others are expressed in retinal and nonretinal cells. ER stress is implicated in RP due to mutations in several genes, as described below.

### Rhodopsin Mutations

Among the genes associated with RP, mutations within the rhodopsin gene account for approximately 25% of cases of autosomal dominantly inherited RP (adRP). Rhodopsin is the visual pigment initially made in the ER and eventually located in the outer-segment discs until used in the visual transduction cascade. AdRP is a human protein folding disease that is frequently caused by a proline-to-histidine mutation at position 23 of rhodopsin (P23H rhodopsin) that leads to its retention in the ER.<sup>21,22</sup> In vitro studies have shown that cells transfected with P23H rhodopsin increased expression of *BiP* mRNA to a level greater than in cells transfected with wild-type rhodopsin.<sup>21,22</sup> Interestingly, activation of the IRE1 $\alpha$  pathway was protective, while prolonged PERK activation was associated with cell death. Elegant studies by Gorbatyuk and colleagues<sup>22</sup> provide immunohistochemical data showing that when HeLa cells are transfected with mutant rhodopsin (P23H) the protein was not able to traffic to the cell membrane and was localized in the cytoplasm, clear evidence of the retention in the ER of a misfolded protein (see figures 1A and B of reference article 14). These cell culture observations have been extended to studies in an animal model of adRP (transgenic rat expressing P23H rhodopsin at high levels). During retinal

development, levels of *BiP* mRNA were high, but diminished with age; however, levels of *Chop* indicative of apoptosis increased significantly with age as the retinopathy advanced in the adRP rat model.<sup>21</sup> Additional experiments, in which *BiP/GRP78* was over expressed using adenoviral vector-mediated delivery in the rat adRP model, resulted in improved a- and b-wave amplitudes of the scotopic electroretinogram and a reduction in photoreceptor cell loss.<sup>22</sup> The field of microribonucleic acid (microRNA) (miRNA) expression profiling and bioinformatics has identified miR-708 in the homeostatic regulation of ER function in photoreceptor cells, specifically preventing excess rhodopsin from entering the ER. Investigators speculate that miR-708 may function analogously to UPR control proteins such as PERK and IRE1 $\alpha$ .<sup>23</sup> In contrast to these studies in the rat adRP model, there have been studies in which the P23H rhodopsin has been genetically expressed in mice. These mice with P23H rhodopsin knocked-in closely mimic the photoreceptor death observed in humans with the P23H mutation. Interestingly in this model, IRE1 significantly upregulated ERAD, triggering pronounced P23H rhodopsin degradation, with minimal activation of PERK and no increase in ATF4 or CHOP.<sup>24</sup> It appears that in this mouse model at least, loss of rhodopsin precedes photoreceptor cell death, underscoring the role of ERAD in this form of RP.<sup>25</sup> In addition to P23H rhodopsin mutations, other mutations of rhodopsin have now been shown to involve increased ER stress, including the single amino acid substitution in amino acid 181 of glutamic acid (E) to lysine (K) (E181K)<sup>26</sup> and the substitution in amino acid 7 of threonine (T) to methionine (M) (T7M).<sup>27,28</sup>

## **cGMP-PDE Mutations**

Mutations of the gene coding for the beta-subunit of the rod photoreceptor-specific cGMP phosphodiesterase 6 (*PDE6B*) underlie cases of autosomal recessive RP (arRP) and account for ~1–2% of all cases of human RP.<sup>29</sup> The *rd1* mouse carries a non-sense mutation of this gene and has proven to be a very useful model for understanding the pathogenic mechanisms of this form of RP. The absence of phosphodiesterase activity leads to increased accumulation of cGMP in photoreceptors, which leads to increased influx of Na<sup>+</sup> and Ca<sup>2+</sup> through cGMP-gated cation channels. The

uncontrolled influx of  $\text{Ca}^{2+}$  triggers apoptosis of photoreceptor cell nuclei so that between postnatal day 10 and postnatal day 21, rod photoreceptor cells are lost. The number of rows of cells in the retinal outer nuclear layer decreases from ~10–12 to ~1–2, representing remaining cones. Interestingly, as the rod cells are lost, there is an increase in expression of BiP/GRP78, phosphorylated eIF2 $\alpha$ , phosphorylated PERK, and caspase-12 over postnatal days 10–14, but levels decrease by postnatal day 21.<sup>30</sup> These data clearly implicate ER stress in the pathogenesis of RP caused by mutations of the PDE- $\beta$  gene.

### **Carbonic Anhydrase Mutation**

Carbonic anhydrase IV (CA4) is another gene which, when mutated, leads to human adRP that involves ER stress. This form of RP (RP17) is caused by an arginine to tryptophan (R14W) mutation in the signal sequence of carbonic anhydrase IV.<sup>31–33</sup> Carbonic anhydrase is a GPI-anchored membrane protein expressed in the choriocapillaris of the eye and in the renal epithelium. Interestingly, the mutation results in an exclusively ocular phenotype. In vitro studies have shown that in cells R14W mutation, which is the RP17 form of adRP, leads to accumulation of carbonic anhydrase IV as unfolded protein in the ER. This gene defect is associated with increased expression of BiP/GRP78, PERK, and CHOP, leading to cell death.<sup>32</sup>

### **LRAT Mutations**

An inherited retinal dystrophy that preferentially affects cones before rods is Leber congenital amaurosis (LCA), the most severe retinal dystrophy in early childhood.<sup>34</sup> Mutations in *RPE65* or the lecithin-retinol acyltransferase gene (*LRAT*) disrupt 11-*cis*-retinal recycling, causing this devastating disease. LRAT catalyzes the esterification of all-*trans* retinol (vitamin A) to all-*trans*-retinyl esters, which are the substrate for RPE65, to produce 11-*cis* retinol. In studies of a murine model of LCA (*Lrat*<sup>-/-</sup> mouse), large quantities of M and S opsins are mislocalized to the inner regions of cones, creating an extra burden on the cell.<sup>35</sup> Interestingly, mislocalized M opsin is degraded, whereas S opsin is resistant to proteasome degradation, resulting in far more toxic aggregation of

S opsin in the ventral and central retina than of M opsin in the dorsal retina. Furthermore, aggregation of S opsin leads to CHOP activation. The UPR in cones copes with mislocalized M opsin more effectively than mislocalized S opsin. Thus, M opsin is degraded by the ERAD pathway, which relieves ER stress. S opsin was resistant to ERAD, resulting in aggregation/accumulation, which induces apoptosis.

## **IRBP Mutations**

Interphotoreceptor retinoid-binding protein (IRBP) is a 140–145-kDa glycoprotein of ~300 amino acid residues that is secreted by photoreceptors into the interphotoreceptor matrix. It protects and solubilizes the visual cycle retinoids by physically binding with 11-*cis* retinaldehyde, 11-*cis* retinol, and all-*trans* retinol.<sup>36</sup> In 2009, the first mutation of the (*IRBP*) gene responsible for RP was reported in patients with the autosomal recessive form of the disease.<sup>37</sup> The mutation was due to an aspartate (D) to asparagine (N) substitution at position 1080 (D1080N) of IRBP. The precise pathogenic mechanisms underlying this form of RP are not known, but recent work demonstrated that the mutant IRBP was not transported to the Golgi apparatus, rather it accumulated in the ER, bound to BiP/GRP78 and PDI.<sup>38</sup> Splicing of ATF4 and cleavage of ATF6 increased significantly in cells that express the D1080N IRBP compared to wild-type IRBP. Additionally, D1080N IRBP induced upregulation and nuclear translocation of CHOP.<sup>38</sup>

The apparent role of ER stress and UPR in some forms of photoreceptor disease has prompted suggestions that therapeutic approaches, which modulate these pathways, may prove beneficial.<sup>35,39,40</sup>

## **USH2A**

Mutations in the *USH2A* gene are the most common cause of Usher syndrome type I,<sup>41</sup> a genetically heterogeneous autosomal recessive disorder characterized by early-onset sensorineural hearing loss and later onset RP. Recent analysis of *USH2A* transcripts revealed that one of the patient's mutations causes exonification of intron 40, a translation frameshift, and a premature stop codon. Western blotting revealed upregulation of GRP78 and GRP94, suggesting

that the patient's other USH2A variant (Arg4192His) caused disease through protein misfolding and ER stress.<sup>42</sup>

## Achromatopsia

In addition to rod dystrophies, cone photoreceptor cells are also vulnerable to genetic defects that compromise function. Congenital achromatopsia is a rare, autosomal recessively inherited condition characterized by lack of cone photoreceptor function.<sup>43</sup> Patients present with pendular nystagmus, absence of color vision, marked photophobia/hemeralopia, and severely reduced visual acuity. Rod responses detected by electroretinography (ERG) are normal; however, cone responses are absent.<sup>44</sup> Until recently, five genes had been associated with achromatopsia, which encode the cone-specific phototransduction cascade (reviewed by Aboshiha and colleagues<sup>45</sup>). The most commonly mutated genes include *CNGA3*, *CNGB3*, which encode the alpha-subunits and beta-subunits of the cGMP-gated cation channel, respectively. Very recently, work from the Lin lab provides compelling evidence that mutations in *ATF6*, the basic leucine-zipper (bZIP) transcription factor that is a key regulator of the UPR, are responsible for some forms of achromatopsia.<sup>46</sup> The highly collaborative study provides the first evidence implicating dysfunction of an ER stress gene in achromatopsia. It used homozygosity mapping and whole-exome and candidate gene sequencing and identified 10 families carrying six homozygous and two compound-heterozygous mutations in the *ATF6* gene. Patients demonstrated foveal hypoplasia and disruption of the cone photoreceptor layer. The findings suggest a crucial and unexpected role for ATF6 in human foveal development and cone function and are particularly noteworthy because, despite the ubiquitous expression of ATF6, when mutated it results in an isolated retinal phenotype.

## Diabetic Retinopathy

Diabetic retinopathy is a major complication of diabetes mellitus, a complex metabolic disorder characterized by deficiency of or insensitivity to insulin. Diabetic retinopathy is a neurovascular disease.<sup>47,48</sup> The microvascular characteristics, which are visible clinically, include pericyte dropout, microaneurysms, intraretinal

hemorrhages, capillary nonperfusion, intraretinal microvascular abnormalities, and neovascularization. The neuronal component is characterized by death of ganglion cells, loss of cells in the inner nuclear layer,<sup>49,50</sup> and functional changes detected particularly using multifocal ERG.<sup>51</sup> ER stress has been implicated in diabetic retinopathy, and investigations have examined features of ER stress in retinal vascular cells and retinal neurons.<sup>52–54</sup>

Regarding the vasculature, retinal homeostasis is regulated in part by the blood–retinal barrier. The outer barrier is comprised of the tight junctions between retinal pigment epithelial (RPE) cells, while the inner blood–retinal barrier is composed of tight junctions between vascular endothelial cells. Breakdown of this barrier is characteristic of diabetic retinopathy. TNF- $\alpha$  is a major proinflammatory cytokine induced by diabetes that plays a key role in endothelial cell injury in diabetic retinopathy. Investigators have shown that ER stress plays a pathogenic role in retinal inflammation and vascular leakage in diabetic retinopathy.<sup>55–57</sup> Interestingly, preconditioning human retinal endothelial cells with very low levels of ER stress-inducing agents such as tunicamycin actually alleviate TNF- $\alpha$ -induced endothelial adhesion molecule expression, retinal leukostasis, and vascular leakage in vitro.<sup>58</sup> The beneficial effects of ER stress preconditioning require that XBP1, a major regulator of the adaptive response to ER, must be activated if ER stress is to be protective of endothelial cell function.<sup>58</sup> There are reports showing that P58<sup>IPK</sup>, a 58-kilodalton inhibitor of protein kinase, which has been shown to be important in ER stress, reduced the level of TNF- $\alpha$  in endothelial cells.<sup>59</sup> Thus, the potential role of modulating ER stress may prove therapeutically useful for the endothelial cell alterations observed in diabetic retinopathy.

Vascular endothelial growth factor (VEGF) plays a key role in the development and progression of diabetic retinopathy.<sup>60</sup> Investigators have shown that homocysteine, which induces ER stress, increased expression of VEGF along with BiP/GRP78.<sup>61</sup> Incubating RPE cells with homocysteine in vitro caused transient phosphorylation of eIF2 $\alpha$  and increased ATF4 protein level. In addition to its effects on vasculature, excess homocysteine induces death of ganglion cells. In a mouse model of hyperhomocysteinemia, diabetes accelerates the loss of these retinal

neurons.<sup>62</sup>

Retinal neurons die in diabetic retinopathy as evidenced by decreased contrast sensitivity,<sup>51</sup> decreased blue–yellow color sensitivity,<sup>63</sup> and reduced electrical responses in full-field and multifocal ERG.<sup>64</sup> ER stress has been implicated in the death of retinal neurons, particularly ganglion cells. Studies subjecting a retinal neuronal cell line to oxidative stress, as observed in diabetic retinopathy, demonstrated increased expression of the ER stress gene BiP/GRP78 as well as PERK, IRE1- $\alpha$ , ATF6, and the apoptosis gene, CHOP.<sup>65</sup> Upregulation of several of these ER stress markers has been detected in neural retinas of the *Ins2<sup>Akita/+</sup>* mouse.<sup>55,65</sup> The *Ins2<sup>Akita/+</sup>* mouse is an endogenous model of diabetic retinopathy characterized by marked apoptosis of retinal neurons, including ganglion cells and cells of the inner nuclear layer and vasculopathy.<sup>66,67</sup> Interestingly, treatment of this mouse with a ligand for sigma receptor 1 ( $\sigma$ R1), a molecular chaperone that binds BiP/GRP78, provided marked neuroprotection against neuronal cell death when it was administered over a period of several weeks.<sup>68</sup> Examination of the ER stress genes in retinas of these mice (using quantitative reverse transcriptase polymerase chain reaction [RT-qPCR]) showed that BiP/GRP78 expression increased in diabetic mice compared with wild-type mice, as did PERK, ATF6, IRE1, ATF4, and CHOP (Fig. 25.4). The retinas of *Ins2<sup>Akita/+</sup>* diabetic mice treated with the  $\sigma$ R1 ligand (+)-pentazocine showed ER stress gene expression levels that were very similar to the age-matched wild-type mice (Fig. 25.4). The data suggest that targeting ER stress may hold promise in treatment of diabetic retinopathy.

**FIG 25.4** Quantitative analysis of ER stress genes in retinas of wild-type versus diabetic mice. Total RNA was isolated from neural retinas of wild-type (WT), C57Bl/6-*Ins2Akita*<sup>+/+</sup> mice, and C57Bl/6-*Ins2Akita*<sup>+/+</sup> administered (+)-pentazocine, a ligand for the molecular chaperone protein sigma receptor 1 ( $\sigma$ R1). The expression of ER stress genes was analyzed by RT-qPCR. There was a significant increase in expression of these genes in diabetic mice (*asterisk*), but expression levels were similar to wild-type mouse retinas when treated with the ligand for  $\sigma$ R1. (Figure adapted from Ha Y, Dun Y, Thangaraju M, et al. Sigma receptor 1 modulates endoplasmic reticulum stress in retinal neurons. *Invest Ophthalmol Vis Sci* 2011;52:527-40; copyright held by Association for Research in Vision and Ophthalmology.)

## Macular Degeneration

The macula is the cone photoreceptor-dense region of the retina; dystrophy of this area is collectively termed macular degeneration. Macular degeneration can develop at an early age through single gene mutations or can present later in life as the much more common multifactorial age-related macular degeneration (AMD).<sup>20</sup> Clinically, patients present with progressive loss of visual acuity, abnormal color vision, and central scotomas. ER stress has been implicated in the pathogenesis of both genetically inherited, early-onset macular dystrophies and multifactorial age-related macular

degenerations.

## Early-Onset Macular Dystrophies

Mutations of at least two genes leading to juvenile macular dystrophy are associated with ER stress, *ELOVL4* and *EFEMP1*. *ELOVL4* encodes a 314 amino acid ER-bound transmembrane protein associated with the long-chain fatty acid synthesis machinery. Retinal tissue has a unique fatty acid composition; the lipid environment is critical for normal retinal functions. While the precise role of *ELOVL4* in photoreceptors is not known, mutations of *ELOVL4* result in an autosomal dominant atrophic macular dystrophy resembling Stargardt macular degeneration, hence the disease is referred to as Stargardt-like macular dystrophy. Wild-type *ELOVL4* is localized to the ER; however, the mutant form of the protein accumulates in the Golgi apparatus.<sup>69</sup> Investigators have transfected cells with the mutant forms of *ELOVL4*, known to cause Stargardt-like macular dystrophy, and observed an increase in the expression of BiP/GRP78 and the UPR apoptosis-associated gene, *CHOP*.<sup>70</sup>

*EFEMP1* (epithelial growth factor [EGF]-containing fibulin-like extracellular matrix protein 1) encodes an extracellular matrix protein, fibulin-3. Fibulin-3 is a glycoprotein that typically undergoes proper folding in the ER is then transported to the Golgi and then secreted. A missense point mutation (arginine-to-tryptophan [Arg345Trp]) results in an early-onset autosomal dominant maculopathy known as Doyme honeycomb retinal dystrophy (also termed malattia leventinese). Mutant forms of the protein accumulate aberrantly in the ER of retinal pigment epithelial (RPE) cells hindering proper secretion to the extracellular milieu.<sup>71,72</sup> To determine the consequences of the Arg345Trp mutation on ER stress, investigators transfected the human ARPE-19 cell line with the mutated *EFEMP1* and demonstrated an upregulation of BiP/GRP78; indeed the level of BiP/GRP78 expression paralleled the intracellular levels of fibulin-3. Additional evidence that the UPR was activated by this mutation was increased IRE-1 endonuclease activity and XBP-2 mRNA processing.<sup>71</sup>

## Age-Related Macular Degeneration

AMD is the leading cause of visual impairment in elderly persons. The macula is the photoreceptor-dense retinal region, which when affected by this disease results in central vision loss. The RPE cells sustain photoreceptor cells through myriad activities including the transport of needed vitamins such as vitamin A and folate, removal of waste, and phagocytosis of shed outer segment discs. RPE cells are vascularized via the choriocapillaris. A hallmark of AMD is the accumulation of lipofuscin and extracellular deposits known as drusen. The retina and RPE are exposed constantly to oxidative stress through intense light exposure, high metabolic activity, oxygen consumption, and the high concentration of polyunsaturated fatty acids making them particularly susceptible to ER stress.<sup>73</sup>

Clinically, AMD is classified as either atrophic (dry) AMD or exudative (wet) AMD,<sup>74</sup> based upon whether neovascularization has developed. A major trigger for exudative AMD is upregulation of VEGF expression and ER stress can trigger this upregulation.<sup>61,72,75</sup> Also implicated in the development of AMD is smoking,<sup>76,77</sup> cigarette smoke extract contains benzopyrene, a potent inducer of ER stress via the PERK pathway.<sup>78</sup> A number of studies performed using human ARPE-19 cells have implicated cigarette smoke in VEGF upregulation and in induction of ER stress.<sup>79–81</sup> Another pathogenic mechanism implicated in AMD is accumulation of age-related lipofuscin N-retinylidene-N-retinylethanolamine (A2E) in RPE, which can confer susceptibility to blue light-mediated damage in the cells. Recent work has shown elevation of GRP78 and CHOP after A2E and blue light-induced damage in human RPE cells.<sup>82</sup>

In vivo studies of AMD implicate ER stress in the disease pathogenesis. For example Dr. C. Chan (National Eye Institute, NIH) developed a mouse model of AMD that has defects in two genes that are involved in immunologic processes.<sup>83</sup> One gene encodes CX3C chemokine receptor 1 (CX3CR1), the receptor for CX3CL1/fractalkine chemokine, which is expressed in RPE, Müller cells, and microglia. Two single nucleotide polymorphisms (SNPs) of CX3CR1 coupled with a decreased number of CX3CR1 transcripts and protein in AMD macula are associated with AMD.<sup>84</sup>

The second gene, *Ccl2* (MCP-1, a CC chemokine), is thought to play a homeostatic, immunoregulatory role in AMD pathogenesis.<sup>85</sup> Aged mice with deficient *Ccl2* or *Ccr2*, the corresponding receptor, develop many cardinal features of AMD, including drusen formation, RPE accumulation of lipofuscin and complement factors, and choroidal neovascularization.<sup>86</sup> To mimic closely the pathologic features of AMD, mice with mutations in these two genes have been crossed to generate *Ccl2/Cx3cr1* mice.<sup>87</sup> These double-knockout (DKO) mice were established in mice that harbor the *Crb<sup>rd8</sup>* mutation and recent data show that DKO<sup>*rd8*</sup> mice recapitulate some human AMD-like features in addition to the retinal dystrophy observed in *rd8* mice.<sup>88</sup> Fundoscopic examination of *Ccl2<sup>-/-</sup>/Cx3cr1<sup>-/-</sup>* (DKO<sup>*rd8*</sup>) mice as early as 4–6 weeks of age revealed drusen-like lesions that progressed to large, confluent areas of yellow deposits in the deep retina and subretinal space by 4–6 months of age and flattened atrophic areas by 6 months of age. Studies of the retinas of these mice suggest that the pathogenesis of AMD may be mediated by ER stress and protein misfolding. Indeed, there is decreased expression at the mRNA and protein level of ERp29, a molecular chaperone protein.<sup>83</sup> Given that AMD is multifactorial and there is no single mutated protein to be targeted, Tuo and colleagues hypothesized that enhancing chaperone activity through the use of chemical and/or pharmacologic chaperone compounds may prove beneficial to many individuals suffering from this devastating sight-threatening disease.<sup>73</sup> A promising example of this concerns the chaperone protein  $\alpha$ B crystallin, a 20-kD member of the small heat shock protein (HSP) family. HSPs prevent aggregation of folded proteins and facilitate intracellular protein trafficking.  $\alpha$ B crystallin is secreted from RPE cells and is taken up by adjacent photoreceptor cells conferring neuroprotection.<sup>89</sup> As increased  $\alpha$ B crystallin is a biomarker for AMD, it may be fruitful to exploit increased secretion toward neuroprotective effects. More recent studies suggest that  $\alpha$ B crystallin is an important regulator of ER stress in RPE.<sup>90</sup> Indeed, RPE cells from  $\alpha$ B crystallin ( $-/-$ ) mice and from human RPE cells transfected with  $\alpha$ B crystallin siRNA are more vulnerable to ER stress induced by tunicamycin.<sup>91</sup> These studies also demonstrated that prolonged ER stress decreases levels of  $\alpha$ B crystallin, thereby exacerbating mitochondrial dysfunction.

## Summary

In summary, ER stress is implicated in a number of retinal diseases, including RP, diabetic retinopathy, early-onset maculopathies, and AMD. It is paradoxical that the UPR, which is triggered by ER stress, can induce cytoprotective effects that restore homeostasis but can also induce cell destructive effects that promote apoptosis. It is not clear how the UPR integrates these opposing outcomes to progress toward survival or death. It has been postulated that the duration of expression of specific branches of the UPR process (i.e., the PERK, IRE1 $\alpha$  or ATF-6 branches) dictates this outcome. Understanding ER stress in retinal diseases is emerging as an area of intense investigation.<sup>92-94</sup> It is hoped that the outcome of these studies will lead to discovery and development of innovative therapeutic intervention strategies for retinopathies.

**Conclusions**

## Introduction

Cell death is an inevitable consequence of life. It plays a critical role in development by eliminating transitory organs and tissues (e.g., hyaloid vessels) and tissue remodeling where cell death allows the removal of excess or unwanted cells (e.g., death of oligodendrocytes in the optic nerve). During life, dead and damaged cells are constantly being replaced to ensure homeostasis and normal functioning of multicellular organisms. However, with increasing age, cell death can exceed replacement, leading to loss of tissue/organ function. Furthermore, injury and disease can lead to excessive cell loss, which overwhelms the organism and leads to functional impairment and even death. The majority of cell death in the retina occurs by apoptosis, which has the big advantage over necrosis that it is self-contained and does not result in an overt inflammatory response. Autophagy, a housekeeping process to maintain cellular homeostasis, can result in cell death when it exceeds a certain threshold. The following chapter will discuss cell death in the retina in detail in the context of development, aging, and diseases such as glaucoma, diabetic retinopathy (DR), and age-

related macular degeneration (AMD). It will further consider the initiating factors in retinal apoptosis and discuss potential therapeutic strategies for preventing retinal cell death and preserving or restoring vision.

## Modes of Cell Death

The Nomenclature Committee on Cell Death (NCCD) has made two subsequent recommendations on guidelines for the identification of modes of cell death since 2005, each time incorporating the latest findings in the area.<sup>1,2</sup> The NCCD concludes that: “Cell death can be classified according to its morphological appearance (which may be apoptotic, necrotic, autophagic or associated with mitosis), enzymological criteria (with and without the involvement of nucleases or of distinct classes of proteases, such as caspases, calpains, cathepsins, and transglutaminases), functional aspects (programmed or accidental, physiological or pathological) or immunological characteristics (immunogenic or non-immunogenic).” While death associated pathways may be “turned on” transiently during several unrelated biologic processes, a cell is normally only considered dead once it has passed an irreversible phase in the “death process.”

## Apoptosis

Apoptosis, or programmed cell death, has been extensively studied due to its critical role in development, tissue homeostasis, and pathology.<sup>3,4</sup> Importantly, apoptosis does not elicit an inflammatory response, thus allowing “physiologic” cell death to take place without pathologic consequences. Morphologic features of apoptosis include rounding up of the cell, reduction in cellular and nuclear volume (pyknosis), nuclear fragmentation, modification of cytoplasmic organelles, plasma membrane blebbing, and engulfment by neighboring cells (Fig. 26.1).<sup>2</sup> Apoptosis can be initiated by a variety of stimuli through two distinct pathways – extrinsic and intrinsic.<sup>5</sup> The extrinsic pathway is triggered by interaction of death receptors present on the cell surface with their cognate ligands (e.g., Fas/CD95 ligand, tumor necrosis factor-alpha

[TNF- $\alpha$ ], TNF ligand superfamily, and TNF-related apoptosis-inducing ligand [TRAIL]) and which can initiate the downstream executioner caspase (cysteine aspartic acid proteases) cascade within seconds of ligand binding.<sup>6</sup> Additionally, dependence receptors including Netrin-1 receptors, DCC (deleted in colorectal cancer) and UNCH5, neogenin, RET (prototypical oncogene tyrosine-protein kinase receptor), TrkC (tropomyosin-related kinase C), ALK (anaplastic lymphoma kinase), ephrin A4 (EphA4), Patched, MET, and some integrins have been identified to participate in alternative extrinsic apoptotic signaling whereby cell death or subapoptotic events may ensue.<sup>7-10</sup> By contrast, the intrinsic pathway is initiated by “stress signals” including oxidative damage, DNA damage, loss of cell–cell contact, growth factor withdrawal, hypoxia, cytosolic Ca<sup>++</sup> overload, and endoplasmic reticulum stress. These signals target the mitochondria and induce the release of proapoptotic factors to the cytosol that activates caspases via mitochondrial outer membrane permeabilization. Excessive or deficient apoptosis is involved in numerous disease states. Readers requiring more detail are directed to the work of Green and Reed.<sup>3,4</sup>

**FIG. 26.1** Apoptotic versus necrotic morphology.

## Necrosis

Necrosis has been defined as a type of uncontrolled cell death occurring in response to alkylating DNA damage, infection, toxins, chemicals, injury, or lack of blood supply.<sup>3,11</sup> Morphologically, necrosis is associated with cytoplasmic swelling (oncosis), rupture of the plasma membrane, swelling of cytoplasmic organelles, and moderate chromatin condensation (Fig. 26.1). The critical pathophysiologic difference between necrosis and apoptosis is inflammation. Necrosis culminates in the uncontrolled release of antigens that activate the immune system and promote inflammation, whereas in apoptosis, cell-bound bodies are formed that are phagocytosed by neighboring cells and there is an absence of inflammation. Recent studies suggest that there is a molecular signaling network that can regulate the necrotic cell death pathway.<sup>12</sup> Specific necrotic signaling mechanisms consist of RIP Kinase homologs 1 and 3 interacting with FAS-associated death domain (FADD), FLIP (FLICE-like inhibitory protein long isoform), and pro-caspase 8. Readers are advised to consult Humphries et al. for a deeper understanding of the process.<sup>13</sup>

## Other

A number of other cell death pathways have been identified, of which autophagic cell death has gained some prominence.<sup>14</sup> Increased autophagy (see below), such as that occurring under starvation, leads to self-destruction of intracellular organelles for provision of nutrients which, if starvation is not reversed, will culminate in self-destruction of cells and tissues.<sup>15</sup> Autophagic cell death is morphologically defined as occurring in the absence of chromatin condensation, massive autophagic vacuolization, and little or no uptake by neighboring cells.<sup>16</sup> Interestingly, autophagy is upregulated in a number of neurodegenerative diseases and thus may contribute to cell loss associated with these conditions. Several other atypical cell death modalities have also been identified, and these are reviewed in Galluzzi et al.<sup>17</sup>

## Cross-Talk Between Cell Death Pathways

Until recently, a requirement for gene expression was documented only for apoptotic and autophagic cell death. Interestingly, certain genes and their products, e.g., p53, Bcl-2 family proteins, and calpain, are important for both these modes of cell death.<sup>11,12,14</sup> Basal p53 activity suppresses autophagy, whereas p53 activation by some stimuli induces autophagy as well as apoptosis mediated by the Bcl-2 family proteins.<sup>12,14</sup> Atg5 is essential for autophagy; however, its truncated form, produced as a result of calpain cleavage, interacts with Bcl-xL to promote cytochrome c release and caspase-dependent apoptosis.<sup>18</sup> Accumulating evidence now suggests that necrotic cell death can also be mediated by a specific set of signal transduction pathways and degradative mechanisms that can contribute to embryonic development and adult tissue homeostasis.<sup>19</sup> Some gene products, such as TNFR, CD95, TRAIL-R, and RIP1, might trigger both apoptosis and necrosis, depending on interaction with other proteins.<sup>11</sup> Moreover, there is cross-talk between these two cell death modalities. For example, inactivation of caspases might cause a shift from apoptosis to necrosis, or a mixture of the two.<sup>11</sup> Thus cell death is not as easily defined as generally believed, and there is considerable cross-talk between the different cell death mechanisms.

## Is Cell Death Bad?

Cell death is often considered as a pathologic endpoint, but is this really the case? During normal development and differentiation we produce an excess of many cell types that undergo apoptosis.<sup>20</sup> Cells are constantly dying and being replaced as part of the overall homeostatic process to remove dysfunctional and damaged cells. In this context cell death is beneficial as it maintains optimal function in multicellular organisms. Provided the balance between loss and replacement remains constant, all is good; however, this is not always the case in aging or pathology where cell death increases and cell replacement decreases, resulting in an impaired organism. One therapeutic approach is to inhibit cell death. While laudable, this may not always be the best option as keeping alive damaged, mutated, or dysregulated cells will be to the detriment of the organism.

# Autophagy and Cell Maintenance

Autophagy is essential for cellular housekeeping and homeostasis through the sequestration and transfer of intracellular components (e.g., protein aggregates, organelles) to lysosomes for degradation.<sup>21,22</sup> In mammalian cells, three primary types of autophagy have been reported: macroautophagy, chaperone-mediated autophagy (CMA), and microautophagy (Fig. 26.2).<sup>23-27</sup>

**FIG. 26.2** The different types of autophagy described in the text.

Macroautophagy is the best-characterized autophagy pathway that targets larger substrates such as protein aggregates, intracellular pathogens, and dysfunctional organelles such as mitochondria for degradation (Fig. 26.2).<sup>21,22,28</sup> The process of macroautophagy involves over 37 autophagy-related proteins (ATGs), which regulate different stages of the autophagic response (Fig. 26.3).<sup>29</sup> Macroautophagy is initiated by the sequestration of the

cytosolic substrate into double membrane-bound phagophores that predominantly originate from the rough endoplasmic reticulum with possible contributions from the plasma membrane or mitochondria.<sup>30–33</sup> The resulting autophagosome acquires endosomal and lysosomal proteins, ultimately maturing into a degradative autolysosome. The mTOR kinase complex is considered central to the signaling pathway of autophagy and can sense regulating conditions such as nutrient abundance, energy state, and growth factor levels.<sup>34,35</sup> The PI3K-III complex, consisting of Vps34 and p150 and activators such as Beclin-1, Ambra1, ATG14, and UVRAG, plays a crucial role in the induction of autophagy by generating PtdIns(3)P-rich membranes, which act as platforms for ATG protein recruitment and autophagosome nucleation.<sup>36</sup> Antiapoptotic BH3 proteins such as Bcl-xL and Bcl-2 bind to Beclin-1, negatively regulating PI3K-III activity and autophagy. Initiation of the mammalian autophagosome membrane formation depends on the ULK1-mAtg13-FIP200-Atg101 complex.<sup>37</sup> Elongation and completion of the phagophore are brought about by two ubiquitin-like conjugation systems: the Atg12-Atg5-Atg16 system and the Atg8-phosphatidylethanolamine (PE) system. Atg7 functions as an E1 enzyme in both systems, while Atg10 and Atg3 act as E2 enzymes for Atg12 and Atg8, respectively.<sup>38,39</sup> The C-terminus of Atg8 is cleaved by Atg4, which primes the protein for conjugation to PE. The Atg12–Atg5–Atg16 complex recruits Atg8-PE to the elongating phagophore.<sup>39,40</sup> At least eight different Atg8 orthologs belonging to two subfamilies (LC3 and GATE-16/GABARAP) occur in mammalian cells.<sup>41,42</sup> LC3s are involved in elongation of the phagophore membrane, whereas the GABARAP/GATE-16 subfamily is essential for a later stage in autophagosome maturation. The N-termini of LC3 and GATE-16 are required for autophagosome–lysosome fusion.<sup>42</sup> Once in the lysosomes, substrates are degraded by the repertoire of lysosomal enzymes.<sup>43</sup> It has been proposed that the autophagic elimination of mitochondria has its own specialized pathway.<sup>26</sup> Critical to this process are the proteins PINK1, the E3 ubiquitin ligase, Parkin, BNIP3, NIX, and possibly p62, a protein that binds to ubiquitin and LC3. PINK1 binds to uncoupled mitochondria, which then facilitates the recruitment of Parkin, which leads to ubiquitination of

mitochondrial surface proteins. The ubiquitinated mitochondrion is then sequestered into the autophagosome, likely through the actions of p62 and LC3.

**FIG. 26.3** The regulatory molecules involved in the different steps of the mammalian macroautophagy pathway. Potential pharmacologic inhibitors used to

block autophagy at different steps are also shown.

Autophagy can be activated by nutrient deprivation and environmental stress. For example, amino acid starvation and reactive oxygen species (ROS) can stimulate autophagy.<sup>44,45</sup> Recently, a distinction has been made between starvation- and stress-induced macroautophagy, also referred to as “quality control” autophagy. It has been observed that autophagic deficient cells tend to accumulate p62-rich aggregates, which in turn cause Nrf2 to be activated after separation from its interacting partner Keap1, which allows Nrf2 to mount an antioxidant response.<sup>46</sup> In addition, histone deacetylase 6 (HDAC6) stands out as a key regulator in the autophagic response to oxidative damage, as it is recruited to ubiquitinated autophagic substrates, where it stimulates autophagosome–lysosome fusion by promoting F-actin remodeling in a cortactin-dependent manner.<sup>47</sup> However, HDAC6 and cortactin are dispensable for starvation-induced autophagy.

CMA differs from the other types of autophagy as it does not involve vesicle formation but, rather, a direct translocation of a specific set of soluble proteins across the lysosomal membrane for subsequent degradation (Fig. 26.2).<sup>48</sup> CMA cargo substrates include enzymes, transcription factors, binding proteins, subunits of the proteasome, and proteins involved in vesicular trafficking and contain a KFERQ-like motif, which is recognized by the cytosolic chaperone, Hsc70. Binding of the chaperone/substrate to the cytosolic tail of lysosome-associated membrane protein type 2A (LAMP-2A), which spans the lysosomal membrane, leads to translocation of the cargo across the membrane and into the lysosomal lumen for degradation.<sup>23</sup> This pathway has been shown to be progressively ineffective with age because of the age-related loss of LAMP-2A.<sup>49</sup>

Microautophagy involves internalization of cytosolic cargo such as cytosolic proteins, glycogen, and ribosomes through invaginations of the lysosomal membrane,<sup>50,51</sup> resembling multivesicular body formation (Fig. 26.2).<sup>24,48,52</sup> Although the molecular mechanisms in mammalian cells are poorly understood, a recent study by Sahu et al. proposes that microautophagy relies on endosomal sorting complexes required for transport (ESCRT) I

and III, which are necessary for the formation of the vesicles in which the cytosolic cargo is internalized.<sup>53</sup> It appears that this pathway also involves Hsc70 interaction with a substrate containing a KFERQ-like motif, also found in CMA, and that mitophagy and CMA may share common upstream pathways.<sup>48,53</sup>

As will be discussed below, autophagy plays a critical role in maintaining retinal homeostasis, together with the proteosomal system, in the removal of damaged proteins and organelles in highly metabolic nondividing cells that exist in a pro-oxidative retinal environment. Autophagy proteins are strongly expressed in the retina (Fig. 26.4). However, problems occur when basal levels of autophagy become dysregulated as either a decrease or increase in autophagy flux will have significantly detrimental effects on cell function.<sup>54</sup>

**FIG. 26.4** Immunolocalization of the autophagy protein LC3 (green) in normal mouse retina. Nuclei are stained

with 4',6-diamidino-2-phenylindole (DAPI: blue) and blood with agglutinin (red). LC3 is strongly expressed in the retinal ganglion cell layer (*RGC*), retinal vessels, a subpopulation of the inner nuclear layer (*INL*), the outer nuclear layer (*ONL*) of rods and cones, and the retinal pigment epithelium (*RPE*) but is only very weakly expressed in the inner plexiform layer (*IPL*).

## Age-Related Retinal Cell Loss

It is well recognized that the human retina undergoes numerous age-related changes that result in altered morphology, reduced function, and cell loss. Not surprisingly, this is associated with a significant reduction of retinal thickness as a function of age.<sup>55-57</sup> Mean retinal thickness is reported to decrease by 0.53  $\mu\text{M}/\text{year}$ <sup>55</sup> and, in the macula, retinal thickness and macular volume decrease by around 0.35  $\mu\text{M}$  and 0.01  $\text{mm}^3/\text{year}$ .<sup>57</sup> Changes in cell morphology include nodular excrescences in rod outer segments;<sup>58</sup> accumulation of lipofuscin in photoreceptor inner segments and the retinal pigment epithelium (*RPE*);<sup>59,60</sup> displacement of nuclei from the outer nuclear layer (*ONL*);<sup>61</sup> and extension of ON-cone bipolar cell and horizontal cell processes into the *ONL*. Such evidence of retinal reorganization and plasticity has also been corroborated by animal studies.<sup>62,63</sup> Reorganization of the dendrites could be an adaptive attempt to compensate for the lost circuitry due to photoreceptor loss and/or to make up for existing, yet dysfunctional, synapses.

There is an age-related decrease in the density of photoreceptor cells in the human retina, with rods appearing to be more vulnerable than cones.<sup>64</sup> In the equatorial retina, cones decrease uniformly at a rate of approximately 16 cells/ $\text{mm}^2$  per year while the decrease in equatorial rods is greatest, 970 cells/ $\text{mm}^2$  per year, between the second and fourth decades.<sup>65</sup> By contrast, cone density remains relatively constant at the fovea up to the ninth decade.<sup>64-66</sup> It therefore appears that rod photoreceptors are more vulnerable to loss during aging than cones and that photoreceptors in the fovea are less susceptible to attrition. Furthermore, compensatory

adaptations have been reported following rod cell degeneration where the space vacated by dying rods is filled by enlarged rod inner segments from neighboring photoreceptors, resulting in similar rod coverage at all ages.<sup>64,67-69</sup> Evidence that cones depend on survival factors secreted by rods may explain the differential vulnerability between rods and cones,<sup>70-72</sup> but this remains a matter of intense debate.

Photoreceptor loss appears to precede the loss of associated neural cells. Retinal nerve fiber layer thickness decreases dramatically with age<sup>73</sup> and is associated with significant retinal ganglion cells (RGC) loss by as much as 150/mm<sup>2</sup> over a period of 40+ years.<sup>56</sup> RGC death at the equatorial regions follows a similar trend to photoreceptor death during aging, thus maintaining a constant photoreceptor-to-RGC ratio.<sup>69</sup> Age-associated degeneration of the rod bipolar cells in the inner nuclear layer (INL) has been reported.<sup>74</sup> Although rod cell death can initiate as early as the second decade of life, the bipolar cells start to degenerate only after the fourth decade and appreciably reduce by the ninth decade<sup>65</sup> indicating that this phenomenon is secondary to rod cell loss. In a more comprehensive study using multiphoton confocal microscopy to quantify neuron densities in the RGC layer, INL, and ONL, the greatest neuronal loss occurred in the RGC layer and ONL in human aging retinas, whereas the INL is relatively preserved.<sup>75</sup> It must also be remembered that RGCs are classified into a number of subtypes and so even a seemingly mild loss of RGC in the initial phases could imply the loss of a major subtype of RGC that could start affecting visual perception.<sup>69</sup>

Despite numerous studies to determine age-related changes in RPE cell density, outcomes vary and are highly dependent on retinal location. Two studies have reported that RPE density decreases with age in the equatorial retina and is greatest in the periphery,<sup>65,76</sup> with an estimated loss of 0.3% per year.<sup>76</sup> By contrast, no significant age-related decrease in RPE cell density was observed at the foveal center, suggesting that, like foveal cones, the RPE cells in this region are more resistant to attrition than those outside the fovea.<sup>65</sup> However, a further study reported that the macular region in aged eyes contained a significant number of apoptotic cells and these were greatest in the fovea.<sup>67</sup> Given the disparity between

studies on age-related changes in RPE cell density, it is not surprising that there is no clear agreement to what extent the RPE-to-photoreceptor ratio changes with age, if at all.<sup>65,76</sup>

Evidence would suggest that age-related cell loss in the retina occurs by apoptosis since occasional apoptotic cells are observed in retinal sections and without the typical inflammatory response that would occur via necrosis. The stimulus for age-related cell loss is also unclear, but since the majority of cells affected are postmitotic or terminally differentiated, the accumulation of stochastic damage as occurs with aging in other tissues is plausible. In particular, oxidative damage is likely to play a significant role since the retina has high oxygen levels, is exposed to light, and has a number of highly metabolically active cell types, making it an ideal environment for the generation of ROS.<sup>77</sup> As previously mentioned, the retina undergoes considerable remodeling throughout life to adapt to age-related cell loss. In addition, there is likely to be a basal level of limited cellular replacement through resident and bone marrow-derived stem or progenitor cells that have the capacity to differentiate into a number of retinal cell types.<sup>78</sup>

## Retinal Damage: Death and Repair

### Introduction

Retinal cell dysfunction and loss are common features of most retinal diseases (e.g., glaucoma, diabetic retinopathy [DR], age-related macular degeneration [AMD]) as well as tissue injury (e.g., retinal detachment, light damage). Such cell loss has a major negative impact on retinal function and can lead to significant visual loss.

### Glaucoma and Ganglion Cell Loss

Glaucoma is a heterogeneous group of diseases that lead to RGC death.<sup>79-81</sup> Pathology is associated with “cupping” of the optic disc due to loss of ganglion cell axons. Analysis of both postmortem specimens and experimental animal models show that RGC death occurs by apoptosis.<sup>82-84</sup> Analysis of retinas from human donors

suffering primary open angle glaucoma demonstrated greater than 15 times more apoptotic cells than the controls.<sup>84</sup> Interestingly, apoptosis also accounts for the selective elimination of about 50% of excess RGCs during developmental organization of the visual pathway.<sup>85</sup> Apoptosis of RGCs in glaucoma has generally been considered to occur as a result of mechanical damage due to an increase in intraocular pressure, but damage to RGCs can also occur in normal-pressure glaucoma.<sup>86</sup> Other insults that have been reported to induce RGC apoptosis are neurotrophin deprivation, glial activation, ischemia, glutamate excitotoxicity, and oxidative stress.<sup>81</sup> Confirmatory data that RGC apoptosis occurs by the intrinsic pathway involving mitochondria come from backcrossing DBA/2J mice that exhibit a spontaneous secondary glaucoma with Bax (one of several BH3 family death proteins) knockout mice resulting in a mouse strain in which glaucomatous neurodegeneration was reduced.<sup>87</sup>

Despite the strong association between oxidative stress, mitochondrial damage, and RGC death, there have been only limited studies on the role of autophagy in RGC maintenance and glaucoma. Rodriguez-Muela and colleagues recently reported that autophagy promotes survival of RGCs after optic nerve axotomy in mice.<sup>88</sup> Calpain-mediated cleavage of Beclin-1 and autophagy deregulation have been reported in a rat model of retinal ischemic injury that recapitulates features of glaucoma.<sup>89</sup> Furthermore, blockade of autophagy increased cell death in cultured RGC, suggesting a prosurvival role for the autophagic process. Activation of autophagy in RGCs occurs after optic nerve transection and increased autophagy offers a protective role in cultured RGCs.<sup>90</sup> Sternberg and colleagues demonstrated that autophagy provided a survival mechanism against caspase-dependent death of neonatal RGCs induced by axon damage.<sup>91</sup> However, some reports fail to support the hypothesis that autophagy is protective to RGCs. Piras et al. recently reported that following ischemia/reperfusion, 3-MA mediated inhibition of autophagy resulted in reduced RGC death,<sup>92</sup> and Park et al. made a similar observation in a chronic hypertensive glaucoma rat model where autophagy inhibition resulted in lower RGC death.<sup>93</sup>

## Diabetic Retinopathy

It has long been recognized that diabetes leads to a loss of pericytes and endothelial cells in the retinal vasculature (Fig. 26.5).<sup>94,95</sup> Cogan and colleagues identified intramural pockets in the vascular basement membrane lacking normal cell contents, referred to as pericyte “ghosts,” as one of the earliest changes in DR.<sup>96</sup> Pericyte loss is accompanied by loss of endothelial cells from the retinal vasculature, leading to “acellular” capillaries (intact vessel basement membrane devoid of cells lining the lumen) and loss of blood–retinal barrier function. Cell death in these populations appears to occur predominantly via the intrinsic apoptotic pathway.<sup>97</sup> These characteristic changes have long been considered a hallmark of DR. However, studies by Barber and others reveal that diabetes is also associated with increased loss of retinal neurons.<sup>98,99</sup> STZ-diabetic rat retinas after 30 weeks of diabetes showed a 22% reduction in the thickness of the inner plexiform layer, a 10% reduction in RGCs, and a 14% reduction in the thickness of the INL.<sup>100</sup> Clinical studies of diabetic patients using scanning laser polarimetry and optical coherence tomography have largely confirmed these findings.<sup>101–103</sup> It is also likely that other neuronal populations such as amacrine cells undergo apoptosis in diabetes.<sup>104</sup> There are many potential initiators of retinal cell apoptosis including hyperglycemia, oxidative stress, reduced blood flow, ischemia, neuroinflammation, and, specifically in the case of retinal neurons, glutamate excitotoxicity.<sup>97,98</sup> Light and electron microscopy have revealed a significant number of pericytes in human and rodent diabetic retinas to have necrotic cell characteristics.<sup>105</sup> While apoptosis is the predominant death pathway of pericytes,<sup>106,107</sup> it is possible that a selective population of these dying cells may undergo programmed necrosis.

**FIG. 26.5** A retinal digest showing pericyte dropout and areas of avascular capillaries in the rat retina (*arrows*). (Courtesy of Ashay Bhatwadekar, University of Florida.)

There is surprisingly little information currently available on the potential role of autophagy in the pathogenesis of DR, even though there is extensive evidence that (1) autophagy is dysregulated in other diabetic tissues<sup>108,109</sup> and (2) damaged mitochondria are associated with the pathogenesis of DR.<sup>97</sup> We have recently reported that autophagy flux is decreased in the retinal cells of diabetic rats compared to controls.<sup>110</sup> Although DR had been originally thought to be purely a microvascular disease, several new findings indicate a role of inflammation in the form of activation of caspase-1 and IL-1 $\beta$  production in the retina of diabetic rodent models.<sup>111-114</sup> In vitro studies indicate increased caspase-1 activity and IL-1 $\beta$  secretion in Müller cells following exposure to hyperglycemic conditions. Kusner et al. demonstrated that inhibition of caspase-1/IL-1 $\beta$  activation prevented Müller cell loss suggesting a possible role of the caspase-1 dependent death pathway in the diabetic retina namely, pyroptosis.<sup>115</sup>

The impact of cell death in the diabetic retina and the order in which different cell types die during the progression of DR remain

unclear. For example, pericyte dropout and acellular capillaries are observed in many diabetic animal models, yet they do not progress to the sight-threatening proliferative stage. Furthermore, the duration of diabetes in many patients may be 15 years or more before clinical abnormalities are observed in the retina, even though vascular and neuronal cell death will be occurring. A possible explanation for this chronic, rather than acute, attrition in the retina is a low level of cellular replacement from resident and bone marrow-derived stem or progenitor cells.<sup>78</sup> Bone marrow-derived progenitor cells have the capacity to differentiate in a range of retinal vascular and neuronal cell types in response to retinal injury and in the case of the retinal vasculature can repopulate acellular capillaries in rodent models of DR.<sup>116,117</sup> However, these bone marrow-derived progenitors are reduced and appear to be dysfunctional in diabetics and thus repair potential is attenuated.<sup>118,119</sup>

## Macular Degeneration

The challenge in studying retinal cell loss mechanisms in AMD is to be able to differentiate between cell loss resulting from disease and that observed in the normal course of aging. However, reports concur that loss of photoreceptors, RPE, and choroidal cells are accelerated in AMD and that this is regional and often focal. Clinically, areas of geographic atrophy (GA) can be observed within the retinal arcades of patients with dry AMD, and these lesions will increase in size with lengthening duration of AMD (Fig. 26.6). Areas of GA show a continuous enlargement over time with a median growth rate of between 1 and 13 mm<sup>2</sup>/year and linear progression.<sup>120,121</sup> The considerable variability between patients is unexplained but could reflect genetic susceptibility, diet, smoking, and light exposure. However, there is concordance of disease progression in bilateral GA.<sup>122</sup> RPE loss is normally associated with a reduction in the choroidal vasculature. Evidence of the degree of choroidal capillary loss and its relationship with RPE loss has been elegantly described by McLeod and colleagues.<sup>123</sup> They observed a linear relationship between the loss of RPE and loss of the choriocapillaris in GA. The vascular area was reduced by 50% in

regions of complete RPE atrophy, and there was extreme constriction of remaining viable capillaries. Adjacent to active choroidal neovascularization, choriocapillaris dropout was evident in the absence of RPE atrophy, resulting in a 50% decrease in vascular area. The authors concluded that the close association observed between degenerating RPE and choriocapillaris suggests that, at least in GA, RPE atrophy occurs first, followed by choriocapillaris degeneration.

**FIG. 26.6** Fundus autofluorescence images showing geographic atrophy in a 74-year-old patient. (A) The patient presented with visual acuity of 20/40 and several areas of retinal pigment epithelial atrophy. (B) Two years later the same patient was re-examined: visual acuity had decreased to 20/200, and there was extensive geographic atrophy, including the foveal area. (Courtesy of Erik Van Kuijk, Ophthalmology and Visual Sciences, UTMB, Galveston, Texas.)

It has largely been considered that photoreceptor cell death occurs as a result of dysfunction or death of the underlying RPE. However, as mentioned earlier, there is significant rod photoreceptor loss as a function of age even in the presence of an apparently healthy RPE.<sup>64</sup> Photoreceptor topography in both dry and wet AMD shows preferential loss of rods over cones.<sup>124</sup> The total number of foveal cones in eyes with large drusen and basal deposits was similar to that of age-matched controls, and the foveal cone mosaic appeared normal. By contrast, cones appeared large

and misshapen with few rods remaining in the parafovea and, by late-stage AMD, virtually all surviving photoreceptors in the macula were cones.<sup>124</sup> In eyes from wet AMD donors, photoreceptors surviving on, or at the margins of, disciform scars were largely cones. Subsequent functional studies supported the histologic evidence for preferential vulnerability of rods in aging and AMD.<sup>125</sup> Although Jackson and colleagues concluded from these histologic studies that photoreceptor loss is secondary to RPE dysfunction or death in AMD, it still remains possible that a photoreceptor abnormality could be the primary effect in AMD and that this leads to subsequent loss of the underlying RPE.

Despite the overwhelming evidence of retinal cell loss in AMD, there are surprisingly few reports on the type of cell death, or the initiating insult(s), in human AMD tissue. Most studies have relied on cell culture assays and animal models with an AMD phenotype, which indicate that cell death occurs primarily by apoptosis. The most detailed report is from Dunaief and colleagues who observed a statistically significant increase in TUNEL-positive apoptotic cells in the inner choroid, RPE, ONL, and INL of AMD donor eyes.<sup>126</sup> This increase in the number of apoptotic cells was evident in 5 of 6 eyes with GA and all eyes with exudative AMD. Interestingly, in eyes with drusen, only a few TUNEL-positive cells were observed in each nuclear layer except the RGC layer. From the same study TUNEL-positive photoreceptors are also evident over an area of disorganized RPE near an edge of atrophy. TUNEL-positive RPE cells were found most commonly near areas of atrophy and occurred more often in AMD eyes than in controls.<sup>126</sup> While an interesting and informative study on cell death in AMD, the number of apoptotic cells seems high, especially in the neural retina, for a slowly progressive condition. By contrast, Xu et al. only observed apoptotic cells in the retina of 4 of 16 AMD donor eyes and the overall numbers of apoptotic cells appeared relatively low.<sup>127</sup> Nordgaard and colleagues undertook proteomic analysis of the RPE from donor eyes at progressive stages of AMD.<sup>128</sup> Several components of apoptotic signaling pathways ( $\alpha$ A crystallin, VDAC1, HSP70, GST- $\pi$ ) demonstrated changes in expression early in AMD or changed linearly with AMD progression. Surprisingly, information on death mechanisms in the AMD is scarce, but there is

evidence from cell culture and animal models for both intrinsic and extrinsic apoptosis pathways. FAS-mediated apoptosis has been observed in retinal cells, which could explain the role of inflammation in AMD,<sup>129</sup> and studies have reported oxidative stress-induced apoptosis by the classic mitochondrial route.<sup>130-132</sup> Recent reports indicate the alternative possibility of both RIP kinase-mediated programmed necrosis as well as the NLRP3 inflammasome-mediated sterile inflammation in RPE subjected to oxidative stress. Hanus et al. reported that oxidative stress-mediated RPE death in vitro could be effectively prevented when RIP kinases that are involved in programmed necrosis are inhibited.<sup>133</sup> The recent finding of Alu RNA accumulation leading to RPE cytotoxicity in geographic atrophy suggests a completely new mechanism of RPE degeneration.<sup>134</sup> Although Alu RNA accumulation stimulates “sterile inflammation” via the NLRP3 inflammasome/MyD88 signaling in the RPE, follow-up experiments suggested that the RPE degeneration does not ensue by the expected caspase-1 mediated pyroptosis.<sup>135</sup> More recent reports suggest the role of programmed necrosis in Alu RNA-mediated cytotoxicity.<sup>133</sup> We and others have recently reported that autophagy flux may be dysregulated in the RPE in AMD.<sup>136-142</sup> Studies in mouse models of AMD as well as human AMD donor samples suggest a decline in established autophagy markers while there is a marked accumulation of p62/Sqstm1, which (amongst its other functions) is a cargo for degradation via autophagy.<sup>137,138</sup> The decline in autophagy is likely due to multiple factors affecting autophagic initiation and/or the fusion of autophagosomes with lysosomes. These include lipofuscin accumulation, susceptibility to oxidative stress, mitochondrial damage, and lysosomal dysregulation, all of which have a strong association with AMD.<sup>140,143</sup> We and others have shown that inhibition of autophagy in RPE leads to lipofuscin accumulation.<sup>138,144</sup> To what extent changes in autophagy flux reflect alterations in the formation or elimination of autophagosomes remains to be determined, and it is unclear whether or not these changes are a cause or consequence of AMD. Lipid peroxidation products reduce autophagy flux and increase lipofuscin accumulation in cultured RPE cells.<sup>145</sup> An increase in lysosomal pH that is associated with the lipofuscin

constituent A2E<sup>146</sup> may impair autophagosome–lysosome fusion, as may the accumulation of lipofuscin granules within the lysosomal vacuome. It has been reported that drusen formation may reflect an increase in both mitochondrial damage and autophagy in the RPE.<sup>142</sup> The researchers speculated that increased autophagy and the release of intracellular proteins via exosomes by the aged RPE may contribute to the formation of drusen. It is important to note that there is substantial cross-talk between autophagy and proteasomal degradation pathways that may also affect the status of the RPE.<sup>136</sup> Nevertheless, elements of the autophagic pathway have been shown to be required for phagocytic degradation of photoreceptor outer segments within the RPE.<sup>147</sup> Silencing of RB1CC1/FIP200, an essential protein for autophagy initiation, results in degeneration of mouse RPE.<sup>139</sup> The current overall opinion on the role of autophagy in AMD is that it is a housekeeping process absolutely essential for RPE function and survival rather than a mode of cellular demise.

A key point to be considered is that cellular repair, cellular replacement, and damage control are critical in retinal homeostasis and a declining antioxidant system together with increased oxidative damage will play a major etiologic role in AMD, and that once the threshold for damage is reached, multiple cellular processes for repair and regeneration will be impacted.<sup>148–151</sup>

## Retinal Detachment

Retinal detachment resulting from full-thickness retinal breaks, subretinal exudation, and/or vitreoretinal traction is a common cause of photoreceptor loss.<sup>152</sup> Cell death is highly dependent on the area and duration of the detachment. Analysis of tissue samples from patients with retinal detachment showed significant numbers of apoptotic cells by 24 hours, which peaked by 2 days and dropped to a low level by 7 days after detachment.<sup>153</sup> These observations have been largely supported by experimental retinal detachment in cats and rats, both of which show a peak of apoptosis between 1 and 3 days postdetachment, which then declines.<sup>154,155</sup> Some apoptotic cells were still evident at 28 days postdetachment. However, there is some debate as to whether apoptosis following

retinal detachment occurs via the intrinsic or extrinsic pathways.<sup>152,156,157</sup> The enzymatic activities of both initiator and effector caspases are elevated in rat retinas following detachment.<sup>158</sup> Paradoxically, pan-caspase inhibition does not completely reverse photoreceptor degeneration postdetachment indicating a possible role of additional caspase-independent cell death modes.<sup>154</sup> For example, RIP3 expression is dramatically elevated in retina after detachment suggesting a role of programmed necrosis.<sup>159</sup> Interestingly, retina RPE separation in rats causes a Fas-dependent activation of autophagy in injured photoreceptors and, if autophagy is inhibited, the time course and number of apoptotic cells is accelerated.<sup>160</sup> Furthermore, prolonging autophagy in detached retina by inhibiting upregulated calpain 1, which cleaves Atg5, can reduce the number of apoptotic cells.<sup>161</sup> Thus it appears that autophagy is activated to regulate the level of receptor apoptosis. The readers are advised to read an excellent review on the subject by Murakami et al.<sup>162</sup>

## Retinal Dystrophies

Retinal dystrophies encompass a heterogeneous group of inherited conditions, with more than 100 genes or loci identified to date.<sup>163</sup> The most common subtype is retinitis pigmentosa (RP), which is characterized by progressive death of retinal rod and cone photoreceptors in which the disease proceeds toward reduction of peripheral field with tunnel vision and finally loss of sight.<sup>163,164</sup> One of the major barriers in the comprehensive identification of the degenerative mechanisms underlying retinal dystrophies is the involvement of multiple causal genes in their pathogenesis.<sup>165</sup> The mode of rod cell death in several animal models of RP suggests death by apoptosis, which is in agreement with findings in RP retinas from donor eyes<sup>166</sup> (reviewed by Travis<sup>167</sup>). Cone cells usually die as a secondary response to rod cell death, possibly because they depend on rod-secreted neurotrophic factors for survival.<sup>70,72</sup>

Studies of apoptotic mechanisms in the photoreceptors of RP models imply the involvement of caspase-dependent as well as independent pathways.<sup>168-170</sup> DNA fragmentation was a regular

feature encountered in the mouse models, indicating that photoreceptors in mouse models die of apoptosis. Administration of caspase-3 inhibitors inhibited photoreceptor apoptosis in the tubby mouse model of Usher syndrome.<sup>171</sup> Caspase-independent modes of apoptosis may involve calpain and Ca<sup>2+</sup> excess in RP.<sup>172</sup> In recent years it has been suggested that, although apoptosis is the primary cell death mode, other modes of cell removal could be involved, including autophagy and complement-mediated lysis.<sup>173</sup> Investigation of different cell death pathways in three independent mouse models of photoreceptor degeneration – the *rd/rd* mouse, the *rds/rds* mouse, and the light-damage model in albino mice – shows that, apart from apoptotic cell death, several oxidative stress markers as well as elements of the autophagic and complement pathways are upregulated. While the induction of oxidative stress response genes is early, the induction of autophagy was only seen in damaged retinas when compared to controls.<sup>173</sup> The authors concluded that autophagy specifically removes damaged photoreceptors from the retina. However, the data may also be interpreted as an attempt in the damaged retina to salvage the photoreceptors from initial stress which, when overwhelming, gives rise to autophagic death. The evidence of upregulation of high-mobility group box 1 (HMGB1) protein in human eyes with retinal detachment suggests that necrosis could also be a mode of photoreceptor death.<sup>174</sup> It could well be this mode of cell death that accounts for some of the caspase-independent photoreceptor death pathways that have hitherto been thought to be apoptosis. Recent findings further support the theory that cone photoreceptors die by a programmed necrotic pathway. Murakami et al. showed that in *Rip3<sup>-/-</sup> rd10* mice, cone photoreceptors do not degenerate although the rods die at the same rate as in control *rd10* mice.<sup>175</sup> Furthermore, RIP kinase inhibitor prevented cone cell degeneration in *rd10* mice. It is possible that necrosis is initiated in the photoreceptors as a secondary response to apoptosis in rod cells. Nevertheless, the heterogeneity of RP and similar retinal dystrophies necessitates the understanding of the earliest mechanisms of disease inception such that customized treatments may be catered according to the nature of disease pathology in a patient. Attempts to block cell death by one strategy may prove to be futile as the protective effect may be

successful for only a short duration, after which the cell might proceed through another death mode.

## Light Damage

The retina is vulnerable to damage from ultraviolet radiation, visible light (400–700 nm), and infrared radiation.<sup>77,176,177</sup> The extent and type of damage are highly dependent upon the wavelength, power, duration, area of coverage, cumulative exposure, and location (e.g., macular versus periphery). Light-induced retinal damage can occur via at least one of three mechanisms: (1) mechanical (high irradiances of short duration that cause sonic shock waves disrupting the tissue irreversibly); (2) photothermal (when incident energy is trapped, causing a rise of temperature 10°C or more); and (3) photochemical (shorter-wavelength visible light is absorbed and dissipated away, causing molecular alterations).<sup>77</sup> Retinal photodamage is highly dependent on the presence of chromophores, of which the most obvious are the visual pigments, and in most species prolonged intense light exposure will lead to significant photoreceptor cell damage.<sup>178</sup> Other important chromophores include hemoglobin, melanin, lipofuscin, macular pigment, and flavins.<sup>77</sup> Photochemical damage has been the most extensively studied form of light damage because it causes retinal damage within the intensity range of ambient visible light.<sup>77,179,180</sup> There are two well-defined types of retinal light damage. Class 1 damage has an action spectrum that is identical to the absorption spectrum of the visual pigment and the initial damage is in the photoreceptors.<sup>77,179,181</sup> Class 2 damage has an action spectrum that peaks at shorter wavelengths, is generally confined to the RPE, and is often referred to as the blue light hazard.<sup>77,179,181</sup>

Most mechanistic studies on retinal photochemical damage have been undertaken in experimental animal models and all show that cell death occurs via apoptosis. Excess light has been shown to trigger apoptosis in rat retinas.<sup>182,183</sup> Low-intensity light exposure for long durations as well as intense light exposure (3000 lux) for short durations up to 2 hours can cause severe photoreceptor degeneration by apoptosis followed by RPE degeneration.<sup>184,185</sup> Higher intensity light (5000 lux for 1 hour) has been shown to

induce RPE permeability and increased secretion of vascular endothelial growth factor (VEGF), which when blocked is neuroprotective to the photoreceptors.<sup>186</sup> Both types of retinal photodamage, induced by exposure to either low- or high-intensity light, are dependent on the presence of, and regeneration of, rhodopsin in the retina.<sup>187-191</sup> The extent of photodamage correlates to the amount of rhodopsin present in the retina prior to the light damage,<sup>192,193</sup> although direct evidence of rhodopsin causing damage is absent. Several rhodopsin intermediates have been implicated as mediators of photo-oxidation, in particular all-*trans*-retinal, which accumulates in the photoreceptor membrane due to decreased reduction by retinol dehydrogenase.<sup>194</sup> Decrease of intracellular calcium levels during the phototransduction cycle has also been suggested to contribute to rhodopsin-mediated injury causing photoreceptor apoptosis.<sup>195</sup> Light-induced photoreceptor apoptosis can either be caspase-mediated or caspase-independent.<sup>196,197</sup> Cellular response will vary according to lighting conditions and all of the discovered pathways may contribute to photoreceptor cell fate depending on the prevalence and type of light damage during an individual's lifetime, contributing to a difference of opinion regarding the mechanisms of cell death observed, and the involvement of caspase and signal transduction pathways. Melanosomes and lipofuscin granules are the most significant fluorophores implicated in RPE damage. Irradiated lipofuscin granules or their constituents can generate high levels of ROS.<sup>198-200</sup> Several models of retinal degeneration in vitro and in vivo demonstrate the role of calcium in inducing cell death by activating degradative proteases such as calpain.<sup>201,202</sup> Adaptor protein 1 (AP-1) signal transduction has also been implicated in bright light-induced photoreceptor death where there is an increase of AP-1 gene expression.<sup>203</sup> Light can also damage RGCs<sup>204</sup> and a subpopulation of RGCs contain the chromophore melanopsin, suggesting that light damage could impact this specific subset of RGCs and contribute to the pathogenesis of glaucoma.<sup>205</sup> The role of autophagy in retinal light damage has only received limited attention, but Kunchithapautham and colleagues have shown that upregulation of autophagy can protect against light damage and oxidative stress in the retina.<sup>206-210</sup>

# Therapeutic Options

## Neuroprotection

Neuroprotection offers a promising approach for preventing or slowing retinal cell loss and is broadly defined as the use of therapeutic agents to prevent, hinder, and, in some instances, reverse neuronal cell death whatever the primary injury.<sup>207,211,212</sup> The strategies for neuroprotection vary considerably dependent upon the target cell, the nature of the factors initiating cell loss, and the stage of disease. Clearly, the ideal time for neuroprotection is in the early stages of the disease before any significant cell death has occurred. Three broad approaches have evolved: (1) blocking the pathways involved in the cellular damage (e.g., antioxidants); (2) inhibiting the cell death path directly (e.g., upregulation of Bcl-2 and inhibition of caspases); and (3) treatment with neurotrophic factors that suppress the intrinsic apoptosis pathway (e.g., brain-derived neurotrophic factor (BDNF), glial-derived neurotrophic factor (GDNF), pigment epithelial-derived factor (PEDF)). A summary of potential neuroprotective agents, their retinal cell targets, and their proposed mechanisms of action is shown in [Table 26.1](#).

**TABLE 26.1**

**A Summary of Potential Neuroprotective Agents, Their Retinal Cell Targets, and Their Proposed Mechanisms of Action**

Target Cell	Mechanistic Target	Therapeutic Approaches
Retinal ganglion cells	Excitotoxicity	Memantine, taurine
	Oxidative stress	Vitamin E
	Mitochondrial damage	Coenzyme Q10
	Neurotrophin deprivation	BDNF, gene therapy
Photoreceptors	Apoptosis	Survival and growth factors (e.g., BDNF, GDNF)
RPE	Apoptosis	Survival and growth factors
	Autophagy	Rapamycin
	Oxidative damage	Antioxidants, lutein, zeaxanthin, zinc
	Lipofuscin system	Reducing the retinoid cycle, glutathione-S-transferase
	Mitochondrial damage	Antioxidants, resveratrol
	Lysosomal system	Elevated pH (A <sub>2A</sub> adenosine receptor agonist)
	Bruch's membrane	Subthreshold laser, MMP upregulation, microbial enzymes

Choroid	Endothelial cell loss	Growth factors (e.g., VEGF)
Inflammation	Alternative complement pathway	Complement pathway inhibitors

BDNF, brain-derived neurotrophic factor; GDNF, glial-derived neurotrophic factor; MMP, matrix metalloproteinase; RPE, retinal pigment epithelium; VEGF, vascular endothelial growth factor.

Light damage in rodents, which results in extensive photoreceptor and RPE cell loss, has been extensively studied in the search for effective neuroprotective agents.<sup>176</sup> Light-induced photoreceptor apoptosis is dependent on the availability of 11-*cis* retinal for rhodopsin regeneration.<sup>187</sup> Acute bright light-induced photoreceptor apoptosis involves activation of nitric oxide synthase (NOS) and generation of nitric oxide (NO), increased intracellular calcium, oxidative damage, and alterations in mitochondrial function.<sup>176,213</sup> Inhibition of NOS activity by NG-nitro-L-arginine methyl ester (LNAME)<sup>213,214</sup> or application of the calcium channel blockers D-diltiazem, nilvadipine, or nicardipine<sup>197</sup> protected photoreceptor cells following cell death in light-damaged retinas. Inhibition of the apoptotic cascade by reduction of the proapoptotic Bcl-2 family members Bax and Bak also protects the retina against light damage.<sup>215</sup> The use of antioxidants that quench ROS such as dimethylthiourea and *N*-phenyl-2-naphthylamine and the administration of exogenous neurotrophic factors including BDNF, ciliary neurotrophic factor (CNTF), basic fibroblast growth factor (bFGF), erythropoietin (Epo), and PEDF have all been shown to be protective against light damage (reviewed by Wenzel et al.<sup>176</sup>). bFGF plays an important role in the endogenous defense against stress of retinal cells. Preconditioning with light<sup>216</sup> or ischemic preconditioning<sup>217,218</sup> increases the expression of bFGF and protects retinal cells against damaging doses of light or increased intraocular pressure. The neuroprotective effect could be enhanced by a combination of bFGF and PEDF.<sup>219</sup> In contrast, no protection resulted against constant light exposure for 1 week when bFGF was expressed locally from a transgene delivered by an adeno-associated viral vector<sup>220</sup> or a simian immunodeficiency viral vector.<sup>221</sup> However, intravitreal injection of recombinant BDNF protein or its release from transgenic cell transplants<sup>222</sup> protects the retina against 1–2 weeks of constant light exposure.

Inhibition of apoptotic pathways in a light-damaged neuron is

relatively straightforward as the cell is otherwise healthy. However, in retinal cells harboring mutations, as is the case in retinal dystrophies, the cell has more than just the apoptotic cascade to address as the cause of the dystrophy and associated cell death will remain unless also treated. Photoreceptors are the target cells as these are the predominant cell type lost in the retinal dystrophies. Studies in animal models with inherited retinal diseases have used similar strategies to those described above for light damage. While considerable success has been achieved, this has not translated to clinical care and gene therapy to reverse the mutation, as in Leber congenital amaurosis, is perhaps a preferable option.<sup>223</sup> Both PEDF and CNTF have shown considerable promise in slowing photoreceptor degeneration, whether provided by intraocular injection or gene transfer, in *rd1*, *rd2*, *rds* P216L, rhodopsin S334ter, and P23H rodent models of inherited degeneration.<sup>224–228</sup> CNTF, released by engineered cells, slowed retinal degeneration in the *rcd1* dog model<sup>229</sup> and, after intravitreal injection, in an autosomal dominant feline model of rod–cone dystrophy.<sup>230</sup> Neurotrophin-3 can induce upregulation of bFGF, and thereby neuroprotection, by activation of TrkC in Müller cells.<sup>231</sup> Viral delivery of a BDNF transgene delayed degeneration induced by the Q344ter mutation in rhodopsin<sup>232</sup> and prolonged release of BDNF from transgenic cell transplants into the eye slowed degeneration in RCS rats.<sup>233</sup> Caspase-3 inhibition is protective in the *rd1* degeneration by delaying cell death<sup>234,235</sup> and preservation of retinal morphology.<sup>236</sup> Caspase-3 inhibitors also provided protection in two other models of inherited retinal degeneration: the S334ter rat<sup>169</sup> and the tubby mouse.<sup>171</sup> Alternative approaches that have reduced photoreceptor loss and slowed the progression of retinal degeneration in animal models include (1) overexpression of the X-linked inhibitor of apoptosis using gene therapy,<sup>237,238</sup> (2) sustained intravitreal delivery of fluocinolone acetonide, which suppresses microglial activation and inflammation,<sup>239</sup> (3) GDNF either given by subretinal injection or conjugated to nanoparticles,<sup>240</sup> and (4) neuroprotectin D1 (NPD1).<sup>130</sup>

Rodent and canine models of glaucoma have shown that agents that block glutamate excitotoxicity, prevent mitochondrial dysfunction, reduce oxidative stress, or enhance neurotrophic

factors all decrease or prevent the loss of RGCs (Table 26.1). The *N*-methyl-D-aspartate receptor antagonist was shown to be a highly effective neuroprotective agent in animal models of RGC death (reviewed by Cheung et al.<sup>241</sup> and Danesh-Meyer<sup>242</sup>). However, the outcome of clinical trials was inconclusive, though a trend for improvement was observed. An alternative agent is brimonidine tartrate, which is a highly selective alpha-2-adrenergic agonist that increases RGC survival in animal models.<sup>243</sup> Coenzyme Q10, which is an essential cofactor of the electron transport chain, has been shown to have some neuroprotective effect on RGCs based on its antioxidant properties.<sup>244</sup> Treatment with exogenous neurotrophins such as BDNF, nerve growth factor, and CNTF have all been shown to slow the loss of RGCs but not to inhibit RGC death in the long term. To improve outcomes, researchers have investigated sustained release of neurotrophic factors via either gene therapy<sup>245</sup> or encapsulated cell technology, which allows the intravitreal implantation of a chamber containing live cells programmed to release CNTF.<sup>246</sup> More direct antiapoptotic strategies have included activation of the Bcl-2 pathways using cilostazol or 5-S-GAD, which increases RGC survival in animal models.<sup>247,248</sup> The retina (and particularly the photoreceptors) is rich in taurine,<sup>249,250</sup> a sulfonic acid that has been widely studied for its cytoprotective properties.<sup>251</sup> Taurine deficiency has been associated with retinal neurodegeneration.<sup>252</sup> The beneficial effect of taurine results from a number of modes: (1) antioxidant properties; (2) inhibition of glutamate-induced calpain activation; (3) inhibition of Ca<sup>2+</sup> influx through voltage-gated calcium channels; and (4) prevention of Bcl-2 downregulation. It has also been shown that taurine may prevent apoptosome activation that results in intrinsic apoptosis activation.<sup>253</sup> Recent reports suggest taurine to be neuroprotective against RGC degeneration and that taurine supplementation increases RGC density in rodent models of glaucoma and retinitis pigmentosa.<sup>254</sup>

RPE cell loss is a hallmark feature of dry AMD. In vitro studies have identified a plethora of agents capable of either directly inhibiting apoptosis with, for example, caspase inhibitors, or indirectly by neutralizing the initiating factors leading to cell death. Macular carotenoids, NPD1, eEpo, resveratrol, and PEDF have all

been shown to confer protection against oxidative stress-induced apoptosis.<sup>255-262</sup>  $\alpha$ B crystallin is apically secreted within exosomes by polarized human RPE and provides neuroprotection to adjacent cells.<sup>263</sup> An alternative approach has been to upregulate antioxidants or molecular chaperones to cope with the increased oxidative stress.<sup>264</sup> Neurotrophic protection of the RPE has been more difficult to model in vivo because there are no reliable models of GA. However, the Age-Related Eye Disease Study demonstrated that oral supplementation with high levels of antioxidants and zinc can reduce the risk of disease progression to advanced AMD.<sup>265</sup> With reports establishing necrosis as a possible mode of RPE degeneration,<sup>133</sup> use of inhibitors that target molecules crucial to both apoptosis and necrosis or the use of a synergistic mixture of apoptosis and necrosis inhibitors may be considered as novel therapeutic modes.

The strategies described above are likely to be equally effective in other retinal conditions resulting in cell death. Imai and colleagues emphasize the importance of exogenous neurotrophic factors in reducing cell loss in DR<sup>266</sup> while BDNF, bFGF, and inhibition of the FAS receptor impede apoptosis following retinal detachment.<sup>154,156</sup>

## Modulating Autophagy

As discussed earlier, autophagy is dysregulated in a number of retinal conditions. However, dependent on the type and stage of the disease, this dysregulation could reflect as decreased or increased autophagy. A similar trend is also observed in cancer and neurodegenerative diseases. Autophagy plays a role in tumor suppression or oncogenesis but can desensitize cells to chemotherapeutic agents.<sup>267</sup> Similarly, upregulation of autophagy can protect against Huntington's disease in mouse models, whereas enhancing autophagosome formation in Alzheimer's disease can exacerbate the accumulation of A $\beta$ .<sup>267</sup> Therefore any therapy must ensure the correct balance of autophagy flux is attained for the targeted disease or cell type.

Many autophagy-related proteins and signaling molecules have been implicated in a number of events of autophagy, including signaling, sequestration, maturation, and degradation. The primary

regulation of autophagy proceeds by mTOR, GCN2, and PI3K-III signaling pathways. Autophagy is negatively regulated by mTOR and Bcl-2/Bcl-xL and positively regulated by PI3K class III and GCN2/eIF2 $\alpha$ . Compounds that inhibit mTOR phosphorylation (rapamycin) or Bcl-2 interaction with Beclin-1 (ABT737) promote autophagy.<sup>268</sup> PI3K-III can be activated by inhibiting the interactions between Bcl-2 and Beclin/Atg6 or by overexpressing Beclin-1 or Beclin-1-BD (Bcl-2 binding defective mutant) and suppression by Vps34 inhibitors, 3-methyladenine, or wortmannin.<sup>269,270</sup> Several mTOR-dependent and mTOR-independent agents have been identified that stimulate autophagy. Rapamycin is a well-established compound for inducing autophagy and attenuating neuronal cell death in a number of in vitro and in vivo experimental models. Other stimulators of autophagy include lithium and trehalose, which enhance autophagy via an mTOR-independent mechanism.<sup>271</sup> Unfortunately, despite their potency, rapamycin and lithium have significant side-effects that lessen enthusiasm for clinical application in chronic neurodegenerative diseases.<sup>272,273</sup> In an attempt to address this, researchers are screening for small-molecule enhancers of rapamycin (SMERs) and small molecule inhibitors of rapamycin (SMIRs) with less cytotoxicity. The efficacy and specificity of compounds that activate autophagy in an mTOR-independent fashion have yet to be established.<sup>272,273</sup> Gene therapy is also a possibility and overexpression of Atg7 can protect against anoxia/reoxygenation injury.<sup>274</sup>

Given the realization of the importance of autophagy in cancer and neurodegenerative diseases, there has been an extensive effort to identify potential therapeutic regulators of autophagy. Those under development include HDAC inhibitors, mTOR inhibitors, BH3 domain mimetics, glycolytic inhibitors, inositol-lowering agents, and protein kinase inhibitors.<sup>271,274-276</sup> Of particular interest in cancer has been the use of the antimalarial drug hydroxychloroquine (HCQ), which serves to inhibit autophagy by perturbing lysosomal function. HCQ is now being assessed in combination with a number of chemotherapy agents in phase I and II clinical trials.<sup>274,275</sup> However, it has long been recognized that HCQ can cause ocular toxicity, with the most serious being an irreversible retinopathy. The dosage parameters associated with

retinopathy are still uncertain, but it has been suggested that, for doses of HCQ less than 6.5 mg/kg, the incidence of retinopathy is minimal.<sup>277</sup> Nevertheless, some clinical trials are testing dosages that exceed these levels. Furthermore, shutting down lysosomal functions, whether it be autophagy or endocytosis, can dramatically alter cellular homeostasis and defense.

Proteins other than the autophagic pathway proteins have been implicated in autophagy. Caspases and calpains play key roles in cleavage and activation or inactivation of autophagy proteins (summarized by Kaminsky and Zhivotovsky<sup>278</sup>). Cross-talk between the autophagy and apoptosis pathways is regulated by caspase cleavage of Beclin-1<sup>279</sup> and also by p62/Sqstm1-Keap1 signaling.<sup>280</sup> Similarly, modulation of the Sirt-1-Foxo pathway also modulates autophagy.<sup>281,282</sup> Modulating reactive oxygen species levels with antioxidant compounds such as resveratrol and curcumin or overexpressing antioxidant enzymes can negatively modulate autophagy. Quenching reactive oxygen species will decrease mitochondrial damage and autophagy initiation. In addition, a lowering of reactive oxygen species will preserve the activity of lysosomal enzymes (reviewed by Scherz-Shouval and Elazar<sup>283</sup>). It is important to keep in mind that, when one type of autophagy is altered, the other types will also be affected. Chronic blockage of CMA promotes upregulation of macroautophagy,<sup>284</sup> whereas acute blockage leads to macroautophagic dysregulation.<sup>285</sup> Cells respond to blockage of macroautophagy by increasing CMA.<sup>285</sup> Acute blockage of the proteasome upregulates macroautophagy,<sup>286</sup> whereas chronic blockage leads to macroautophagic dysregulation.<sup>287</sup> Some subunits of the proteasome are degraded by CMA,<sup>288</sup> which may explain why blockage of CMA is associated with proteasome dysregulation.<sup>284</sup> Interactions of microautophagy with other proteolytic systems remain undiscovered. Furthermore, recent findings suggest that autophagy may be inhibited in AMD both in the initiation as well as in the lysosomal maturation.<sup>137,138</sup> Enhancing autophagy in the initiation stages may not prove to be beneficial if lysosomal function itself is compromised. Hence, therapeutic strategies based in autophagy-modulation in retinal diseases like AMD need to be carefully designed keeping the lysosomal aspect under

consideration.

## Cellular Replacement

Replacement of dead or dysfunctional cells in the retina is vital to preserve and/or restore tissue and organ function. While amphibians and fish exhibit robust retinal regeneration, arising from the RPE and intrinsic Müller glial cell-derived progenitors respectively, this is not observed in mammals, where cellular replacement in the retina is limited even in response to injury.<sup>289–294</sup> A number of endogenous retinal stem and progenitor populations have been reported but many, such as those observed in the ciliary margin zone, remain controversial.<sup>290</sup> Progenitor gene expression in Müller glia following retinal injury has been observed in rodents, for example expression of bipolar and photoreceptor markers,<sup>294</sup> though there is no definitive evidence that these cells have regenerative function. The bone marrow may be an alternative source of endogenous reparative cells. Using chimeric mice transplanted with bone marrow cells expressing green fluorescent protein, it has been shown that bone marrow-derived cells would home to the site of retinal injury and differentiate into astrocytes, macrophages/microglia, endothelial cells, pericytes, and RPE.<sup>116,117</sup> However, recruitment and integration is limited.

Transplantation of RPE cells has been extensively investigated, as these cells can be readily generated from embryonic stem cells (ESC) or induced pluripotent stem cells (iPSC).<sup>295–297</sup> ESC and iPSC-derived cells have been successfully transplanted into animal models of retinal degeneration and have been shown to restore vision. Additionally, a number of phase I/II clinical trials have been initiated involving transplantation of RPE derived from hESC and hiPSC in humans. Schwartz et al.<sup>298</sup> published preliminary reports of two phase I/II clinical trials involving hESC-derived RPE transplant in patients with Stargardt macular dystrophy and AMD.<sup>299</sup> The cells were not found to exhibit abnormal hyperproliferation, and some recovery of vision was observed, though limited.<sup>298,299</sup> An ongoing clinical trial in Japan investigating transplant of RPE sheets as opposed to cells may result in greater recovery of vision.<sup>300</sup> Central nervous system stem cells (HuCNS-

SC) have been found to protect the photoreceptor layer following subretinal injection into rats<sup>301</sup> and are currently being investigated in a phase I/II clinical trial (NCT01632527).

While a promising strategy, there remain concerns that (1) ESC may result in teratoma formation;<sup>302</sup> (2) iPSC contain protein-coding point mutations;<sup>303</sup> (3) success with RPE transplantation in humans has been modest;<sup>298,299,304,305</sup> and (4) transplantation is normally into a severely degenerated retina with late-stage disease.<sup>304,305</sup> Replacing the RPE may be insufficient in late-stage disease, as the overlying photoreceptor layer and neural retina are likely already too dysfunctional for visual recovery as a result of RPE regeneration alone. Additionally, subretinal transplant of cells may also lead to damage, such as intraocular hemorrhage or retinal detachment. To overcome this, a recent study infected bone marrow-derived cells *ex vivo* with lentiviral vector expressing the RPE-specific gene *RPE65* and injected these cells into the circulation of mice in which the RPE had been destroyed by sodium iodate.<sup>306</sup> These systemically delivered cells homed to the neural retina/Bruch's membrane interface in large numbers and showed restoration of a functional RPE layer, with typical RPE phenotype, including coexpression of another RPE-specific marker, CRALBP, and photoreceptor outer-segment phagocytosis. Most importantly, retinal degeneration was prevented and visual function was restored to levels similar to those found in normal animals.<sup>306</sup>

Critically, the systemic delivery of the modified cells is noninvasive, allowing for delivery without disruption of the subretinal space necessary for transplantation of ESC, iPSC, and HuCNS-SC-derived cells. Due to the decreased risk, if applicable in humans, systemic delivery of therapeutic cells potentially allows for treatment in the early stages of disease where damage to the neural retina is limited. Human bone marrow-derived CD34<sup>+</sup> cells have been shown to be tolerated in NOD/SCID mice and in humans following intravitreal injection in two phase I/II clinical trials, with no worsening of vision and no evidence of intraocular inflammation.<sup>307-309</sup> Incorporation of the cells into the damaged macula was also observed, indicating a promising therapeutic potential for bone marrow-derived cells in RPE replacement.<sup>308</sup>

Repair of the neural retina is more complicated due to the need to

form the requisite neural connections to perform vision. The most cited study is that of MacLaren and colleagues, who showed that donor cells can integrate into the adult or degenerating mouse retina provided the donor cells are derived from the developing retina at a time coincident with the peak of rod genesis.<sup>310</sup> Importantly, these transplanted cells integrated and differentiated into functional rod photoreceptors that formed synaptic connections, and improved visual function in the host animals. Human ESC or iPS have been shown, under the right conditions, to be able to differentiate into rods and cones<sup>311,312</sup> and when transplanted into the adult mouse retina can differentiate into photoreceptors and restore light responses in Crx-deficient mice.<sup>313</sup> Since it is not the intention of this chapter to provide a detailed review of regenerative medicine for retinal repair, the reader is pointed to the following reviews<sup>290,311</sup> and [Chapter 37](#) (Stem cells and cellular therapy).

## Conclusions

Cell death is a major feature of retinal injury and disease. Preventing cell loss or replacing the lost cells is now becoming a realistic option with a number of pharmacologic agents in clinical trials and Food and Drug Administration approval for cell replacement therapies. The last 20 years have seen an exponential increase in our knowledge of cell death pathways in the retina and the identification of targets for therapeutic intervention. However, while considerable improvement has been observed in animal models of retinal cell loss, translation into the clinic has, to date, only shown modest success. It is likely that different approaches will be required for different retinal conditions as preserving a cell with a debilitating genetic mutation is likely to be detrimental to the retina, while preventing apoptosis of normal cells following retinal detachment or light damage would be beneficial. Similarly, autophagy has been shown to play a protective role in a number of retinal diseases, but the balance is critical as excess autophagy will lead to removal of essential organelles and loss of cell function while too little autophagy will lead to the buildup of damaged organelles. A further problem is that all these therapeutic

approaches will remain limited if the initiating factors resulting in cell loss are not also addressed. Finally, we have to address the clinical limitation that intervention is often not until the late stage of disease when extensive cell death has already taken place, and thus we need to consider strategies for treating much earlier if we are to prevent significant retinal cell loss. Despite these hurdles, our ever-increasing understanding of retinal pathogenesis and cell death, together with improved pharmacologic screening for novel therapeutic agents, will almost certainly result in major advances in clinical treatment over the next decade.

## Introduction

The eye has been long recognized as an immune privileged site.<sup>1,2</sup> Yet many disorders of the retina are driven by inflammation or by significantly altered immune responses. In addition to the archetypical immune-mediated disorders such as uveitis, examples include aging degenerative conditions, diabetic retinopathy (DR), and vascular ischemic events with immune consequences. This chapter will introduce the notion of immune regulation in the eye, rather than the historical strict definition of privilege; the latter evokes concepts of immune sequestration and relative immune incompetence, which is not the case. Instead, like most tissues and organs, the eye is bestowed with mechanisms that regulate immune responses and contain inflammation, the function of which is to protect and sustain tissue function in the face of constant insult and potential damage. This understanding of immunologic activities in the eye, particularly regarding the regulation of immune cell activation, regulation of vascular barriers, and interactions with systemic immunity, sets the stage for appreciating when immune responses are beneficial to maintain function during disease, and when immune responses require to be dampened to prevent ensuing damage.<sup>3,4</sup>

The historical idea that the retina is sequestered from systemic immunity and has “immunologic ignorance” has been largely dispelled. We now know that both the retina and choroid (including the ciliary body) are bestowed with a network of immune competent cells, such as microglia and choroidal macrophages, dendritic cells, and mast cell populations.<sup>5</sup> Further, there is active regulation of vascular barriers with perivascular macrophages and interaction with Müller glia.<sup>6</sup> A multitude of cognate and soluble mediators control cell activation in the eye,<sup>3</sup> including contributions from traditional nonimmune cells such as retinal pigment epithelium and astroglia<sup>7</sup> (Fig. 27.1). Not surprisingly, mechanisms of immune regulation (immune privilege) are implied by the need to combat against persistent damaging events such as oxidative stress, aging, and lifestyle events (e.g., smoking and obesity). These insults are compounded by genetic polymorphisms and epigenetic regulation of gene

expression, as illustrated by age-related macular degeneration (AMD).<sup>8,9</sup> By examining specific disorders, this chapter will highlight the immune regulatory mechanisms that operate in the eye, as well as the role of tissue-specific and system-wide immune responses in the context of uveitis, multifactorial degenerative conditions such as AMD, and dysregulation during angiogenesis.

**FIG. 27.1** Immune regulation within the retina. The retina is endowed with many immunoregulatory mechanisms. The retinal pigment epithelium (RPE) monolayer extends across the bottom of the figure. The apical microvilli of the RPE interdigitate with the outer segments of the photoreceptors. Multiple star-shaped microglia are shown within the retina, as are elongated, vertically oriented Müller cells. Perivascular macrophages are shown in the upper left. Microglia and choroidal myeloid cells (dendritic cells and

macrophages) sense the environment and regulate inflammatory responses. The healthy tissue sets the threshold for responses through inhibitory receptors (e.g., CD200R, SIRP $\alpha$ ) or via the TGF- $\beta$  or  $\alpha$ -MSH rich environment. Regulation via neuronal cognate interactions is augmented by the regulatory functions of FasL expressing-RPE, in addition to mediators such as PD-1–PD-L1 interactions, TGF- $\beta$  secretion, and inhibitory peptides. Activation of myeloid cells in the eye results primarily in IL-10 release; while other proinflammatory cytokines are also produced, the default response is regulation. Müller cells and microglia interact to maintain neuronal health, as well as the integrity of the inner blood–retinal barrier. DC, dendritic cell; NO, nitric oxide; pDC/mDC, plasmacytoid DC/myeloid DC; Treg, T regulatory cell.

## Innate Defenses in the Maintenance of Retinal Health

As Fig. 27.1 illustrates, there are numerous cellular, cognate, and soluble mediators that regulate unnecessary and unwanted cellular activation, attenuate heightened immune responses, and maintain the vascular barrier. The innate immune defenses in this system are comprised of myeloid cells such as dendritic cells, monocytes, and macrophages, and the closely related microglia. These cells present antigen to T cells and may produce cytokines in response to nonspecific stimuli such as bacterial lipopolysaccharide (LPS). In the eye, myeloid cells are prone to producing regulatory cytokines such as IL-10, rather than inflammatory cytokines. This feature may aid in preserving tissue and cellular homeostasis, and limit inflammatory damage.

In the face of an aging process that includes tissue, cellular, and immune senescence, the retina may be vulnerable to a variety of noxious challenges that also activate host defense systems. From an immunologic perspective, the eye is endowed with a variety of immune response strategies that activate in response to insults, sometimes to excess, but also serve to counteract excessive immune

activation and control pathologic damage. The major components will be considered briefly.

## Tissue Resident Macrophages

Microglia initially populate the developing retina and are derived from the yolk sac.<sup>10,11</sup> These cells are capable of division in the tissue, and maintain a signature transcriptome<sup>12,13</sup> that differentiates them from tissue macrophages and recent immigrant monocyte-macrophage populations. However, bone marrow-derived cells that become tissue macrophages may replenish the microglia population of the retina.<sup>14</sup> Populations of macrophages are found around the inner retinal vasculature (within the glial limitans), while microglia are generally situated in the inner and outer plexiform layers. However, when microglia are activated they can divide and become highly motile, migrating to the areas of tissue damage. There they may act as antigen-presenting cells, thus assisting to bridge and engage adaptive immune responses.<sup>15-19</sup>

The phenotype of microglia is typical of resident macrophage populations (Fig. 27.2 and Table 27.1). Their function is to maintain homeostasis, through cognate receptors that downregulate their activation (e.g., CD200-CD200R);<sup>20-22</sup> to secrete neurotrophins to support glial and neuronal function;<sup>23</sup> phagocytosis;<sup>24</sup> and to secrete immunomodulatory cytokines such as IL-10, produce indoleamine 2,3-dioxygenase (IDO), and express B7-H1.<sup>25,26</sup> In contrast, fully activated microglia can behave akin to recent monocyte-macrophage immigrants and potentiate inflammatory responses.<sup>27</sup> Unchecked innate activation proceeds to inflammasome activation and secretion of potent inflammatory mediators. Also of note, the monocyte-macrophage population, including microglia, is very plastic. This property results in a range of behaviors and responses that depend on the environmental context, and on the cognate and soluble cues that monocytes receive.<sup>28,29</sup> Monocyte-macrophages have been classified into subtypes (Table 27.1) in an effort to correlate phenotype with function, but these designations must be taken in the context of ongoing cell plasticity.

**FIG. 27.2** The many subtypes of macrophages.

Microglia are derived from yolk sac during development and may self-renew independently of bone marrow hemopoietic precursors.<sup>11</sup> Nonetheless, macrophages are derived from a common bone marrow progenitor; both in the bone marrow and in the tissues, macrophages require CSF-1 for viability. Upon entering tissues, microglia and macrophages respond to their environment and are plastic. This has led to a classification of tissue resident macrophages versus classically and alternatively activated macrophages (also termed M1 and M2). The development of these subtypes depends on the cognate and soluble signals that condition the cells. The resulting phenotypes lead to production of signature cytokines that effect their function as either cytopathic (when conditioned by IFN- $\gamma$  and LPS) versus wound healing (when conditioned by IL-4/IL-13). NOS2+, enzyme Nitric Oxide Synthase 2+.

<b>Function</b>	TH1 responses Killing Tumor resistance	Killing of parasites Allergy	Th2 activation Immunoregulation	Immunoregulation Matrix remodeling Tissue restoration

The inflammasome is a multiprotein complex comprising a sensor protein, the adaptor protein ASC (apoptosis-associated speck-like domain containing caspase recruitment domain), and the inflammatory protease caspase-1. This complex is responsible for activation of many inflammatory processes. The assembly of the inflammasome signaling platform occurs due to conformational changes in the sensor protein, which in turn recruits caspase-1 to the complex and promotes the activation of caspase-1. Once activated, caspase-1 cleaves the inactive precursors of two proinflammatory cytokines, interleukin (IL)-1 $\beta$  and IL-18, the mature forms of which are secreted from cells.<sup>30-33</sup> The eye is endowed with inflammasome-forming sensors as receptors on cell surfaces, within cytoplasm, and on the nucleus.<sup>34</sup> These include the NLRP receptor molecules (nucleotide binding domain and leucine-rich repeat containing pyrin domain family), which belong to the Nod-like receptor family of proteins, such as NLRP1, NLRP3, and NLRC4; or Absent In Melanoma (AIM 2), a receptor of the HIN (interferon [IFN] inducible nuclear proteins) family of proteins. The NLRP3 inflammasome is clearly involved in host defense. For example, activation of IL-1 $\beta$  by an inflammasome is required to control certain pathogenic viral, bacterial, and fungal infections efficiently. However, excess IL-1 $\beta$  activity contributes to a variety of

diseases.<sup>35</sup> The NLRP3 inflammasome is also central in the pathogenesis of autoinflammatory disorders; its activity has been implicated in pathologies such as Alzheimer's disease, cancer, type 2 diabetes, and most recently AMD. Regulation of the NLRP3 inflammasome is poorly understood, but probably involves the integration of signals from a number of stimuli, such as cellular damage and stress. Inflammasome-dependent biologic effects may be mediated not only by IL-1 $\beta$  and IL-18, but also by the multifaceted activities of caspase-1. Thus, there may be secondary effects of protecting against inflammasome activation, such as when autophagy is increased.<sup>36,37</sup>

## Immune Regulation by the Nonimmune Cell Compartment

The retinal pigment epithelium (RPE) not only comprises the outer retinal barrier, but is also a key contributor to immunoregulatory properties of the eye. This includes canonical features such as Fas Ligand (FasL) expression,<sup>38,39</sup> and secretion of immunomodulatory cytokines such as TGF- $\beta$  and immunoregulatory neuropeptides, including  $\alpha$ -melanocyte stimulating hormone ( $\alpha$ -MSH).<sup>40</sup> In experimental models,  $\alpha$ -MSH modulates macrophage-monocyte populations toward an alternatively activated pathway. Adaptive immunity is attenuated via FasL expression, resulting in the death of Fas-expressing T cells. Programmed cell death of T cells may also be induced through RPE PD-L1 expression,<sup>41</sup> or through generation of Treg cells supported, in part, by RPE-derived CTLA-4.<sup>42,43</sup> The RPE also protects against complement-induced damage<sup>44-47</sup> through membrane complement regulatory proteins (CD46, CD59) and generation of Complement Factor H (CFH).

Müller cells are the predominant glial cell type in the retina and are immune competent: they secrete cytokines, regulate immunity, and respond to danger signals through pathogen recognition receptors such as Toll-like receptors (TLR).<sup>48</sup> Under certain conditions, the Müller glia may induce suppression of T-cell responses. However, they also promote T-cell responses by producing IL-1 and by acting as antigen-presenting cells.<sup>49,50</sup> Moreover, experimental studies indicate that intercellular

interactions between Müller cells and both the inner retinal barrier (glial limitans) and microglia are essential for immune health. For example, activated microglia secrete neurotrophins (including CNTF, NT-3, and NGF) detected by Müller glia (which express neurotrophin receptor p75<sup>ntf</sup> and TrkC), with reciprocal effects on photoreceptor survival.<sup>23</sup>

## Blood–Retinal Barriers

The well-described anatomic barriers, namely the inner retinal vasculature and the outer retinal RPE barrier, regulate immune traffic. Both the retinal endothelium and the RPE have well-formed junctional complexes, including tight junctions and adherens.<sup>51</sup> During experimental autoimmune uveitis (EAU), inflammation is accompanied by upregulation of adhesion molecules (e.g., p-selectin and ICAM-1), loss of junctional complexes, and transendothelial migration of leukocytes.<sup>52,53</sup> Further, compelling data support the conclusion that endothelium also regulates T-cell traffic. This occurs through “classic” migratory pathways such as chemotaxis, rolling, adhesion, and transmigration. In addition, B-cell secretion of a peptide initiates a regulatory cascade that results in production of sphingosine-1-phosphate by endothelial cells, which inhibits trafficking of T cells.<sup>54</sup> Similarly, endothelial cells express molecules such as CD200 that also influence the migration and activation of innate cells.<sup>19</sup> Together, the available data suggest a complex role for retinal endothelium, in which blood–retinal barriers are not absolute but allow trafficking of cells and immune surveillance;<sup>25</sup> yet the endothelium maintains the ability to control cell traffic, unless overwhelmed through systemic immune activation.<sup>55</sup>

## The Role and Limits of Persistent Immune Activation in Maintaining Eye Health

Medzhitov first introduced the idea of parainflammation as a tissue-adaptive response to noxious stress or malfunction that is intermediate between basal and inflammatory states.<sup>56</sup> Briefly, in the basal state, tissue resident macrophages (principally retinal

microglia, and retinal perivascular macrophages or choroidal macrophages) are largely quiescent, but when activated promote an adaptive change with short-term benefits, providing ongoing tissue homeostasis. In contrast, parainflammatory responses are low level but ongoing and chronic. The purpose of parainflammation is to regulate homeostasis and tissue function in the face of persistent tissue insult with cell and immune activation responses. When a tissue is exposed to prolonged stress or malfunction, immune activation and inflammation ensues, and parainflammatory regulatory mechanisms are overwhelmed. Dysregulated or absent parainflammation has been proposed to play an important role in the progression of diabetes, atherosclerosis, and obesity, as well as AMD. Parainflammation has been illuminated experimentally in the aging retina and during degeneration.<sup>4</sup> These observations and concepts add complexity to the notion that immune activation and recruitment of macrophages may be required to help process photoreceptor and RPE byproducts, and thereby control overt inflammation, tissue dysfunction, and ultimately cell death. Moreover, in other models, it appears that the organ/tissue-specific regulatory threshold to maintain tissue homeostasis may be reset following every insult.<sup>57</sup>

## The Aging Influence

Because the prevalence of retinal disease increases with age, the effect of aging and senescence on regulation of immune responses is important. Senescence is a loss of cellular potential to divide and grow, with consequences that influence immune responses. For example, senescence induces a p38 MAPK-mediated senescent-associated secretory phenotype that is proinflammatory,<sup>58-60</sup> with increased secretion of chemokines and proinflammatory cytokines (e.g., IL-6 and IL-1 $\alpha$ ); increase in mTOR-dependent autophagy; oxLDL secretion; and mROS upregulation. These activities potentiate inflammation, particularly innate immune activation and tissue infiltration. Cellular senescence in the eye is manifest in specific cellular responses. Hallmarks include changes in cell morphology (e.g., altered astrocyte and microglial morphology<sup>61,62</sup>); phenotypic changes that include altered telomerase and  $\beta$ -

galactosidase activities; release and cell loss of HMGB1; decline in lamin B1 (a nucleus stabilizer); and gH2AX nucleolar expression. While senescence may be present in retinal disorders, aging also influences the immune response. Adaptive T-cell immune responses exhibit both exhaustion and senescence. The mechanisms underlying each are independent, although both are compounded by age,<sup>63,64</sup> and both are central to individuals' response to chronic and persistent tissue damage and infection.

## **Autoinflammation and Autoimmunity**

In health, appropriate immune responses protect the eye and maintain tissue homeostasis, but direct tissue destruction occurs when responses are aberrant. If immune responses ensue in the absence of foreign pathogens, the term “auto” is used to indicate that the consequent harm to host tissues is driven by a response against self. When the mediators of these inappropriate responses are cells of the innate immune system, this is described as “autoinflammation.” Conversely, damage caused by self-directed cells of the adaptive immune system (T and B lymphocytes) is called “autoimmunity.” Neither phenomenon occurs in isolation; once initiated, the full immune repertoire with varying contributions from each of its elements is brought into play. The magnitude of immune responses and accompanying tissue destruction are consequences of the underlying health of affected ocular tissues, the immune status of the host (both at a systemic and tissue level), and the balance of other homeostatic mechanisms. The latter include metabolic factors such as lipid profiles, control of glucose storage and action, and levels of tissue oxidative stress.<sup>65,66</sup>

At its most extreme, autoimmune and autoinflammatory intraocular inflammation is explosive, acute, and potentially rapidly devastating for vision. Conversely, when chronic, low-grade, subclinical tissue inflammation exceeds homeostatic (i.e., parainflammatory) levels, this can gradually progress over years to cause loss of retinal function. Importantly, chronic inflammation creates a local environment that is conducive to neovascularization. These pathologies further illustrate the idea that ocular immune privilege is a relative, rather than absolute, phenomenon. Once

immune responses are triggered, they can affect a variety of neural, vascular, endothelial, and epithelial components of the eye. Autoimmune responses ultimately exhibit all the features of conventional inflammatory cascades in other organs, and cause irreversible loss of vision through damage to the tissues responsible for sight.<sup>25</sup>

## Erosion of Eye Health in the Absence of Infectious Disease

### Autoinflammation and Autoimmunity as Classic Paradigms of Immune-Mediated Damage to Host Retinal Tissues

The most canonical examples of retinal autoinflammation and autoimmunity are in genetic diseases, which present in childhood. These have helped to reveal the mechanisms that underlie the dysregulation of both innate and adaptive immune responses. Blau disease is caused by gain-of-function mutations in *NOD2*, which regulates inflammasomes (see Tissue Resident Macrophages). This results in loss of tissue homeostasis in a range of organs, and is principally manifest clinically in the eye, skin, and joints.<sup>67</sup>

Heightened responses to tissue danger signals trigger the secretion of IL-1 $\beta$  and IL-18 through a caspase-1-controlled intracellular cascade. This creates a proinflammatory environment in which adaptive immune cells are inappropriately recruited to healthy tissues, in the absence of pathogens that would normally trigger these immune responses.<sup>68</sup> If these immune responses continue unabated, pathologic tissue destruction occurs. Similarly, in IPEX syndrome, regulatory T cells (Tregs) have a loss-of-function mutation affecting their master transcription factor FoxP3. In health, Tregs suppress adaptive immune responses to self-tissues, and their loss unleashes multiorgan autoimmunity. The most complete clinical manifestation of IPEX leads to death in infancy.<sup>69</sup>

Experimental models of both autoimmune and autoinflammatory diseases that are similar to these human diseases and that affect a range of organs have further uncovered the principles of these immune abnormalities. However, in man the exact triggers for

pathologic autoinflammatory and autoimmune diseases are rarely well defined, and the consensus is that both autoinflammation and autoimmunity often contribute.<sup>70</sup> Pure noninfectious pathologies may result from heightened innate tissue inflammatory tone (either due to genetic polymorphisms or to environmental triggers), or adaptive immune responses against self-antigens which have escaped regulatory control. In addition, immune deviations triggered by previous infections may contribute, or bystander damage to self-tissues may take place during clearance of an infectious agent.<sup>71</sup> However, even in the most typical examples of noninfectious uveitis such as birdshot chorioretinopathy, there is no definitive serologic evidence of autoantibodies to self-antigens. This contrasts with classic autoimmune conditions affecting nonocular tissues, such as rheumatoid factor and anticitrullinated protein antibodies in rheumatoid arthritis, and antinuclear antibodies in systemic lupus erythematosus. Hence, although a wide range of well-characterized human uveitic entities have no known infectious trigger, their etiology remains unknown but putatively autoimmune. These diseases are often phenotypically similar to animal models of ocular autoimmunity, which are stimulated by specific retinal antigens. This circumstantial evidence therefore suggests they are caused by aberrant immune responses against self.<sup>72</sup> There are also well-defined associations between certain uveitic entities and major histocompatibility complex (MHC) class II human leukocyte antigens (HLAs), such as the link between Vogt–Koyanagi–Harada's syndrome and HLA-DR4. These observations further support the notion of underlying self-directed CD4<sup>+</sup> helper T-cell responses, similar to that in other MHC class II polymorphism-associated diseases.<sup>73</sup> However, the majority of reported HLA associations in intraocular inflammation are with MHC class I alleles, the most common of which is HLA-B27-associated anterior uveitis. Because class I HLAs primarily present antigen to CD8<sup>+</sup> T cells, the possibility of an undiagnosed viral infectious cause remains.

## **Nonuveitic Diseases of the Retina That Have Autoimmune or Autoinflammatory**

## Components

Abnormal inflammatory responses directed against self-tissues are most readily recognized in uveitis, where there are frank clinical signs of breakdown of the blood–ocular barrier. These include white cells suspended in the aqueous and vitreous humor and overt features of retinal vasculitis, retinal pigment epithelitis, edema within the neuroretina, and choroidal infiltrates that are clearly visible with a slit-lamp biomicroscope. However, the ocular tissue destruction that results during other more common diseases, such as AMD and DR, also has a major inflammatory drive. In these cases, inflammation takes place at a tissue level that is beyond the optical resolution achievable with current instruments used for clinical observation.

The chronic onslaught of environmental stresses with aging heightens the readiness of tissue resident innate immune cells, such as retinal microglia, to proceed to overt inflammation.<sup>56</sup> Although not a frank dysregulation of innate immunity as is seen in Blau syndrome, parainflammation (see The Role and Limits of Persistent Immune Activation in Maintaining Eye Health) provides the immunologic context for altered tissue homeostasis and a chronic inflammatory environment. Additional insults such as oxidative stress, or an increased level of proinflammatory metabolites, can potentiate this. Stress at this level induces an insidious recruitment of monocytes and T cells from the peripheral circulation, contributing to an emerging milieu of soluble mediators. These immune responses may harm self-tissues either directly, or indirectly through the induction of choroidal neovascularization.<sup>74,75</sup> In DR, leukostasis occurs in the retinal circulation, when immune cells adhere to an activated retinal vascular endothelium. Further, hyperglycemia affects innate immune cell function. These two factors, coupled with the breakdown of the blood–ocular barrier and neovascularization of the retinal circulation, generate a proinflammatory drive that is harmful to retinal tissue.<sup>76,77</sup> Although neither AMD nor DR fit the definitions of inflammasome-mediated inflammation or antigen-specific inflammation seen in classic autoinflammatory and autoimmune syndromes, they still represent nonuveitic immune-mediated retinal diseases resulting from secondary immune responses that destroy self-tissues.

## The Potential for Nonocular Infections to Augment Immune Responses Directed Against Self-Tissues in the Eye

In theory, autoimmunity against ocular proteins can be driven by infections at nonocular sites. This is best illustrated in animal models of uveitis, where an adaptive immune response in the eye is elicited by systemic immunization using retinal proteins.<sup>78</sup> However, intraocular inflammation does not result if the animal is injected with retinal antigens alone. This is because antigen-specific T cells are not activated through antigen recognition in the absence of a second signal from antigen-presenting immune cells. In experimental models, antigen-presenting cells need to be nonspecifically stimulated by pattern recognition receptors, such as by engagement of either evolutionarily conserved proteins that are common to a range of infectious pathogens (e.g., lipopolysaccharide), or indirectly by host-tissue derived danger signals.<sup>79,80</sup> In the case of direct ocular infection, such as in exogenous bacterial endophthalmitis following cataract surgery, both innate and adaptive immune responses are triggered by bacteria present in the eye; in this case, autoimmune disease does not follow, presumably due to the destructive outcome of the profound infection. However, the infectious innate immune stimulus can be nonocular, followed by consequent antigen-specific autoimmune responses in the eye. Hence, an autoimmune response is only observed in the retina of an experimental animal immunized with interretinal binding protein if tubercular proteins and often pertussis toxin are also injected intraperitoneally.<sup>72</sup> Although there is no direct proof of this paradigm in human disease, anecdotes suggest that intraocular inflammation, which improves with immunosuppressive therapy, can go into remission following treatment of latent tuberculosis infection.<sup>81</sup> These observations imply that removing systemic nonocular innate immune triggers leads to resolution of associated adaptive immune responses in the eye. The relevance of this phenomenon may extend equally to other nonuveitic retinal pathologies. There are many features in common with the neurodegeneration observed in Alzheimer's disease and AMD. It is well documented that an acute deterioration in the

cognitive ability of Alzheimer's patients can be precipitated by a bacterial urinary tract infection, and acute systemic inflammation exacerbates neurodegeneration both experimentally and in patients.<sup>82,83</sup> By implication, a parallel acceleration of inflammatory pathology associated with AMD may accompany nonocular systemic infectious disease.

## **Inflammation, Vascular Regulation, and Pathologic Angiogenesis (Neovascularization)**

Pathologic angiogenesis occurs in numerous ocular disorders, particularly retinal disorders. To some extent, altered immune responses occur in all pathologic angiogenesis. In considering mechanisms, it is important to distinguish between types of inflammation in any of these conditions, whether retinopathy of prematurity, diabetes, or AMD. Altered immune responses may be apparent in the activation of constituent cell populations (e.g., microglia, Müller glia, and endothelial cells) without evidence of pathologic inflammation, or be obvious, such as when immune cells infiltrate from the periphery. The absence of infiltrating cells does not mean absence of inflammation, absence of altered immunity, or absence of defects in immune homeostasis.

The degree of contribution of inflammation during angiogenesis depends upon the pathology. In uveitis (intraocular inflammation), altered vasculature is common, but pathologic angiogenesis occurs infrequently. Despite this, neovascularization occurs from the retinal circulation<sup>84</sup> (not always as a consequence of ischemia), and via the choroid as choroidal neovascularization (CNV).<sup>85</sup> Neovascularization can be prevalent in some low-grade persistent inflammatory uveitic conditions.<sup>86</sup> Its link with inflammation has been corroborated in experimental models, where angiogenesis is frequently observed with persistent inflammation.<sup>87</sup> In uveitis, breakdown of barriers provided by capillary and postcapillary venular architecture is common, accompanied by uveitic macular edema. Studies of the HIF-driven vascular endothelial growth factor (VEGF)-mediated CNV in neovascular AMD indicate a role

for inflammation, further illustrating the close interplay between inflammation, vascular health, and the potential for pathologic angiogenesis when inflammation is present.

## Role of Macrophage Subtypes in Pathologic Angiogenesis

As introduced above, the function and phenotype of macrophage subtypes is conditioned by signals encountered within the tissue microenvironment. In mice, the paradigm of M1 and M2 macrophages (Table 27.1) has been studied with respect to angiogenesis in other fields as well as in the retina.<sup>88-91</sup> Classic activation generates M1 macrophages, which have proinflammatory functions. Alternatively, activated M2 macrophages confer responses related to wound healing, and are capable of generating VEGF and promoting angiogenesis. However, pathologic angiogenesis is observed most commonly in the presence of M2 macrophages.<sup>92</sup> The role of macrophages in driving a VEGF-dependent angiogenic response is supported by recent evidence from studies using the laser-induced CNV model. These studies demonstrate that early initiation of choroidal angiogenesis is dependent upon macrophage phagocytosis of damaged RPE components. This in turn elicits an Arg-1<sup>+</sup>, VEGF<sup>+</sup> M2 phenotype. On the other hand, macrophage subtypes are plastic, and functional outcomes may not be straightforward. For example, IFN- $\gamma$  and TLR4 ligation (with LPS) can generate VEGF<sup>+</sup> M1 macrophages, but prostaglandin (PG) E<sub>2</sub> remains a potent stimulus for the generation VEGF<sup>+</sup> M2 macrophages as well. Similarly, macrophages that are alternatively activated via IL-4 can result in a sFlt-1-secreting M2 cell in mouse and man<sup>93</sup> (Fig. 27.3). In man, macrophages associated with CNV or in specimens of AMD retina that are assessed using immunohistochemistry confirm the nature of VEGF-expressing CD68<sup>+</sup> cells<sup>94</sup> (Fig. 27.2). Finally, as noted elsewhere, perturbing macrophage function can attenuate neovascularization in experimental models.<sup>95</sup>

**FIG. 27.3** M2 macrophages can serve divergent functions. The contribution of alternatively activated M2 (Arg-1<sup>+</sup>) macrophages to angiogenesis is polarized, depending on signals and conditioning they receive.

Both PGE<sub>2</sub> and IL-4 (Th2 cytokines) may drive macrophages toward an M2 phenotype, but the functional response to each is quite discrete. PGE<sub>2</sub> generates proinflammatory cells that secrete high levels of VEGF and low levels of sFlt-1; in contrast, IL-4 generates M2 cells that secrete high levels of sFlt-1 secretion, and as a result are antiangiogenic.

## Role of Pathologic Angiogenesis in DR

In DR, advanced glycation endproducts (AGE) are recognized and accumulate at endothelium. This, along with loss of pericytes and capillary occlusion, are all instrumental in the progression of disease that leads to a breakdown of vascular integrity. Ischemia, edema, and finally neovascularization are also associated with changes in microglial distribution<sup>96</sup> and infiltration of VEGF-secreting monocyte-macrophage populations. Inflammation also plays a central role in the progression of DR.<sup>97</sup> For example, receptors for AGE (RAGE)<sup>98</sup> are widely expressed on retinal cells in DR, and upregulate proinflammatory pathways. A proinflammatory environment has been described in animal models and human studies, which is exacerbated by DR's hypoxic-ischemic environment. The central role of inflammation in DR is further reflected in the upregulation of tumor necrosis factor (TNF)- $\alpha$ , IL-1 $\beta$ , monocyte chemoattractant protein 1 (MCP-1/CCL2), and

macrophage inflammatory protein (MIP)/CCL3. Transcripts for all of these have been detected in the ischemic–hypoxic retina. These proinflammatory cytokines, particularly TNF- $\alpha$  and IL-1 $\beta$ , are thought to play a major role in the breakdown of the blood–retinal barrier and in the degeneration of retinal capillaries. CCL2 and RANTES/CCL5 are significantly elevated in sera of patients with severe nonproliferative diabetic retinopathy, compared with those who have less severe retinopathy. Increased C-reactive protein (CRP), IL-6, TNF- $\alpha$ , and especially the adhesion molecules intercellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1, and E-selectin are associated with nephropathy, retinopathy, and cardiovascular disease in both type 1 and type 2 diabetes. In proliferative diabetic retinopathy, vitreous cytokine levels of IL-6, IL-8, and CCL2 are strongly correlated with elevated VEGF.

Thus, the pathogenesis of diabetic retinopathy is a highly complex and multifactorial process. Hyperglycemia perturbs the metabolic and hemodynamic equilibrium, affecting multiple cell types. Their signature molecular responses lead ultimately to the formation of AGE, oxidative stress, glial activation, and inflammation. These conditions result in neural and vascular damage. As with the CNS, maintaining the health of retinal neurons depends on functional interactions between neurons, glial, microglia, and blood vessels, termed the “neurovascular unit.” When these functional interactions are impaired in DR, such as when driven by ischemic inflammation, regulation is impaired correspondingly. This includes impaired remodeling via endothelial progenitor cell (EPC) recruitment. Recently, therefore, the available evidence has suggested that diabetic retinopathy is a neurovascular complication that results from changes to the neurovascular unit, rather than from isolated neuroglial or vascular alterations.<sup>99</sup> Neural apoptosis and gliosis (activation of glial cells, including astrocytes and Müller cells with a resulting proinflammatory environment) are thus the final, canonical histologic features of diabetic neurodegeneration.<sup>100</sup>

## Inflammation and AGE-Related

# Macular Degeneration

For many years, the term degeneration denoted numerous mechanisms of cellular decay, but none of them intoned immune mechanisms. Immune mechanisms have come to the forefront recently as a possible explanation for the underlying changes noted in the degenerative diseases, including those in the eye.<sup>101</sup>

Atherosclerosis, heart disease, and Alzheimer's disease are examples of diseases where immune mechanisms appear to be centrally important to the disease process. Importantly, it appears that changes can be seen in the systemic immune system as well as in the eye. Here, AMD, a major public health problem, will be used as an example of a disease affected by both systemic and local degenerative changes in inflammatory responses. For convenience, these will be addressed separately.

## Systemic Inflammatory Changes During AMD

Patients with ocular inflammatory disorders such as uveitis, while clearly demonstrating alterations within the eye, have demonstrable and characteristic alterations in the circulating immune system. This is being noted now in many degenerative conditions. Perhaps the best known example is that of CFH. CFH is a regulatory protein, which suppresses formation of the C3 cleavage enzyme and inhibits the alternative pathway of complement activation. Complement gene polymorphisms have been clearly implicated in the development of AMD.<sup>102-104</sup> However, it is important to remember that about a third of whites, most of whom have healthy eyes, have the Y402H variant that is most often linked to AMD. Further, while differences in complement regulation between those with the variant and the wild type alleles have been reported,<sup>105</sup> no functional immune mechanism has been found to explain this association, at least in the canonical pathways of complement activation. Further, the same CFH variant has been reported in patients with sarcoidosis, most of whom were black,<sup>106</sup> as well as those with multifocal choroiditis.<sup>107</sup> As a group, blacks do not develop advanced AMD. However, CFH may play an important role in RPE homeostasis. Genomewide associations have

now demonstrated DNA variants in several other genes, many of which involve the complement system (Table 27.2).

**TABLE 27.2**

**Genetic Risk Factors Associated With Age-Related Macular Degeneration<sup>a</sup>**

Gene Symbol	Gene Name	Major Function	Location	Variant
<i>CFH</i>	Complement factor H	Regulation of complement activation	1q32	rs380390, rs1061170, rs1410996, rs10737680
<i>CFB</i>	Complement factor B	Alternative pathway of complement activation	6p21	rs641153, rs415667, rs541862
<i>C2</i>	Complement component 2	Classic pathway of the complement system	6p21	rs9332739, rs9380272
<i>C3</i>	Complement component 3	Activation of both classic and alternative complement pathways	19p13	rs2230199, rs1047286
<i>CFI<sup>b</sup></i>	Complement factor I	A serine proteinase regulating the complement cascade	4q25	rs10033900
<i>ARMS2</i>	Age-related maculopathy susceptibility 2	Retina homeostasis	10q26	rs10490924
<i>HTRA1</i>	HtrA serine peptidase 1	Proteolysis, negative regulation of BMP and TGF $\beta$ signaling pathway	10q26	rs11200638, rs3793917
<i>APOE</i>	Apolipoprotein E	Cholesterol homeostasis and cell apoptosis	19q13	APO $\epsilon$ 4, APO $\epsilon$ 2
<i>TIMP3</i>	TIMP metalloproteinase inhibitor 3	Metalloendopeptidase inhibitor	22q12	rs9621532
<i>HLA</i>	Major histocompatibility complex	Antigen processing and presentation, immune response	6q21	Cw-0701, B-4001, DRB1-1301
<i>IL8</i>	Interleukin 8	Neutrophil chemotactic and activating factor	4q13-q21	rs4073
<i>CX3CR1</i>	Chemokine (C-X3-C motif) receptor 1	Macrophage chemotaxis and microglial cell activation	3q21	T280M
<i>TLR3<sup>b</sup></i>	Toll-like receptor 3	Pathogen recognition and activation of innate immunity	4q35	rs3775291
<i>TLR4<sup>b</sup></i>	Toll-like receptor 4	Pathogen recognition and activation of innate immunity	9q33	rs4986790
<i>CETP</i>	Cholesteryl ester transfer protein, plasma	Cholesterol homeostasis	16q21	rs3764261
<i>LIPC</i>	Hepatic lipase	Triglyceride hydrolase and ligand/bridging factor for receptor-mediated lipoprotein uptake	15q21-q23	rs10468017
<i>VEGFA</i>	Vascular endothelial growth factor A	Angiogenesis, artery morphogenesis, blood coagulation	6q12	rs4711751
<i>COL10A1</i>	Collagen, type X, alpha 1	Extracellular matrix organization	6q21-q22	rs1999930

<i>TNFRSF10A</i>	Tumor necrosis factor receptor superfamily, member 10a	Transduces cell death signal and induces cell apoptosis	8q21	rs13278062

## Systemic Complement C5a and TH17-Mediated Immune Responses in AMD

Mouse studies suggested that C5a provides both an activating and survival stimulus to T cells.<sup>108,109</sup> T cells from peripheral blood of AMD patients have larger numbers of the receptor for C5a on their cell surfaces when compared to control subjects.<sup>110</sup> This increased number of receptors is associated with several observations that demonstrate immune activation. In vitro experiments with T cells from both AMD patients and control subjects, in which C5a was added to the cultures, resulted in enhanced production of IL-22 and IL-17. Blocking the C5a receptor reversed this enhancement. Of interest, both control subjects and AMD patients with higher IL-17 and IL-22 production had the risk allele.<sup>110</sup> These findings invite speculation that CFH's role in controlling responses is at the level of the adaptive immune system. In addition, enhanced cytokine responses were noted when monocytes were added to the in vitro cultures, and neutralization of IL-1 $\gamma$  or IL-6 markedly dampened these responses. Further, and similar to mouse studies, an enhanced number of C5aR on human T cells protected them from undergoing apoptosis. In addition, the peripheral blood cells from AMD patients often demonstrate anamnestic responses to retinal antigens. The development of choroidal neovascularization in AMD patients in association with activated macrophages found in peripheral blood has also been reported.<sup>111</sup>

## Systemic Cytokines and Autoantibodies

Altered T-cell responses are not the only systemic differences in AMD patients. When circulating cytokines were assessed, IL-22 and

IL-17 levels were significantly elevated in patients as compared to controls; further, these changes were seen early in the disease process. The higher cytokine levels in patients were particularly notable in those with the CFH variant. Penfold et al.<sup>112</sup> reported the presence of antiglial fibrillary acid protein (GFAP) in the sera of AMD patients. This is a marker for activities of retinal astrocytes, which help to maintain the blood–ocular barrier. In addition, other antibodies directed to retinal antigens have been found circulating in AMD sera. These include antibodies to CEP adducts, alpha-crystallin, alpha-enolase, and annexin II.<sup>113–115</sup> Hollyfield et al. connected in vitro experiments and in vivo observations by producing AMD-like lesions in mice exposed to an oxidative product.<sup>116,117</sup> In these studies, mice were immunized with CEP adducts formed by the covalent interaction with an oxidation fragment of docosahexanoic acid (DHA), resulting in antibodies against CEP and development of retinal pathology.

## Inflammatory Changes Seen in the AMD Eye

In addition to the systemic alterations which are readily detected in AMD, various inflammatory processes are found directly in the eye itself as well. These are considered in detail below.

### Oxidative Stress in the Eye

Oxidative processes occur through the removal of electrons from molecules. In biologic systems, energy is released when lipids, proteins, and carbohydrates are oxidized to form carbon dioxide and water. Oxidative reactions may also result in the production of reactive oxygen intermediates (ROIs), such as free radicals, hydrogen peroxide, and singlet oxygen. ROIs, which can damage other molecules, increase under conditions of irradiation, aging, reperfusion, inflammation, increased partial pressure of oxygen, cigarette smoke, and air pollution.<sup>118</sup> The biologic mechanisms that prevent the detrimental effects of ROIs include cellular compartmentalization, repair of DNA and proteins, and neutralization by antioxidant compounds. The retina is an ideal environment for the generation of ROIs for several reasons: (1) high oxygen consumption; (2) high levels of cumulative irradiation; (3)

RPE phagocytosis, which is an oxidative stress that produces ROIs; (4) high levels of polyunsaturated fatty acids in the photoreceptor outer-segment membranes; and (5) abundant photosensitizers in the neurosensory retina and RPE.<sup>118</sup>

Oxidative stress results when there is an imbalance between prooxidants and antioxidants, leading to molecular damage and/or a disruption of redox signaling.<sup>119</sup> Inflammation and oxidative stress are closely interrelated: inflammatory cells can generate ROIs, and oxidative stress can induce inflammation through nuclear factor-kappa B (NF- $\kappa$ B)-mediated inflammatory gene expression.<sup>119</sup> Oxidative stress plays a role in the pathogenesis of several retinal disorders, including AMD. Multiple changes are associated with the aging eye, including thickening of Bruch's membrane, accumulation of lipofuscin in the RPE, and loss of parafoveal rods. In a model outlined by Curcio et al.<sup>120</sup> and others, the RPE and Bruch's membrane are modified or damaged by oxidative stress and enzymatic processes over time. The materials retained at these sites, including lipoproteins, may be modified by oxidative stress, and then become stimuli for inflammation.<sup>120</sup>

## **Oxidative Stress and Inflammation in AMD**

Several studies have provided further evidence that oxidative stress is involved in AMD pathogenesis. Crabb et al. performed a proteomic analysis of drusen from normal and AMD donor eyes.<sup>121</sup> These studies identified multiple proteins modified by oxidation that were found more frequently in drusen from AMD eyes. These oxidation-related products included cross-linked molecules of carboxyethyl pyrrole (CEP) protein adducts, tissue metalloproteinase inhibitor 3, and vitronectin. Carboxymethyl lysine, an AGE produced through oxidation of carbohydrate, was also isolated. Significant elevation of an oxidation product-related receptor was also found in eyes with the advanced dry form of AMD. In another general proteome study by Yuan et al.,<sup>122</sup> approximately 60% of the elevated proteins were involved in immune responses or host defense, including complement factors C5 and C7,  $\alpha$ -crystallin A,  $\alpha$ -crystallin B, and major histocompatibility complex (MHC) class II molecule DR $\alpha$ .

## Other Immune Alterations in the AMD Eye

Cells from eyes with inflammatory diseases, including AMD, exhibit upregulated expression of immune receptors and molecules.<sup>123,124</sup> Enhanced receptor expression has been noted, particularly at the outer retina, especially the expression of IL-17RC. This is a receptor for a dimer of IL-17A and IL-17F. Clearly immune activation can occur via this receptor, altering RPE function. In addition to IL-17RC, IL-17, and IL-22 transcripts are also increased in the eye. Interestingly, IL-22 has a negative effect on human RPE cells, decreasing total tissue resistance and increasing apoptosis.<sup>125</sup> As discussed above, the NLRP-3 inflammasome promotes cleavage of pro-IL-1beta and IL-18, and may play a role in negatively regulating angiogenesis.<sup>126</sup>

Numerous histopathologic studies of AMD eyes have documented the presence of macrophages and multinucleated giant cells, mainly associated with vascular channels and breaks in Bruch's membrane (Fig. 27.4).<sup>127-132</sup> Macrophage subtype changes have been noted in the eyes of patients with AMD, including a change in the M1/M2 ratio in AMD eyes compared to that in control eyes of the same age.<sup>132</sup>

**FIG. 27.4** Age-related macular degeneration (AMD). Scattered inflammatory cells (*arrows*) are found in an AMD lesion. (Hematoxylin and eosin, ×200.)

While the systemic alterations noted are an indication of general immune activation, many of these changes would also be observed specifically in the cluster of characteristics termed immunosenescence.<sup>133</sup> Some of the cardinal features of immunosenescence include an impaired ability to respond to new antigens, while at the same time unsustained memory responses appear to be coupled with a greater propensity for autoimmune responses. These factors are believed to lead to a lingering, low-grade inflammation, and possibly are major contributors to the development of rheumatoid arthritis.<sup>134</sup> It is therefore plausible that the phenomenon of immunosenescence also contributes to the pathogenesis of inflammation in the aging eye.

## Targeting Inflammation Through Molecular Stratification: Genetics and Beyond

Clearly one major impetus to better understand the underlying mechanisms that lead to degenerative disorders such as AMD is to prevent or reverse these. It is likely that AMD results from many mechanisms. A large randomized and controlled clinical trial, the Age-Related Eye Disease Study (AREDS), demonstrated that vitamin and mineral supplementation reduced the risk progression from intermediate to advanced AMD.<sup>135</sup> Although the exact mechanism is unknown, one hypothesis is that the AREDS vitamin formulation counteracts oxidative stresses in the retina.

Understanding the mechanistic role of CFH may unlock new strategies as well. Other genetic alterations may also help define the various paths that lead to this disorder. Gene therapy for eye diseases has gained considerable interest in the past years, and the potential approaches continue to change and improve.<sup>136</sup> An alternative strategy is to evaluate the epigenetic alterations associated with the genes that lead to degenerative disorders. Epigenetic studies could target the mechanisms that lead to expression of gene products, separately from the gene sequence itself. Epigenetic therapy is already effective in treating some

cancers, and is beginning to be used in autoimmune diseases such as juvenile idiopathic arthritis.<sup>137</sup> We have shown that epigenetic therapy provides benefit, decreasing the development of disease in a uveitis model (Nussenblatt et al., unpublished data). Silencing or activating genes either by affecting the promoter site, or via histones, will certainly be a future therapeutic approach.

An AMD clinical trial demonstrated the benefits of immunomodulatory medications such as sirolimus and daclizumab;<sup>138</sup> ongoing studies are now investigating complement component inhibitors.<sup>139</sup> While systemic immunomodulation did appear to have an effect on the course of advanced AMD, this is not a viable long-term strategy for multiple reasons, including cost and the age of the patients. However, anti-IL-17 and IL-22 therapy administered locally to the eye may be useful in preventing changes that appear to result from the presence of these respective cytokines. A larger goal would be to reverse systemic immunosenescent changes. Finally, from a public health perspective it would be far more attractive to prevent AMD than to treat it. Developing treatments based on oral tolerance could be one such approach,<sup>140</sup> which showed promise in treating uveitis patients.<sup>141</sup> In an inflammatory disease model, oral tolerance downregulated IL-17 expression,<sup>142</sup> and such therapy with appropriate fragments could be continued for long periods of time.<sup>143</sup>

## Conclusion

Retinal disease results from an intricate mixture of factors that include direct and indirect effects of inflammation and immune responses. Many of the recent findings that help explain immune-mediated pathogenesis suggest opportunities for interventions. In the future, treatment and preferably prevention of retinal diseases will likely use combinations of options. These include local and systemic immunomodulation, targeting senescent changes, epigenetic remodeling, and tolerance. Such multipronged approaches might best attack the many complex interacting pathways associated with aging, oxidative stress, and inflammation.

Angiostatin and Endostatin

Other Factors With Recent Interest in Angiogenesis

### **Conclusions**

## **Introduction**

The search to dissect the molecular mechanisms of ocular

angiogenesis dates back to 1948 when Michaelson postulated that a soluble and diffusible growth factor was responsible for retinal vascular growth in development and disease.<sup>1</sup> In the late 1980s and early 1990s vascular endothelial growth factor (VEGF) was identified as this diffusible growth factor, ushering a new paradigm in the understanding as well as treatment of ocular neovascular diseases.<sup>2-6</sup> Since then our knowledge of ocular neovascularization continues to grow as new molecules are discovered, new interactions between molecules are elucidated, and our understanding of the pathogenesis of specific retinal diseases evolves. The last step is essential for developing of new strategies with improved therapeutic targeting.

Retinal neovascularization occurs in diseases such as diabetic retinopathy (DR), retinopathy of prematurity (ROP), ischemic retinal vein occlusions (RVOs), and other retinopathies such as sickle-cell disease. On the other hand, choroidal neovascularization is the hallmark of exudative (wet) or neovascular age-related macular degeneration (nvAMD) but can also be encountered in a variety of other conditions, such as outer retinal retinochoroidopathies, trauma, myopia, angioid streaks, and macular dystrophies, or without any identifiable cause (idiopathic) (Fig. 28.1).

**FIG. 28.1** Forms of abnormal angiogenesis encountered in ocular neovascular disorders. (A) The vascular network of the retina consists of the superficial and intraretinal vascular plexus, which provide oxygen and nutrients to the inner two-thirds of the retina. The outer one-third of the retina (photoreceptors and retinal pigment epithelium, RPE) receives its blood supply from the choroidal circulation. (B) Retinal neovascularization involves the proliferation of new vessels from the superficial retina at the

vitreoretinal interface. These fragile and tortuous neovessels often result in hemorrhage, fibrosis, and traction of the retina. (C) In choroidal neovascularization, new vessels arising from the choroidal circulation grow through breaks in Bruch's membrane under the RPE, neurosensory retina, or a combination of both. (D) In some cases, neovascularization forms in the neurosensory retina and at later stages may form anastomoses with the choroidal circulation, which is also known as retinal angiomatous proliferation or retinochoroidal anastomosis. *BM*, Bruch's membrane; *CC*, choroidal circulation; *GCL*, ganglion cell layer; *INL*, inner nuclear layer; *POS*, photoreceptor outer segments; *RPE*, retinal pigment epithelium. ## Impact of Abnormal Retinal and Choroidal Angiogenesis

Neovascularization is part of the aberrant wound healing response occurring in response to continuous tissue injury occurring in diseases such as DR, nvAMD, RVOs, and ROP, all of which contribute to the major causes of blindness in developed countries. DR is the leading cause of blindness among the working-age population in industrialized countries. An estimated 93 million people worldwide have some form of DR and about 28 million have sight-threatening stages of DR.<sup>7</sup> About 50% of patients with diabetes develop various degrees of diabetic retinopathy after 25 years with the disease.<sup>8</sup> RVOs constitute the second most common cause of vision loss due to retinal vascular disease,<sup>9</sup> whereas ROP has become the leading cause of childhood blindness affecting up to 30% of premature infants in developing countries and 5–8% of infants in industrialized countries.<sup>10</sup> About 1.75 million people in the United States are estimated to have neovascular AMD, and this number is supposed to double to 3 million by 2020. Additionally, there are nearly 200,000 new cases of wet AMD each year.<sup>11</sup>

## Normal Retinal Vascular Development

Vasculogenesis is the de novo formation of blood vessels from endothelial precursors. On the other hand, angiogenesis is the process by which new blood vessels are formed from preexisting blood vessels. Angiogenesis primarily occurs through “sprouting,” whereby activated endothelial cells secrete proteolytic enzymes that dissolve basement membrane around the parent vessel and align themselves to form a new capillary sprout. By curving and elongating, the sprouts form tubes with lumens, which anastomose to form loops. Mesenchymal cells are recruited to form smooth-muscle cells, or pericytes, and new basement membrane is deposited.<sup>12</sup> More recently it has been demonstrated that hemangioblasts migrate to the human choroid during development and give rise to the choriocapillaris in a process called hemovasculogenesis (blood vessels and blood cells form simultaneously from common precursors).<sup>13</sup>

Normal retinal vascularization begins at the most superficial level of the inner retina at the optic nerve head and radiates outward, reaching the retinal periphery at about 40 weeks in humans.<sup>1</sup> A meshwork of astrocytes that enter the retina at the optic nerve and grow peripherally lay a road map for retinal vascularization.<sup>14,15</sup> The endothelial “tip cells” of growing retinal vessels extend along the processes of underlying astrocytes, which secrete VEGF.<sup>16–18</sup> Pericytes associated with retinal blood vessels also promote retinal vascular growth by secreting VEGF and inducing VEGF receptors in endothelial cells through transforming growth factor-beta 1 (TGF- $\beta$ 1).<sup>19,20</sup>

The vasculature of the eye is completely formed shortly after birth and is normally quiescent and nonproliferating in adults.<sup>1</sup> An active balance of pro- and antiangiogenic influences is required to maintain homeostasis. Abnormal angiogenesis occurs when environmental changes result in tissue expression of molecules that favor the growth of abnormal new vessels. In these ocular diseases, angiogenesis occurs chaotically and does not conform to normal retinal vascular anatomy, leading to vision-threatening disease with hemorrhage, exudation, and ultimately fibrosis and retinal cell death.

## Pathogenesis of Retinal Angiogenesis

Abnormal or pathologic retinal vascularization usually occurs as a combination of two processes. The first process involves vascular injury and subsequent retinal capillary loss resulting in tissue hypoxia. The second process is characterized by deregulated vascular growth driven by a state of hypoxia. There are several experimental models supporting the idea that hypoxia is the primary stimulus for pathologic retinal angiogenesis and VEGF seems to be the cardinal growth factor to date mediating retinal angiogenesis. The first correlation of VEGF with ocular angiogenesis in vivo came from studies in monkey eyes with experimental retinal ischemia following laser vein occlusion, which demonstrated that VEGF levels correlated with the degree of neovascularization.<sup>6,21,22</sup>

In DR, sickle-cell retinopathy, and RVOs, neovascularization is a consequence of retinal capillary nonperfusion and tissue ischemia.<sup>23,24</sup> The cellular response to reduced oxygen levels is mediated by the transcriptional regulator hypoxia-inducible factor 1 (HIF-1). This is a heterodimeric complex protein made up of an oxygen-dependent alpha unit and a constitutively expressed nuclear beta unit. Hypoxia prevents the ubiquitin proteasome system degradation of the transcription factor HIF-1-alpha (HIF-1 $\alpha$ ). Stable HIF-1 $\alpha$  binds to the promoter region of its major target genes, resulting in upregulation of factors such as VEGF, placental growth factor (PlGF), angiopoietin-1 (ANGPT1) and angiopoietin-2 (ANGPT2), erythropoietin (Epo), and platelet derived growth factor (PDGF)-B, which are key molecules in angiogenesis (Fig. 28.2).<sup>25-27</sup> VEGF acts as a potent endothelial cell mitogen, stimulating their proliferation.<sup>28,29</sup>

**FIG. 28.2** The hypoxia-inducible factor (HIF) pathway. Simplified representation of HIF regulation under normoxia and hypoxia. Under normoxic conditions (left), HIF is degraded by the proteasome through a process involving hydroxylation and then ubiquitination of HIF molecules by von Hippel–Lindau (VHL) protein complex. Under hypoxic conditions, HIF-1 $\alpha$  accumulates in the cytoplasm and dimerizes with HIF-1 $\beta$ . The dimer then translocates to the nucleus, upregulating a number of proangiogenic molecules, including VEGF, vascular endothelial growth factor; PlGF, placental growth factor, PDGF- $\beta$ , platelet-derived growth factor- $\beta$ ; ANGPT1/2, angiopoietins 1 and 2; and EPO, erythropoietin. (Courtesy of Aristomenis Thanos,

In addition to endothelial cells, several key cells involved in normal retinal vascularization, including pericytes, astrocytes, and Müller glial cells, also play a role in abnormal retinal angiogenesis. Pericyte loss is among the first pathologic changes in DR and is thought to contribute to multiple vascular changes including the loss of formed vessels, the loss of normally growing vessels, and abnormal angiogenesis.<sup>20,30</sup> Experimental models suggest astrocytes may stabilize vessels and restrict growth of normal vessels to the appropriate retinal layers. Müller cells influence retinal neovascularization as they may secrete more proangiogenic factors such as VEGF rather than antiangiogenic factors such as pigment epithelium-derived factor, also now known as Serpin peptidase inhibitor, Clade F, member 1; SERPINF1 (PEDF/SERPINF1) in the setting of retinal ischemia.<sup>31</sup> Lastly, hypoxia leads to degeneration and focal disruptions in the glial sheath surrounding retinal blood vessels, allowing neovascularization to extend beyond the retinal surface and into the vitreous cavity.<sup>32</sup>

It is widely accepted that the vitreous plays a significant role in the pathogenesis and propagation of retinal angiogenesis. The posterior vitreous cortex consists of densely packed type II collagen fibrils and other extracellular matrix components, which offer an ideal scaffold for endothelial cell proliferation and new blood vessel development. The attachment of the cortical vitreous to the retina is mediated primarily through the proteins laminin and fibronectin, which have critical roles in angiogenesis.<sup>33</sup> Histologic analysis of neovascular tissue from patients with proliferative DR (PDR) reveals it is intertwined with vitreous collagen.<sup>34</sup> Moreover, clinical evidence confirms that eyes with DR and central RVO and concurrent posterior vitreous detachment are less likely to develop posterior segment neovascularization compared to eyes with intact posterior cortical vitreous.<sup>35</sup>

DR, ROP, and RVOs are among the ischemic diseases leading to retinal neovascularization and are discussed below so that through these disease processes we may understand more about mechanisms of retinal angiogenesis.

## Retinal Neovascularization in Diabetes

Pathologic retinal neovascularization in DR takes place in two phases: an initial vascular dropout/occlusion phase is followed by abnormal vascular growth. Chronic hyperglycemia leads to vascular injury with basement membrane thickening, pericyte loss, microaneurysms, and vascular leakage.<sup>36,37</sup> While the exact mechanism remains ill defined, many biochemical pathways (protein kinase C, nuclear factor (NF)- $\kappa$ B, mitogen-activated protein kinase) have been involved in the pathogenesis of early DR. Oxidative injury, microthrombi formation, inflammatory mediator upregulation, and leukostasis have all been observed to aggravate vessel loss.

DR behaves as chronic inflammatory disease in many ways, and there is a growing body of evidence suggesting a key role for inflammation in vascular dropout and neovascularization. Early inflammation promotes increased vasopermeability and leukostasis, while persistent inflammation is accompanied by the rise of proinflammatory cytokines.<sup>38-40</sup> Specifically, cytokines such as tumor necrosis factor-alpha (TNF- $\alpha$ ), interleukin (IL)-1 $\beta$ , intercellular adhesion molecule (ICAM), inducible nitric oxide synthase (iNOS), and IL-6 are elevated in patients with PDR.<sup>40-43</sup> Localized inflammation is thought to lead to leukostasis through the interaction of ICAM and CD18.<sup>44-47</sup> Leukostasis leads to microvascular occlusion, nonperfusion, and ischemia, which induces the upregulation of angiogenic factors. IL-1 $\beta$  can promote endothelial cell proliferation, propagate inflammation, and upregulate HIF-1 $\alpha$ .<sup>48,49</sup> TNF- $\alpha$  can promote angiogenesis, endothelial cell sprouting, and macrophage-induced angiogenesis is mediated through TNF- $\alpha$ .<sup>50,51</sup> TNF-receptor p55-deficient animals are protected from retinal neovascularization in animal models.<sup>52</sup> Inhibitors of inflammation such as cyclooxygenase 2 inhibitors and aspirin have been shown to curtail vascular pathology and neovascularization.<sup>38,44,53</sup>

The proinflammatory environment is characterized by elevated matrix metalloproteinases (MMPs), which degrade the extracellular matrix, a step necessary for angiogenesis. Additionally, MMP-9 is not only induced by IL-8<sup>54</sup> but also activates IL-8,<sup>55</sup> which recruits more inflammatory cells, feeding a destructive positive-feedback

loop. Insulin<sup>56</sup> and PEDF<sup>57</sup> are degraded by MMP-9, leading to a state of more insulin resistance and neuronal peril. Beránek et al. in 2008 showed MMP-2 and MMP-9 to be elevated in patients with PDR.<sup>58</sup>

As a consequence of vascular degeneration and dropout there is inadequate supply of oxygen and nutrients for proper cellular metabolism. This state of hypoxia leads neurons and supporting astrocytes to secrete proangiogenic factors such as VEGF and insulin-like growth factor (IGF)-1. Clinical studies have substantiated the role of VEGF in DR.<sup>59,60</sup> VEGF levels are elevated in patients with PDR and anti-VEGF intervention is of immediate benefit.<sup>61-72</sup> Panretinal photocoagulation may not decrease VEGF levels in the short term (and may increase proinflammatory cytokines);<sup>73,74</sup> however, successful laser retinal ablation decreases VEGF over the long term.<sup>60</sup>

Before the discovery of VEGF and its important role in DR, hypophysectomy studies had revealed a role of growth hormone (GH) and associated factors in DR. IGF-1 levels have been shown to be elevated in the vitreous of patients with PDR relative to control eyes.<sup>75-77</sup> Although there may be a role for IGF-1 in retinal neovascularization, our understanding of IGF-1 in DR remains unclear.<sup>78</sup> IGF-1 may act indirectly via VEGF. Studies of cultured RPE cells demonstrated that adding IGF-1 in vitro increased VEGF mRNA and secreted protein.<sup>79</sup> The accumulation of advanced glycation endproducts (AGE) after long-term exposure to hyperglycemia caused an increase in IGF-1 synthesis in human monocytes, suggesting a role for inflammatory pathways.<sup>80</sup>

Another proangiogenic factor, erythropoietin (Epo), has also been shown to play a role in DR.<sup>81</sup> Epo is involved in the generation of red blood cells but has been shown to be synthesized in astrocytes and its receptors have been detected in photoreceptors. In the adult mouse retina, acute hypoxia stimulates Epo expression via HIF-1 $\alpha$ .<sup>82</sup> Epo has been shown to have neuroprotective effects in various models.<sup>83,84</sup> Epo levels are higher in the vitreous of patients with PDR, and inhibition of both Epo and VEGF leads to greater inhibition of neovascularization.<sup>81</sup> However, since Epo has neuroprotective effects, its inhibition for neovascularization may come with significant collateral damage.

Angiopoietins are molecules that bind endothelial Tie receptors and are involved in developmental as well as pathologic angiogenesis, such as in the case of PDR. Vitreous level of Ang 2 and VEGF were significantly higher in patients with PDR than in controls or those with inactive PDR and the levels of Ang 2 correlated significantly with that of VEGF, suggesting an association of Ang 2 and VEGF with angiogenic activity in PDR.<sup>85</sup> A nuclease-resistant RNA aptamer that binds and inhibits Ang 2 but not the related Tie2 agonist, Ang 1, inhibited basic fibroblast growth factor (FGF)-mediated neovascularization in the rat corneal micropocket angiogenesis assay, demonstrating that a specific inhibitor of Ang 2 can act as an antiangiogenic agent.<sup>86</sup>

More recently another potent angiogenic factor, angiopoietin-like 4 (ANGPTL4), was identified in patients with PDR. ANGPTL4 is upregulated in hypoxic retinal Müller cells in vitro and the ischemic retina in vivo. Expression of ANGPTL4 was increased in the aqueous and vitreous of patients with PDR, independent of VEGF levels, and localized to areas of retinal neovascularization. In a recent study, inhibiting the effects of ANGPTL4 was additive to anti-VEGF treatment.<sup>87</sup>

In addition to elevation of proangiogenic factors, there is also an imbalance of antiangiogenic factors in diabetic retinopathy. PEDF, now known as serpin peptidase inhibitor clade F member 1 (SERPINF1), is considered to be the most potent inhibitor of neovascularization, inhibiting endothelial cell migration with a median effective dose of 0.4 nM.<sup>88</sup> It specifically interferes with neovasculature and not with established vessels due to its mechanism of action through Fas/FasL and its cooperation with angiogenic factors. SERPINF1 upregulates FasL on endothelial cells, whereas angiogenic factors induce its essential partner Fas receptor on neovessels but not on established vessels.<sup>89</sup> In PDR, it has been found that PEDF levels are downregulated compared to controls.<sup>90</sup> PEDF also has neuroprotective effects, and thus seems to be an ideal candidate for therapeutic intervention.

## Neovascularization in Vascular Occlusions

Similar to diabetic retinopathy, tissue ischemia and subsequent

elevation of angiogenic factors are thought to be of major importance in neovascularization after RVOs. The role of VEGF in particular has been well established. Aiello et al. in 1994 showed increased VEGF levels in the vitreous of patients with active neovascular central RVO (CRVO);<sup>60</sup> in the same year, Miller et al. showed evidence that VEGF is temporally and spatially correlated with ocular angiogenesis in a primate model of CRVO and that blockade of VEGF could inhibit iris neovascularization.<sup>91</sup> Most recently the clinical benefit of anti-VEGF in CRVO has been established.<sup>92–97</sup> Several proinflammatory cytokines have been shown to be elevated in CRVO, including monocyte chemoattractant protein (MCP)-1, IL-6,<sup>98</sup> and ICAM-1.<sup>99–101</sup> Additionally, antiangiogenic factors such as PEDF have been shown to be downregulated in CRVO with macular edema.<sup>102</sup> The alterations of cytokines seen in CRVO not only lead to potential neovascularization but are also major contributors to vascular leakage and macular edema. To this aim, combination treatment approaches with anti-VEGF and corticosteroids have been suggested.<sup>103,104</sup>

## Neovascularization Associated With Retinopathy of Prematurity

Retinal neovascularization in ROP is a complex phenomenon, where genetic, developmental, environmental, and disease-associated factors come into play. First, retinal vasculature development begins at about the fourth month of gestation and is complete at about 40 weeks. Therefore, full retinal vascular development is accomplished mostly in utero, where the fetus is in a relatively hypoxic environment (average  $PaO_2$  is 25–35) and exposed to the placental and maternal cytokines and growth factors.<sup>105,106</sup> The placenta is known to be secreting several proangiogenic cytokines, including VEGF, and PlGF.<sup>107</sup> Several pivotal cell signaling pathways and growth factors are involved in retinal vascularization, including the VEGF-signaling pathway, IGF-1, and the Wnt-signaling pathway, among others.<sup>108</sup> Premature birth disrupts this well orchestrated process, as the fetus is exposed into a new environment, which renders the developing vascular

endothelial cells unresponsive to the normal developmental stimuli.

During retinal vascular development, VEGF expression is regulated by retinal oxygen tension and therefore VEGF mRNA is upregulated in astrocytes of the nonvascularized (hypoxic) retina and downregulated in vascularized areas.<sup>108</sup> VEGF acts through VEGFR2 on the filopodia of tip cells to guide blood vessel development.<sup>18</sup> In ROP, VEGF has been shown to be elevated, and the importance of VEGF upregulation in the proliferative phase of this disease has been shown in humans, since blockade of VEGF with anti-VEGF antibodies showed significant efficacy in infants with less development of myopia.<sup>109-115</sup> It should be noted that due to the dual role of VEGF in development and disease concerns about timing and safety of VEGF inhibition in ROP have been raised.<sup>116-118</sup>

In addition to VEGF, IGF-1 as was mentioned before plays an important role in ROP by allowing VEGF to enhance endothelial cell survival and promote early vascular development.<sup>119</sup> Infants with low IGF-1 levels 3 weeks postpartum had higher risk for developing ROP.<sup>120,121</sup> A clinical trial investigating the effect of recombinant human IGF-1 administration in premature infants in increasing normal retinal vascular development and preventing neovascular ROP is currently in phase II clinical trials in the United States and in Europe (NCT01096784).

High oxygen administration at birth was among the first factors to be found critical in the pathogenesis of ROP. Excessively high levels of oxygen in incubators, used to save the lives of premature infants, led to an ROP epidemic and the realization that reducing the level of oxygen given to premature babies reduces the incidence of ROP.<sup>122,123</sup> The detrimental effects of high and/or fluctuating oxygen concentrations were validated in the oxygen-induced retinopathy (OIR) models, where alternating oxygen concentrations induce retinal neovascularization.<sup>124-126</sup> Although these models lack significant features of human ROP (absence of ridge tissue, involution of RNV, and absence of neovascular complications such as hemorrhage and traction retinal detachment), they have been instrumental in the dissection of the molecular mechanisms involved in ROP and retinal neovascular diseases in general. The association between high oxygen levels and ROP led to the

development of the 2-phase hypothesis for ROP almost 30 years before the classification of human ROP in zones and stages. According to this, in the first phase there is a delay or halting in physiologic retinal vascular development due to prematurity as well as hyperoxia-induced endothelial cell damage and subsequent vasoattenuation. As the peripheral avascular retina continues to develop in the absence of a developing vascular bed, it becomes relatively hypoxic and secretes proangiogenic factors, which promote retinal neovascularization and abnormal vasoproliferation into the vitreous (second phase). It is possible that the rate of change of oxygenation rather than the absolute level may be more important for disease progression, and there have been reports that return to high oxygen levels for prolonged time with gradual decline to normal oxygen levels may halt and reverse the disease.<sup>127-129</sup>

Oxygen level changes cannot fully account for disease progression and other factors have been implicated in RNV seen in ROP. Evidence from OIR models shows that oxidative stress and reactive oxygen species (ROS) play a role in the pathologic neovascularization.<sup>130</sup> Clinical trials for lutein<sup>131</sup> and N-acetyl cysteine<sup>132</sup> supplementation failed to show any significant benefit; however, a meta-analysis for vitamin-E supplementation concluded that it can reduce the risk of stage 3 ROP by 52%.<sup>133</sup> The discrepancy between treatment efficacies between the OIR model and human ROP underlines the limitation of our animal models and the complex pathophysiology of human disease.

## Neovascularization in Uveitis

Inflammatory eye diseases may be complicated by neovascularization, which occurs due to two primary mechanisms: occlusive retinopathy (resulting in retinal ischemia) and inflammation. Occlusive retinopathy is the prominent characteristic in diseases with retinal vasculitis. These include Eales disease, Behçet disease, sarcoidosis, lupus, and retinitis associated with infectious such as cytomegalovirus (CMV), syphilis, tuberculosis, and herpes simplex virus (HSV), which can result in necrotizing vasculitis.<sup>134</sup> However, neovascularization of the disc has been seen

in other uveitic cases without apparent ischemia.<sup>135</sup> Given the fact that neovascularization can regress with corticosteroid and other immune-suppressive treatments, it seems that inflammation alone may be sufficient for retinal neovascularization in this heterogeneous group of diseases.<sup>136–138</sup> In the setting of uveitis, the breakdown of the blood–ocular barrier results in the accumulation of inflammatory cells, cytokines, and growth factors in the vitreous, which significantly alter the retinal microenvironment. The transcription factor NF-κB is critical for the inflammatory response and has been found to affect the expression of a variety of proinflammatory and proangiogenic cytokines and growth factors, including VEGF, IL-1β, IL-6, and TNF-α. These cytokines have been found to be elevated in the vitreous of patients with uveitis.<sup>139</sup> VEGF is still a key molecule in uveitis-associated neovascularization, and several studies have shown benefit (albeit partial) of anti-VEGF therapy.<sup>140,141</sup>

## Mechanisms of Choroidal Angiogenesis

Choroidal neovascularization (CNV) denotes the growth of new blood vessels that originate from the choriocapillaris into the subretinal pigment epithelium (sub-RPE) or subretinal space. A *sine qua non* for the development of CNV is the disruption of Bruch's membrane (BM), which can occur with prolonged inflammation (nvAMD, outer retinal retinopathies, infectious etiologies), trauma (choroidal rupture, myopia, iatrogenic), defective BM secondary to systemic disease (angioid streaks), or without any identifiable cause (idiopathic). However, CNV lesions in pathologic myopia are associated with considerably less retinal edema, subretinal fluid (SRF), and pigment epithelial detachments (PEDs) compared with CNV associated with AMD.<sup>142</sup> In addition, myopic CNVM is usually smaller in size and has less need for chronic anti-VEGF suppression. This underlines that the development of CNVM in myopia may share some signaling pathways with CNVM seen in AMD, but with different root causes and pathogenetic mechanisms.

The development of the laser-induced model of CNV originally

described by Ryan has had a significant impact in our understanding of the molecular events involved in choroidal angiogenesis and has become the most widely used model in nvAMD research.<sup>143</sup> Although this model does not fully recapitulate the stages of nvAMD, it has been widely used in the preclinical testing of several antiangiogenic drugs.<sup>144</sup> Additionally, the surgical extraction of choroidal neovascular membranes from patients with nvAMD and their subsequent histopathologic examination increased our understanding about the complex pathways leading to CNV in nvAMD.<sup>145</sup> Below we will discuss the components involved in CNV, especially in the context of nvAMD (Fig. 28.3).

**FIG. 28.3** Choroidal neovascularization (CNV). Presumed pathologic stages required for the development and progression of CNV. (A) Low-grade inflammation and tissue hypoxia at the sites of soft

drusen trigger the secretion of vascular endothelial growth factor (VEGF) by retinal pigment epithelium (RPE) and photoreceptor cells. Macrophages are attracted to the area in response to locally secreted chemoattractants or drusen components (e.g., monocyte chemoattractant protein-1, complement factor H). Accumulation of proangiogenic M2-macrophages. (B) Rupture of Bruch's membrane as a prerequisite for the development of CNV, which is thought to occur due to the local secretion of matrix metalloproteinases by RPE, choroidal endothelial cells, or macrophages. This proteolytic degradation of Bruch's membrane activates the wound-healing response at the choroidal–RPE interface. (C) Angiogenic cytokines such as VEGF and basic fibroblast growth factor induce the activation and proliferation of choroidal endothelial cells through the breaks in Bruch's membrane. Macrophages migrate into the subretinal space and promote the angiogenic response. (D) The newly formed vessels lack pericytes, are leaky and fragile, and often result in subretinal fluid accumulation or hemorrhage. (E) Growth factors secreted locally induce the transdifferentiation of RPE cells and its further migration from the monolayer into the stroma of the lesion. Maturation of the neovascular membrane with recruitment of fibroblasts, transdifferentiated RPE cells, and inflammatory cells. (F) The endpoint of this wound-healing response is the formation of a disciform lesion, characterized by aberrant fibrous tissue proliferation severely affecting the function of overlying photoreceptors. *bFGF*, Basic fibroblast growth factor; *MMPs*, matrix metalloproteinases. Thanos, MD.)

## Aging and Senescence of the Retinal Pigment Epithelium (RPE)

The incidence and progression of nearly every feature of AMD, including CNV, relates to age.<sup>146</sup> Lipofuscin, a byproduct of photoreceptor outer-segment digestion by lysosomes, increases

with age in RPE as lysosomal activity decreases in RPE with aging. Progressive accumulation of lipofuscin is thought to result in disturbance of RPE function. Aged RPE cells may decrease production of antiangiogenic molecules such as PEDF as successive passage of cultured RPE cells results in diminished production of PEDF.<sup>147-149</sup>

## **Drusen, Basal Lamina/Linear Deposit Formation**

Soft drusen, unlike hard drusen, appear to be an important associated and predisposing feature of CNV. It is thought that membranous accumulation of debris as part of a diffuse disturbance of the RPE, softening of hard drusen, and cleavage in basal lamina/linear deposits may aid in the formation of soft drusen.<sup>150-154</sup> Histopathologic studies also reveal that basal lamina deposits (accumulating between the plasma and basement membrane of the RPE) and basal linear deposits (with a thickening of the inner collagenous zone of the Bruch's membrane) also have important associations with CNV.<sup>155</sup> Therefore, abnormal deposits that occur with diffuse distribution pattern between the RPE layer and Bruch's membrane are predisposing features of CNV. It is hypothesized that deposits between the RPE layer and Bruch's membrane may block the diffusion of oxygen and nutrients from choriocapillaris to the RPE monolayer and photoreceptors.<sup>156</sup> This speculative localized cellular hypoxia could result in overexpression of angiogenic growth factors such as VEGF, which, in turn, induce neovascularization from the choroidal vasculature. Additionally, the deposits are known to contain components of the immune response, and thus may act as initiators of inflammation.<sup>157-160</sup> The deposits may also serve as a reservoir for sequestration of factors such as advanced glycation end-products (AGE)<sup>161,162</sup> that may affect the function of adjacent RPE and choroidal endothelial cells.

## **Enzymatic and Mechanical Disruption of Bruch's Membrane**

In CNV, activated endothelial cells migrate through Bruch's membrane; this process occurs by degradation of an intact Bruch's membrane, or growth through an existing Bruch's membrane break. Clinicopathologic studies suggest that occult CNV (type 1) is neovascularization proliferating under the RPE and is less permeable/active than classic CNV (type 2) in which the neovascularization has penetrated the BM/RPE complex.<sup>163</sup> It is also important to note that there is yet a third type of neovascularization (type 3) in which there is proliferation of new vessels within the retina itself with a perfusing arteriole and draining venule that can be accompanied by compensatory retinal telangiectatic changes and formation of a retinal–choroidal anastomosis (RCA) through breaks in the BM/RPE complex.<sup>164</sup> Bruch's membrane may be disrupted when the balance between proteolytic enzymes such as matrix MMPs and their inhibitors, the tissue inhibitors of metalloproteinases (TIMPs), favors a proteolytic environment. RPE cells express MMP-1 (interstitial collagenase),<sup>165</sup> MMP-2 (72-kDa gelatinase),<sup>165,166</sup> MMP-3 (stromelysin), and MMP-9 (92-kDa gelatinase),<sup>165</sup> as well as TIMP-1,<sup>166,167</sup> TIMP-2, and TIMP-3.<sup>167</sup> Thus, proteolysis of Bruch's membrane may potentially result from reduced expression of TIMPs or increased expression of MMPs. MMPs also play an important role in degrading the extracellular matrix at the leading edge of neovascular fronds. It has been shown that decreases in thickness and integrity of the elastic layer of Bruch's membrane are seen in the macula of eyes with AMD but not in controls.<sup>168</sup> Lysyl oxidase-like (LOXL) protein 1 has been shown to guide the spatially defined deposition of elastin and is essential for the maintenance of elastic fibers. LOXL1-deficient mice have been shown to develop increased neovascularization after laser injury.<sup>169</sup> Impairment in other components of the Bruch's membrane such as collagen XVIII has been shown to affect CNV formation in animals. Collagen XVIII knockout mice develop normal choroidal vasculature; however, they demonstrate increased size and leakage of laser-induced CNV.<sup>170</sup>

Transgenic mice with an intact Bruch's membrane that overexpress VEGF in photoreceptors develop subretinal neovascularization; however, the subretinal vessels extend from retinal vessels rather than the choroidal vasculature.<sup>171</sup> In contrast,

transgenic mice that overexpress VEGF in RPE cells show intrachoroidal CNV.<sup>172</sup> These findings support the notion that CNV requires both the expression of an angiogenic factor and a break in Bruch's membrane (by proteolysis, physical disruption, or preexisting break).

Macrophages are an alternative source of enzymes (such as MMPs) that could cause focal disruption of Bruch's membrane.<sup>173</sup> Histopathologic studies reveal that macrophages accumulate near thinned segments of Bruch's membrane.<sup>174</sup> In AMD, the RPE shows increased expression of MCP-1, a factor critical for macrophage recruitment.<sup>175</sup> Macrophages in the choroid may subsequently degrade Bruch's membrane, thus forming a passage that can be used by activated choroidal endothelial cells to gain entrance to the sub-RPE space.

## Macrophages and Microglial Cells, and CNV

Macrophages (Mφs) are an additional source of angiogenic growth factors that may promote the development of CNV and pharmacologic depletion of macrophages diminishes the lesion size and severity in experimental laser-induced CNV.<sup>176,177</sup> Activated Mφs show increased expression of inflammatory cytokines such as TNF-α and IL-1β, which may promote angiogenesis by stimulating VEGF expression in RPE.<sup>178</sup> Polarization of Mφs into classical proinflammatory M1-like and alternative proangiogenic M2-like, two extremes in a continuum of polarization states,<sup>179</sup> seems to be crucial for the angiogenic switch in nvAMD degeneration.<sup>180</sup> Rho-associated kinase (ROCK) signaling is involved in Mφ polarization and ROCK inhibitors have been tested in neovascular disease.<sup>180,181</sup> It has been shown that the number of M2 Mφs are increased compared to M1 macrophages in normal aging eyes,<sup>182</sup> and furthermore, aging macrophages show impaired cholesterol efflux and switch to angiogenic phenotype promoting neovascular AMD,<sup>183</sup> which partially supports the fact why age is the most crucial risk factor for nvAMD.<sup>184</sup>

Microglial cells (MC) – the resident Mφs of the retina – are involved in phagocytosis of injured and dead cells.<sup>185</sup> Dysfunction of phagocytosis of accumulating debris may lead to further

inflammation.<sup>186</sup> In addition, accumulation of microglia in the subretinal space has been reported in animal models of AMD.<sup>187</sup> CX3CR1 is a cytokine produced by MC, and an association between AMD and CX3CR1 has been reported.<sup>188,189</sup> In CX3CR1-deficient mice, accumulation of MCs in the subretinal space has been observed, contributing to drusen formation and photoreceptor degeneration,<sup>190</sup> whereas a double knockout of MCP1 and CX3CR1 in an animal model leads to an AMD phenotype with spontaneous CNV formation.<sup>191,192</sup>

## Complement, AMD, and CNV

Studies of human donor eyes have shown increased levels of C-reactive protein and decreased complement factor H (CFH) in the RPE/Bruch's membrane/choriocapillaris region of eyes with AMD compared to controls, suggesting a role of complement and inflammation in the progression of the disease.<sup>193</sup> Complement components have been detected in drusen,<sup>151,152,157-160</sup> and an animal model of CD59 knockout leads to increased CNV.<sup>194</sup> Most recently, a Y402H polymorphism in complement factor H (CFH) has been associated with increased risk of AMD and likely wet AMD.<sup>195-198</sup> This particular allele of CFH leads to decrease in its activity and thus an increased complement-mediated inflammation since CFH is a negative regulator of the alternative pathway. Other human studies have identified protective haplotypes in two other genes encoding complement proteins, factor B (abbreviated as BF, fB, or Fb) and complement component 2 (C2).<sup>199</sup> The alternative complement regulates pathologic angiogenesis, and Fb<sup>(-/-)</sup> mice show an increased number of neovessels at postnatal day 17 in the OIR model,<sup>200</sup> and mice deficient in the central complement component C3 displayed increased neovascularization in the same model.<sup>201</sup> However, another study showed that fB deficiency was protective in a laser model of CNVM.<sup>202</sup> In that same study they showed the antiangiogenic role of a soluble factor consisting of the N terminus of mouse factor H, containing the AP-inhibitory domain, linked to a complement receptor-2 targeting fragment. CFH polymorphisms were reported to affect response to anti-VEGF with CFH Y402H CC being accompanied with a poor response to

anti-VEGF therapy,<sup>203,204</sup> yet the CATT trial reported that although specific alleles for CFH, ARMS2, HTRA1, and C3 may predict the development of AMD, they did not predict response to anti-VEGF therapy.<sup>205</sup> Complement-based therapies have been mostly targeting dry AMD, but early clinical trials have not been encouraging.<sup>206</sup>

## Angiogenic and Antiangiogenic Factors in Neovascularization

### Angiogenic Factors

#### Vascular Endothelial Growth Factor

VEGF, also known as VEGF-A or VEGF-1, is expressed as five mRNA splice variants in humans: isoforms 121, 145, 165, 189, and 206.<sup>207</sup> VEGF is a heparin-binding dimeric glycoprotein with disulfide-linked subunits, which share significant sequence homology with the A and B chains of PDGF.<sup>208</sup> VEGF 121 is entirely soluble and unbound to extracellular matrix. VEGF 165 is intermediate and binds somewhat to extracellular matrix. VEGF 189 is almost entirely sequestered to extracellular matrix and cell surface sites.<sup>209,210</sup> VEGF 165 is the predominantly expressed isoform when human cDNA libraries are screened, and is optimal for bioavailability and biologic potency. It is the critical isoform for both developmental and pathologic retinal angiogenesis.<sup>16,210,211</sup> Two other related endothelial growth factors, VEGF-B and VEGF-C, have structural homology to VEGF and appear to play roles in tumor angiogenesis and in the development of the lymphatic system, as does VEGF-D.<sup>212</sup> VEGF-C, also known as VEGF-2, has been shown to promote angiogenesis in the rabbit ischemic hindlimb model.<sup>213</sup> VEGF-E has similar angiogenic activity to VEGF-A, primarily through VEGF receptor 2.<sup>214</sup>

VEGF was first identified in tumor models as a vasopermeability factor and initiator of angiogenesis upregulated by hypoxia. In addition to being the strongest endothelial cell mitogen, VEGF has been shown to induce the expression of plasminogen activators in microvascular endothelial cells, which is important in the extracellular proteolysis necessary for capillary formation.<sup>215</sup> VEGF

induces the expression of endothelial cell  $\alpha_1\beta_1$  and  $\alpha_2\beta_1$  integrins, which are important in migration.<sup>216</sup> There is also in vitro evidence that VEGF upregulates endothelial cell fenestrations in kidney glomerulus, choroid plexus, and even the choriocapillaris.<sup>217</sup> Leukocyte adhesion has been shown to be important in vascular leakage. VEGF increases the expression of ICAM-1 on endothelial cells, resulting in increased leukostasis, which mediates the breakdown of the blood–retinal barrier.<sup>45,218</sup>

Both high- and low-affinity VEGF receptors have been identified on not only endothelial cells, but also on bone marrow-derived and retinal epithelial cells.<sup>219–221</sup> They belong to the family of tyrosine kinases requiring phosphorylation to be activated upon ligand binding. VEGFR-1 (FMS-like tyrosine kinase or FLT-1 in human) and VEGFR-2 (fetal liver kinase 1 or Flk-1 in the mouse; TKR-C in the rat; kinase insert domain receptor or KDR in the human) are expressed on endothelial cells, whereas VEGFR-3 (FLT4) is primarily found on lymphatic endothelial cells.<sup>222</sup> Although VEGF binds to both VEGFR-1 and VEGFR-2, the latter is primarily responsible for endothelial cell mitogenesis, survival, and permeability.<sup>223</sup> VEGFR-1 may be important in development by sequestering VEGF, preventing it from interacting with VEGFR-2.<sup>224</sup> VEGFR-1 has an established role in monocyte chemotaxis.<sup>225,226</sup> VEGF-C has also been shown to be a ligand for VEGFR-2 and VEGFR-3.<sup>213</sup> Synergism between FGF-2 and VEGF has been demonstrated by the finding that FGF-2 increases VEGFR-2 expression in microvascular endothelial and aortic endothelial cells.<sup>227</sup> In addition to the receptor tyrosine kinases, VEGF also interacts with a family of coreceptors, the neuropilins, which may enhance its angiogenic function.<sup>228</sup>

Several growth factors cause upregulation of VEGF gene expression, including epidermal growth factor, TGF- $\alpha$  and  $\beta$ , IGF-1, FGF, and PDGF, implicating both paracrine and autocrine release of these factors in the hypoxic regulation of VEGF.<sup>219,229</sup> It has been shown that TGF- $\beta$  is upregulated in RPE cells in CNV and hypothesized to play a role in modulating the effects of VEGF and basic FGF.<sup>230</sup> Both TGF- $\beta$  and IL-1 induce VEGF expression in cultured choroidal fibroblasts.<sup>231</sup> VEGF and TGF- $\beta$  can upregulate connective tissue growth factor (CTGF), a proangiogenic and

profibrotic growth factor found in CNV.<sup>232</sup> However, the relative importance of these growth factors, in comparison with VEGF, has not been determined.

## **Fibroblast Growth Factor-2**

Acidic and basic fibroblast growth factor are prototype members of the FGF family. Basic FGF or FGF-2 is a fibroblast mitogen, and one of the first angiogenic factors identified and suspected in ocular neovascularization. FGF-2 has been called “the stored growth factor” because much of the cell-associated FGF-2 is found in the extracellular matrix.<sup>233</sup>

FGF-2 has been implicated in various aspects of angiogenesis. It stimulates endothelial cell proliferation and migration and induces the production of proteases.<sup>234</sup> FGF-2 is angiogenic in vivo in the chick chorioallantoic membrane (CAM) and corneal micropocket bioassays at very low levels.<sup>235,236</sup> FGF-2 has been isolated from many normal tissues and tumors of mesodermal and neuroectodermal origin, as well as in CNV membranes.<sup>230,237-239</sup>

One of the arguments against FGF-2's role in pathologic angiogenesis is its lack of a definitive signal peptide for secretion.<sup>240</sup> However, a number of alternative pathways for FGF-2 release have been postulated, including the ATP-binding cassette (ABC) transport proteins, selective exocytosis, and cell death or injury.<sup>241-243</sup> During sublethal injury, cells may transiently release FGF-2. Using cultured aortic endothelial cells, McNeil and colleagues have demonstrated that mechanical wounding by scraping leads to efficient release of FGF-2 from injured cells<sup>241</sup> (also reviewed by D'Amore<sup>242</sup>). In an experimental model of optic nerve crush in the mouse, FGF-2 immunostaining is dramatically increased in the retinal photoreceptor layer.<sup>244</sup> Finally, injury to the corneal epithelium leads to release of FGF-2, which binds to basement membrane.<sup>243</sup> These and other observations suggest that FGF-2 may act as a “wound hormone” both in maintenance of tissue integrity and repair after injury.

## **Integrins**

The integrins are a family of cell adhesion proteins that are heterodimer combinations of 15  $\alpha$  and 8  $\beta$  subunits, and are

important regulators of angiogenesis. They mediate endothelial cell adhesion to the extracellular matrix, which facilitates proliferation, migration, and response to prosurvival or apoptotic signals in the formation of new vessels.<sup>245</sup> Different integrins can bind to the same ligand, but initiate different intracellular signaling pathways. Also, one integrin can bind to multiple ligands; in addition to extracellular matrix components, ICAMs important for leukocyte adhesion can also be bound to integrins.<sup>246</sup>

$\alpha_v\beta_3$  has been demonstrated to inhibit endothelial cell apoptosis in newly sprouting blood vessels through the regulation of NF- $\kappa$ B.<sup>247</sup>  $\alpha_v\beta_3$  and  $\alpha_v\beta_5$  are highly expressed on angiogenic endothelial cells and have been demonstrated in neovascular tissue of experimental models and in clinical specimens.<sup>248,249</sup> Friedlander and colleagues found both  $\alpha_v\beta_3$  and  $\alpha_v\beta_5$  expressed in neovascular tissue from eyes with proliferative DR, whereas only  $\alpha_v\beta_3$  was expressed in neovascular tissue from AMD and ocular histoplasmosis syndrome.<sup>249</sup> Blocking the integrins halts angiogenesis in the chick CAM and corneal neovascularization models, and integrin binding also partially suppresses retinal neovascularization.<sup>250,251</sup>

## Ang and Tie2

Ang-1 is a 70-kDa glycoprotein that is chemotactic for endothelial cells, and is postulated to play a role in the assembly of nonendothelial cell components and the formation of capillary sprouts.<sup>252,253</sup> Ang-1 binds to Tie2, a tyrosine kinase receptor, which is expressed on endothelial cells and early hematopoietic cells.<sup>254,255</sup> Knockouts of the gene encoding Ang-1 or its receptor Tie2 are embryologically lethal, with failure to recruit smooth-muscle and pericyte precursors. Tie2 has also been demonstrated in quiescent and angiogenic vasculature in adults and may play a role in vascular maintenance.<sup>255,256</sup> Ang-2 also binds strongly to Tie2 but does not result in phosphorylation of the receptor; instead, it acts as a competitive inhibitor preventing Ang-1 binding.<sup>257</sup> It has been postulated that Ang-2 binding mediates endothelial cell survival signals by making them more responsive to VEGF, resulting in neovascularization. However, with VEGF inhibition, Ang-2 binding

results in apoptosis.<sup>257</sup> In the rabbit cornea micropocket model, neither Ang-1 or Ang-2 alone induced corneal neovascularization, but either Ang-1 or Ang-2 added to VEGF promoted neovascularization, with Ang-2 having the more potent effect.<sup>258</sup> Transgenic mice overexpressing Ang-2 demonstrate disruption of blood vessel formation and are similar in phenotype to Ang-1-deficient mice.<sup>257</sup> A phase II study of the angiopoietin 1 and 2 peptibody trebananib for the treatment of angiosarcoma, a rare malignant endothelial cell tumor with upregulation of the angiopoietin system (Tie2 and Ang2), was well tolerated, but lack of response led to closure of this study.<sup>259</sup> A more recent study of treatment of diabetic macular edema with an inhibitor of vascular endothelial-protein tyrosine phosphatase that activates Tie2 showed preliminary positive results.<sup>260</sup> Additional studies are needed to understand better the role of the Ang and Tie2 in ocular angiogenesis.

## **Matrix Metalloproteinases**

The extracellular matrix of the microvasculature is a highly dynamic structure containing collagens, laminins, fibronectins, proteoglycans, and other proteins. Growth factors such as FGF-2 are localized there, and integrins mediate interactions between cells and the extracellular matrix. The extracellular matrix is remodeled during development and angiogenesis, with degradation of existing matrix and synthesis of new matrix material permitting migration and proliferation of endothelial cells. Degradation is accomplished by 16 known MMPs and plasmin. Plasmin is synthesized as a latent proenzyme, plasminogen, which requires proteolytic activation by enzymes such as urokinase-type plasminogen activator. This activation can be inhibited by plasminogen activator inhibitors. The MMPs are likewise synthesized as latent proenzymes and require proteolytic activation. The active MMPs can be inhibited by four known specific tissue inhibitors (TIMPS) and  $\alpha$ -macroglobulin. For a review of the MMPs and their inhibitors, see Hadler-Olsen et al.<sup>261</sup>

VEGF has been shown to induce tissue factor and MMP production in endothelial cells, and MMP production in smooth-muscle cells via Flt-1.<sup>262,263</sup> AGE also caused increased MMP-2 mRNA in choroidal endothelial cells in vitro.<sup>264</sup> Another interaction

has been demonstrated between MMP-2 and the integrin  $\alpha_v\beta_3$ , which are functionally associated on the surface of angiogenic blood vessels; upon their binding, collagenolytic activity is increased. A naturally occurring fragment of MMP-2, termed PEX, has also been shown to prevent binding of MMP-2 to  $\alpha_v\beta_3$ , acting to decrease the proteolytic activity.<sup>265</sup> Thus, endogenous MMP fragments and TIMPs serve to regulate the invasive new vessels. MMP-9 is one of the major inducible MMPs. Its levels in the basal state seem to be suppressed by the energy sensor AMP-activated protein kinase (AMPK).<sup>266</sup> Human neutrophils have been shown uniquely to release TIMP-free MMP-9 to provide a potent catalytic stimulator of angiogenesis.<sup>267</sup>

## Antiangiogenic Factors

### **Pigment Epithelium-Derived Factor (PEDF); Serpin Peptidase Inhibitor, Clade F, Member 1 (SERPINF1)**

PEDF is a 50-kDa serpin protease that was first discovered as a secreted protein from human fetal RPE cells.<sup>268</sup> PEDF is the most potent antiangiogenic growth factor identified to date.<sup>88</sup> PEDF has been demonstrated to promote apoptosis in proliferating endothelial cells through increasing the interaction of Fas ligand with its receptor Fas. This seems to be the only cell type where PEDF promotes apoptosis.<sup>89</sup> PEDF has also been shown to signal cellular differentiation of retinoblastoma cells in vitro.<sup>268</sup>

Furthermore, a neuroprotective role for PEDF has been identified in neural cerebellar granule cells where PEDF caused the expression of antiapoptotic genes through the activation of NF- $\kappa$ B.<sup>269</sup> In retinal degeneration slow (RDS) mutant mice, PEDF was shown to protect photoreceptors from undergoing apoptosis.<sup>270</sup> Thus, the signaling cascades that are activated by PEDF lead to cell-specific actions to promote both survival and cell death.

Immunohistochemical studies have shown PEDF to be expressed in the RPE cells, the interphotoreceptor matrix, ganglion cells, and in the ciliary neuroepithelium.<sup>271,272</sup> PEDF is also bound to components of the extracellular matrix. In vitro, hypoxia causes a decrease in PEDF expression while VEGF is increased.<sup>88</sup> In vivo, levels of PEDF were shown to be decreased in the vitreous of

patients with proliferative DR and wet AMD, such that PEDF levels correlated inversely with neovascularization.<sup>273–275</sup>

PEDF may have therapeutic potential as both a neuroprotective and antiangiogenic agent. The fact that it is both differentiation-promoting and antiangiogenic has popularized its study in tumor research. Using gene therapy approaches to administer PEDF may also be important in treating ocular neovascularization. Both intravitreal and subretinal adenoviral-associated PEDF have been used to treat retinal ischemia and CNV in mouse models, and overexpression of PEDF has been shown to inhibit neovascularization and inflammation.<sup>276–278</sup> However, there has been no follow-up of an early phase I dose-escalation study of adenovirus mediated PEDF study in neovascular age-related macular degeneration (AMD).<sup>279</sup>

## Angiostatin and Endostatin

Angiostatin is a 38-kDa peptide identified in a murine model of Lewis lung carcinoma, where it was thought to inhibit tumor metastasis at distant sites.<sup>280</sup> It was found to be an internal fragment of plasminogen.<sup>280</sup>

Endostatin is a 20-kDa peptide isolated from murine hemangioendothelioma and has been identified as the C-terminal fragment of collagen XVIII.<sup>281</sup> Mice that lack collagen XVIII form larger and leakier laser-induced CNV.<sup>170</sup> Finally, circulating endostatin has been identified in human plasma.<sup>282</sup> Both angiostatin and endostatin have been proposed as potential therapeutic agents to treat ocular neovascularization; however, up to now they have not found success in clinical use and there has been controversy over their perceived biological effects.

## Other Factors With Recent Interest in Angiogenesis

Recent studies have focused on the role of interleukin-18 (IL-18).<sup>283–287</sup> Initially termed interferon-gamma-inducing factor, IL-18 induces IFN- $\gamma$  expression in responsive cells. IFN- $\gamma$  was shown to be antiangiogenic<sup>288,289</sup> and to prevent laser-induced CNV in mice.<sup>290</sup> Doyle et al. have shown IL-18 to be protective in models of

neovascular AMD,<sup>286</sup> a point contested by Hirano et al.,<sup>291</sup> although Hirano et al. used a less bioactive molecule and at different dosage. Further studies by Doyle et al. using primates continue to show protective role in CNV at physiologic levels of the cytokine.<sup>283,292</sup> Shen et al. showed that intraocular IL-18 levels increased significantly after treatment with ranibizumab particularly and correlated with good visual outcome, in addition intraocular injection of IL-18 reduced VEGF-induced leakage and neovascularization.<sup>293</sup> A clinical trial will be able to give more definitive answers.

PDGF is a dimeric glycoprotein composed of two A (-AA) or two B (-BB) chains or a combination of the two (-AB) and is a potent mesenchymal cell mitogen involved in angiogenesis and is overexpressed in atherosclerotic plaques.<sup>294-296</sup> PDGF has been very important in embryo development and studies from transgenic mice have also pointed out to its importance in vascular pericytes. In 1997 Lindahl et al.<sup>297</sup> discovered that that deficiency in *Pdgfb* results in loss of microvascular pericytes and development of numerous capillary microaneurysms. Lack of *Pdgfb* resulted in embryonic lethality but also the inability of sprouting capillary endothelial cells to attract PDGF-receptor-beta-positive pericyte progenitor cells.<sup>297</sup> Endothelial cell specific loss of *Pdgfb* resulted in viable mice but with abnormal density of pericytes and a strong inverse correlation between their density and the formation of microvascular abnormalities all the way to proliferative retinopathy when pericyte density was less than 50% of normal.<sup>30</sup> PDGF-BB and FGF2, but not PDGF-BB and VEGF or VEGF and FGF2, synergistically induced angiogenesis and long-lasting functional vessels in a model of hindlimb ischemia.<sup>298</sup> Because of its somewhat distinct role in angiogenesis (pericytes, compared to endothelial cells) compared to VEGF, investigators have studied the potential synergistic treatment in angiogenesis. Its expression has been reported in the outer nuclear layer of the macula from patients with AMD and in the serum.<sup>299,300</sup> Clinical trials have progressed and results from Phase III have shown no benefit compared to anti-VEGF monotherapy. It should be noted that hypomorphic *Pdgfb* alleles has been associated with idiopathic basal ganglia calcification in both humans and mice and it is thought to be related

to the loss of endothelial PDGF-B and correlates with the degree of pericyte and blood–brain barrier deficiency.<sup>301</sup>

## Conclusions

Ever since Michelson's hypothesis about a soluble and diffusible growth factor mediating ocular neovascularization, our knowledge about retinal and choroidal angiogenesis has expanded considerably. Undoubtedly, anti-VEGF agents revolutionized the treatment of ocular neovascular diseases and provided the proof of concept for molecular targeting as a therapeutic approach. The continuous discovery of new molecules and signaling pathways involved in these processes revealed the complexity of their pathogenesis, but also offers new candidate therapeutic targets. Given the redundancy of cellular signaling pathways, combination treatments with multiple agents may be needed for optimal therapy although the anti-leakage efficacy of anti-VEGF treatment seem to leave little room for short term efficacy improvement in many of these diseases.

## **Introduction**

More than 100 years ago a fascinating discovery was made. Different tissue samples were placed into the anterior chamber of dogs or rabbits and then were observed for 4 months. Surprisingly, the induced intraocular inflammation was limited, and most of the tissue samples placed in the anterior chamber were not rejected. In contrast, heterografts placed in other parts of the body did not survive.<sup>1</sup> This experiment was the first to identify the eye as a site of immune privilege, although the significance of this finding was not appreciated until many years later: it was not until the 1940s that Sir Peter Medawar correctly identified the connection between these

results and the immune system.<sup>2</sup>

Today, we know that the eye is a unique and complex organ that has developed multiple mechanisms to protect itself against frivolous immunologic attacks and inflammation in order to maintain its delicate structure and function. The blood–ocular barrier system, which is formed by the blood–aqueous barrier and the inner and outer blood–retinal barriers, limits the passage of ions and proteins to maintain homeostasis and to sequester tissue-specific antigens. The pathogenesis of diabetic retinopathy provides evidence for the importance of an intact blood–retinal barrier: one of the earliest changes detected in diabetic retinopathy is dysfunction of the inner blood–retinal barrier.<sup>3,4</sup> Furthermore, in addition to the blood–ocular barrier, many active factors within the eye contribute to a downregulatory immune environment (DIE).<sup>5</sup> The blood–ocular barrier and the DIE are mechanisms that depend on each other's proper function and together are central to preserving the immune privilege of the eye. Immune privilege is instrumental in curbing excessive inflammation and preserving normal function. However, immune privilege may be lost under certain conditions and situations, resulting in retinal autoimmunity and ocular inflammation. A breakdown of the blood–retinal barrier can be found in cystoid macular edema, while a loss of the DIE occurs in many forms of uveitis and now is thought to play a critical role in the development of age-related macular degeneration (AMD).<sup>6</sup>

In the past, all retinal autoimmunity was perceived as pathogenic, and active suppression of retinal immunity was presumed necessary to maintain the health of the eye. However, studies have shown that retinal autoantibodies are present in normal controls,<sup>7a</sup> and constitutive expression of proinflammatory ligands have been found in the normal retina in high concentration.<sup>7b</sup> Moreover, animal optic nerve injury studies have revealed that retinal autoimmunity may be beneficial in limiting collateral damage to the retinal ganglion cells.<sup>8</sup> Thus, retinal autoimmunity can be viewed as a “double-edged sword,” with both protective and destructive effects.

## Blood–Ocular Barrier

At the end of the 19th century the German bacteriologist and immunologist Paul Ehrlich experimented with staining tissues in animal models. When he injected dyes into the bloodstream, almost all tissues became intensely colored, though notably the brain remained unstained.<sup>9</sup> A few decades later, one of Ehrlich's students, Edwin Goldmann, performed the experiment the other way around, by injecting dyes into the cerebrospinal fluid. This time the brain became stained and the rest of the body remained dye-free.<sup>10</sup> Goldmann correctly concluded that there is a barrier restricting the passage of soluble material between the two compartments – the blood and the cerebrospinal fluid. In the same year, in 1913, Schnaudigel used trypan blue to demonstrate a similar barrier between the bloodstream and the retina of rabbits.<sup>11</sup>

Today we know that anatomic structures within the eye limit flux between the blood and much of the eye itself.<sup>12</sup> The blood–ocular barrier consists of two main components: the blood–aqueous barrier and the blood–retinal barrier. The blood–aqueous barrier is formed by the ciliary body nonpigmented epithelium, Schlemm's canal endothelium, and the endothelium of the iridal capillaries.<sup>13</sup> The blood–retinal barrier is located at two levels. The nonfenestrated capillaries of the retinal vessels form the inner blood–retinal barrier, and tight junctions of the retinal pigment epithelium (RPE) form the outer blood–retinal barrier.<sup>14</sup>

Together, these blood–ocular barriers limit the passage of ions to maintain homeostasis in the aqueous humor and vitreous, while they also prevent other blood-borne molecules from entering the eye. Hydrophilic molecules in particular have a low permeability across the blood–ocular barrier.<sup>15</sup> Conditions that involve breakdown of the blood–ocular barrier characteristically lead to inflammation and allow drugs and other molecules to penetrate more easily into the eye. It is not surprising that many eye diseases are associated with alterations of the blood–ocular barrier, although it may be difficult to distinguish whether blood–ocular barrier dysfunction is more of a cause or an effect of disease.

## Blood–Retinal Barrier in Cystoid Macular

## Edema

Cystoid macular edema and the potential for subsequent vision loss is associated with many different etiologies, since ocular trauma, intraocular inflammation, and vascular degeneration all may cause increased permeability of the blood–retinal barrier. The inner and outer plexiform layers of the retina act as diffusion barriers against continuous fluid distribution. Therefore, a breakdown of the inner blood–retinal barrier causes cysts mainly in the inner nuclear layer, whereas serum leakage from the outer blood–retinal barrier pools into cystic spaces in the Henle fiber layer.<sup>16</sup>

## Blood–Retinal Barrier in Diabetic Retinopathy

The initial insult in both nonproliferative and proliferative diabetic retinopathy is chronic hyperglycemia, which leads to retinal hypoxia. Compensatory mechanisms like vasodilation provide a temporizing means to increase retinal blood flow under hypoxic conditions. However, after exhaustion of autoregulation, loss of retinal vascular pericytes and disruption of the pericyte-endothelial-cell complex may occur, which then leads to a disruption of endothelial tight junctions in the retinal vasculature.<sup>4,17</sup> Plasma leakage from the now permeable inner blood–retinal barrier may cause retinal edema and subsequent vision loss. Furthermore, chronic hyperglycemia induces hypoxia-mediated expression of growth factors and cytokines that upregulate pathways resulting in leukocyte adhesion, endothelial cell injury, and increased permeability of endothelial cells, as well as the abnormal blood vessel growth of proliferative diabetic retinopathy.<sup>18–20</sup>

## Basic Concepts of Immunology

Early work on ocular immune privilege focused on the importance of the blood–ocular barrier and the lack of direct lymphatic drainage from the eye.<sup>2</sup> Although an intact blood–ocular barrier is undeniably important for ocular immune privilege, today we know

that ocular immune privilege is more complex than simply isolating tissue-specific antigens. To more fully understand the concepts of ocular immune privilege and retinal autoimmunity, we have to understand basic concepts in immunology and then examine how these immunologic components actively function in the eye.

## Innate Immunity

There are two systems of immunity, innate and adaptive, coexisting to keep pathogens out. Innate immunity, the more primitive system, is nonspecific and immediate in response. A variety of pattern recognition receptors (PRR) recognize conserved microbial patterns – for example, Toll-like receptors recognize lipopolysaccharides (LPS) on gram-negative bacterial outer membranes – and trigger a nonspecific inflammatory response.<sup>21</sup> The key components of innate immunity are epithelial barriers, monocytes, macrophages, natural killer (NK) cells, polymorphonuclear cells, eosinophils, basophils, and plasma proteins belonging to families of the complement cascade, clotting cascade, and acute-phase reactants.

## Adaptive Immunity

In contrast, adaptive immunity, as the name implies, changes depending on prior and current environments. The key cellular components of adaptive immunity are the B and T lymphocytes, which possess unique receptors for recognizing billions of different antigenic epitopes, to encompass most molecules of biologic interest.<sup>22</sup> Immunoglobulins, expressed by B cells, and T-cell receptors (TCR), expressed by T cells, form in the absence of exogenous stimulation and have unique configurations that confer specificity in antigen recognition. Each clone of lymphocyte expresses molecularly identical receptors on the cell surface; hence, in order to recognize billions of different epitopes, there are billions of unique lymphocytes. After maturation in the thymus (T cells) and the bone marrow (B cells), cells remain quiescent in G<sub>0</sub> of the cell cycle until they encounter a complementary antigen with sufficient affinity to their receptors. A molecule binding one of these B- or T-cell receptors in the presence of appropriate

costimulation is the initiating event to trigger a specific immune response targeting elimination of the bound molecule, or antigen. If this molecule is pathogen-derived, immune activation will lead to the elimination of the pathogen, but if the molecule is self-derived, then immune activation may lead to autoimmunity, tissue injury, disease, and destruction of host tissue. It is important to realize that the random process for creating antibodies and T-cell receptors will generate lymphocyte receptors that bind to self antigens with high affinity;<sup>23</sup> we will examine the processes to protect the body from these potentially self-reactive lymphocytes in more detail in the following sections of this chapter.

Activation of a naive lymphocyte results in proliferation of that lymphocyte to produce clones, each with that same unique receptor that recognizes a single epitope of the inciting antigen. There are two major classes of T cells: CD4<sup>+</sup> T cells and CD8<sup>+</sup> T cells. Activated CD8<sup>+</sup> T cells become effector cytotoxic T cells, while the cytokine environment during activation of naive CD4<sup>+</sup> T cells is responsible for differentiation into three major types of effector T cells: Th1, Th2, and Th17 cells. Interleukin (IL)-12 expression leads to Th1 cell production, IL-4 leads to Th2 production,<sup>24</sup> and IL-1 and IL-23 lead to Th17 differentiation.<sup>25</sup> Some Th1 and Th2 cell clones will become memory cells that drive the enhanced immune response if the antigen is re-encountered. The rest of the Th1 cells will secrete cytokines targeted at macrophages and other cells that mediate cellular immunity. In contrast, Th2 cells will stimulate B cells to proliferate and produce antibody, mediating humoral immunity. Th17 cells are a recently discovered family of T-helper cells that are capable of producing IL-17.<sup>26</sup> Th17 cells play an important role in combating various bacterial and fungal species by producing IL-23, but increased numbers of Th17 cells also can be found in patients with autoimmune diseases like uveitis, multiple sclerosis, and rheumatoid arthritis.

The immune response can be compared to the neural reflex arc, which has an afferent limb, a central process, and an efferent limb. In the immune afferent limb, antigens are captured, processed, transported, and presented to the lymphocytes. Dendritic cells and macrophages, both bone marrow-derived, act as antigen presenting cells (APCs) by phagocytosing and endocytosing antigens,

processing the antigens, and then presenting the processed antigens in conjunction with special major histocompatibility complex (MHC) molecules on the cell surface. There are differences in B and T lymphocytes antigen presentation: B-cell receptors can engage a naive antigen directly, while TCRs only can recognize peptide fragments presented on special surface molecules (MHC classes I and II). MHC class I molecules, which are present in most cells, present peptides derived from protein degradation in the cytoplasm (intracellular antigens such as viral and other intracellular microbial products), while MHC class II molecules, which are present in APCs and lymphocytes, present peptides from phagocytic vesicles (extracellular antigens from the microenvironment).

The central limb of the immune response consists of antigen-specific lymphocyte activation and differentiation. Activation of naive lymphocytes requires APCs and only occurs in the organized lymph tissues in secondary lymphoid organs such as lymph nodes, spleen, tonsils, and Peyer's patches. After an APC-antigen complex engages a lymphocyte, costimulation is required for full lymphocyte activation.<sup>27</sup> APCs themselves provide the necessary costimulation needed for lymphocyte activation by upregulating an array of surface molecules (CD80, CD86, intercellular adhesion molecule-1, lymphocyte function-associated molecule-3, and CD40) that function as ligands for lymphocyte receptors. Costimulation also involves APCs secreting soluble cytokines such as IL-12, IL-6, IL-10, and IL-1 $\beta$ .

Upon CD4<sup>+</sup> T-cell activation, the CD4<sup>+</sup> lymphocytes proliferate and secrete an array of cytokines, including IL-2, IL-3, granulocyte-macrophage colony-stimulating factor, interferon-gamma (IFN- $\gamma$ ), and IL-4, that serve as growth and stimulation factors for the lymphocytes and APCs, hence amplifying the proliferation process. In addition, IL-2, IFN- $\gamma$ , and IL-4 promote the differentiation of CD8<sup>+</sup> T lymphocytes to mature cytotoxic T lymphocytes (CTLs). The cytokine production by CD4<sup>+</sup> T cells also promotes activation and differentiation of B lymphocytes with IFN- $\gamma$  and IL-2 stimulating B cells to produce complement-fixing immunoglobulin G (IgG) antibodies, while IL-4, IL-5, IL-6, and IL-10 stimulate production of noncomplement-fixing IgG, IgE, or IgA antibodies.

The final products after central processing in the lymphoid tissues are activated effector CD4<sup>+</sup>, CD8<sup>+</sup>, and B cells that have receptors specific for the inciting antigen.

These effector cells are transported, predominantly via a hematogenous route, to the site of the inciting antigens to execute the efferent limb of the immune response. While the engagement and activation of B cells can be direct, T cells require APCs for antigen recognition. Activated lymphocytes may engage the targeted antigen and also may recruit other components of the immune system. Activated B cells secrete antigen-specific antibodies to directly kill/lyse the target and also recruit polymorphonuclear cells, in a complement-dependent manner. Activated CD4<sup>+</sup> T cells secrete cytokines such as IFN- $\gamma$  and tumor necrosis factor-alpha (TNF- $\alpha$ ), which in turn recruit the cells of the innate immune system, such as monocytes, macrophages, and NK cells, to the site to effect the actual destruction of the antigen or pathogen. Activated CD8<sup>+</sup> CTLs lyse targeted cells and produce proinflammatory cytokines, especially IFN- $\gamma$ . In this way, the adaptive immune system directs the innate immune system components to target the inciting antigen or pathogen. Cytokines involved in this inflammatory response then perpetuate a positive feedback loop: at the target sites, vessels become leaky, the vascular endothelial cells display ligands that bind to receptors on the immune cells, and chemokines secreted by the local inflammatory cells attract more immune effector cells to the site.

## Immune Regulation

Since the genome has the capability to generate both self- and nonself-recognizing antibodies and TCRs, mechanisms must be in place to contain and/or prevent the activation of self-reactive lymphocytes. The first line of defense against autoimmunity targets T lymphocytes within the thymus and B cells within the bone marrow, before such cells enter the bloodstream. APCs within the thymus present a variety of self-peptides to developing T cells; those T cells with receptors that recognize self molecules with high affinity are clonally deleted via apoptosis, a mechanism known as central tolerance.<sup>28</sup> A similar selection process to eliminate self-

reactive B cells occurs in the bone marrow.<sup>29</sup> Central tolerance is a well-described mechanism to prevent autoimmunity, but we now know that there is an alternate pathway to apoptosis for T cells identified as self-reactive within the thymus; a subset of these self-reactive T cells differentiate into regulatory T cells.

The CD4<sup>+</sup> CD25<sup>high</sup> forkhead box protein 3 (Foxp3)<sup>+</sup> regulatory T cell, otherwise known as the Treg cell, is crucial for maintaining immune homeostasis by preventing autoimmunity.<sup>30</sup> Mouse studies show that peripheral Foxp3<sup>+</sup> T-cell depletion quickly leads to a fatal lymphoproliferative autoimmune response.<sup>31</sup> A related human disease, immune dysfunction, polyendocrinopathy and enteropathy (IPEX) syndrome, is an X-linked recessive disorder caused by *Foxp3* mutations; IPEX patients exhibit T-cell hyperactivation and severe autoimmune disease, likely as a result of Treg cell dysfunction.<sup>32</sup> Treg cells help maintain peripheral self-tolerance by modifying the functions of both CD4<sup>+</sup> and CD8<sup>+</sup> cells, either directly through T-cell to T-cell interactions or indirectly through APCs.<sup>33</sup> Treg cells may develop in the thymus, during negative clonal selection, or in the periphery when a CD4<sup>+</sup> T cell encounters its corresponding antigen-APC in an environment unfavorable for T cell activation, such as a low level of antigen, inadequate costimulation, mucosal antigen administration, or an environment high in IL-2, transforming growth factor-beta (TGF)- $\beta$ , IL-10, and/or retinoic acid.<sup>34</sup> The molecular mechanisms underpinning Treg cell development and function are an active area of research.

Not all self-reactive lymphocytes are detected before entering the peripheral bloodstream, and in fact, peripheral autoreactive T cells and B cells exist even in normal individuals. Many tissue-specific antigens, like the eye-restricted molecules, may not be expressed in the thymus or bone marrow, or self-reactive cells may have escaped the selection process by other mechanisms. Hence, an immunologic response triggered by a self-reactive lymphocyte remains a potential threat, and mechanisms to contain these autoreactive immune cells are crucial to prevent autoimmunity.<sup>35,36</sup>

The functional properties of the APCs offer many opportunities for modulation. First, the antigen can be sequestered from APCs by physical barriers or by rendering APCs incapable of antigen capture in the antigen's microenvironment (sequestration). Second, the

ability of the APC to degrade, process, and express the antigen can be inhibited. Third, the antigen-bearing APC may be prevented from migrating to the lymphoid tissues. Lastly, either inadequate costimulation or too much costimulation can inhibit lymphocyte activation, even in the presence of an APC with a high-affinity epitope.<sup>37</sup> Effector T cells need costimulatory signals both centrally and peripherally, and the expression of cytokines such as IL-10 or TGF- $\beta$  can lead to anergy or reprogramming of the lymphocytes into cells that secrete immunosuppressive cytokines, thereby further suppressing autoimmunity.<sup>38,39</sup>

Another type of immune regulation targets antigen-specific immune effector cells such as Fas ligand-induced apoptosis of lymphocytes.<sup>40,41</sup> The immune-reactive lymphocytes express the CD95 receptor (Fas receptor). On encountering the Fas ligand, which is expressed in immunoprivileged eye tissues such as the cornea and retina, Fas receptor-expressing lymphocytes undergo apoptosis. Other molecular mechanisms, such as TNF- $\alpha$  production by immune and accessory cells, such as Müller cells and RPE cells during antigen encounter, also may result in lymphocyte apoptosis, thereby deleting these immune-reactive cells.

## The Eye as an Immune-Privileged Site

The eye has been recognized as an immune-privileged site for more than 100 years, with heterogenous tissue grafts surviving within the eye but not in other parts of the body. In the 1940s Sir Peter Medawar demonstrated prolonged, often indefinite, survival of skin grafts in the anterior chamber of the eye only if the skin graft remains unvascularized.<sup>2</sup> Others have expanded on Medawar's work to show that (1) various tissues, including allogeneic skin grafts, thyroid tissues, neuronal retinal tissue, and allogeneic tumor cells, also can survive in the anterior chamber of the eye for prolonged periods,<sup>42</sup> and (2) a similar immune privilege occurs when allogeneic tissue was placed in the vitreous cavity and the subretinal space.<sup>43,44</sup> Although Medawar and others attributed this immune privilege to an intact blood–ocular barrier and absence of direct lymphatic drainage, now we know that ocular immune privilege involves more than tissue-specific antigen sequestration.

Many studies show that ocular immune privilege is a complex, dynamic process involving immunoregulatory mechanisms as well as anatomic factors.

After all, even immune privilege is influenced by the immunogenic strength of the antigens expressed by the cells. Tumors expressing MHC-encoded alloantigens had limited survival in the anterior chamber of recipient mice; whereas tumors that expressed weaker transplantation alloantigens showed much longer survival.<sup>45</sup> Additionally, certain eye tissues are known to be immune-privileged, i.e., these tissues themselves elicit an altered immune response and less rejection when transplanted elsewhere in the body. Such ocular tissues include the cornea, the RPE, and probably the retina. When transplanted beneath the capsule of the kidney, a nonimmune-privileged site, cornea demonstrated extended survival compared with other ocular tissues like the conjunctiva.<sup>46</sup> Both passive factors, such as the blood–retinal barrier, and active factors, such as the DIE, are essential to establish and maintain ocular immune privilege (Table 29.1).

**TABLE 29.1**  
**Components Contributing to Ocular Immune Privilege**

PASSIVE	
Blood–retinal barrier	Nonfenestrated vascular endothelium of the retinal vessels and tight junctions among the retinal pigment epithelium
Lack of lymphatic drainage	Absence of lymphatics in the retina – lymphatics are present in the choroid
Tissue fluid drainage	Tissue fluid drains via the hematogenous route
Reduced expression of MHC	Antigen presentation is reduced by reduction of MHC class I and II molecules and APCs. The APCs are altered by the microenvironment to promote immune regulation
Reduced APCs in the retina	
APCs with altered function	
ACTIVE	
Immunosuppressive	TGF- $\beta$ , $\alpha$ -MSH, VIP, CGRP, MIF, IL-1 receptor antagonist and free cortisol microenvironment
Factors expressed on cell surface	CD95 ligand, CD59, CD55, CD46

APC, antigen-presenting cell; CD, nomenclature for surface proteins of human leukocytes; CGRP, calcitonin gene-related peptide; IL, interleukin; MHC, major histocompatibility complex; MIF, migration inhibitory factor; MSH, melanocyte-stimulating hormone; TGF, transforming growth factor; VIP, vasoactive intestinal

peptide.

## Transportation of Antigens

As first identified by Medawar,<sup>2</sup> the blood–ocular barrier keeps tissue-specific antigens sequestered. There is an absence of lymphatics in the retina, although there is evidence that antigen may still be able to be transported to the lymph nodes.<sup>47</sup> However, tissue drainage via the hematogenous route, instead of via the lymphatic route, may alter ocular APC function.<sup>48</sup>

## Downregulatory Immune Environment

The DIE is an evolutionary adaptation of the eye to protect itself against excessive inflammation. A small focus of inflammation in the eye has a far greater impact than one of similar size in most other areas of the body. The posterior segment utilizes several active factors that help maintain the local immunoenvironmental balance in a downregulatory state. Active factors include the downregulatory effect of Müller cells in cell-to-cell contact with lymphocytes.<sup>49</sup> Furthermore, there are many other factors that affect the DIE, including ocular cells (NK T cells, RPE, microglia, F4/80<sup>+</sup> macrophages) as well as cell surface and soluble factors in the ocular microenvironment (CD95 ligand, CD55, CD59, CD46, IL-10, IL-11, TGF- $\beta$ ,  $\alpha$ -melanocyte-stimulating hormone, vasoactive intestinal peptide, calcitonin gene-related peptide, macrophage migration-inhibitory factor, IL-1-receptor antagonist, and free cortisol). Normal retina has reduced expression of MHC class I and II molecules and an absence of bone marrow-derived cells that function within tissues as APCs.<sup>50a</sup> Cultured RPE cells expressing sCD54 and PGE2 can downregulate T lymphocyte production of CCL3 and CCL4, which dampens the immune response.<sup>50b</sup> All of these factors contribute to actively downregulate immunologic activity in an attempt to prevent autoimmunity.<sup>5</sup>

## Downregulatory Immune Environment in Age-Related Macular Degeneration

Several findings in patients with AMD (e.g., variants of CFH, HTRA-1, PLEKHA1 and Toll-like receptors, activated macrophages in the blood, autoantibodies to retinal components) point to a role for the immune system in AMD.<sup>6</sup> Neovascular AMD is associated with loss of the DIE,<sup>51</sup> and results from a masked, randomized pilot study indicate that systemic antiinflammatory therapy may be beneficial in treating wet AMD, in combination with anti-vascular endothelial growth factor (VEGF) agents.<sup>52</sup>

## Anterior-Chamber-Associated Immune Deviation

Anterior-chamber-associated immune deviation (ACAID) is the best-studied immune-privilege phenomenon in the eye<sup>53</sup> and clearly demonstrates that immune privilege involves more than tissue-specific antigen sequestration. In animal models of ACAID, antigen inoculation into the anterior chamber induces peripheral tolerance to the antigen. Although its name implies that it is a phenomenon unique to the anterior chamber, there is evidence that the same mechanisms are at work in the vitreous and subretinal space.<sup>44</sup>

There are many bone marrow-derived APCs in the iris, trabecular meshwork, and ciliary body,<sup>54</sup> and these APCs reach the spleen via the hematogenous route, bypassing the afferent lymphatics and the lymph nodes. These ocular APCs are different from APCs in other parts of the body, since the ocular APCs show reduced capacity to activate cell-mediated immune mechanisms and in fact, drive differentiation of suppressor cells to induce tolerance to the ocular antigen. The microenvironment of the eye also contains factors such as TGF- $\beta_2$  that are able to reprogram APCs from conventional sites, if exposed to the eye microenvironment, to secrete less IL-2, express less CD40 (a costimulatory signal for T-cell activation), and produce more mature TGF- $\beta$ , which suppresses T-cell activation.<sup>55a</sup>

Disruption of the ocular environment may interfere with ACAID. For instance, experiments in mice show that after laser retinal burn treatments in one eye, anterior chamber antigen inoculation of either the treated or the untreated eye does not lead to the peripheral tolerance seen in mice without laser treatment.<sup>55b</sup>

Although there are active soluble factors in the aqueous humor

that can inhibit T-cell activation in vitro, decrease the ability of NK cells to lyse their target,<sup>56</sup> and block complement activation,<sup>57</sup> the eye is not left defenseless against pathogens. It still retains certain immune functions to deter pathogenic invasion. Antibodies in the aqueous are capable of neutralizing viruses, and terminally differentiated cytotoxic T cells can bind and kill their target cells as they do elsewhere in the body.<sup>58</sup>

## Retinal Antigens and Experimental Autoimmune Uveoretinitis

Animal experimentation allows in vivo study of ocular immunology. Several animal models for autoimmune posterior uveitis have been described (Table 29.2). Wacker and Lipton developed the experimental autoimmune uveoretinitis (EAU) model in 1968,<sup>59</sup> which still is commonly used today, since it is a good animal model for human ocular autoimmunity. This model is mostly self-limited and requires administration of an adjuvant, as well as the pathogenic antigen, for disease induction. The EAU model has been instrumental in eliciting immune mechanisms, identifying pathogenic epitopes of autoantigens within the eye, and evaluating therapeutic strategies with clinical relevance.

**TABLE 29.2**  
**Animal Models for Autoimmune Posterior Uveitis**

Model	Antigen	Target	Clinical Disease
Experimental autoimmune uveoretinitis (EAU)	S-antigen	Photoreceptor layer of the retina	Posterior uveitis and retinal vasculitis, like sympathetic ophthalmia, VKH, and Behçet disease
	IRBP		
	Rhodopsin		
	Recoverin		
Experimental melanin protein-induced uveitis (EMIU)	Phosducin		
	Melanin proteins		
Experimental autoimmune pigment epithelial uveitis (EAPU)	Tyrosinase-related proteins 1 and 2	Choroid	Chronic panuveitis and posterior uveitis, like SO and VKH
	Retinal pigment epithelium membrane protein-induced	Retinal pigment epithelial cells	Posterior uveitis

IRBP, interphotoreceptor retinoid-binding protein; SO, sympathetic ophthalmia; VKH, Vogt–Koyanagi–Harada.

Using the EAU animal model, several retinal antigens, including S-antigen (arrestin), interphotoreceptor retinoid-binding protein (IRBP), rhodopsin, recoverin, and phosducin, have been shown to have uveitogenic properties. Immunization with these antigens or fragments of these antigens can induce ocular inflammation in susceptible guinea-pigs, rats, mice, rabbits, and monkeys. The resulting disease resembles various human uveitic conditions, such as ocular sarcoidosis (Fig. 29.1), Vogt–Koyanagi–Harada disease, sympathetic ophthalmia, and Behçet disease (Fig. 29.2). Much of our understanding of retinal autoantigens is derived from EAU models using S-antigen, IRBP-derived peptides, and, to a lesser extent, rhodopsin, recoverin, and phosducin.

(Panel A courtesy of Dr Chi-Chao Chan, Laboratory of Immunology, National Eye Institute. Panel B courtesy of Associate Professor Soon-Phaik Chee, Singapore National Eye Center.)

## S-Antigen

S-antigen, a 48-kDa protein also known as arrestin, was first identified in the soluble fraction of retinal extracts and is one of the antigens most commonly used to induce EAU.<sup>60</sup> As S-antigen was the first autoretinal antigen implicated in the pathogenesis of uveitis,<sup>61</sup> its sequence and role in normal retinal function have been studied extensively.<sup>62,63</sup> S-antigen is a highly conserved protein expressed in retinal photoreceptor cells and in pinealocytes, the melatonin-secreting cells of the pineal gland. In photoreceptor cells, the main function of S-antigen (or arrestin) is to drive recovery of the rod phototransduction cascade by inactivating light-activated phosphorylated rhodopsin; arrestin-bound rhodopsin is unable to bind the G protein transducin, which halts downstream G protein signaling.<sup>64</sup> Immunization of susceptible animals (such as Lewis rats but not mice) with S-antigen induces a predominantly CD4<sup>+</sup> T-cell-mediated inflammatory response in the retina, uveal tract, and pineal gland.<sup>65</sup> Six peptide fragments of S-antigen have been identified as uveitogenic, including the major uveitogenic peptide M (sequence 303–320).<sup>62</sup> Some of the fragments are species-specific in their uveitogenicity.<sup>65</sup> Although studying uveitogenic properties of S-antigen in animal models has provided understanding of general uveitis mechanisms, the relevance to human uveitis needs

to be more fully explored. S-antigen also has been implicated in the pathogenesis of uveitis through molecular mimicry. Several exogenous (baker's yeast, *Escherichia coli*, hepatitis B virus, streptococcal M5 protein, Moloney murine sarcoma virus, and baboon endogenous virus) and endogenous (human leukocyte antigen (HLA) B-derived peptide, tropomyosin) antigens share sequence homology with peptide M of S-antigen.<sup>66</sup> Some of these homologous antigens have been shown to be uveitogenic in the EAU models, and lymphocytes from animals immunized with M peptide cross-reacted and proliferated when stimulated with peptides derived from some of these other antigens.

Antistreptococcal monoclonal antibodies were found to recognize several uveitogenic peptides of S-antigen,<sup>67</sup> which further suggests that immunologic mimicry between self and exogenous antigens from an infectious agent may be a potential mechanism in the pathogenesis of uveitis in humans.

### **Interphotoreceptor Retinoid-Binding Protein**

IRBP is a major protein of the interphotoreceptor matrix, functioning as a transporter of retinoids between the retina and RPE, and it can induce EAU in both mouse and rat.<sup>68</sup> Similar to S-antigen, IRBP also is found in both the retina and the pineal gland, and induction of EAU with IRBP will cause disease in both locations. Depending on the dose of antigen used and the species of model animal, a spectrum of disease ranging from hyperacute to chronic relapsing disease has been induced. The inflammatory response targets the photoreceptor layer, producing histopathology similar to lesions seen in human uveitis, with retinal vasculitis, retinal and choroidal granulomas, focal serous retinal detachments, photoreceptor loss, and formation of sub-RPE infiltrates that resemble the Dalen–Fuchs nodules seen in patients with Vogt–Koyanagi–Harada disease and sympathetic ophthalmia.<sup>69</sup> Disease activity in the murine IRBP EAU model peaks at 5 and 10 weeks after immunization, with apparent disease remission between 6 and 8 weeks after immunization, simulating the relapsing course of human uveitis.<sup>70</sup> The relatively long duration of disease activity and the relapsing course of disease in this model make it a preferred model for evaluating therapeutic strategies in chronic uveitis.

## Rhodopsin

Rhodopsin is the visual pigment of rod photoreceptor cells, belonging to the larger family of G-protein-coupled receptors.<sup>71</sup> It is a membrane-bound protein comprised of a polypeptide chain, the opsin, and a covalently bound chromophore, 11-*cis* retinal. The function of rhodopsin is to capture photons and trigger the phototransduction cascade, and its function is blocked by binding to S-antigen, as described above. The uveitis induced in susceptible animals such as guinea-pigs, rabbits, rats, and monkeys is typically a retinitis with multifocal destruction of photoreceptor cells, showing dense mononuclear and polymorphonuclear cell infiltrates in the retina and anterior uvea in severe disease.<sup>72</sup> There are three distinct immunopathogenic sites on the molecule; sequence 230–250 (extracellular loop V–VI) is the most uveitogenic and is comparable to S-antigen and IRBP in terms of induced disease severity.<sup>73</sup> The role of rhodopsin autoantigens in human diseases is still unclear. Romano and coworkers have demonstrated an elevated antirhodopsin antibody titer in patients with normal-pressure glaucoma, which suggests the possibility that an antiretinal antibody and autoimmunity may play a role in the optic neuropathy of normal-pressure glaucoma.<sup>74</sup>

## Recoverin

Recoverin is a 23-kDa calcium-binding protein that controls photoreceptor light adaptation by functioning as a calcium sensor, although the underlying mechanisms differ somewhat between rods and cones.<sup>75</sup> Recoverin also is found in bipolar cells, pinealocytes, and certain tumor cells, though recoverin's function in these nonphotoreceptor cells is unknown.<sup>76</sup> Immunization of Lewis rats with high doses of recoverin, as well as with the major immunopathogenic epitope of recoverin, sequence 62–81, produced EAU similar in severity, histology, and duration to other retinal autoantigens such as S-antigen.<sup>77,78</sup> In humans, recoverin has been identified as a self-antigen in cancer-associated retinopathy.<sup>79</sup> Anti-recoverin autoantibodies have been demonstrated to induce apoptosis of photoreceptors, which is further suggestive of a pathogenic role for these autoantibodies.<sup>80</sup> It is important to note that in some cases of human disease, retinal dysfunction and high

levels of antirecoverin antibodies occur prior to the cancer diagnosis, but can help point to the underlying malignancy. Having a low threshold for detecting this condition with antiretinal antibodies may improve prognosis in the case of a life-threatening disease.

## **Phosducin**

Phosducin is a 33-kDa protein, a cytosolic regulator of G-protein-mediated signaling, found in the retina and also in nonretinal tissues such as liver, lung, heart, and brain.<sup>81</sup> Immunization with phosducin in Lewis rats produces mild to moderate EAU characterized by late onset, relatively mild ocular inflammation that primarily affects the posterior segment.<sup>82</sup> It is unclear whether phosducin autoantibodies play a role in human disease.

## **Novel Ocular Autoantigens**

Researchers have used a variety of in vitro techniques to identify novel ocular autoantigens with the potential for pathogenicity. For instance, uveal autoantigen with coiled coil domains and ankyrin repeats (UACA) in patients with Vogt–Koyanagi–Harada disease,<sup>83</sup> a retinal autoantigen targeting the connecting cilium region of photoreceptors in a patient with Waldenström macroglobulinemia and retinal dysfunction similar to cancer-associated retinopathy,<sup>84</sup> and heat shock protein 27 (HSP27) in Behçet disease<sup>85</sup> all have been identified as autoantigens. Additional testing, often in animal models, to determine pathogenicity is the next logical step.

# **Retinal Autoimmunity**

## **Autoimmunity in Human Uveitis**

Although nearly five decades have elapsed since the first EAU model was published, translating EAU model findings to human uveitis and determining the extent of the role of retinal autoimmunity in human uveitis remains a work in progress. Since lymphocytes reactive to retinal antigens have been demonstrated in normal individuals,<sup>86</sup> as well as in those with retinal disease,<sup>87</sup> immunoregulatory mechanisms must exist to prevent pathologic

retinal autoimmunity in normal individuals. To further these investigations, multiple clinical studies have examined human lymphocyte proliferative responses to S-antigen, IRBP, and peptides derived from patients with uveitis. Increased lymphocyte proliferative responses to S-antigen were reported in patients with Behcet's disease during periods of active ocular inflammation compared to periods of disease quiescence.<sup>88</sup> Lymphocyte proliferative responses to S-antigen, S-antigen-derived peptides (peptides M and G), and uveitogenic peptide derived from IRBP (R16) were found in patients with idiopathic uveitis but not in healthy controls or patients with systemic connective tissue disease.<sup>89</sup> A lymphocyte proliferation response was mounted to at least one of the 20 tested peptides spanning the entire sequence of S-antigen in half of the patients with idiopathic uveitis, whereas there was no response to the peptides in the normal controls.<sup>90</sup> A study evaluating oral tolerance by feeding S-antigen to uveitis patients showed a good clinical response, with less immunosuppression required.<sup>91</sup> Together, these studies provide further support for the possible pathogenic roles of retinal autoantigen in uveitis.

Although both EAU animal models and human uveitis can result from a CD4<sup>+</sup> Th1 or a Th17 effector response driving autoimmunity, there are differences in the T-cell specificities in antigen response between animals and humans.<sup>92</sup> Patients with uveitis, due to epitope spread, may respond to more than one peptide, i.e., several epitopes are recognized in the same patient, while animals with EAU tend to respond only to the inciting antigen. There is no common pattern of lymphocyte response in clinical studies reported so far. Early clinical studies on the humoral response showed the presence of antiretinal autoantibodies, including anti-S-antigen antibodies in the sera of some uveitis patients (Fig. 29.3),<sup>93,94</sup> but there was no good correlation between presence or levels of autoantibodies and clinical disease. Moreover, anti-IRBP antibody was reported to occur in the same frequency in the sera of patients with uveitis and normal controls, with the only noted difference being the stronger affinity of the antibodies in patients with uveitis.<sup>95</sup>

**FIG. 29.3** Photomicrograph showing antiretinal antibodies in the serum of a patient with Vogt–Koyanagi–Harada disease reacting immunohistochemically to the photoreceptor layer of the monkey retina (*arrows*). (Courtesy of Dr Chi-Chao Chan, Laboratory of Immunology, National Eye Institute.)

The relationship between humoral and cellular responses to these autoantigens was studied in a group of patients with endogenous uveitis such as birdshot retinochoroidopathy, retinal vasculitis, and Behçet disease. The antibody titers to S-antigen and IRBP were found to be decreased during active inflammation periods and the lymphocyte responses to S-antigen were found to be more frequent in the period preceding a relapse of ocular inflammation, supporting the pathogenic roles of these lymphocytes in retinal autoimmunity.<sup>96</sup> The role of humoral and cellular responses to retinal autoantigens remains unclear, and it is possible that different subsets of patients with uveitis respond to different epitopes and antigens, resulting in the wide spectrum of clinical disease encountered.

## Role of Retinal Autoimmunity in Protection

Retinal autoimmunity may not always be pathogenic. Studies on central nervous system (CNS) injury and its reparative process have revealed a possible beneficial role of autoimmunity in limiting self-injury during insults to the CNS. Axonal injury in the CNS leads not only to the degeneration of the affected axon but also the

neighboring axon through self-destructive compounds released by the degenerating axon into the microenvironment.<sup>97</sup> Studies have revealed that autoreactive T cells directed against myelin antigens have beneficial effects on CNS myelinated axons after a mechanical crush injury,<sup>98</sup> and it has been proposed that this neuroprotective activity exhibited by autoimmune T cells may be a physiologic process to cope with stressful conditions.<sup>99</sup> Interestingly, rodent strains that are more resilient against developing experimental CNS autoimmune disease also are better able to mount an autoimmune response after CNS injury that results in a better outcome.<sup>100</sup> Extrapolating these CNS observations to the retina provides a possible explanation for the protective effect of vaccination on retinal ganglion cells, when vaccination with peptides derived from IRBP is performed prior to optic nerve injury.<sup>8</sup> It appears that the immune system not only protects the body against invading pathogens but also protects it from toxic substances released by self tissues during trauma and stress.<sup>101</sup> The autoreactive cells that induce neuroprotection and those that induce autoimmune disease may share the same specificity and phenotype, thus having the potential to be protective and destructive at the same time. From these findings, it appears that the ability to protect the eye from inflammation and injury does not solely depend on mechanisms conferring immune privilege but rather on a precise regulation of autoimmunity.

## **Role of Retinal Autoimmunity in Infection**

The role of infection in the pathogenesis of eye autoimmunity has long been suspected, but there is no conclusive validative study. Possible causative relationships have been hypothesized between infections and ocular autoimmunity such as streptococcus, herpesvirus, and Behçet disease;<sup>102</sup> gram-negative bacteria and HLA B27-associated uveitis;<sup>103</sup> and herpesviruses and serpiginous choroiditis.<sup>104</sup> Infection as an exogenous trigger for inflammation in the eye is an enticing possibility as infections have been linked to the pathogenesis of many other autoimmune diseases such as rheumatic fever,<sup>105</sup> inflammatory bowel disease,<sup>106</sup> and sarcoidosis.<sup>107</sup> Antiretinal antibodies in the serum of patients with

toxoplasmosis retinochoroiditis<sup>108</sup> and antiretinal and anti-RPE antibodies in murine coronavirus retinopathy<sup>109</sup> have been reported. Taken together, these reports provide support for a role of infection in retinal autoimmunity. Even in the current EAU animal models, bacterial-derived products like mycobacteria in complete Freund's adjuvant, LPS, and pertussis toxin are used as adjuvants to promote the development of autoimmune disease.<sup>110</sup> The adjuvant in EAU has been shown to effect many changes that could sensitize the animal's immune system to the antigen, including changing the blood–tissue barrier to allow infiltration of inflammatory cells,<sup>111</sup> promoting the Th1 response,<sup>112</sup> stimulating APCs,<sup>113</sup> and enhancing the innate immune response.<sup>114</sup> It is feasible that similar infection-related mechanisms may drive pathogenesis of human uveitis, by sensitizing the immune system to eye-restricted antigens, which are expressed systemically in low levels below the immune activation threshold.

On the other hand, there is evidence that immunologic mimicry may play a role in uveitis pathogenesis as molecular homology exists between certain retinal autoantigens and peptides derived from microbes, such as the M peptide derived from S-antigen and the streptococcal cell wall peptide, the yeast's histone peptide, and certain viral agents.<sup>67,115</sup> Molecular mimicry has also been suspected of playing a role in disease susceptibility with certain HLA haplotypes, like HLA B27 for acute anterior uveitis,<sup>116</sup> HLA B51 for Behçet disease,<sup>117</sup> and HLA-A29 for birdshot retinochoroidopathy.<sup>118</sup> Synthetic peptides derived from HLA-B molecules such as B27 and B51 have amino acid sequence homology with an S-antigen peptide that was reported to induce EAU in animals.<sup>119</sup> Lymphocytes from Behçet disease patients with uveitis respond to peptides derived from both HLA-B molecules and S-antigen, again demonstrating possible immunologic mimicry.<sup>120</sup> Further studies showed sequence homology between this same S-antigen peptide, a rotavirus peptide, and a casein protein, and cross-reaction in cellular immunity between these peptides was demonstrated in animal studies.<sup>121</sup> Together these studies present the possibility that exogenous factors like infection or foreign proteins may break down tolerance and induce autoimmunity via immunologic mimicry.

Another proposed mechanism for sensitizing the immune system to eye-restricted antigens involves the microbiota, the community of microorganisms that colonize the body surface. Intestinal microbes can activate Th17 cells.<sup>122</sup> Recent work with a type of IRBP EAU mice that develop spontaneous uveitis shows that activated Th17 cells are present in gut mucosa prior to development of uveitis. Modifying the components of the intestinal microbiota in these animals with administration of a broad-spectrum antibiotic delays the onset of uveitis and alleviates the disease course, raising the possibility that interactions with the intestinal microbiota also may be a trigger for uveitis in humans.<sup>123</sup>

The guardian that prevents pathologic autoimmunity is immunologic tolerance to self antigens. Immune tolerance, usually maintained by mechanisms described earlier, can be lost or modulated. Work examining heat shock protein (HSP) in an animal model shows that HSPs can modulate APC function, resulting in loss of immune tolerance.<sup>124</sup> HSPs, especially microbial HSPs, have been implicated in the pathogenesis of Behçet disease<sup>125</sup> and have been shown to worsen inflammation in the eye in animal studies.<sup>126</sup> Therefore, one may speculate that an infection and the subsequent release of microbial HSPs could be the initial triggering event, resulting in altered APC function and a subsequent loss of immune tolerance, leading to autoimmunity.

All of the pathogenic hypotheses discussed above are difficult to test for a number of reasons. First, uveitis is a heterogeneous disease. Second, evidence of the initial triggering event usually is difficult to identify, given the delay between the trigger and disease presentation. Lastly, a single disease may have multiple triggering mechanisms, and different triggers may lead to the same disease.

## Conclusion

Retinal autoimmunity may be a physiologic process as well as a pathologic one, given its role in organ- and tissue-specific protection from injury and stress in the normal retina. The physiologic role of retinal autoimmunity may account for the lymphocyte proliferative responses to retinal antigens detected in normal subjects, but there still is much that is unknown about the

maintenance of the fine balance between protection and destruction in retinal autoimmunity, given that these paradoxical roles may reside in the same group of cells. With rapid technologic advances in molecular immunology, new tools are available to help unravel the roles of retinal autoimmunity in both physiologic and pathologic states. The subsequent elucidation of molecular mechanisms should assist in developing novel targeted therapeutic strategies for the management of retinal autoimmunity-induced diseases in the near future.

## Introduction

Macular edema is a common phenomenon in various diseases where fluid accumulates in the extracellular space within the retinal neuropile. This phenomenon relates to Starling's law which predicts that macular edema will develop if the hydrostatic pressure gradient between capillary and retinal tissue is increased. In the retina this can occur in the presence of elevated blood pressure, or if

the osmotic pressure gradient is decreased by excessive protein accumulation in the extracellular space.<sup>1</sup> The edema is also related to concomitant breakdown of the inner and outer blood–retinal barriers (BRBs) which are modulated by imbalances in cytokines and growth factors that disturb the integrity of the tight junctions of the capillary endothelium and retinal pigment epithelium (RPE).<sup>2</sup>

Both focal, diffuse, and the cystic forms of edema are characterized by extracellular accumulation of fluid, specifically in Henle's layer and the inner nuclear layer of the retina, but also in the subretinal space. The compartmentalization of the accumulated fluid is likely to be due in part to the slow dispersal of accumulated extracellular fluid that occurs within the plexiform layers as a consequence of the tightly packed neuronal and glial parenchyma combined with impaired fluid clearance mechanisms. Recent evidence indicates that edematous changes to the inner retina can also occur as a consequence of disruption of the normal homeostatic function of the Müller glia. This can lead to intracellular, cytoplasmic swelling of these cells that span the entire inner retina, which exacerbates disruption of the retinal interstitium and contributes to the development of edema and neurodegeneration.

## Macular Edema as a Result of Various Disease Mechanisms

### Causes of Macular Edema

In general, formation of macular edema is related to metabolic changes, ischemia, hydrostatic forces, inflammatory and toxic mechanisms, or mechanical forces that occur to various degrees in the different conditions (Table 30.1 online).

**TABLE 30.1**

**Causes of Macular Edema in Relation to the Underlying Disorders**

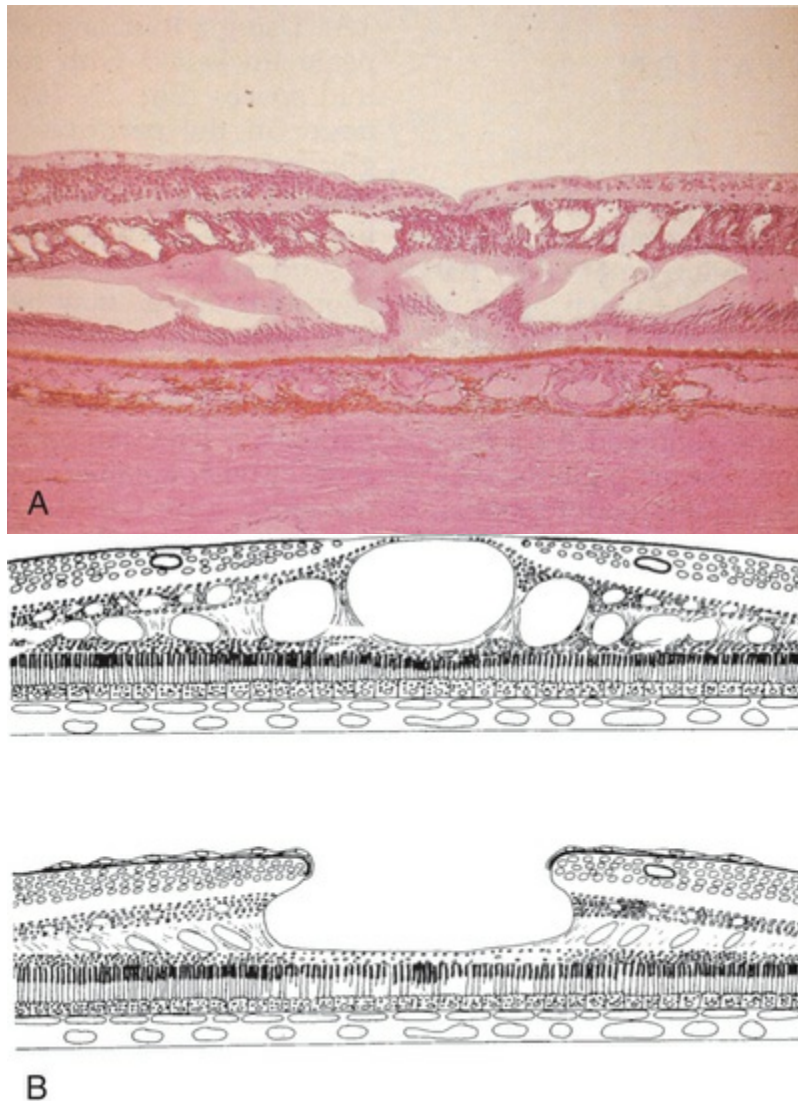

Disease Group	Disorder	Pathogenesis
Metabolic alterations	Diabetes	Abnormal glucose metabolism Aldose reductase Both inner and outer BRB are affected

	Retinitis pigmentosa	CME: leakage at the level of RPE
	Inherited CME (autosomal dominant)	Müller cell disease: leakage from perifoveolar capillaries
Ischemia	Vein occlusion Diabetic retinopathy	Predominantly inner BRB (retinal capillary hypoperfusion)
	Severe hypertensive retinopathy HELLP syndrome Vasculitis, collagenosis	Outer BRB (ischemic hypoperfusion of the choroid: serous detachment)
Hydrostatic forces	Retinal vascular occlusions Venous occlusion Arterial hypertension Low IOP	Increased intravascular pressure Failure of the BRB
Mechanical forces	Vitreous traction on the macula	Epiretinal membranes with tangential traction Vitreomacular traction syndrome
Inflammation	Intermediate uveitis	Mediated by prostaglandins CME is considered indication for treatment
	Postoperative CME	Perivascular leukocytic infiltrates
	DME	Diabetic leukostasis mediates vascular leakage by endothelial cell apoptosis
	Choroidal inflammatory diseases Vogt–Koyanagi–Harada syndrome Birdshot retinochoroidopathy	Lymphocytes: T-cells, microglia activation
Pharmacotoxic effects	For example: Epinephrine (in aphakia) Betaxolol Latanoprost	Mostly via prostaglandins

BRB, blood–retinal barrier; CME, cystoid macular edema; DME, diabetic macular edema; HELLP syndrome, Hemolytic anemia, Elevated Liver enzymes, and Low Platelet count; IOP, intraocular pressure.

The classic pattern of cystoid macular edema (CME) with a petaloid appearance originating from the fluorescein leakage from perifoveal capillaries may be seen in cases of advanced edema of various origins ([Fig. 30.1A](#)). This includes postsurgical CME as well as CME associated with one of the following conditions: diabetes, vascular occlusion, hypertensive retinopathy, epiretinal membranes, intraocular tumors (e.g., melanoma, choroidal hemangioma), intraocular inflammation (e.g., pars planitis), arterial macroaneurysm, inherited retinal disorders such as retinitis pigmentosa, choroidal neovascularization, and radiation retinopathy.

**FIG. 30.1** (A) Histologic section of the fovea area demonstrating cystoid macular edema with large cystic spaces in the outer nuclear and plexiform layer as well as in the inner nuclear layer. (B) Schematic drawing.

Given the heterogeneous etiology of macular edema, its effective treatment depends upon a better understanding of the underlying pathogenesis.

Metabolic alterations have a causal role in diabetic maculopathy, but also in inherited diseases such as the autosomal dominant form of macular edema or macular edema in retinitis pigmentosa. Furthermore, ischemia of the peripheral retina leads to formation of macular edema. Decreased perfusion of the retinal capillaries on the arterial side is seen, for example, in vein occlusion and diabetic retinopathy, whereas ischemia plus decreased perfusion of the choroid with associated serous retinal detachment occurs in severe

hypertensive retinopathy, in eclampsia, or in rheumatoid disorders. Following retinal vein occlusion, the intravascular pressure increases and leads to dysfunction of the BRB. Similarly, hydrostatic forces are effective in arterial hypertension or in eyes with low intraocular pressure and may cause fluid accumulation in the macula. Mechanical traction such as in epiretinal membranes or in vitreomacular traction syndrome may also promote macular edema by physical forces.

Inflammation is important in the pathogenesis of macular edema in conditions such as posterior uveitis, postoperative CME (Irvine–Gass syndrome), diabetic macular edema (DME), and various diseases linked to choroidal inflammation such as Vogt–Koyanagi–Harada disease and birdshot retinochoroidopathy. All prostaglandin-like pharmacologic agents, even if applied topically for treatment of glaucoma, can induce macular edema via a cytokine response similar to inflammatory conditions.

The knowledge of the basic mechanisms involved in vascular leakage is essential for the development of an effective clinical treatment. Development of optimal strategies for treating retinal edema may depend on determining the ratio of the contribution of intra- and extracellular mechanisms to edema and measuring how this ratio changes among patients, retinal disease, and even during disease progression. It should also take into account the site of disturbance (i.e., breakdown of inner or outer BRB or both). With the growing understanding of the pathophysiology of the macular edema, the therapeutic thinking is likely to change from a merely symptomatic treatment (either surgical or medical) to a treatment that targets specifically the causal factors involved in its formation (e.g., cytokine or growth factor inhibition).

## **Molecular and Cellular Alterations Leading to Macular Edema**

Much of the knowledge on the pathophysiology of macular edema has been determined from extensive studies based on animal models, especially relating to early-stage diabetic retinopathy, experimental autoimmune uveitis, and ischemia-induced leakage. A variety of techniques measuring accumulation of material from

plasma in the neural retina have been investigated as indicators of permeability. Such accumulation seems diffuse in nature, and focal defects have not been reproducibly described in diabetic mice; as well, interpretations of techniques involving tracer accumulation have not been validated in terms of “gold standard” permeability surface area product.<sup>3</sup> Interestingly, edema has not been demonstrated in the retina of diabetic mice based on retinal thickness measurements despite the indication of increased permeability.

The BRB consists of the retinal pigment epithelium (RPE) layer (outer BRB), and the vascular endothelium (inner BRB), that prohibit the passage of macromolecules and circulating cells from the vascular compartment to the extracellular compartment and therefore to the intraretinal or subretinal space.<sup>4</sup> Intracellular edema (formerly also referred to as “cytotoxic edema”) is defined as cellular swelling that occurs independent of the BRB. Extracellular edema (sometimes referred to as “vasogenic edema”) is characterized by retinal thickening in association with loss of BRB integrity (Fig. 30.2). Combinations thereof are possible.

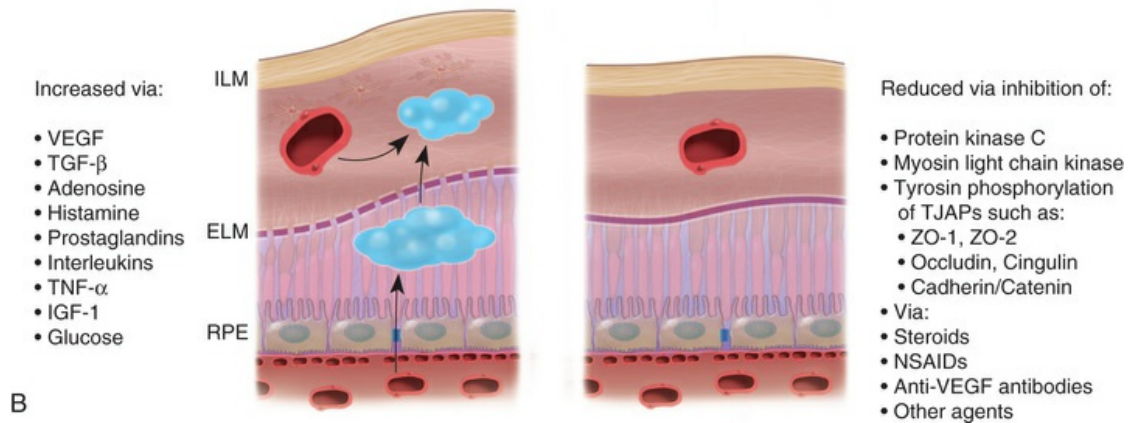

**FIG. 30.2** Blood–retinal barrier (BRB) and breakdown in vascular disease. (A) Normal retinal tissue. Dotted line marks the outer BRB at the level of the retinal pigment epithelial cells. The inner BRB is at the level of the endothelial cells of retinal vessels. Further

structural guidance is given by Müller cells. (B) Diabetic retinopathy: note the large caveolae of fluid and accumulation of blood cells in the retinal tissue resulting of a breakdown of the inner BRB. (Courtesy of Sarah Coupland, MD, Liverpool.)

The breakdown of the inner BRB, as a result of a variable contribution of dysfunction of intercellular junctions, increased transcellular transport, or endothelial cell and pericyte dysfunction/loss, leads to an increased vascular permeability (Fig. 30.3 online). The initial site of damage that results in the increased vascular permeability is controversial to date. Although impairment of the perivascular supporting cells such as pericytes and glial cells might play a role, endothelial cell dysfunction and injury seems more likely to be the first pathogenetic step towards the breakdown of the BRB early in the course of the disease. In order to dissect the molecular and pathophysiologic mechanisms that lead to the accumulation of fluid in the macular area, most knowledge from preclinical models is related to diabetic models.

**FIG. 30.3** Pathogenesis of macular edema and vascular leakage. (A) In general, water outflow through vessels is possible via three major routes: paracellular via dysfunction of tight junctions, transcellular via increased transport, e.g., mediated via growth factors, and finally directly via endothelial gaps after cell death. (B) Vascular leakage is increased by a variety of factors including growth factors and inflammatory cytokines. Leakage in turn is decreased by steroids, inhibition of tight-junction formation or antibodies to factors inducing leakage. *ELM*, external limiting membrane; *ILM*, internal limiting membrane; *RPE*, retinal pigment epithelium; *TJAPs*, tight junction-associated proteins. Other abbreviations, see text.

While for diabetes and ischemic retinopathies the inner-BRB is believed to play a dominant role in vascular leakage, the importance of the outer BRB has recently been supported.<sup>5</sup> The outer BRB separates the neural retina from the choroidal vasculature, which is responsible for approximately 80% of the blood supply in the eye (Fig. 30.4).

**FIG. 30.4** The retinal pigment epithelial (RPE) cells represent the outer blood–retina barrier (BRB). In the normal healthy retina, the transretinal water fluxes are mediated by Müller cells and pigment epithelial cells. These water fluxes are inevitably coupled to fluxes of osmolytes; to K<sup>(+)</sup> clearance currents. For this purpose, the cells express a complex, microtopographically optimized pattern of transporters and channels for osmolytes and water in their plasma membrane. Aquaporin-4 is a water channel that is abundantly expressed in Muller cells, but also in the RPE cells, and that permits the flow of water into the cell. In conditions of ischemia or inflammation, aquaporin-4 levels rise, and more fluid will enter the cells as described in previous slide. Ischemic/hypoxic alterations of the retinal microvasculature involve a downregulation of K<sup>(+)</sup> channels in the perivascular Müller cell end-feet and in the RPE cells. This means a closure of the main pathway that normally generates the osmotic drive for the redistribution of water from the inner retina into the blood. The result is an intracellular K<sup>(+)</sup> accumulation which, then, osmotically drives water from the blood into cells (i.e., in the opposite direction) and causes cell swelling, edema, and finally results in cyst formation.

The outer BRB-specific leakage of fluorescent macromolecules can be visualized in diabetic and ischemic rodents, and substantial leakage of macromolecules through the outer BRB can be detected. The role of the outer BRB is largely underestimated but has significant clinical implications.

## Cell-to-Cell Junctions and Vascular Permeability

Fluid homeostasis and capillary permeability are regulated by the complex intercellular communications within the cells of the neurovascular unit which comprises endothelial cells, pericytes and closely associated macro- and microglia and neurons. This cellular unit responds dynamically to complex circulatory and neural cues to control blood flow and regulate the intercellular junctions of the inner BRB. Intercellular junctions are complex structures formed by the assembly of transmembrane and cytoplasmic/cytoskeletal protein components. At least four different types of endothelial junctions have been described: tight junctions, gap junctions, adherence junctions, and syndesmos. Tight junctions are the most apical component of the intercellular cleft and are most relevant for the BRB (Fig. 30.5 online). Although the molecular structure of tight junctions generally appears to be similar in all barrier systems, there are some differences between epithelial and endothelial tight junctions, and between tight junctions of peripheral and retinal endothelial cells.<sup>6</sup> Expression of selected endothelial cell tight-junction genes and particularly that of occludin and claudin-5 are reduced in the diabetic retina.<sup>7</sup> In contrast to tight junctions in epithelial systems, structural and functional characteristics of tight junctions in endothelial cells respond promptly to ambient factors. It is likely that inflammatory agents increase permeability by binding to specific receptors that transduce intercellular signals, which in turn cause cytoskeletal reorganization and widening of the interendothelial clefts. For example, tumor necrosis factor (TNF)- $\alpha$  signals through protein kinase C (PKC) $\zeta$ /nuclear factor (NF)- $\kappa$ B alter the tight-junction complex and increase retinal endothelial cell permeability.<sup>8</sup> Endothelial junctions also regulate leukocyte extravasation. Once leukocytes have adhered to the endothelium, a coordinated opening of interendothelial cell junctions occurs.

**FIG. 30.5** Intercellular junctions in endothelial cells: Endothelial cells are connected and communicate with each other by tight junctions and adherens junctions. Tight junctions resemble a major part of the inner blood–retinal barrier. They are built by different proteins including occludin, ZO-1, and the claudin family.

Fluid moves from the retina to the choroid largely due to the osmotic pressure exerted by the proteins in the choroidal stroma and disruption of this normal flow can lead to significant edema. Especially in the context of ischemia and diabetic retinopathy, there is evidence that the RPE becomes dysfunctional and that leakage from the choriocapillaris occurs in unison with impaired fluid clearance contributing to retinal edema. When the RPE shows stress responses resulting from oxidative or nitrosative damage, this can result in significant loss of fluid control and damage to junctional integrity. Similar to the breakdown of the inner BRB, the breakdown of the outer BRB is associated with a significant depletion of the occludin in the RPE of ischemic and diabetic rodents.

## Inflammation and Vascular Permeability

“Inflammation” comprises a broad range of reactions from intravascular leukostasis and reactive glial activation as seen in diabetic retinopathy to overt inflammatory responses as in pars planitis, or choroidal inflammatory diseases.

Diseases not primarily called inflammatory such as diabetes present with activated leukocytes with abnormal adherence to the retinal vascular endothelium.<sup>9,10</sup> So-called leukostasis is initiated by activation of vascular endothelium and circulating myeloid cells such as neutrophils and monocytes. In diabetes, for example, the leukostasis phenomenon is typified by immune cells becoming trapped in narrow-channel retinal capillaries leading to occlusion and nonperfusion which is one of the first histologic changes in diabetic retinopathy and occurs prior to any apparent clinical pathology. Adherent leukocytes play a crucial role in diabetic retinopathy by directly inducing endothelial cell death in capillaries<sup>11</sup> causing vascular obstruction and vascular leakage. Endothelial cell death precedes the formation of acellular capillaries.<sup>3</sup> With time, however, acellular capillaries prevail and become widespread. Although the mechanism of this destructive process remains elusive, it is clear that the interaction between the altered leukocytes and the endothelial cells and the subsequent endothelial damage represents a crucial pathogenic step<sup>9,11,12</sup> (Fig. 30.6 online). This process is triggered by various growth factors and inflammatory cytokines. Inflammatory cytokines such as TNF- $\alpha$  decrease the protein and mRNA content of the tight-junction proteins zonula occludens (ZO)-1 and claudin-5.<sup>8</sup> TNF- $\alpha$  and interleukin-1 beta (IL-1 $\beta$ ) are elevated in the vitreous of diabetic patients and in the retina of diabetic rats associated with increased retinal vascular permeability and leukostasis<sup>13,14</sup> (Fig. 30.7 online). Furthermore, TNF- $\alpha$  is involved in ischemic vascular changes.<sup>15</sup> While a variety of cells may express these cytokines including endothelial cells, perivascular cells, and Müller glia, a bulk of expression is probably linked to activation of retina-resident microglia and infiltrating monocytes.

**FIG. 30.6** Inhibition of retinal pathology in long-term hyperhexosemic ICAM-1- and CD-18-deficient mice: trypsin digests demonstrating a large destruction of the capillary network comparable to nonproliferative diabetic retinopathy with acellular capillaries and microaneurysms in 24-months hyperhexosemic mice. The capillary network in mice with a “noninflammatory” phenotype (CD-18- or ICAM-1-deficient) demonstrates almost normal capillaries. (Reproduced with permission from Jousen AM, Poulaki V, Le ML, et al. A central role for inflammation in the pathogenesis of diabetic retinopathy. *FASEB J* 2004;18:1450–2.)

**FIG. 30.7** Inflammatory mediators are involved in leukocyte-endothelial interaction that via reduction of tight junction protein expression and induction of apoptosis results in vascular leakage.

While this is typical for overt inflammatory retinal disorders such as uveitis, such cell activation responses are now known to also be central to inflammatory responses developing during diabetic retinopathy. For example, a number of *in vitro* studies and *in vivo* investigations of animal models and human postmortem specimens indicate that activation of retinal microglia could play an important regulatory role in diabetes-mediated retinal inflammation by modulating cytokine expression and other pathologic responses. Monocytes that infiltrate the retina are distinct from microglia, and they reside in proximity to blood vessels (perivascular macrophages) or within various layers of the neuropile. While both monocytes and microglia have important roles in retinal homeostasis, they are also central to neuroinflammation responses that lead to retinal edema.<sup>16,17</sup>

In the inner retina, metabolic substrates, such as glucose, flow from vascular endothelium to astrocytes to neurons. In the outer retina, substrates reach Müller cells and photoreceptors from the choroid via the RPE<sup>18</sup> (Fig. 30.8).

**FIG. 30.8** (A) Müller cells are the communicators of the retina and are one of the principal locations for

intracellular fluid accumulation in patients with macular edema. The image on the left shows in orange the Müller cell in the healthy retina stretching through the retina from the ganglion cell layer to the retinal pigment epithelium. Some of the early changes are due to changes of the Müller cells and ionic channels as they control the tight junctions. (B) Alteration of the drainage mechanisms. *RMG*, retinal Müller glia.

Microglia associate intimately with neurons that express molecules, such as CX3CL1 (fractalkine) and CD20, that negatively regulate microglial activation through their respective receptors. As such, perturbation of expression of ligand or receptor during stress would activate microglia to produce proinflammatory cytokines and acquire an activated morphology. Activated microglia produce chemokines such as monocyte chemoattractant protein-1, inducing expression of adhesion molecules, which can promote the leukostasis of neutrophils on endothelium, and potentially inducing the extravasation of inflammatory macrophages.<sup>18,19</sup> Induction of glial fibrillary acidic protein (GFAP) is a marker of glial activation and increased expression of this protein occurs in Müller cells from the retinas of diabetic patients, but also after ischemic injury. The importance of Müller cells on the formation of neuronal and vascular pathology has been confirmed in transgenic models recently.<sup>20</sup>

## **Growth Factors, Vasoactive Factors, and Vascular Permeability**

The disruption of endothelial integrity leads to retinal ischemia with an ensuing hypoxia response by the oxygen-deprived retina. At a molecular level this is typified by stabilization and nuclear translocation of hypoxia-inducible factor-1 alpha (HIF-1 $\alpha$ ) in the neurons and glia. HIF-1 $\alpha$  is one of a family of hypoxia-inducible transcription factors that bind to hypoxia response elements in inducible target genes and control gene expression of proteins such as erythropoietin (EPO), vascular endothelial growth factor (VEGF), and glucose transporters. VEGF is most well appreciated in the ophthalmology field since it drives iris and retinal neovascularization.<sup>9,21,22</sup> Also known as vascular permeability factor

(VPF), VEGF is 50,000 times more potent than histamine in causing increased vascular permeability.<sup>23-25</sup> Previous work has shown that retinal VEGF levels correlate with diabetic BRB breakdown in rodents<sup>26</sup> and humans.<sup>27</sup> Flt-1(1-3Ig)F<sub>α</sub>, a soluble VEGF receptor, reverses early diabetic BRB breakdown and diabetic leukostasis in a dose-dependent manner.<sup>21</sup> Early BRB breakdown localizes, in part, to retinal venules and capillaries of the superficial inner retinal circulation<sup>28</sup> and can be sufficiently reduced by VEGF inhibition (Fig. 30.9 online). Although VEGF is only one of the cytokines involved in the pathogenesis of the vascular leakage, it is likely to be one of the most effective therapeutic targets.

**FIG. 30.9** Vascular endothelial growth factor (VEGF) is the key mediator of vascular damage and finally proliferation in the diabetic retina.

On a cellular level, VEGF has been implicated in many different mechanisms that lead to macular edema. VEGF has, for example, been shown to decrease the proteins responsible for the tightness of the intercellular junctions and induces rapid phosphorylation of the tight-junction proteins occludin and ZO-1 resulting in the breakdown of the BRB.<sup>29</sup> VEGF-induced BRB breakdown appears to be effected via nitric oxide.<sup>22</sup> VEGF also increases paracellular transport without altering the solvent drag reflection coefficient.<sup>30</sup> Furthermore, VEGF activation of PKC stimulates occludin phosphorylation and contributes to endothelial permeability.<sup>31</sup>

There are established tight connections between inflammation and VEGF expression.<sup>22</sup> Müller-cell derived VEGF has been shown to be essential for diabetes-induced retinal inflammation and vascular leakage.<sup>32</sup>

To determine the significance of Müller cell-derived VEGF in diabetic retinopathy, VEGF expression in Müller cells was disrupted with an inducible Cre/lox system and diabetes-induced retinal inflammation and vascular leakage was examined in these conditional VEGF knockout (KO) mice. Diabetic conditional VEGF KO mice exhibited significantly reduced leukostasis expression of inflammatory biomarkers, a reduced depletion of tight-junction proteins, reduced numbers of acellular capillaries, and reduced vascular leakage compared to diabetic control mice.

In vitro investigations on cell–cell interactions by D’Amore and coworkers demonstrated an inhibitory effect of transforming growth factor (TGF)- $\beta$  secreted by pericytes on endothelial cell growth. In diabetic retinopathy formation of sorbitol via aldose reductase leads to PKC activation resulting in pericyte damage and subsequently a loss of the inhibitory balance via TGF- $\beta$  secretion<sup>33</sup> (Fig. 30.10).

**FIG. 30.10** Transforming growth factor beta (TGF- $\beta$ ) is

involved in an inhibitory balance between pericytes and endothelial cells.

High glucose concentration leads to increased diacylglycerol (DAG) by two pathways: de novo synthesis and through dehydrogenation of phosphatidylcholine (PC). Increased levels of DAG mediate PKC activation. Several studies have shown that a decrease in retinal blood flow occurs with PKC activation. Conversely, inhibition of PKC with LY333531 (Eli Lilly, Indianapolis, IN) normalized decreased retinal blood flow in diabetic rats.<sup>34,35</sup>

PKC activation causes vasoconstriction by increasing the expression of endothelins (ET), especially ET-1. The expression of endothelins can be induced by a variety of growth factors and cytokines including thrombin, TNF- $\alpha$ , TGF- $\beta$ , insulin, and vasoactive substances including: angiotensin II, vasopressin, and bradykinin.

Furthermore, retinal vascular endothelial cells are very sensitive to histamine. Several studies have documented increased vascular histamine synthesis in diabetic rats and humans.<sup>36-38</sup> The administration of histamine reduces ZO-1 protein expression and thus correlates with vascular permeability. The H1 receptor stimulates PKC that has been implicated in increased retinal vascular permeability.<sup>39</sup> Interestingly, Aiello and coworkers showed that administration of LY333531, a PKC- $\beta$  isoform-selective inhibitor, does not significantly decrease histamine-induced permeability but rather VEGF-induced permeability. In contrast, administration of non-isoform-selective PKC inhibitors did significantly suppress histamine-induced permeability.<sup>40</sup>

Furthermore, in vascular endothelial cells, advanced glycation endproducts (AGE) may affect the gene expression of ET-1 and modify VEGF expression. The AGE-stimulated increased VEGF expression is dose- and time-dependent and additive to hypoxia.<sup>41,42</sup>

## **Endothelial Cell Death and Vascular Permeability**

Where intraluminal pressure falls below a critical closing pressure, the tone of the arteriolar wall cannot be maintained and the downstream capillary bed collapses and endothelial cells may

become “fibrin locked.” Endothelial cells deprived of their circulation and nutrition die and only acellular basement membranes persist. Similarly, a reduction in retinal perfusion pressure, often linked to carotid/ophthalmic artery insufficiency, can have similar retinal manifestations, and in extreme circumstances, there may be retrograde filling of arteries from fellow veins. Stasis of the blood flow in capillaries after venous or arterial occlusions results in rapid apoptosis of endothelial cells.<sup>43</sup>

Similarly, in diabetes, BRB breakdown is at least in part due to endothelial cell damage and apoptosis. The proapoptotic molecule Fas-ligand (FasL) induces apoptosis in cells that carry its receptor Fas (CD 95).<sup>44</sup> There is evidence that FasL is expressed on vascular endothelium where it functions to inhibit leukocyte extravasation. The expression of FasL on vascular endothelial cells might thus prevent detrimental inflammation by inducing apoptosis in leukocytes as they attempt to enter the vessel. In fact, during inflammation and ensuing TNF- $\alpha$  release, the retinal endothelium upregulates several adhesion molecules<sup>45</sup> that mediate the adherence of the leukocytes, but also downregulates FasL thus allowing leukocyte survival and migration to active sites of inflammation. In experimental diabetic retinopathy, inhibition of Fas-mediated apoptotic cell death reduces vascular leakage.<sup>46</sup> The cumulative endothelial cell death during the course of diabetes plays a causal role in the pathogenesis of the diabetic vascular leakage and maculopathy.

## **Extracellular Matrix Alterations and Vascular Permeability**

In diabetic retinopathy matrix changes are mostly related to basement membrane thickening of the capillaries which arises because of increased synthesis of protein components such as collagen IV, fibronectin, and laminin in combination with reduced degradation by catabolic enzymes. Degradation of the extracellular matrix affects endothelial cell function at many levels causing endothelial cell lability, which is required for cellular invasion and proliferation, or influencing the cellular resistance and therefore the vascular permeability. The degradation and modulation of the extracellular matrix is exerted by matrix metalloproteinases

(MMPs), a family of zinc-binding, calcium-dependent enzymes.<sup>47</sup> Elevation of MMP-9 and MMP-2 expression has been shown in diabetic neovascular membranes,<sup>48,49</sup> although a direct effect of glucose on MMP-9 expression in vascular endothelial cells could not be shown.<sup>50</sup> It is probable that MMPs participate at various stages during the course of the BRB dysfunction and breakdown. Their actions include early changes of the endothelial cell resistance with influence on intercellular junction formation and function<sup>51</sup> to active participation in endothelial and pericyte cell death<sup>52</sup> that occurs late in the course of the disease. Taken together, the degradation of extracellular matrix affect the blood vessels not just because then the blood vessels do not have support (i.e., mechanical effect) but also via altered interactions between endothelial cells and perivascular cells and an altered distribution of soluble growth factors and cytokines.

Although basement membrane thickening is a hallmark lesion in diabetic retinopathy it is still uncertain if it is of primary or secondary importance in the development of microvasculopathy. In the context of vasopermeability abnormalities, changes to this extracellular matrix impact the integrity of the neurovascular unit and normal cell–cell communication. Even from a structural perspective, changes in protein and proteoglycan composition of the basement membrane, as occurs in diabetes, influence charge selectivity which contributes to capillary barrier function.

## **Transcellular Transport and Vascular Permeability**

Disruption of the BRB is an early phenomenon in preclinical diabetic retinopathy (PCDR). Two vascular permeability pathways may be affected: the paracellular pathway involving endothelial cell tight junctions, and the endothelial transcellular pathway mediated by endocytotic vesicles (caveolae and pinocytotic transport). Despite the fact that pinocytotic transport is critically involved in the transepithelial fluid exchange, its role in the pathogenesis of increased vascular leakage in diabetes is just emerging.<sup>53,54</sup> The importance of the regulation of fluid homeostasis by active cellular transport of nutrients and fluid via pinocytosis is underlined by recent data suggesting a transient induction of the paracellular pathway and prolonged involvement of transcellular endothelial

transport mechanisms in the increased permeability of retinal capillaries in diabetes.<sup>7</sup>

It is currently known that one of the factors involved in the regulation of pinocytotic transport is VEGF. VEGF increases vascular permeability not only by disrupting the intercellular tight junctions between the retinal endothelial cells but also by inducing the formation of fenestrations and vesiculo-vacuolar organelles. The role of VEGF in the disruption of the pinocytotic transport that is translated into increased vascular permeability in disease states is still controversial.<sup>55</sup> Whereas in highly permeable blood vessels the number of pinocytotic vesicles at the endothelial luminal membrane transporting plasma IgG is significantly increased, no fenestrations or vesicles were found in the endothelial cells of the VEGF affected eyes when examined by electron microscopy.

## **Neurovascular Coupling**

Neuronal degeneration is a common feature of long-standing macular edema but has been recently shown to occur early in the pathogenesis of various origins of macular edema.

The retina consists of a network of neurons and specialized sensory cells (photoreceptors, bipolar cells, horizontal cells, amacrine cells, and ganglion cells) and glia (astrocytes, Müller cells, and microglial cells) that comprise approximately 95% of the tissue, with blood vessels representing less than 5% of the retinal mass.<sup>56</sup> As the network of retinal neurons and glia are intimately linked, there is no doubt that the neural and vascular components of the retina are closely associated by metabolic synergy and paracrine communication.<sup>18,57</sup>

There are complex neural, glial and vascular cell interactions occurring with both large and small retinal vessels and these play important roles in controlling retina homeostasis, including blood flow, water balance, and vasopermeability. The phenomenon called neurovascular coupling refers to the process by which retinal blood flow and vasoreactivity is matched to the metabolic (particularly oxygen) demands of the neuropile.<sup>58</sup> This interplay between the cell-types can become dysfunctional in disease states. For example, in the diabetic retina, regulation of vascular smooth muscle reactivity is depressed and this correlates with the severity of

retinopathy.<sup>59–61</sup> In an animal model of diabetes, the impairment of neurovascular coupling in the retina has been attributed to alterations in the NO signaling pathway since the response could be restored by inhibition of the enzyme inducible nitric oxide synthase (iNOS).<sup>62,63</sup> Such interactions can increase or decrease blood flow depending on local oxygen concentration, but how this switch occurs remains unclear.<sup>62,64</sup>

## Mechanical Factors Involved in the Formation of Macular Edema

Clinical and anatomic evidence indicates that abnormalities in the structure of the vitreoretinal interface may play an important role in the pathogenesis of DME.<sup>65–67</sup> It was suggested that vitreoretinal adhesions in diabetic eyes are stronger than the shear forces of traction from vitreous shrinkage and this in turn may lead to the development of vitreomacular traction and subsequently to macular edema.<sup>68</sup> The risk of developing diffuse macular edema was 3.4-fold lower in the group of eyes with complete posterior vitreous attachment or complete vitreoretinal separation compared to the eyes with vitreomacular adhesion.<sup>69</sup>

The vitreous humor is a gel-like structure composed mostly of water (99%), hyaluronic acid, and collagen. A structural barrier between the vitreous cavity and the retina is formed by the internal limiting membrane (ILM), which is localized between the innermost layer of the retina and the outer boundary of the vitreous. The ILM shows typical ultrastructural characteristics of a basal lamina, is found in close contact with the foot processes of Müller cells, and contains proteins that are typically found in basal laminae such as collagen type IV and laminin.<sup>70</sup> Striated collagen fibrils of the vitreous cortex insert into the inner portion of the ILM,<sup>71</sup> which is also known as the hyaloid membrane of the vitreous. Detachment of the posterior hyaloid membrane with aging or pathology results in a condensation of the posterior vitreous surface (*membrana hyaloidea posterior*). In youth, there is adhesion between the vitreous cortex and the ILM that is stronger than Müller cells themselves and Müller cell foot processes become separated from their main cell body and remain connected to the posterior aspect of

the ILM when this is separated from the retinal surface.<sup>72</sup>

There has been a controversial discussion regarding the embryonic origin of the ILM, which can be demonstrated as early as 4 weeks after gestation in the human eye.<sup>73,74</sup> Traditionally, the ILM has been considered to be synthesized by Müller cells. This concept has been challenged by data presented from Sarthy and coworkers, who investigated the expression of collagen type IV during development of the mouse eye.<sup>75</sup> ILM proteins appear to originate largely from lens and ciliary body, although a contribution of retinal glial cells in ILM synthesis cannot be excluded. In support of this are data that show that also other ILM proteins such as perlecan, laminin-1, nidogen, and collagen XVIII are expressed predominantly in lens and ciliary body, but are not detected in the retina.<sup>76</sup>

Diffuse DME has been found in association with an attached, thickened, and taut posterior hyaloids.<sup>77</sup> As immunocytochemical staining for cytokeratin (found in RPE) and GFAP (found in astrocytes and Müller cells) demonstrated the existence of RPE and Müller cells or astrocytes in the premacular posterior hyaloid, it suggested a possible role for cell infiltration in the development or maintenance of macular edema. It remains to be elucidated whether these cells in the posterior vitreous cause macular edema physiologically rather than mechanically through the production of cytokines.

[Fig. 30.11](#) is a schematic illustration of macular edema of different origins.

**FIG. 30.11** (A) Schematic illustration of macular edema. *BRB*, blood–retinal barrier. (B) Pathophysiologic changes in macular edema of different origin.

## Clinical Endpoints in Macular Edema

Best corrected visual acuity (BCVA) is the only endpoint that has

gained acceptance by regulatory and health technology agencies as being patient-relevant. BCVA, for example, has been used as primary outcome measure in all landmark clinical trials on new treatments for macular edema.<sup>78-85</sup>

However, BCVA alone does not provide a good indication of the visual function and potential restrictions patients may experience as a result of disease. Indeed, several eye disorders may adversely affect the visual function and the quality of life of individuals without impacting on BCVA. Furthermore, in certain diseases, BCVA is only affected once irreversible damage has taken place. Thus, new validated endpoints able to better capture functional deficits that affect and restrict patients as well as incipient changes related to early disease are needed. This may comprise distinct psychophysical tests, e.g., low luminance acuity, retinal sensitivity by microperimetry (photopic and scotopic) as a surrogate for topographic localization of retinal deficits.

Structural outcomes related to patient-reported outcomes or predictive of future functional loss and disease progression should be also sought. Besides an improvement of current imaging protocols (spectral domain optical coherence tomography SD-OCT) new approaches may include active eye-tracking technology. Phase variance OCT (PV-OCT) allows for volumetric imaging of the retinal vasculature of the eye. This novel approach, also referred to as OCT-angiography, has the added advantage of a noninvasive imaging technique not requiring potentially toxic contrast agents such as fluorescein, however not presenting vascular perfusion, but rather the outer vascular outlines. To overcome this problem and to better assess perfusion Doppler-OCT technology is currently being developed. Oximetry in diabetic retinopathy has extensively been reported.<sup>86</sup> Longitudinal data on oxygenation, perfusion, and oxygen extraction of the retina is currently lacking in diabetic retinopathy and is currently being generated. In the future, combination of Doppler-OCT with oximetry measures will allow determination of oxygen concentration and tissue metabolism as well as delineation of normoxic and hypoxic retina. All the above imaging technologies require validation and, in the context of macular edema, would need to demonstrate their value on this particular disorder.

Ideally, in order to identify the most adequate outcome measures, an integrated approach should be conducted, which should include a visual function and structural assessment, an evaluation of patients' perception of the impact of the disease in their daily living through patient reported outcomes (PROs), and, importantly, a study of molecular markers at the different stages of the disease process. Given the high output that such an approach would generate, a robust data management would be needed to allow integrating data of the individual patient and compare them with data from peer groups. To achieve this, a system medicine approach could be used which, by integrating all data generated, would allow improved characterization of disease phenotypes, better understanding of disease mechanisms, establishment of predictive models of disease progression and response to treatment. Advanced machine learning/statistics procedures need to be used to identify correlations between different parameters to gain insights into disease mechanisms and to identify and validate biomarkers: computational models of disease status within individual patients are required. For this reason object-oriented modeling systems, based on standard human pathway information, need to be adapted to the situation in the eye. As models become more complex and parameters become better defined, unknown mechanisms can be identified as systematic mismatches between prediction and measurement, accelerating progress in the identification of disease mechanisms, clinical endpoints, and biomarkers, revealing matches between different biomarkers that show relevance for prognosis of disease progression or susceptibility to treatment approaches.

## **Treatment of Macular Edema**

The current therapy for macular edema targets conditions where mechanical traction, hydrostatic force, or inflammation play a pathogenetic role. Laser photocoagulation, pharmacologic approaches, and surgical measures are the most frequently used therapies.

## Laser Treatment

Many studies have demonstrated a beneficial effect of photocoagulation therapy for DME.<sup>87-92</sup>

Traditionally argon laser photocoagulation was used to treat DME in an attempt to stabilize vision and prevent further visual loss. The Early Treatment of Diabetic Retinopathy Study (ETDRS) showed that laser treatment reduced the risk of moderate visual loss by 50% during 3 years of follow-up; however, only a small proportion of patients (<3%) experienced visual improvement of  $\geq 15$  letters.<sup>88</sup>

Recent randomized trials have shown that a much higher proportion (about 30%) of patients with DME can experience a clinically relevant ( $\geq 10$  ETDRS letters) improvement in visual acuity following laser treatment. Thus, in a study conducted by the (US–Canadian) Diabetic Retinopathy Clinical Research network ([DRCR.net](http://DRCR.net)), laser treatment for “center-involving DME” achieved gains of  $\geq 10$  letters in 32% of patients at 2 years.<sup>93,94</sup>

The probability of improvement was similar in naive eyes and those that had previously received  $\geq 3$  laser treatments. Similarly, in a more recently conducted study by [DRCR.net](http://DRCR.net), an improvement in visual acuity of  $\geq 10$  letters was observed in 28% of patients who had received laser treatment after one year.<sup>85,95,96</sup> Thus, it is clear that laser treatment can actually improve, not just stabilize, vision in some patients. Appropriate selection of patients, however, is required. It is likely that people with “thinner” retinas would respond better to laser treatment than those with “thicker” retinas, and thus, be clinically effective and cost-effective in the former, as suggested by the UK National Institute for Health and Care Excellence (NICE) Single Technology Assessments for anti-VEGF therapies.<sup>97</sup> There may be other factors that modulate clinical response; and ability to identify the “responders” in advance would be of great benefit to patients and to health services.

Laser treatment to areas of peripheral retinal ischemia, as determined by wide-angle fluorescein angiography, has been evaluated in small studies with good preliminary success (Tornambe PE, personal communication).

The exact mechanism of action of laser photocoagulation-induced resolution of DME still remains unknown. A laser-induced

destruction of oxygen-consuming photoreceptors has been discussed as well as cell death and scarring (involving gliosis and RPE hyperplasia) induced by the temporary raise in tissue temperature. Oxygen that normally diffuses from the choriocapillaris into the outer retina can now diffuse through the laser scar to the inner retina, thus relieving inner retinal hypoxia.<sup>98,99</sup> There are contrasting data whether an increased preretinal oxygen partial pressure is involved and allows for microvascular repair in the treated areas.<sup>100,101</sup>

When studying the diameter of retinal arterioles, venules, and their macular branches before and after macular laser photocoagulation in eyes with DME, the macular arteriolar branches were found to be constricted by 20.2% and the venular branches 13.8%. This was attributed to an improved retinal oxygenation caused by the laser treatment leading to autoregulatory vasoconstriction, improving the DME.<sup>102</sup>

According to another theory, the beneficial effect of laser photocoagulation is due to an enhanced proliferation of RPE and endothelial cells leading to a repair and restoration of the BRB.<sup>103</sup> RPE cells may respond to the injury in several ways: if the lesion is relatively small, the RPE defect can be filled by cell spreading; if the defect is relatively large, the cells can proliferate to resurface the area, and the RPE can produce cytokines (e.g., TGF- $\beta$ ) that antagonize the permeabilizing effects of VEGF.<sup>104,105</sup>

While focal laser coagulation reduces hypoxic areas and directly occludes leaky microaneurysms, the rationale for grid laser treatment in DME is not yet well established. Potentially, grid laser may have its beneficial effect by thinning the retina, bringing retinal vessels closer to choroidal vessels, permitting the retinal vessels to constrict by autoregulation, thereby decreasing retinal blood flow and consequently decreasing edema formation.<sup>106</sup> This theory, however, cannot be reconciled with the fact that current techniques used for focal/grid laser treatment for DME, including subthreshold laser (as opposed to what was used initially, which implied applying a much stronger laser) do not cause cell death. The effect of the laser can be observed even when damage is not detected by current imaging modalities including fundus autofluorescence imaging. Similarly, by using this milder form of treatment, reported

side-effects of laser, such as choroidal neovascularization (CNV) are no longer seen (Fig. 30.12). A lack of an effect of laser treatment in cases of diffuse edema, especially when causing large increases in retinal thickness, may occur (Fig. 30.13).

**FIG. 30.12** (A) Complications after grid laser coagulation: enlarged central retinal pigment epithelial scars of the left eye, no obvious macula edema. (B) Early phase fluorescein angiography demonstrates choroidal neovascularization lesion growing from earlier photocoagulation scars at the right eye. (C) Late phase with increased leakage of fluorescein.

**FIG. 30.13** (A) Grid laser treatment in persistent diffuse diabetic macular edema has limited effects. (B) The optical coherence tomography imaging demonstrates no difference in retinal thickness prior to and 3 months after grid laser treatment.

## Medical Treatment

## **General Aspects of Systemic and Topical Medical Therapy**

In many cases, macular edema is caused by a generalized health problem such as diabetes, high blood pressure or inflammatory conditions.<sup>107</sup> These systemic diseases need to be treated prior to undertaking any other therapeutic measures. There have been several reports in the literature that such treatments – particularly in diabetes, high blood pressure, and inflammatory diseases – can cure macular edema without any additional specific ocular treatment.<sup>108</sup>

Modification of the systemic blood flow including hyperbaric oxygen treatment is thought to alter blood flow via vasoconstriction, and facilitates the reformation of damaged junctional complexes in the vessel wall. However, despite an improvement in visual acuity in patients with chronic CME after cataract extraction, there was no correlation to macular edema.<sup>109</sup> In uveitis-associated CME hyperbaric oxygen had no significant effect. Other rheologic treatments, such as plasma membrane filtration, demonstrated good effects in initial studies; however, these treatments did not enter large-scale prospective studies.<sup>110</sup> Still there is no evidence that rheologic measures have any effect on inflammatory macular edema or DME.

Medical treatment of macular edema so far is best established in postsurgical and predominantly inflammatory edema, e.g., in uveitis, but gaining importance in the treatment of DME. The majority of the therapeutic strategies inhibit the release of inflammatory mediators and therefore target the pathogenetic factors responsible for the altered vascular permeability.

Medical treatment for macular edema consists of therapeutic agents that are collectively categorized into four groups: carbonic anhydrase inhibitors, nonsteroidal antiinflammatory drugs, corticosteroids, and anti-VEGF therapies.

### **Carbonic Anhydrase Inhibitors**

Carbonic anhydrase (CA) inhibitors have been used clinically for over 20 years in the treatment of macular edema. The initial observation on its therapeutic efficacy was reported in 1988 in a

study of 41 patients with CME of various etiologies.<sup>111</sup> The rationale of CA inhibitors as a therapeutic agent in the treatment of macular edema is to improve the ability of the RPE to pump fluid out of the retina by modulation of the polarized distribution of CA at the level of the RPE.<sup>112</sup>

In the retina, CA is found in the cytoplasm of red/green cones (albeit not in rods) and especially inside Müller cells. The RPE, however, appears to contain almost exclusively the membrane-bound form of CA.<sup>113</sup> The latter appears to regulate and modulate the extracellular pH gradients created by the metabolic activity of cells and may act as a bicarbonate channel.<sup>113,114</sup> The CA activity in the RPE shows a clear-cut polarized distribution with a large amount of enzyme on the apical surface of the cell, whereas there is less CA activity on the basolateral portion of the cell membrane.<sup>115</sup> Further immunohistochemical differentiation has shown the isozyme IV is responsible for apical CA activity in the RPE.<sup>113</sup> Intravenous injection of acetazolamide has been shown to decrease the pH in the subretinal space in both chicks and cats.<sup>113,116</sup> This acidification was followed immediately by a reduction of the subretinal volume, and it has been postulated that it is the acidification that induces changes in ion and consequent fluid transport through the RPE<sup>115</sup> (Fig. 30.14).

**FIG. 30.14** (A) Schematic diagram showing selected ion channels in the retinal pigment epithelium. Note that carbonic anhydrase inhibitors act on the bicarbonate/chloride exchange channel in the basal membrane, and nonsteroidal antiinflammatory drugs (NSAIDs) have been shown to act on the chloride channel in the basal membrane of the retinal pigment epithelium. Both channels are associated with transcellular fluid transport. (B) Membrane-bound carbonic anhydrase (CA IV) 55 kDa.

Under normal conditions, roughly 70% of the subretinal fluid is removed by metabolic transport to the choroid. In an *in vivo* rabbit model, this fluid transport, which is driven to a large extent by active ion transport through the RPE, can be enhanced by acetazolamide.<sup>117,118</sup> Furthermore, experiments in an animal model of iatrogenically induced retinal detachments showed that the disappearance of fluorescein through the RPE increased by 25% after intravenous injection of acetazolamide.<sup>119</sup> The same authors also observed a marked increase in resorption of subretinal fluid at a higher dosage of 50–65 mg/kg body weight. Further studies on the frog RPE demonstrated that active chloride and bicarbonate transport probably occurs at the basal surface, which faces the choroidal blood supply, and it was postulated that subretinal fluid absorption occurs at this level.<sup>114</sup>

Currently, there are no randomized clinical trials available, confirming the beneficial effect of CA inhibitors in the treatment of macular edema. However, evidence from nonrandomized studies

suggests improved visual function in patients with postsurgical macular edema (e.g., after cataract surgery or buckling procedures) following this therapy.<sup>111,120</sup> The effect lasts only as long as the patient takes the drug (on–off-effect, tachyphylaxis).<sup>120</sup> Similarly, the favorable reports that were described regarding the application of CA inhibition in patients with macular edema secondary to retinitis pigmentosa are not supported by long-term observations. With the continuous use of methazolamide a rebound phenomenon is observed, but might also be attributed to disease progression.<sup>121</sup>

While there is no indication for the application of topical CA inhibitors (e.g., dorzolamide) for prophylaxis or treatment of macular edema, the systemic treatment with CA inhibitors is worthwhile when the edema is proven to come from the RPE (as determined by stereoangiography). Contrary to tenacious clinical habit, the use of CA inhibition for intraretinal macular edema as a result of inner blood–retinal barrier breakdown is not based upon scientific evidence to date. The use of CA inhibitors for diabetic macular edema is not recommended.

## **Nonsteroidal Antiinflammatory Drugs (NSAIDs)**

As cyclooxygenase inhibitors block the synthesis and release of prostaglandins, nonsteroidal drugs have been investigated in the prophylaxis and therapy of postsurgical CME. The action is based on the inhibition of the enzyme cyclooxygenase, which in turn inhibits the production of prostaglandins, a degradation product of arachidonic acid in the eye.<sup>122</sup> Diclofenac sodium in high doses inhibits the formation of leukotrienes, which amplify cellular infiltration during an inflammatory reaction. Other NSAIDs have been shown to modulate chloride movement, and, as a consequence, fluid movement through the RPE.<sup>123</sup> The effect of COX-inhibitors on inflammatory aspects of DME was only demonstrated in preclinical studies<sup>13</sup> (Fig. 30.15).

**FIG. 30.15** Interaction of nonsteroidal antiinflammatory drugs with vascular endothelial growth factor (VEGF) and inflammatory cytokines and their signaling pathways.

Thus, NSAIDs target the inflammatory mediators that are responsible for the edema formation, and although they may not be an optimal stand-alone treatment, they can be used as steroid-sparing agents. Topical NSAIDs have become the mainstay in the treatment of inflammatory CME.<sup>124</sup> The clinical efficacy of topical NSAIDs has been shown to be of value both in the prevention<sup>125–127</sup> and in the treatment<sup>128,129</sup> of inflammatory CME, particularly when related to cataract surgery. Two double-masked, placebo-controlled studies in which corticosteroids were not used demonstrated that ketorolac 0.5% ophthalmic solution, administered for up to 3 months, improves vision in some patients with chronic CME after cataract surgery.<sup>130,131</sup> A meta-analysis of the results from several randomized controlled trials (RCTs) suggested that NSAIDs are beneficial as a medical prophylaxis for aphakic and pseudophakic CME and as medical treatment for chronic CME.<sup>132</sup>

On the basis of these findings, it has been suggested to employ topical NSAIDs in the treatment of inflammatory CME, especially

when related to ocular surgery. This effect is independent of the presence of DME.<sup>133</sup>

There may be several explanations for why NSAIDs are unlikely to improve vision in DME, such as chronic edema, inflammation, and ischemia that induce permanent structural alterations. Although effects on diabetic vascular leakage were achieved in preclinical studies,<sup>13</sup> there is so far no evidence for an effect of NSAIDs in DME. A recent Cochrane review did not identify any RCTs investigating the effects of topical NSAIDs in the treatment of diabetic CME.<sup>133</sup> The review has identified the need for well-designed, adequately powered RCTs that should aim to include a large sample size with an adequate follow-up period of up to one year.<sup>134</sup>

## Corticosteroids

Steroids are currently regaining attention for the treatment of various forms of macular edema. Corticosteroids block the release of arachidonic acid from cell membranes by inhibiting the enzyme cyclooxygenase and thus reduce the synthesis of prostaglandins, but they also have a multitude of other antiinflammatory effects by acting, among others, on IL-1 and by reducing vascular permeability<sup>135</sup> (Fig. 30.16A). Their additive antiinflammatory effect to NSAIDs has been shown to be useful in the treatment of various postoperative inflammatory conditions. One potential mode of action is the increased resorption of fluid through the RPE, although the exact mechanism of this is not as yet clear. Steroids specifically stabilize endothelial tight junctions and increase their numbers.<sup>136,137</sup> Another action of steroids is the downregulation of the production of the VEGF, which, in turn, renders the BRB tighter (Fig. 30.16B). Steroids also downregulate VEGF production,<sup>138</sup> specifically in the retina,<sup>139,140</sup> and this explains the clinical observation that the application of steroids both intravitreally and into the sub-Tenon space can reduce macular edema considerably. Furthermore, steroids have been shown to prevent the induction of VEGF production by platelet-activating factor and platelet-derived growth factor.<sup>141</sup> Triamcinolone also inhibits IL-6- and VEGF-induced angiogenesis downstream of the IL-6 and VEGF receptors.<sup>142</sup> Leukocyte adhesion plays an important role in macular

edema – particularly so in diabetic maculopathy.<sup>11,12</sup> The endothelial damage resulting from this leukocyte adherence to vessel walls is mediated by nitric oxide, adhesion molecules, and other inflammatory mediators.<sup>22,143</sup> Sub-Tenon triamcinolone inhibits leukocyte-endothelium interactions in the retina and downregulates adhesion molecules of retinal vascular endothelium<sup>144</sup> and thus decreases the retinal thickness.

**FIG. 30.16** (A) Action of steroids on arachidonic acid. (B) Action of steroids on growth factor release. *BRB*, blood–retinal barrier; *PAF*, platelet-activating factor; *PDGF*, platelet-derived growth factor; *VEGF*, vascular endothelial growth factor.

The Müller cells represent a further site of action of steroids.<sup>145</sup> Macular edema is thought to be partly linked to the downregulation of the Müller cell protein Kir4.1.<sup>145</sup> The resultant

increase in intracellular K<sup>+</sup> leads to the uptake of proteins and osmotic swelling of the Müller cells via aquaporin 4 channels. The administration of triamcinolone reduces the production of VEGF, arachidonic acid, and prostaglandins, allowing the reactivation of fluid clearance by Müller cells via endogenous adenosine and an increase in TWIK-related acid-sensitive potassium (TASK) channels. These processes lead to an efflux of potassium thus correcting the downregulation of the Kir4.1 protein.<sup>145</sup>

Corticosteroids have different potency levels depending on their chemical composition,<sup>146</sup> and the newer synthetically produced compounds show an up to 25-fold increase in activity, as compared to cortisone. These new agents, such as triamcinolone, dexamethasone, and fluocinolone acetonide, have fluor at the 9 $\alpha$  position, which increases corticosteroid receptor binding. Routes of clinical administrations are manifold, including topical, periocular, intraocular, oral, and intravenous routes. Sub-Tenon injections of corticosteroids are widely used in patients with asymmetric or unilateral uveitis. The advantages of the periocular injections are high concentrations of corticosteroids in the posterior segment of the eye, and reduction of the adverse effects compared to systemic administration. Intraocular levels of corticosteroids are identical between sub-Tenon and retrobulbar administration.<sup>147</sup> For oral administration, the initial high dose (1–1.5 mg/kg) is subsequently decreased according to clinical effect.<sup>148</sup>

Another therapeutic option is the administration of steroids as intravitreal injections or sustained release implants in order to obtain high local concentrations, maximizing their antiinflammatory, angiostatic, and antipermeability effects while minimizing systemic toxicity.<sup>149</sup>

Depending on the cause of the macular edema, local or systemic routes may be chosen (e.g., in posterior uveitis, systemic steroids may be required to control the systemic inflammation whereas in macular edema secondary to vein occlusion local therapies may be more appropriate).

Several randomized trials have evaluated the use of fluocinolone, dexamethasone, and triamcinolone in patients with DME and vein occlusion, as summarized below.

## Triamcinolone.

Triamcinolone is a corticosteroid which can be delivered by intravitreal bolus injection. It has been widely used in macular edema of various origins including DME and edema secondary to vein occlusion. For DME, there have been several randomized trials comparing triamcinolone with laser; none showed benefit of triamcinolone. However, as stated below (see [anti-VEGF](#) section, ranibizumab) subgroup analysis of the [DRCR.net](#) demonstrated similar gains in pseudophakic eyes in patients with DME receiving triamcinolone to those observed in patients receiving ranibizumab.<sup>150</sup>

Furthermore, in this group, triamcinolone appeared to be cost-effective when compared with ranibizumab.<sup>151</sup> The use of currently available triamcinolone formulations, however, has not been licensed for intraocular use. Despite not being licensed, triamcinolone is still used in postsurgical CME that does not respond to NSAIDs although there is no RCT evidence supporting this use.

## Fluocinolone.

Fluocinolone acetonide is delivered intravitreally as a sustained release implant (Iluvien, Alimera Sciences). It is a small intravitreal implant for DME. The efficacy of this fluocinolone acetonide implant was assessed in two randomized, multicenter, double-masked, parallel, 36-month clinical trials in patients with DME. There were 956 patients in the “Fluocinolone Acetonide for Diabetic Macular Edema” studies which compared fluocinolone acetonide with sham control.<sup>152</sup>

As in RISE and RIDE (see below), despite the fact that the standard of care treatment for DME at the time this trial was initiated was laser (focal/grid) photocoagulation, the fluocinolone comparator arm was sham. “Rescue laser” was allowed after week 6 and retreatments could be performed after month 12. At 3 years, ~28% of patients gained  $\geq 15$  in letters in the fluocinolone group compared with 18.9% in the sham group. The benefit doubled in patients who reported duration of DME  $\geq 3$  years at baseline. Almost all phakic patients in the fluocinolone acetonide insert groups developed cataract, but their visual benefit after cataract

surgery was similar to that in pseudophakic patients. Rescue laser was required in ~37% of patients in the fluocinolone group and 60.7% in the sham. As anticipated, in phakic eyes cataract surgery extraction rates were found to be 80% in the fluocinolone group vs. 27.3% in the sham group. In the overall clinical trial population (excluding subjects with baseline IOP>21 mmHg), the proportion of fluocinolone-treated subjects requiring treatment with IOP-lowering drops was 38% compared to 14% in the sham-treated group. The incidence of incisional glaucoma surgery at month 36 was 4.8% in the low-dose group and 8.1% in the high-dose insert group.

The microimplant has been approved in 17 European countries as well as in the United States. In the UK, NICE has recommended the use of fluocinolone in pseudophakic patients with DME that show an insufficient response to other medications.<sup>153</sup> In Germany fluocinolone acetonide is indicated for treating DME in patients “who are insufficiently responsive to first line therapy.”

Fluocinolone acetonide has been used for the treatment of uveitis<sup>154,155</sup> as well as vein occlusion.<sup>155</sup> Data on Iluvien from RCTs in these indications are still pending. Similar to Ozurdex (see below), there is evidence that Iluvien is of value to vitrectomized patients as the release is independent of the presence of the vitreous.<sup>156</sup>

## **Dexamethasone.**

Dexamethasone has the highest relative strength of any corticosteroid used in ophthalmic practice. Dexamethasone (Ozurdex; dexamethasone 700 µg intravitreal implant, Allergan), is a commercially available implant which can be delivered to the vitreous cavity by means of an injectable device.<sup>157</sup>

It is approved in most European countries and the United States for the treatment of DME, macular edema secondary to posterior uveitis and vein occlusion.

There were two initial studies assessing the efficacy of dexamethasone implants for DME; one compared two doses of dexamethasone with no treatment; the other compared an unspecified dose of dexamethasone vs. dexamethasone plus laser vs. laser alone.<sup>158,159</sup>

Both studies found dexamethasone gave an improvement in visual acuity, regressing to baseline after 3 months. Cataract and raised intraocular pressure were the main side-effects. In October 2014, members of the MEAD (Macular Edema: Assessment of Implantable Dexamethasone in Diabetes) study group published the results of their 3-year, randomized, sham-controlled trial of dexamethasone intravitreal implant (DEX) in patients with DME.<sup>160</sup>

The mean number of treatments given over 3 years was 4.1, 4.4, and 3.3 with DEX implant 0.7 mg, DEX implant 0.35 mg, and sham, respectively. The percentage of patients with  $\geq 15$ -letter improvement in best corrected visual acuity (BCVA) from baseline at study end was greater with DEX implant 0.7 mg (22.2%) and DEX implant 0.35 mg (18.4%) than sham (12.0%;  $p \leq 0.018$ ). The study also reported a greater mean average reduction in central retinal thickness (CRT) from baseline in both the 0.7 mg and 0.35 mg dexamethasone implant compared to sham. As with all steroid compounds, the rates of cataract-related adverse events in phakic eyes were higher in the dexamethasone groups (threefold) when compared to those in the sham arm. The investigators stated that increases in IOP were usually controllable with medication or no therapy within the 3 years. In the UK NICE has recently approved the use of the dexamethasone intravitreal implant for DME in eyes with an artificial lens (pseudophakic) where other treatments were ineffective or not suitable.<sup>161</sup>

The Geneva Study assessed patients with macular edema secondary to branch or central retinal vein occlusion receiving DEX implant 0.7 mg ( $n=421$ ), DEX implant 0.35 mg ( $n=412$ ), or sham ( $n=423$ ) in the study eye. At day 180, patients could receive DEX implant 0.7 mg if BCVA was  $< 84$  letters or retinal thickness was  $> 250 \mu\text{m}$ . Single and repeated treatment with DEX implant had a favorable safety profile over 12 months. A  $\geq 15$ -letter improvement in BCVA from baseline was achieved by 30% and 32% of patients 60 days after the first and second DEX implant. The IOP increases were usually transient and controlled with medication or observation; an additional 10.3% of patients initiated IOP-lowering medications after the second treatment.<sup>162</sup>

The slow release effect of Ozurdex is independent of the presence of the vitreous and clinical findings do not differ between

nonvitrectomized and vitrectomized eyes<sup>163</sup> (Fig. 30.17 online).

**FIG. 30.17** (A) Course of a 62-year-old type 2 diabetic patient. Insulin therapy since 2004; HbA1c 7.2, hypertension. Medication: insulin, enalapril, statin, aspirin. All horizontal scans of the left eye. During 3 years, 15 injections with ranibizumab. Finally stable

situation over 18 months after last injection. (B)  
Angiogram of the patient in panel A demonstrating few  
areas of capillary nonperfusion in the midperiphery, but  
no proliferation.

## Antiangiogenic Treatment

Several clinical trials have assessed the effectiveness of anti-VEGF therapies, including bevacizumab, ranibizumab, and aflibercept, for the treatment of DME and edema secondary to vein occlusion. Anti-VEGFs are administered by intraocular (intravitreal) injection. A summary of the evidence available from the largest trials on these therapies is provided below.

### Ranibizumab.

Ranibizumab (Lucentis, Novartis Europharm Limited, Camberley, UK) is a recombinant humanized IgG1 kappa isotype monoclonal antibody fragment (Fab) designed for intraocular use. It binds to and inhibits the biologic activity of human VEGF-A. It has a half-life of approximately 9 days.

RESTORE randomized 354 patients with “center-involving DME” to receive one of the three following treatments: ranibizumab (0.5 mg) + sham laser, ranibizumab (0.5 mg) + laser, or sham injection + laser. Participants in the ranibizumab arms had a minimum of three monthly injections, after which injections were continued until stable BCVA or BCVA of 6/6 was achieved on two consecutive visits. Treatment was reinitiated if VA decreased due to recurrence of DME. The primary outcome was mean average change in VA from baseline to months 1–12.<sup>164</sup>

After one year, there was a greater gain in BCVA in the ranibizumab groups (37% and 23% of patients with  $\geq 10$  and  $\geq 15$  letter gain, respectively, in the ranibizumab + sham laser arm; and 43% and 23% of patients with  $\geq 10$  and  $\geq 15$  letter gain, respectively, in the ranibizumab + laser arm) than in those receiving laser only. The median number of injections was seven.

In the RISE and RIDE trials, patients were randomized to one of three arms: ranibizumab 0.3 mg monthly, ranibizumab 0.5 mg monthly, or sham injection. Monthly treatments with ranibizumab

were given for the whole duration of the study (24 months). “Rescue” laser was allowed, but there was not an active laser arm, despite the fact that laser was the standard of care for eligible patients when the studies were initiated. In RISE and RIDE, 377 and 382 patients were randomized, and the primary outcome of both trials was the percentage of patients with a  $\geq 15$  letters gain at 24 months.<sup>165</sup>

The trial showed that ~45%, 40%, and 18% of patients in the 0.3-mg ranibizumab, 0.5-mg ranibizumab, and sham arms, respectively, gained  $\geq 15$  letters. Also, in patients receiving ranibizumab, there was less retinopathy progression. Interestingly, “rescue” laser was required in ~40% of patients in the 0.3-mg ranibizumab arm and ~35% in the 0.5-mg ranibizumab arm, suggesting that in these patients, monthly ranibizumab injections were not sufficient to control DME. Laser treatment was also given to 74% of patients in the sham group; thus, 26% of patients appear not to have received any treatment.

In a randomized trial conducted by the Diabetic Retinopathy Clinical Research Network patients with “center-involving DME” were randomized to one of four arms: sham injection + prompt laser; ranibizumab (0.5 mg) + prompt (3–10 days after injection) laser; triamcinolone (intraocular) + prompt laser; or ranibizumab (0.5 mg) + deferred ( $\geq 24$  weeks after injection) laser. The study included 691 patients (854 eyes). Intravitreal injections of ranibizumab (or sham) were given monthly through the first 12 weeks of the study; from Week 16 onwards a complex algorithm for retreatment was used. The primary outcome was the mean change in BCVA from baseline to year 1. At 1 year a significant gain in BCVA was achieved in the ranibizumab + prompt and deferred laser arms vs. the non-ranibizumab groups ( $p < .001$ ), with ~50% of patients experiencing  $\geq 10$  letter gain and ~30% of patients achieving gains of  $\geq 15$  letter after a median of 8–9 injections. This occurred even though a high proportion of cases (72% of eyes) in the deferred laser group did not receive any laser.<sup>150</sup> It should be noted, however, that although at 1 year only 28% of patients in the deferred laser group had received laser, this percentage increased to 42% at 2 years and 46% at 3 years suggesting that, in a considerable number of patients, ranibizumab alone did not

suffice.<sup>166</sup>

A meta-analysis of these studies undertaken by Ford et al. concluded that ranibizumab improved results obtained with laser alone, considering both mean change in BCVA and the proportion of patients with  $\geq 15$  letter gain. Surprisingly, there was no benefit of adding laser to ranibizumab by either of these outcome measures.<sup>167</sup>

Several studies have demonstrated the value of ranibizumab in vein occlusion. A meta-analysis by the Cochrane group of the available RCT evidence suggests that repeated treatment of nonischemic macular edema secondary to branch retinal vein occlusion (BRVO) with the anti-VEGF agent ranibizumab may improve clinical and visual outcomes at 6 and 12 months. However, the frequency of retreatment has not yet been determined, and the impact of prior or combined treatment with laser photocoagulation on the primary outcome is unclear.<sup>168</sup>

A posthoc analysis of the two phase III clinical trials conducted for vein occlusion demonstrated the relevance of OCT as a predictive measure for early versus late or incomplete ranibizumab response. Among ranibizumab-treated patients, 71.2% (0.3 mg) and 78.5% (0.5 mg) in the CRUISE study and 79.1% (0.3 mg) and 84.7% (0.5 mg) in the BRAVO study had central foveal thickness (CFT) of 250  $\mu\text{m}$  or less at month 3 and therefore were categorized as early ranibizumab responders. Visual outcome at months 6 and 12 was reduced in 0.5 mg ranibizumab-treated patients with central retinal vein occlusion (CRVO) who had persistent CME at month 3. It also was reduced in CRVO for those with CFT of more than 250  $\mu\text{m}$  at month 3 who were treated with 0.3 mg ranibizumab. This suggests that late or incomplete responders do need careful follow-up.<sup>169</sup>

Currently several RCTs are ongoing that determine the use of ranibizumab in macular edema of other origin including radiation retinopathy.

### **Bevacizumab.**

Bevacizumab (Avastin, Genetech Inc., San Francisco, CA) is a full-length humanized antibody that binds to all types of VEGF and is used successfully in cancer therapy as a systemic drug. Despite its widespread use for intravitreal therapy around the world, it is not licensed for this application.

Its potential usefulness in DME was tested in the BOLT trial, in which patients were randomized to receive bevacizumab or laser.<sup>170</sup>

BOLT was a small RCT that included 80 patients; people with macular ischemia were excluded because they were considered unsuitable for laser treatment. Laser was performed according to the modified ETDRS criteria; focal or grid laser treatment for DME was applied to treat all leaking microaneurysms in areas of retinal thickening or to areas of edema or nonperfusion (based on fluorescein angiography) located at least at 500  $\mu\text{m}$  from the fovea (only rarely is treatment applied closer) in order to obtain mild “gray” burns. Bevacizumab was given every 6 weeks until week 18, after which it was continued until retinal status was considered stable if the central retinal thickness was  $>270 \mu\text{m}$ . The main outcome measure was BCVA at 1 year.<sup>170</sup>

A greater gain in BCVA was observed in the bevacizumab vs. laser arm, with 31% and 12% of patients having a  $\geq 10$  letter and  $\geq 15$  letter gain, respectively, following bevacizumab, compared with 5% and 8% following laser. The median number of injections required was nine. Interestingly, in this trial, success of laser treatment was much lower than that observed in the ranibizumab studies described above. Similarly, studies demonstrating a long-term benefit of bevacizumab in vein occlusions have been published.<sup>171</sup>

Head-to-head trials for age-related macular degeneration (AMD) demonstrated similar effects on visual acuity for both ranibizumab and bevacizumab over extended periods.<sup>172-174</sup>

It is likely there is no difference in the effectiveness and safety profile when used for the treatment of macular edema. This is supported by recently published systematic reviews. Compared to no treatment, repeated intravitreal injection of anti-VEGF agents (ranibizumab, aflibercept, and bevacizumab) in eyes with CRVO and macular edema improved visual outcomes. All agents were relatively well tolerated, with a low incidence of adverse effects in the short term; however, the number of injections differed slightly among the different anti-VEGF agents.<sup>175,176</sup>

### **Aflibercept.**

Aflibercept (Eylea, Regeneron-Bayer HealthCare) is the most recent addition to the anti-VEGF family of drugs. It is a fully human

recombinant fusion protein designed to bind all isoforms of VEGF-A as well as placental growth factor (PlGF), thereby inhibiting the activation of VEGF receptors.

Its suitability and efficacy in treating DME was assessed in the DA VINCI trial<sup>177,178</sup> and in the VISTA and VIVID trials.<sup>81</sup> The 221 patients in the DA VINCI trial were randomized to either laser only or to one of four regimens of intravitreal aflibercept; 0.5 mg every 4 weeks; 2 mg every 4 weeks; 2 mg every 4 weeks for 3 months then every 8 weeks; 2 mg every 4 weeks for 3 months, then PRN (“as needed”). The mean change in BCVA at 6 months (primary outcome) demonstrated superior visual gain in all aflibercept arms compared to laser.<sup>13</sup> The  $\geq 10$  letters gain was highest in the 2-mg-every-4-weeks subgroup, at 64%, whereas the 0.5-mg-every-4-weeks group demonstrated 34% of patients gaining  $\geq 15$  letters. After one year, data from 79% of patients were available and showed that the 6-month gain of  $\geq 10$  letters in the 2-mg-every-4-weeks group had risen to 71%. This group also had the highest percentage of patients with  $\geq 15$  letters gain; this gain compared to 30% and 11% gain of  $\geq 10$  letters and  $\geq 15$  letters, respectively, in the laser arm at this time point.<sup>86</sup>

A total of 872 patients (eyes) with type 1 or type 2 diabetes mellitus and “center-involving DME” were randomized to receive intravitreal aflibercept injection (IAI) 2 mg every 4 weeks (2q4), IAI 2 mg every 8 weeks after five initial monthly doses (2q8), or to macular laser photocoagulation. The primary outcome was the change from baseline in BCVA at one year. The proportion of eyes gaining  $\geq 15$  letters was 41.6% and 31.1% vs. 7.8% in VISTA, and 32.4% and 33.3% vs. 9.1% in VIVID in the 2q4, 2q8 vs. laser arms, respectively. The mean reduction in central macular thickness was also significantly greater in the two IAI arms. The study concluded that IAI demonstrated significant superiority in functional and anatomic endpoints over laser, with similar efficacy in the 2q4 and 2q8 groups.

Similarly there is data demonstrating the effectiveness of aflibercept in retinal vein occlusion. The Galileo study is the phase III trial investigating patients with CRVO receiving either 2 mg intravitreal aflibercept or sham injections every 4 weeks for 20 weeks. At week 52, the mean percentage of patients gaining 15

letters or more was 60.2% in the aflibercept group and 32.4% in the sham group.<sup>83,179</sup>

The mean central retinal thickness in DME eyes treated with anti-VEGFs was high (405  $\mu\text{m}$  DRCR.net; >460  $\mu\text{m}$  RISE and RIDE; 412–426  $\mu\text{m}$  RESTORE; >479  $\mu\text{m}$  VISTA and VIVID). As evidence suggests that patients with central retinal thickness of less than 400  $\mu\text{m}$  appear to be the best candidates for laser, the high central retinal thickness in RCTs of anti-VEGF could have potentially favored anti-VEGF groups.

The VIBRANT study represents the pendant in branch vein occlusion: a total of 183 patients received either 2 mg intravitreal aflibercept injection every 4 weeks from baseline to week 20 or grid laser at baseline with a single grid laser rescue treatment, if needed, from weeks 12 through 20. The mean improvement from baseline BCVA at week 24 was 17.0 ETDRS letters in the intravitreal aflibercept group and 6.9 ETDRS letters in the laser group.<sup>180</sup>

## Other Medical Treatments

There are several active areas of investigation in the DME research field. These include novel therapies and potential new biologic targets.

Steroid-sparing immunosuppressive drugs are frequently used as additional, second-line agents, particularly in patients with severe intraocular inflammation and CME.<sup>2</sup> The rationale for these treatments relies on the inhibition of several different proinflammatory cytokines, which are specifically involved in causing macular edema by breaking down the BRB in intraocular inflammatory disorders.

Apart from the well-known agents such as VEGF, prostaglandins, and leukotrienes, these cytokines also include insulin-like growth factor 1, IL-6, stromal cell-derived factor 1, and hepatocyte growth factor. Particularly elevated levels of intraocular VEGF and IL-6 have been correlated with the severity of uveitic macular edema<sup>181</sup> and treatments directed specifically against these factors have been proposed.

Promising results have also been reported using interferon  $\alpha 2$ <sup>182</sup> as a treatment for long-standing refractory CME in uveitis. In addition, a beneficial effect of interferon on inflammatory CME was

noted in a retrospective study of patients with multiple sclerosis-associated intermediate uveitis.<sup>183</sup> Others reported comparable efficacy of cyclosporine A to prednisolone in the treatment of macular edema in patients with endogenous uveitis.<sup>184</sup> Anti-TNF therapy has also been demonstrated as a promising therapy for uveitic macular edema.<sup>185</sup> Somatostatin analogs such as octreotide may also be effective in the treatment of CME by blocking the local and systemic production of growth hormone, insulin-like growth factor, and VEGF.<sup>186</sup> Treatment with octreotide resulted in marked improvement, or even complete resolution of CME in uveitic patients.<sup>187</sup> Similarly, Ca-Dobesilate prevents the BRB breakdown induced by diabetes, by restoring tight-junction protein levels and organization and decreasing leukocyte adhesion to retinal vessels. The protective effects of Ca-Dobesilate is likely to involve the inhibition of p38 MAPK and NF-κB activation, possibly through the inhibition of oxidative/nitrosative stress.

A major goal of treating patients with diabetic retinopathy should be a good control of blood glucose, blood pressure, and plasma lipids.

Fenofibrate has been shown to retard significantly the rate of diabetic retinopathy (DR) progression in adults with type 2 diabetes (T2D), including the development of macular edema. Fenofibrate as an oral agent is effective in preventing progression of established diabetic retinopathy in type 2 diabetes. Thus, in the FIELD study, fenofibrate (200 mg/day) reduced the requirement for laser therapy and prevented disease progression in patients with preexisting diabetic retinopathy.<sup>188</sup>

In the ACCORD study, fenofibrate (160 mg daily) with simvastatin resulted in a 40% reduction in the odds of retinopathy progressing over 4 years, compared with simvastatin alone. This occurred with an increase in HDL-cholesterol and a decrease in the serum triglyceride level in the fenofibrate group, as compared with the placebo group, and was independent of glycemic control.<sup>189</sup>

## Surgical Approaches

Vitreotomy with or without peeling of the posterior hyaloid membrane may be beneficial for the treatment of DME in eyes with

vitreomacular traction that are resistant to laser photocoagulation and/or steroid injection.

There is clinical evidence that traction forces at the vitreoretinal interface may play an important role in the pathogenesis of macular edema. Several authors have studied vitrectomy for persistent macular edema and have suggested that release of the tractional forces at the vitreomacular interface may improve resolution of the macular edema and restore visual acuity ([Fig. 30.18](#)).

**FIG. 30.18** Type 1 diabetic patient, 38 years old, HbA1c 6.5, previous mild proliferative retinopathy. Epiretinal membrane with macular edema. Epiretinal membrane on the horizontal scan with macular edema. After removal of the epiretinal traction, persistent edema which was nonresponsive to injections with ranibizumab.

Although pars plana vitrectomy may be considered as a very simple surgical procedure, its manifold effects on a cellular level are becoming better understood.<sup>2</sup>

The initial rationale for using vitrectomy in cases of macular edema was entirely structural, i.e., aimed at the removal of vitreous traction on the macula.<sup>65,190</sup> The effect of traction on retinal structures becomes more understandable using Newton's third law: to any action there is always an equal reaction in the opposite direction. The force of vitreoretinal traction will thus be met by an equal and opposite force in the retina, resulting in the retinal tissues being pulled apart. Eventually this results in the lowering of the tissue pressure within the retina, which in turn increases the difference between the hydrostatic pressure in the blood vessels and the tissue and contributes thus to edema formation (Starling's law). Releasing the traction will increase tissue pressure and lower the hydrostatic pressure gradient, reducing the water flux from blood vessels into retinal tissue.<sup>1</sup>

Vitreoretinal traction associated with macular edema has been identified in diabetic retinopathy, following complicated cataract surgery (Irvine–Gass syndrome), and in several other disease entities. The removal of such traction by vitreoretinal surgery has been found to be beneficial.<sup>65,190,191</sup> Peeling of the ILM of the retina ensures complete release of tractional forces, removes a potential diffusional barrier, and inhibits re proliferation of fibrous astrocytes.<sup>192</sup> The rationale for vitrectomy (removal of the hyaloid) plus peeling of the ILM is the postulated improvement of fluid diffusion from the retina to the vitreous cavity.

To evaluate the effect of ILM peeling on the long-term visual outcomes in eyes with diffuse, nontractional DME, 116 eyes of 58 patients were randomized to either ILM peeling or vitrectomy without peeling (fellow eye). Differences in BCVA between the two groups were not significant at any time point. Thus, ILM peeling does not affect the postoperative vision significantly, while vitrectomy alone seems to be beneficial.<sup>193</sup>

The beneficial effect of vitrectomy is thought to be based – at least in part – on two mechanisms. Firstly, it has been found, for example, that oxygen transport between the anterior and posterior segments of the eye is increased in the vitrectomized-lensectomized

eyes.<sup>194,195</sup> Others have shown that pharmacologic vitreolysis also improves oxygen diffusion within the vitreous cavity.<sup>196</sup> This means that following vitrectomy and/or posterior vitreous detachment, the transport of molecules to and from the retina is increased.

Secondly, it has been shown that several growth factors such as VEGF, IL-6, platelet-derived growth factor, and others are secreted in large amounts into the vitreous during proliferative vasculopathies such as diabetic retinopathy or retinal vein occlusion,<sup>197,198</sup> and it is conceivable that a complete vitrectomy will remove this excess of growth factors mechanically with the desired effect of a restitution of the BRB. The rapid clearance of VEGF and other cytokines may thus help to prevent macular edema and retinal neovascularization in ischemic retinopathies, such as diabetic retinopathy and retinal vein occlusions. Vitreous clearance of growth factors may indeed have the same effect as the presence of, for example, VEGF antibodies in the vitreous cavity.<sup>1,199,200</sup> This part of the effect will be only temporary as those growth factors would be released again as a result of the disease into the vitreous fluid.

## Discussion and Conclusion

In DME, with anti-VEGF intravitreal injections clinically relevant visual acuity improvements (of 10 ETDRS letters or more) are likely to be achieved, at best, in 50–60% of patients and long-term treatment is required. This is similar in the case of RVO. Steroids are less than ideal given their side-effects. Therefore, there is an obvious need for the development of more effective and targeted treatments that can be satisfied only by a better understanding of the pathophysiology of macular edema. There is a need to determine which core outcome measures should be used, both in clinical trials determining the clinical effectiveness and cost-effectiveness of new treatments for macular edema and in clinical practice. Furthermore, clinically feasible retreatment criteria need to be determined.

Ischemic maculopathy remains untreatable. A foveal avascular zone of more than 500  $\mu\text{m}$  should be considered ischemic. The value of current treatments for ischemic maculopathy is uncertain.

Early intervention in macular edema is undoubtedly advantageous, as the risk of ultrastructural alterations induced by a persistent macular edema increases with time. To date, however, most surgical approaches (except in patients with tractional membranes) will only be considered for persistent macular edema that is not responsive to laser treatment or pharmacologic approaches. Earlier intervention could be possibly more advantageous.

The different treatment approaches are likely to affect the clinical course of macular edema at variable time points and for different time periods. While the effect of intravitreal steroids is known to wear off with time, this may be also the case for other treatments. Any therapeutic approach should be evaluated for the duration of its anticipated beneficial effect and beyond. As macular edema requiring treatment appears to be mostly chronic, a follow-up period of one year is unlikely to suffice. It is unlikely that one treatment will fit all patients, even with the same condition. Recognizing patients' characteristics that may predict who will respond to which treatment is essential: i.e., a stratified system medicine approach is required.

## Introduction

In rhegmatogenous retinal detachment (RRD) the separation of the neural retina from the retinal pigment epithelium (RPE) initiates a complex series of cellular and molecular changes.<sup>1</sup> Left untreated, RRD results in permanent visual loss; however, early intervention may be associated with good visual outcomes, suggesting that some of these molecular changes may be arrested or reversed.<sup>2,3</sup>

By studying the cellular and molecular changes that occur after detachment and/or reattachment, clinicians may gain a more precise understanding of the degenerative processes within the retina that lead to visual impairment and the mechanisms underlying the serious complications of detachment, such as proliferative vitreoretinopathy (PVR). In addition, these insights may aid the development of future treatment strategies and adjunctive therapies aimed at improving visual outcomes.

This chapter reviews the many changes that occur in retinal cells following RRD and the ensuing process of morphologic recovery following reattachment, as revealed by human case series and studies of experimental retinal detachment and reattachment in animal models.

## Use and Limitations of Animal Models in the Study of Retinal Detachment

Human studies of cellular changes following acute RRD are limited to isolated case reports as surgical management does not routinely involve removal of retinal tissue. More recently data have become available from patients undergoing macular translocation surgery in which the retina is detached as part of the procedure, allowing sampling of the retina as early as 1 hour following detachment.<sup>4</sup> In patients with advanced stages of RRD and PVR, surgical management may involve excising areas of scarred retinal tissue, allowing histopathologic analysis. However, the data from human studies is still limited by small numbers, the challenges of sampling and analyzing small retinal specimens, and an inability to study cellular recovery following reattachment.<sup>4-7</sup>

This difficulty in obtaining retinal tissue from patients with RRD has led to the use of animal models. Animal models have been developed in a variety of mammalian species from rodents to primates, most commonly in rabbits and cats, and more recently in mice. The feline retina is rod-dominant, and has an intraretinal circulation that is excluded from the photoreceptor layer and a choroidal circulation that supplies the photoreceptor layer. The rabbit retina is also rod-dominant but has no intraretinal vasculature, with the inner retina being supplied by vessels that lie on the vitreal surface. The rabbit retina has proved to be a more difficult animal model in long-term experiments because the retina tends to degenerate very rapidly following detachment; for short-term studies, however, (i.e., 3–7 days) rabbits continue to be a valuable model.

Ideally the characteristics of an experimental detachment should closely mimic those found in humans while allowing for precise control over the extent of separation between the two layers (detachment height), the location of the detachment, its surface area, and the onset of detachment (or reattachment) time. A number of methods have been used to simulate human RRD in animal models. These range from creating large retinal tears to subretinal injections of fluid or viscous substances. Experiments where retinal detachment induction is standardized with a micropipette provide a controlled environment for analysis; however, they differ from the clinical pattern of events in which acute retinal tears of variable size are induced by vitreoretinal traction at the time of posterior

vitreous detachment. It is possible that retinal tearing may act as a more potent stimulus for cellular disorganization, loss, and remodeling, leading more rapidly to the advanced pathology usually seen following longer periods of retinal detachment in animal models. Although experiments involving animal models may differ in methodology, species used, and outcome measures, they have yielded similar results to give a relatively detailed profile of the changes that occur after detachment. Retinal tissue removed from human postmortem specimens and from patients undergoing retinal detachment surgery has demonstrated changes similar to those seen in animal models.<sup>6-8</sup>

Animal models have proved invaluable in providing insight into the regenerative capacity of photoreceptor cells and the ability of reattachment to slow, stop, or reverse changes induced by detachment. They also continue to provide opportunities to test adjunctive agents targeting neuroprotection and wound healing before progressing to human surgical trials. Further, in mouse models the large variety of genetic mutations that exist provides additional scope to the study of retinal detachment and potential gene therapies.

## Cellular Changes in Response to Retinal Detachment

Descriptions of the cellular response to RRD are frequently divided into those observed in the early stages of retinal detachment and those observed in more chronic cases and in PVR. There is, however, a continuous progression of pathologic change.

### Acute Retinal Detachment

Acute RRD, i.e., changes occurring within the first 3 days, has been extensively documented.

A rapid response to retinal detachment has been shown to occur within 15 minutes, including phosphorylation of fibroblast growth factor receptor (FGFR-1) and increased expression by RPE and Müller cells of extracellular signal-regulated kinase and activator

protein transcription factor.<sup>9</sup> This initiates a cascade of events that leads to a number of molecular and cellular changes within the retina and RPE.

## **RPE–Photoreceptor Interface**

The earliest structural effects of retinal detachment are seen at the interface of photoreceptor outer segments and the RPE.<sup>10</sup> The mature RPE is a polarized monolayer of neuroepithelial cells that rests on Bruch's membrane, between the choriocapillaris and the neural retina.<sup>11</sup> The relationship of the apical surface of the RPE to differentiated photoreceptors is anatomically complex. There are no actual cellular junctions between the two layers in the mature eye, but the two are adherent, with the degree of adhesion varying among species.<sup>12</sup> With the onset of retinal detachment changes to this interface include alterations in the RPE apical surface, proliferation of RPE cells, migration of cells into the subretinal space, degeneration of photoreceptor outer segments, and changes in photoreceptor outer-segment renewal.<sup>1</sup>

Within a few hours of retinal detachment, the long and elaborate sheet-like and villous processes that normally ensheath the outer segments are lost and replaced by a “fringe” of short microvilli (Fig. 31.1).<sup>13</sup> At the same time, the overall surface morphology of the RPE cells changes into a rounded contour, as cytoplasm protrudes past the normal limits of the apical surface into the subretinal space, and the nucleus becomes displaced to a more apical position<sup>10,14</sup> (Fig. 31.2).

**FIG. 31.1** Electron micrograph of the retinal pigment epithelium (RPE) 1 day after production of a retinal detachment. Compared with normal RPE cells, the apical surface is mounded. The sheet-like apical projections that normally ensheath the outer segments have been replaced by a homogeneous fringe of short, microvillous processes (*MV*). In this particular cell, the nucleus (*N*) is displaced into the mounded region. The cells' lateral junctions are indicated by arrows. *SRS*, subretinal space. (Reproduced with permission from Anderson DH, Stern

WH, Fisher SK, et al. Retinal detachment in the cat: The pigment epithelial–photoreceptor interface. *Invest Ophthalmol Vis Sci* 1983;24:909.)

**FIG. 31.2** Scanning electron micrograph of the apical surface of the retinal pigment epithelium 6 weeks after production of an experimental detachment, demonstrating the pronounced mounding response of the epithelial cells. (Reproduced with permission from Anderson DH, Stern WH, Fisher SK, et al. Retinal detachment in the cat: The pigment epithelial–photoreceptor interface. *Invest Ophthalmol Vis Sci* 1983;24:910.)

In the feline model, experiments using  $^3\text{H}$ -thymidine have shown that within 72 hours of retinal detachment the RPE has begun to proliferate and may be observed as areas of hyperplasia within the RPE monolayer.<sup>10</sup> This proliferative response transforms the RPE's uniform monolayer into a heterogeneous morphology in which strands of cells extend from the original monolayer into the subretinal space or result in the formation of multiple layers of cells whose polarity does not necessarily match that of the original monolayer (Fig. 31.3). This effect is limited to the region of detachment; in attached regions the RPE remains mitotically quiet, suggesting that attachment to the neural retina acts to keep the RPE mitotically inactive and its apical surface highly differentiated.<sup>15–17</sup> The proliferative response of the RPE cells also appears to be self-limiting with only low levels of proliferation observed after long detachment intervals (e.g., 12–14 months) in owl, monkey, and cat retinas<sup>10,16</sup> (Box 31.1 and Fig. 31.4).

**FIG. 31.3** Light micrograph of an area of retinal pigment epithelium (RPE) cell proliferation in a cat retina detached for 14 days and reattached for 30 days. Three layers of RPE cells are present (*L1–L3*), each displaying different surface polarity. The apical surfaces of L1 and L2 face each other, as do the basal surfaces of L2 and L3. The basal lamina of L2 is clearly evident (*arrow*). Only outer-segment fragments (*asterisk*) appear near the inner segment (*IS*) tips ( $\times 800$ ). *ONL*, outer nuclear layer. (Reproduced with permission from Anderson DH, Guerin CJ, Erickson PA, et al. Morphological recovery in the reattached retina. *Invest Ophthalmol Vis Sci* 1986;27:174.)

### Box 31.1

## Clinical Correlates

Retinal pigment epithelial (RPE) proliferation can be seen as subretinal pigment deposition in chronic retinal detachments. It is likely that the demarcation lines noted in human retinal detachments represent zones of proliferated RPE occurring at transitions between detached and attached regions of the eye (Fig. 31.4).

**FIG. 31.4** Color fundus photograph of a chronic retinal detachment with a pigmented demarcation line indicating the interface between attached and detached retina.

The subretinal space is usually free of cells; however within 24 hours of retinal detachment a number of cell types (polymorphonuclear neutrophils, monocytes, and macrophages) migrate into this space from the choroidal and retinal capillaries.<sup>10,18</sup> Free RPE cells are also seen in the subretinal space within 72 hours of retinal detachment and frequently contain outer-segment fragments, indicating that they may play a role in phagocytosis of cellular debris.<sup>10,18</sup>

## Photoreceptors

Within 12 hours of experimental retinal detachment, photoreceptor outer segments show evidence of structural damage. Initially, the distal end of the outer segment becomes vacuolated or distorted, and by 24–72 hours, all rod and cone outer segments are significantly shorter and distorted with disoriented discs.<sup>19</sup> The degeneration of outer segments may proceed until those in the zone of detachment appear only as empty sacs of membrane attached to the connecting cilium.<sup>10</sup>

Outer-segment debris is shed into the subretinal space where it is phagocytosed by RPE cells and macrophages that have migrated into the area.<sup>10,18</sup>

Although retinal detachment interrupts the process of disc production and shedding, outer-segment-specific proteins continue

to be produced but localize to abnormal cellular locations. Opsin, normally concentrated in the outer segment, begins to accumulate in the plasma membrane vitread to the outer segment within a day following experimental retinal detachment (Fig. 31.5).<sup>19</sup> Peripherin/rds, another outer-segment protein specific to the disc rims, is also redistributed and begins to appear in cytoplasmic vesicles.<sup>20</sup> Cone outer-segment proteins appear to be more susceptible to damage, with redistributed cone opsins persisting for just 1 week following retinal detachment, after which their expression is downregulated.<sup>21</sup>

**FIG. 31.5** Laser scanning confocal images of normal (A), 7-day (B), and 28-day (C) cat retinas, as well as a human detached retina (D), labeled with isolectin B4 (green), antiglial fibrillary acidic protein (anti-GFAP)

(blue), and antirod opsin (red). In the normal retina, isolectin B4 labels microglia in the inner plexiform layer (*IPL*) (and blood vessels), anti-GFAP labels astrocytes and Müller cell endfeet, and antirod opsin labels rod outer segments (*OS*) (A). Following 7 days of detachment isolectin B4 labeling illustrates an overall increase in the number of microglia and their presence in the outer retina, rod opsin becomes mislocalized to the photoreceptor cell bodies, and GFAP increases in Müller cells (B). At 28 days numerous microglia can be observed throughout the retina, photoreceptor cell bodies are extruded out of the retina, and Müller cell processes extend into the subretinal space (C). A similar pattern of increased numbers of microglia, rod opsin mislocalization, and increased GFAP labeling is observed in human detached retinas (D). Note rod axons extending into the inner retina in (D), a common phenomenon in cat retinas following detachment and reattachment. *GCL*, ganglion cell layer; *INL*, inner nuclear layer; *ONL*, outer nuclear layer.

During the first day of a detachment, the inner segments appear essentially normal, but between the first and third days, they begin to show signs of degeneration: most commonly swelling, disruption, and loss of mitochondria (and loss of anticytochrome oxidase labeling) in the ellipsoid region,<sup>2,22</sup> an overall disruption of the organized rough endoplasmic reticulum and Golgi apparatus in the myoid region, and, within a few days, an overall size reduction of the inner segment. It is interesting to note that the connecting cilium, which is essential for production of the outer segment, is retained even in severely affected inner segments in long-term detachments. This is crucial as its loss would prevent regeneration of outer segments following reattachment. Similarly, the loss of mitochondria also has the potential to affect the photoreceptors' ability to regenerate significantly, because the metabolic rate in these cells is among the highest of any in the body.

The outer nuclear layer contains the cell bodies of the photoreceptor cells. These cell bodies extend a process toward the outer plexiform layer, where they form synapses with second-order neurons. Rods and cones have characteristic synaptic terminals called spherules and pedicles respectively.<sup>23</sup> The outer plexiform

layer also contains the processes of second-order neurons, the cell bodies of which lie in the inner nuclear layer. These processes synapse with each other and with the photoreceptors. The photoreceptor cell bodies and synaptic terminals show a rapid response to detachment with extensive vacuolization, degeneration of mitochondria, and disorganization of the microtubules and actin filaments. Cell death via the apoptotic pathway peaks at day 3 following retinal detachment but continues at low levels for as long as the retina is detached. Photoreceptor death has been shown to differ significantly in different mouse strains, suggesting that genetic factors also play a role in cellular response to retinal detachment.<sup>24</sup> Photoreceptor apoptosis appears to be mediated via caspases 3, 7, and 9.<sup>25,26</sup> Recent studies have shown that, when caspase pathways are blocked, receptor interacting protein (RIP) kinases promote necrosis and overcome apoptosis inhibition. Therefore, targeting of both caspase and RIP kinase pathways is required for effective photoreceptor protection<sup>27</sup> (Box 31.2).

## Clinical Correlates

More recently, photoreceptor apoptosis has also been demonstrated in human retinal specimens, with a peak at day 2 following RRD.<sup>28</sup> Ethnic variations in severity of retinal detachment have been demonstrated and may also reflect genetic differences in cellular response to injury.<sup>29</sup>

Following cell death, some photoreceptors are extruded into the subretinal space where they are phagocytosed by macrophages while others appear to undergo degeneration and phagocytosis within the outer nuclear layer.<sup>30</sup>

Not all photoreceptors degenerate at the same rate; areas of extensive degeneration coexist with areas of relatively intact photoreceptors.<sup>19</sup> Rod cell bodies appear to degenerate quicker than cones following retinal detachment.<sup>21</sup> In a region in which nearly all of the rod cell bodies show signs of degeneration and even cell death, neighboring cone cell bodies may look relatively intact. Consistent with this observation, the rod spherules appear to be particularly susceptible to the effects of detachment. These synaptic terminals are normally filled with synaptic vesicles and contain one

or two large presynaptic ribbons. When the retina has been detached for 3 days, many of these terminals appear depleted of vesicles, except for a few that remain as a halo around a greatly truncated or fragmented ribbon.<sup>31</sup> Many terminals appear as if they have “retracted” into the cell body, and some synaptic structures generally associated with the outer plexiform layer now occur within the outer nuclear layer (Fig. 31.6).<sup>31,32</sup> As with the cone and rod photoreceptor cell bodies, the cone synaptic terminals seem to survive the early effects of detachment better than the rod terminals do. Although their shape can change fairly dramatically, they do not appear to retract and by electron microscopy they remain filled with synaptic vesicles.<sup>32,33</sup>

**FIG. 31.6** Laser scanning confocal images of normal (A) and 28-day detached (B) cat retinas labeled with antisynaptophysin (green), anti-protein kinase C (anti-PKC) (red), and antineurofilament (blue). In the normal retina, antisynaptophysin labels synaptic vesicles in the rod and cone terminals in the outer plexiform layer as well as synaptic terminals in the inner plexiform layer, anti-PKC labels rod bipolar cells, and antineurofilament labels ganglion cell axons and horizontal cell processes (A). After detachment, rod terminals retract into the outer nuclear layer (ONL), as evidenced by the synaptophysin labeling, the dendrites of rod bipolar cells extend into the ONL, while horizontal cell processes grow through the ONL into

the subretinal space (B). Neurofilament labeling also increases in some ganglion cell bodies (B). *GCL*, ganglion cell layer; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *OPL*, outer plexiform layer.

## Second-Order Neurons and Nonneuronal Cell Types

At the same time as rod spherules are retracting, processes from the rod bipolar cells and horizontal cells (labeled with antibodies to protein kinase C, and neurofilament protein, respectively) appear to retract from the rod spherules and then begin to grow beyond the normal layer of photoreceptor synaptic terminals, into the outer nuclear layer and even beyond, sometimes extending into the subretinal space (Fig. 31.7).<sup>32</sup>

**FIG. 31.7** Laser scanning confocal images illustrating the neurite sprouting of second- and third-order neurons as well as the formation of sub- and epiretinal Müller cell scars in the feline retina following a 28-day detachment. (A) An antibody to neurofilament protein (red) labels ganglion cell bodies in the ganglion cell layer (GCL) and neurites from ganglion cells within an epiretinal membrane (*arrowheads*) as well as horizontal cell bodies and neurites from these cells

extending through the outer nuclear layer (*ONL*) into a subretinal glial scar (green; *arrows*). An antibody to glial fibrillary acidic protein (GFAP; green) labels intermediate filaments in Müller cells throughout the retina as well as those in the subretinal (*arrow* in panel B) and epiretinal membranes. (B,C) An antibody to GAP 43 (red) labels activated ganglion cell bodies (*asterisks* in panels C and D), dendrites in the inner plexiform layer, and neurites that extend through the retina into subretinal (green; *arrow* in panel B) and epiretinal (*arrowheads* in panel C) glial scars. An antibody to GFAP (green) labels intermediate filaments in Müller cells throughout the retina and in the subretinal scar. (D) An antibody to neurofilament protein (red) labels an activated ganglion cell (*asterisk*) and newly formed neurites extending from the base of its cell body (*arrowheads*). An antibody to synaptophysin (green) labels synaptic terminals in the outer and inner plexiform layers. (E) An antibody to neurofilament protein (red) labels horizontal cell neurites within a glial scar (green; labeled with anti-GFAP) in the subretinal space in a retinal flat-mount preparation. “ToPro” labeling (blue) shows the presence of photoreceptor nuclei just below the glial scar. (Panel B reproduced with permission from Lewis GP, Fisher SK.

Upregulation of glial fibrillary acidic protein in response to retinal injury: its potential role in glial remodelling and a comparison of vimentin expression. *Int Rev Cytol* 2003;230:263.)

Just as changes in the synaptic terminals are accompanied by the growth of processes from the rod bipolar cells and horizontal cells into the outer nuclear layer,<sup>31,32</sup> ganglion cells also become reactive and begin to reexpress growth-associated protein (GAP)-43, a protein expressed early in cell body development for the formation of synaptic connections between ganglion cell axons and the brain.<sup>34</sup> As in the case of horizontal cells, ganglion cells show dramatic and extensive remodeling, growing processes that appear to be attracted to Müller cells.<sup>35</sup> By contrast, rod bipolar cell dendrite growth is less aggressive, being targeted towards the retracted terminals of the rod photoreceptors.

Within 24 hours of retinal detachment nonneuronal cell types, for example, astrocytes, Müller cells, pericytes, capillary endothelial

cells, and microglia, also display signs of proliferation.<sup>16,17</sup> By 2 days, some labeled Müller cell nuclei are translocated from their normal positions on the vitreal border of the inner nuclear layer into the outer plexiform and outer nuclear layers (Fig. 31.8).<sup>36</sup> The proliferative response peaks 3–4 days after detachment and declines slowly to very low levels several weeks later. Microglia, a form of macrophage in the central nervous system that usually lie dormant in the retina, are activated and begin to divide and migrate to the outer retina (see Fig. 31.5). Microglial proliferation is observed to differing degrees in different species and is thought to play a role in photoreceptor cell death, possibly by modifying the production of neuroprotective trophic factors by Müller cells.<sup>30</sup>

**FIG. 31.8** Laser scanning confocal images of rabbit retinas detached for 3 days (A) and 7 days (B), and immunolabeled with antivimentin (green) and anti-BrdU (red). An intravitreal injection of bromodeoxyuridine (BrdU) was given on day 3, and the animals were euthanized either 4 hours later or 4 days later on day 7. BrdU labeling is present in Müller cell nuclei in the inner nuclear layer on day 3, after which they migrate to the outer retina and contribute to the formation of subretinal scars (*brackets*) at day 7 (B). *GCL*, ganglion cell layer; *INL*, inner nuclear layer; *ONL*, outer nuclear layer.

Changes in the Müller cell are seen within 1 day of retinal detachment, including changes in protein expression and early growth of their processes.<sup>37</sup> Within 3 days Müller cell bodies have migrated to the outer nuclear and outer plexiform layers (Fig. 31.9)

and processes begin to extend into the subretinal space through localized disruptions in the outer limiting membrane. Müller cell processes within the feline retina express both vimentin and glial fibrillary acidic protein (GFAP); however, segments of the processes extending through the outer limiting membrane into the subretinal space preferentially express vimentin (Fig. 31.10).<sup>37</sup> These processes appear to penetrate the outer limiting membrane preferentially adjacent to cone photoreceptors, often growing for long distances on the photoreceptor border.<sup>37</sup> Müller cells stimulated to divide on day 3 appear to ultimately contribute to the formation of subretinal scars.<sup>36</sup>

**FIG. 31.9** Laser scanning confocal images of normal (A) and 3-day detached (B) rat retinas immunolabeled with antiglial fibrillary acidic protein (GFAP) (blue), antivimentin (green), and antinestin (red). In the normal retina GFAP is present only in the astrocytes and vimentin is present only in Müller cells; no nestin labeling is apparent. After retinal detachment, there is a dramatic upregulation of all three proteins. They are expressed throughout the Müller cells' cytoplasm but at different levels, giving the “rainbow” appearance of the labeling. *GCL*, ganglion cell layer; *INL*, inner nuclear layer; *ONL*, outer nuclear layer.

**FIG. 31.10** Laser scanning confocal images illustrating the early stages of Müller cell growth on to the subretinal and epiretinal surfaces of the feline retina. (A) Antibodies to glial fibrillary acidic protein (GFAP) (green) and vimentin (red) label intermediate filaments within Müller cells throughout the retina. The red process (*arrow*) in the outer nuclear layer is labeled predominantly with the antibody to vimentin and represents a Müller cell that is just beginning to extend into the subretinal space. (B) A flat-mounted preparation, viewed from the photoreceptor surface and labeled with antibodies to GFAP (green) and vimentin (red). It shows the predominance of vimentin in a Müller cell process in the very early stages of extending into the subretinal space. (C) An antibody to GFAP (green) labels a Müller cell process just entering the subretinal space. An antibody to CD44 (red) labels fine filopodia on this process as well as the Müller cell microvilli (*MV*). (D) An antibody to GFAP (green) labels

a Müller cell's process entering the subretinal space (*arrow*) directly adjacent to a peanut agglutinin-labeled cone photoreceptor (red). (E) A flat-mounted preparation, viewed from the vitreal side of the retina, labeled with antibodies to GFAP (green) and vimentin (red). It shows a predominantly GFAP-labeled Müller cell process in the earliest stage of extending on to the vitreal surface of the retina. (The vimentin labeling in the background is in the Müller cells' endfeet.) *ONL*, outer nuclear layer. (Reproduced with permission from Lewis GP, Fisher SK. Up-regulation of glial fibrillary acidic protein in response to retinal injury: its potential role in glial remodeling and a comparison to vimentin expression. *Int Rev Cytol* 2003;230:263. Copyright 2003, with permission from Elsevier.)

Astrocytes, the other glial cell type in the retina, also undergo their own remodeling response following retinal detachment, albeit less prominent than Müller cells. This is more readily seen in the mouse retina, where the Müller cell response does not overwhelm that of the astrocytes as it can in the feline or human retina. Indeed, astrocyte processes become highly jagged and irregular after detachment compared to those in normal retina.<sup>38</sup> While the processes do not appear to grow laterally across the retina in the mouse retina, they can often be observed extending deep into the inner retina, often along blood vessels (Fig. 31.11).

**FIG. 31.11** Laser scanning confocal images illustrating astrocytes in a mouse retina (wholemound orientation). (A) Normal mouse retina showing relationship between

astrocytes (red; anti-GFAP) and retinal blood vessels (green; collagen IV). (B) Following 5 weeks of retinal detachment the astrocytes (red; anti-GFAP) appear more irregular and jagged compared with normal retina.

A number of pharmacologic agents, working through different mechanisms, have been shown to slow cell proliferation and glial scar formation following experimental RRD. These therapies include alkylphosphocholines,<sup>39</sup> an inhibitor of the Akt/mTOR pathway,<sup>40</sup> anti-VEGF agents such as ranibizumab,<sup>41</sup> and an inhibitor of the alpha5Beta1-fibronectin interactions.<sup>42</sup> At present these have not been used outside animal models.

## Chronic Retinal Detachment and Proliferative Vitreoretinopathy

Although animal models remain the main source of data regarding more long-term neuronal remodeling following RRD, human studies of retinectomy specimens removed at the time of surgery also exist.<sup>6</sup> These studies show close correlation with results from feline and primate models.

### Photoreceptors

The degree of photoreceptor cell death and its timing are species-dependent. In the feline model, there is a significant decrease in the number of photoreceptor cells by 1 month after detachment, and this number continues to decline until the outer nuclear layer loses about 80% of its cell population by 90 days after detachment.<sup>19</sup> In regions severely affected by photoreceptor degeneration, the outer nuclear layer can be reduced in thickness to one or two cell layers. In humans, a histopathologic study by Wilson and Green of retinal detachment in postmortem eyes also showed atrophy of the photoreceptor layer in 26.5% of retinas examined<sup>17</sup> (Box 31.3).

### Clinical Correlates

Cell death in the photoreceptor cell layer is likely to be a significant factor in visual recovery after reattachment, particularly in

detachments of more than a few days' duration. Finding a strategy for preserving photoreceptors may lead to an improvement of the visual outcome after reattachment surgery. A number of factors have been successful at reducing cell death in animal models including brain-derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF), and basic fibroblast growth factors (FGF-1, FGF-2), the free radical scavenger edaravone, the antibiotic minocycline, and the Fas receptor inhibitor MET12.<sup>43-49</sup> Increasing the concentration of environmental oxygen breathed has also yielded positive results.<sup>22,50</sup>

The loss of cells from the photoreceptor layer occurs by cell death and the extrusion of photoreceptor cell bodies past the outer limiting membrane into the subretinal space. Photoreceptor cell death by apoptosis and necrosis<sup>25,27,51,52</sup> has also been documented in human studies.<sup>8,53,54</sup> The mechanism by which cells are extruded into the subretinal space is not understood, but they have clearly lost their differentiated phenotype, appearing as rounded cells with very little cytoplasm. With increasing chronicity of retinal detachment, disorganized lamellar debris rather than discrete packets of outer-segment discs are found in the subretinal space, providing additional evidence that discs are not shed and phagocytosed in the normal manner.

## Second-Order Neurons and Nonneuronal Cell Types

Beyond 3 days of detachment, Müller cell processes often extend into the subretinal space through localized disruptions in the outer limiting membrane. These processes become more commonplace and elaborate as detachment time lengthens. Immunocytochemical labeling and confocal imaging studies demonstrate their unique nature. In felines, Müller cell processes within the retina that preferentially express vimentin in the outer portion of the cell grow into the subretinal space.<sup>37</sup> At the presumed earliest stage of their growth, the vimentin-expressing processes beyond the outer limiting membrane assume the appearance of filopodia while retaining their preferential expression of vimentin over GFAP.

Microvilli normally extend from the apical surface of the Müller cells, just beyond the outer limiting membrane. These processes are richly decorated with the protein CD-44. As the Müller cell filopodia intrude into the subretinal space, their surface remains decorated with “microspikes” of CD-44. The presence of CD-44 on the apical microvilli and subretinal outgrowths may provide for sites of molecular interaction between the growing processes and components of the subretinal space, perhaps providing some clue to their preference for growing adjacent to cone photoreceptors.<sup>55</sup> These Müller cell processes can grow for long distances on the photoreceptor border, often forming a multilayered “glial scar” **Box 31.4** in the subretinal space (see [Fig. 31.5C](#) and [Box 31.4](#)).

### Clinical Correlates

Subretinal Müller cell processes are responsible for the formation of subretinal membranes often seen in patients with chronic retinal detachment and proliferative vitreoretinopathy. These may subsequently inhibit photoreceptor recovery and limit visual acuity. Subretinal membranes may also cause visual distortion by preventing proper flattening of the retina or by disturbing the contour of the overlying retina. Clinically, subretinal membranes differ in nature to those seen on the retinal surface, and this may be partly explained by the different expression of proteins on their surface.

In a study of 16 retinectomy specimens taken from patients with PVR, Sethi et al. demonstrated that the response to prolonged RRD with PVR in humans was similar to that observed in chronic detachment in animal models.<sup>6</sup> In humans, as in animal models, photoreceptors were degenerate and intracellular redistribution of opsin proteins to the plasma membrane was observed. In cones, labeling with anti-M/L cone opsin showed degenerate outer segments and faint staining of swollen inner segments and, in severe PVR, staining of cone opsins was absent. Rod synaptic terminals showed remodeling with extension of rod bipolar cell dendrites and horizontal cell processes into the outer nuclear layer. There was also upregulation of neurofilament and GAP-43 expression in large ganglion cells with neurite sprouting. All

retinectomy specimens showed a marked upregulation of Müller cell and astrocyte expression of GFAP and vimentin, with areas of increased glial tissue replacing degenerated retinal neurons (Fig. 31.12).<sup>6</sup> In some sections Müller cells, together with microglia, breached the inner limiting membrane and extended onto the retinal surface where they formed one of the components of an epiretinal membrane (see Fig. 31.5D). Müller cell processes also formed confluent subretinal membranes (Fig. 31.12). Ongoing photoreceptor apoptosis has also been demonstrated in human PVR.<sup>54</sup>

**FIG. 31.12** Laser scanning confocal images of human retinas that had been previously reattached, illustrating similar responses to detachment as those observed in the feline model. (A) Rod axons (*arrows*; red; antirod

opsin) extend into the inner retina, and Müller cells upregulate their expression of glial fibrillary acidic protein (*GFAP*) (green). (B) Synaptic terminals (green “dots”; antisynaptophysin) become scattered within the outer nuclear layer (*ONL*), indicating the presence of retracted rod terminals, while the green “dots” in the inner nuclear layer (*INL*) represent terminals of “overgrown” rod axons. (C) Müller cells (green; anti-*GFAP*) grow on to the subretinal surface (*arrow*) and on to the vitreal surface (*asterisk*). In the absence of outer segments, antirod opsin (red) labels rod cell bodies. (D) Müller cell outgrowths (green; anti-*GFAP*) grow beyond the inner limiting membrane to form an epiretinal membrane on the vitreal surface of the retina (*asterisk*). *GCL*, ganglion cell layer. (Panels C and D reproduced with permission from Sethi CS, Lewis GP, Fisher SK. Glial remodelling and neuronal plasticity in human retinal detachment with proliferative vitreoretinopathy. *Invest Ophthalmol Vis Sci* 2005;46:329–42.)

## Retinal Reattachment

Clinical evidence shows that retinal reattachment is associated with good visual outcomes, particularly if the macula is rapidly reattached, and that visual recovery may continue for some time following surgery.<sup>56,57</sup> This suggests that some of the changes described above may be reversible or have little effect on visual function, when measured by Snellen acuities and patient reported outcomes.<sup>58</sup> A number of factors are associated with poor visual outcomes, including involvement of the macula, the duration and extent of the detachment, and the development of PVR.<sup>3</sup> Development of PVR is associated with a significant deterioration in visual outcomes, and this is likely to reflect more than just the length of detachment as good outcomes can still be achieved in patients who undergo multiple operations for retinal detachment with no clinical PVR.<sup>2,56</sup>

Feline models have shown that rapid retinal reattachment is associated with a good but not complete restoration of neural circuitry.<sup>2,19</sup> This has also been observed clinically in human case series, for example in patients undergoing translocation surgery:

despite only minor changes in neuronal remodeling being observed prior to reattachment, some patients still developed PVR postoperatively.<sup>4</sup> This suggests that the retina had been primed or activated by retinal detachment and that this process remained active despite subsequent rapid reattachment.<sup>4</sup> This is consistent with the observation that within 15 minutes of retinal detachment there are changes in growth factor expression that may lead to irreversible changes in cellular structure.<sup>9</sup> For example, in rabbits and cats a single intravitreal injection of 1  $\mu$ g of basic fibroblast growth factor (bFGF) leads to FGFR internalization, Müller cell proliferation, an increased expression of GFAP and vimentin, and the growth of Müller cell processes onto the vitreal surface of the retina.<sup>59,60</sup> It is possible therefore that, in some patients, the cellular events initiated by this rapid response to retinal detachment may persist despite reattachment, resulting in the development of PVR following retinal reattachment or translocation surgery.

Animal models have given us a clearer understanding of cellular recovery following retinal reattachment. In the feline model, retinal reattachment within 1–3 days is very effective at reversing the cellular changes induced by retinal detachment.<sup>2,19</sup> Retinal recovery relies on reestablishing the cell-to-cell contact of RPE cells and photoreceptors. This involves redifferentiation of the RPE apical surface, re-ensheathment of the regenerating outer segments (which differs for rods and cones), and probably synthesis of interphotoreceptor matrix components. Finally, the photoreceptors and RPE must also reestablish a functional relationship. For example, a normal balance between disc addition and disc shedding must be restored if the outer segments are going to attain normal length. Clinical evidence indicates that this process may occur over months or even years.<sup>57</sup> In addition, the transport of ions and molecules between the retina and RPE, which is affected to an unknown degree when the two cell layers are separated from each other, must also be restored. For example, retinoids (chemically distinct forms of vitamin A), coupled with their binding proteins, must be transported back and forth between the neural retina and the RPE as part of the visual cycle.<sup>61</sup>

In the feline model, retinal reattachment following a 3-day detachment results in recovery of the outer segments to

approximately 70% of their length at 28 days, arrested photoreceptor apoptosis, and a reduction in cellular proliferation.<sup>62</sup> Regenerating outer segments may appear shortened and misaligned with respect to each other and stacking of the disc membranes is often abnormal. In monkey retinas detached for 1 week, rod and cone outer segments regain approximately 30% of their normal mean length within 7 days of reattachment, 60% of their length after 30 days, and 100% by 150 days.<sup>63</sup> In the first 30-day interval, the mean disc membrane assembly rate in rods is approximately one-third slower than the normal rate. Disc shedding, on the other hand, appears to engage after the first reattachment week. Photoreceptor recovery may also be determined by the duration of retinal detachment prior to reattachment. In cat retinas detached for periods longer than 7 days, many outer segments remained shorter than normal several months after reattachment,<sup>64</sup> implying that defects in the assembly or shedding phases (or both) of the renewal process may persist well beyond 30 days of reattachment in retinas detached for longer durations. Long-term reattachment experiments are expensive because of the cost of maintaining experimental animals, but they may be highly informative given our lack of understanding of long-term recovery and indications that visual recovery may continue for a very long time after reattachment in humans.

Retinal reattachment may also stimulate the formation of scar tissue. The development of PVR following retinal reattachment surgery remains the major cause of surgical failure. In the feline model, reattachment induces growth into the vitreous of Müller cell processes, that form epiretinal membranes.<sup>19,35</sup> These have a different structure and a different intermediate filament composition compared to those that grow into the subretinal space.<sup>37</sup> The initial outgrowths into the vitreous occur as thin “wispy” extensions of the endfoot region and have an intermediate filament population that is dominated by GFAP instead of vimentin. These Müller cell processes then act as a substrate for ganglion cell neurite growth.<sup>35,65,66</sup> In humans and animal models rod axons are also stimulated to grow by retinal reattachment, and this may be seen as neurite extensions into the inner retina and beyond to the vitreal surface within epiretinal membranes (Fig.

31.13).<sup>6,19,65</sup>

**FIG. 31.13** Laser scanning confocal images of two different epiretinal membranes removed from human patients with proliferative vitreoretinopathy and immunolabeled with antineurofilament, for neurites (red) and antigial fibrillary acidic protein for glial cells (blue). Neurites were invariably observed in all membranes examined but only in regions containing glial cells.

Restoration of retinal anatomy following reattachment is not uniform. The morphologic appearance has been described as a “patchwork,” with areas of variability in outer-segment length and levels of protein expression within the same retina (Fig. 31.14).<sup>19,62</sup> There is also variability between different retinas.<sup>19,62</sup> Although this may reflect the variations in the extent (detachment height) and duration of detachment seen clinically in humans, this patchwork appearance is still observed in controlled detachment experiments. In the feline model, in areas where the apposition of the retina with the apical surface of the RPE is restored, photoreceptors are quick to regenerate. In some areas where RPE cells may have proliferated with rounded apical surfaces and/or reversal of cellular polarity, bearing little resemblance to normal RPE, photoreceptor outer-segment regeneration following retinal reattachment is far more likely to be abnormal.<sup>67</sup> In areas where photoreceptor recovery is poor, microglia remain activated, suggesting that they may play a role in modulating recovery.<sup>30</sup> Similarly, in areas where Müller cell hypertrophy has led to the formation of a subretinal scar, photoreceptors only show limited signs of recovery with no outer-

segment regeneration.

**FIG. 31.14** Laser scanning confocal images illustrating the “patchy” recovery that occurs in the feline retina following reattachment. (A–C) Retinas are labeled with biotinylated peanut agglutinin lectin (red; labels cone matrix sheaths) and anticellular retinaldehyde-binding protein (green; labels the retinal pigment epithelium [RPE]). (A) Normal, control retina. (B–D) Retinas detached for 3 days and reattached for 28 days. (B) In many areas of the reattached retina, the cone matrix sheath appears similar to that observed in normal (A) retina. (C) In some regions, however, the cone matrix sheaths appear greatly truncated. In these areas the RPE sits adjacent to the inner segments, indicating little regeneration of either rod or cone outer segments (OS). (D) When the reattached retina is labeled with antirod opsin (red), regions within the reattached area can show different levels of OS regeneration. In some regions, rod OS are quite long and there is no rod opsin labeling in the outer nuclear layer (ONL) (left half of micrograph), while in an adjacent region, rod OS are truncated and rod opsin is redistributed to the rod cell

bodies (right half of micrograph). The green in (D) represents labeling of the photoreceptor synaptic terminals with an antibody to synaptophysin. *OPL*, outer plexiform layer. (Reproduced with permission from Lewis GP, Sethi CS, Linberg KA, et al. Experimental retinal reattachment – a new perspective. *Mol Neurobiol* 2003;28:159.)

At present it seems reasonable to conclude that a return towards completely normal retinal morphology occurs gradually over a timespan of months or years, even after brief episodes of detachment.<sup>57,64</sup> Incomplete morphologic recovery may, however, be sufficient to subserve near-normal vision, although functional correlates in humans are lacking.

**Conclusion**

## **Introduction**

Retinal detachment is defined as the accumulation of fluid between the neurosensory retina (NSR) and the underlying retinal pigment epithelium (RPE) in the remnant of the embryonic optic vesicle.<sup>1</sup> The different layers involved can presently be analyzed in vivo by optical coherence tomography (OCT). Retinal pigment epithelial detachment (PED) results from a separation between the RPE basement membrane and the inner collagenous layer of Bruch's membrane.<sup>2</sup> These abnormalities imply a dysfunction of the RPE that may be caused by choroidal or retinal diseases or both. The term "central" refers to the form of the disease causing visual symptoms due to the presence of serous detachments in the macular area.

## Anatomic Constituents

### Retinal Barrier

The RPE forms the outer retinal barrier (BRB), composed of a single polarized monolayer of cells. (The inner BRB being formed of tight junctions between retinal capillary endothelial cells.) The outer BRB is located at the tight junctions between the apical lateral membranes of the RPE cells. Tight junctions are complex structures that are dynamically regulated. The integrity of the BRB is fundamentally important for the health and function of the inner and the outer retina.<sup>3</sup> It is a particularly restrictive physiologic barrier. BRB regulates the flow of nutrients, metabolic waste products, ions, proteins, the movement of solutes, and water flux between the fenestrated capillaries of the choroid and the photoreceptor layer into and out of the retina. Various mechanisms to accomplish its tasks are used including membrane pumps, transporters, and channels, transcytosis, metabolic alteration of solutes in transit, and passive but selective diffusion. The last category includes tight junctions, which regulate transepithelial diffusion through the spaces between neighboring cells.

### Bruch's Membrane

Bruch's membrane (BM) is a unique pentalaminar structure, which

is strategically located between the RPE and the choroidal capillaries. It is believed there are structural connections between the RPE and Bruch's membrane. The inner portion of Bruch's membrane is the basement membrane of the pigment epithelial cells, to which the cells adhere. Local electron-dense areas can be seen in this basement membrane, and it is thought these represent sites of insertion of collagen fibers from the inner collagenous layer of Bruch's membrane into the basement membrane. The outer limit of Bruch's membrane is the basement membrane of the choriocapillaris, the collagenous and elastic layers lying in front. BM is an elastin- and collagen-rich extracellular matrix that acts as a molecular sieve partly regulating the reciprocal exchange of products between the retina and the general circulation.

## The Choriocapillaris

The choriocapillaris is a continuous plexus of large capillaries (50  $\mu\text{m}$  in diameter) that lies in a single plane beneath the RPE. The wall of the choriocapillaris facing Bruch's membrane is fenestrated with circular openings (fenestrae) measuring approximately 800 Å. The fenestrae of the choriocapillaris are unique in that they have a diaphragm covering them, unlike those seen in the renal glomerulus.

These fenestrae allow easy movement of macromolecules into the extracapillary compartment. Fluid and macromolecules escaping from these leaky vessels percolate through Bruch's membrane and have access to the basal side of the RPE.<sup>4</sup>

## Mechanism of Normal Attachment

The RPE plays a critical role in the visual cycle and photoreceptor outer-segment phagocytosis. Furthermore, it is the main transport pathway between the inner retina and the choriocapillaris through the Müller cells.<sup>5</sup> The mechanisms by which the retina is normally maintained in apposition to the pigment epithelium, and the pigment epithelium to Bruch's membrane, have not been defined, although many factors have been identified. Mechanical and metabolic factors intervene in the attachment from the RPE to the

photoreceptors on one side and to Bruch's membrane on the other side.

## Mechanical Factors

The physiologic mechanisms of adhesion of the neural retina to the RPE are highly synergistic and complex and involve mechanical and metabolic factors.<sup>6</sup> Briefly, these include the active and passive metabolism of the RPE, the properties of the interphotoreceptor matrix (IPM), and established pressure gradients between the retina and choroid.

## Adhesion

Mechanical forces inside the subretinal space (SRS) include the matrix material between the NSR and RPE and the complex anatomic relationship with the outer segments of the photoreceptors.<sup>7</sup>

The IPM is a highly organized structure with interconnected domains surrounding cone and rod photoreceptor cells and extends throughout the subretinal space. The IPM is thought to have several prominent functions including serving as a receptor for growth factors, regulating retinoid transport, participating in cytoskeletal organization in surrounding cells, and regulation of oxygen and nutrient transport.<sup>8</sup> The IPM occupies the interface between the matrix **and** may act as a glue binding the NSR and the RPE. The IPM has structural components that remain attached to both the RPE and the cones and become apparent when the RPE is peeled off.<sup>9</sup> Cones and rods are surrounded by a specific matrix.<sup>10,11</sup> Cell adhesion molecules or receptors may be involved in this interaction between the matrix and the cellular membranes.<sup>12,13</sup>

Factors that affect the physicochemical properties of the IPM and enzymes that degrade some of its components such as proteoglycan-degrading enzymes (given intravitreally or directly into the IPM in primate eyes) weaken retinal adhesion.<sup>14</sup> Similarly, hyaluronidase and neuraminidase degrade chondroitin sulfate proteoglycan and sialoglycoconjugates, respectively. This decreased adhesion suggests that the IPM plays a role in normal retina–RPE adhesion.<sup>15</sup>

No data are available on the influence of repeated intravitreal injections of any compound on RPE and IPM adhesion and intracellular RPE transport in humans and animals.

The mechanism by which interdigitations of RPE apical villous processes and photoreceptor outer segments contribute to retinal adhesion is still not yet clear. They play a crucial role in disc phagocytosis and renewal, but their role in adhesion is uncertain.<sup>16</sup> They may provide a frictional resistance or an electrostatic force that opposes separation, but the magnitude of this is unknown.<sup>16</sup> However, three mechanisms have been proposed. These include the continuous process of phagocytosis of photoreceptor outer segments by RPE cells during which the two cells are intimately connected,<sup>17</sup> the frictional forces that result from the interdigitations, and the possible presence of electrostatic interaction between the cell membranes.<sup>18</sup>

Intercellular adhesion molecule-1 (ICAM-1) is an endothelial- and leukocyte-associated transmembrane protein long known for its importance in stabilizing cell–cell interactions and facilitating leukocyte endothelial transmigration. Upon cytokine stimulation, i.e., interleukin-1 (IL-1 $\beta$ ) and tumor necrosis factor-alpha, the concentrations of ICAM-1 greatly increase.<sup>19</sup> The role of interphotoreceptor retinoid-binding protein (IRBP)'s function in promoting Müller cell delivery and retrieval of retinols may be critical to photoreceptor and RPE function and integrity.

## **Pressure Gradient**

Passage of fluid from the vitreous, across the retina and RPE, and out of the SRS is associated with a pressure gradient from the vitreous.

Mechanical forces include active transport across the RPE, and passive hydrostatic and oncotic forces. Fluid is driven towards the choroid by active transport across the RPE and by passive hydrostatic and oncotic forces, which is blocked in the normal eye by the RPE tight junction barrier.

The high oncotic pressure in the choroid, when compared to the vitreous, maintains the necessary fluid dynamics for intact retinal attachment in causing outward movement of the water. In addition, osmolarity modifies the spontaneous resolution speed in

experimental nonrhegmatogenous retinal detachments induced by subretinal injection.

Formed vitreous acts in maintaining adhesion between the retina and RPE.<sup>20</sup> Whether the vitreous plays a direct role in retinal adhesion is yet to be determined, although some studies suggest the physical structure of the vitreous might be of importance in maintaining retinal apposition.<sup>20,21</sup>

## Metabolic Factors

Metabolic factors that affect retinal adhesion are intricate.

### Oxygenation

Retinal adhesion is markedly decreased during ischemia<sup>22,23</sup> and is restored with oxygenation.<sup>24</sup> This can either be due to the effect of released RPE lysosomal enzymes on IPM<sup>25</sup> or due to the effect of ischemia on active RPE fluid transport.<sup>26</sup> The importance of metabolic factors in retinal adhesion is also inferred from the effect of many drugs that interfere with the pH and RPE fluid transport activity.

### Water Movement

The RPE actively transports water from the SRS to the choroid. This active transport, as well as dehydrating the SRS, is a crucial factor in maintaining adhesion. RPE fluid transport is normally limited by the retina, which resists water flow from the vitreous. Fluid exits partially through the trabecular meshwork and the uveo scleral route; however, a small proportion tends to exit from the vitreous to the choroid by virtue of the intraocular and choroidal oncotic pressures.<sup>27</sup>

In addition, the high osmotic pressure in the choroid causes outward movement of water.<sup>28-30</sup> Also, the RPE is continuously moving ions toward the choroid with the associated movement of water.<sup>31</sup>

This constant water movement induces the apposition of the tissues. In human fetal (hf) RPE cells, acute exposure to interferon (IFN)- $\gamma$  increased transepithelial fluid absorption from the retinal to the choroidal side of the tissue.<sup>5</sup> In addition, the IFN-cystic fibrosis

transmembrane conductance regulator (CFTR) pathway in RPE is also activated by nitric oxide, which is continually produced in large amounts by the inner retina and perhaps by the choriocapillaris. Therefore, normal retinal metabolism helps dehydrate the SRS and maintain a close anatomic relationship between the photoreceptors and RPE.

An inward movement of fluid from the choroid into the vitreous could lead to retinal separation from the RPE because of retinal resistance to flow.<sup>32,33</sup>

## Mechanisms of Impairment

### Impairment of Water Movement

The retina will stay attached whether or not the RPE is intact, but retinal function requires the RPE barrier. Clinical serous detachments are unlikely to form solely as a result of small RPE defects or leaks, since the active and passive transport systems for removing subretinal fluid are both strong. The primary pathology in most cases of serous retinopathy is a diffuse metabolic or vascular abnormality of RPE fluid transport, and RPE defects or leaks are necessary and represent only secondary components of the disease.<sup>34</sup>

The development of a retinal PED is related to disorders in fluid outflow between the sensory retina and Bruch's membrane.<sup>35</sup> The normal nonvascular nature of Bruch's membrane is due to suppression by RPE of inward growth of choroidal blood vessels. The stimulus to change in growth factor production by RPE is unknown, but it is surmised that it may be due to lack of metabolic supply from plasma as a result of reduced diffusion of material through the thickened Bruch's membrane, or from reduced oxygen supply consequent upon changes in the choroidal capillaries.<sup>36</sup>

Detachment of the RPE is likely to be the consequence of increased resistance of Bruch's membrane to water flow. The mechanisms underlying this process are attributed to increased deposition of lipids,<sup>37</sup> enhanced collagen crosslinking, and alteration in the ratio of tissue-dissolving enzymes and their inhibitors.

In hypotony, in which it is assumed that water movement across the retina is severely reduced, clinically detectable detachment of the neuroretina from the pigment epithelium is extremely rare; it is much more characteristic under these circumstances for fluid to accumulate within the choroid.

In choroidal effusion syndrome, fluid accumulates between the choroid and the neuroretina in the absence of a retinal hole. In rhegmatogenous retinal detachment accumulation of fluid between the neuroretina and pigment epithelium is most commonly associated with retinal hole; in this instance the subretinal fluid is thought to be derived from the hyaloid cavity and to enter the SRS through the hole.

An intricate synergy of these factors is primarily responsible for maintaining retinal adhesion under normal conditions.

## Occurrence of Detachment

A serous detachment will form if there are conditions that drive fluid against the normal gradients into the SRS and that limit its subsequent removal by active and passive transport. As long as the RPE is able to pump the leaking fluid into the choroidal circulation, no fluid accumulates in the SRS and no retinal detachment occurs. However, if the process continues and the normal RPE pump activity becomes overwhelmed, or if the RPE activity decreases because of RPE loss or decreased metabolic supply (e.g., ischemia), then fluid starts to accumulate and a retinal detachment occurs.<sup>38</sup> This type of retinal detachment can be also due to accumulation of blood in the SRS (hemorrhagic retinal detachment).

A continued influx and a reduced absorptive capacity of the surrounding RPE maintain the detachment. Protein will diffuse continuously out of the SRS, and high subretinal protein content will be maintained only if there is continued entry of new fluid with protein.

Most subretinal fluid is absorbed rapidly by active transport across the RPE. However, in the presence of damage to the RPE BRB, subretinal fluid is rapidly cleared by IFN- $\gamma$  receptors localized to the basolateral membrane of human RPE which inhibit, when activated, cell proliferation and migration, decrease RPE

mitochondrial membrane potential, alter transepithelial potential and resistance, but also significantly increase transepithelial fluid absorption. In vivo experiments showed that IFN- $\gamma$  can remove extra fluid deposited in the extracellular or SRS between the retinal photoreceptors and RPE.<sup>5</sup> Removal of this extra fluid can be blocked by a combination of inhibitors injected into the SRS. In addition, the IFN-CFTR pathway in RPE is activated by nitric oxide, which is continually produced in large amounts by the inner retina and, perhaps, by the choriocapillaris. IFN- $\gamma$  regulates retinal hydration across the outer BRB, helps dehydrate the SRS, and maintains a close anatomic relationship between the photoreceptors and RPE.<sup>39</sup>

## Persistence and Resorption of Serous Detachments

When the retina separates from the RPE secondary to retinal detachment of any type, the outer retina becomes ischemic due to loss of its blood supply from the choroid. Photoreceptor cell degeneration has been shown to increase as the distance between the RPE layer and the photoreceptor layer increases. The earliest light microscopic manifestations include accumulation of subretinal fluid with loss of photoreceptor outer segments, and if the process persists, the entire photoreceptor cell layer becomes atrophic.<sup>40-42</sup>

Apoptosis appears to play an important role in the time-dependent photoreceptor cell degeneration that occurs following retinal detachment.<sup>43</sup> In cases of chronic detachment, more prominent changes occur, including cystic and macrocystic retinal degeneration, retinal thinning, RPE alterations, demarcation lines, large drusen, choroidal neovascularization (CNV) at the ora serrata, and iris neovascularization secondary to angiogenic factor elaboration by the ischemic detached retina. As the detachment is mostly centered on the macula, the foveal cones at a distance from the RPE are less likely to receive adequate oxygenation and other nutrients from the choriocapillaris. After retinal reattachment, photoreceptor atrophy in the fovea typically occurs after a long duration.<sup>44</sup>

Subretinal fluid is removed both by active transport across the

RPE and by passive hydrostatic and oncotic forces that work most effectively when the RPE barrier has been damaged. Saline subretinal fluid is removed across the RPE into the choroidal space primarily by RPE metabolic activity.<sup>45</sup> cGMP, acetazolamide, and hyperosmotic agents experimentally facilitate its resorption. Clinical retinal detachments invariably contain protein, which slows the absorption of fluid. The biochemical interplay between the RPE and the retinal photoreceptors is affected.<sup>45</sup>

Potential sources of variation in the dynamics of precipitation and resorption of subretinal lipid include the surface area of the source of leakage and its effective pore size, the surface area of the site(s) of resorption, the active fluid and salt resorption capacity of the RPE, the phagocytic activity of the RPE and infiltrating macrophages, and the degree of infiltration of phagocytic cells in the SRS.<sup>46</sup>

The effects of intraocular pressure, vitreous pressure, and gravity on the resorption of small experimental retinal detachments (blebs) made with Hanks' solution or autologous serum was shown to be limited to normal subretinal fluid absorption. Neither liquefaction of the vitreous nor intra ocular pressure has a significant influence on fluid absorption.<sup>47</sup>

## **Clinical Manifestations of PED and Serous Retinal Detachments**

Serous detachments, with elevation of the retina, occur in a variety of diseases. Regardless of the mechanism, all types of exudative or transudative retinal detachments, are characterized by fluid accumulation in the SRS, in the absence of retinal breaks or traction.

The source of the fluid is the vessels of the choroid, or *of* the retina, or *of* both. This can occur in a variety of vascular, inflammatory, or neoplastic diseases of the retina, RPE, and choroid<sup>48</sup> in which fluid leaks outside the vessels and accumulates under the retina. It is suggested that the primary pathology in most serous retinopathies is a diffuse metabolic or vascular abnormality of fluid transport, and that RPE defects or leaks are necessary but only secondary components of the disease.

Serous detachment of the neuroretina is observed under multiple circumstances: vascular diseases include malignant hypertension, toxemia of pregnancy, retinal vein occlusion, Coats' disease, retinal angiomatous diseases, and polypoidal choroidal vasculopathies. It is a characteristic of central serous retinopathy, which appears to be associated with focal dysfunction of the RPE secondary to dysregulation of the choroidal vasculature. Detachment of the retina from the RPE is also seen in primary choroidal disorders such as tumors, choroidal inflammation, ischemia, and in a variety of other conditions falling into the category of uveal effusion syndrome.

Accumulation of fluid between Bruch's membrane and the RPE is seen consistently in only one situation: PED. This occurs in the young as a manifestation of central serous retinopathy and in the elderly as a manifestation of age-related macular disease (AMD). The differentiation between various kinds of PEDs is essential because each PED type is a distinct entity that has a specific pathogenesis, natural history, prognosis, and optimal treatment strategy. Multimodal imaging of PED, enhanced depth imaging optical coherence tomography, and indocyanine green angiography allow a better analysis of the subretinal pigment epithelium compartment and could even enable visualization and localization of the entire branching neovascular network of CNV within fibrovascular (FV)-PED without dye injection.<sup>49,50</sup>

## Serous Retinal Detachment Associated With Choroidal Dysregulation

### Central Serous Chorioretinopathy

The separation of the outer segments of photoreceptors from the RPE by subretinal fluid should slow down the exchange of all-*trans* and 11-*cis* retinal. The RPE–photoreceptor visual cycle serves mainly the rods, and cone function is supported by a separate visual cycle within the sensory retina<sup>51</sup> and is thus less affected by the separation from the RPE.

Central serous chorioretinopathy (CSC) is a disease in which the NSR becomes detached, supposedly due to a single or multiple focal lesions within the RPE, which leaks into the SRS overlying

dysregulation of the choroidal vasculature. With indocyanine green angiography (ICGA), it has been demonstrated that CSC primarily affects the choroidal circulation and causes multifocal areas of choroidal vascular hyperpermeability.<sup>52,53</sup> PED shown by biomicroscopy, fluorescein angiography (FA), ICGA, and optical coherence tomography (OCT) can be seen in early stages of CSC, under the SRD. The location of these PEDs is the same as the location of the leakage in FA. Spontaneous resolution is the usual outcome.<sup>54</sup> The serous detachment extends significantly beyond the leak if the tight junctional RPE barrier under the elevated retina (except directly over the areas of leakage) is intact, since fluid would otherwise leave under hydrostatic and osmotic pressure.<sup>55</sup>

Chronic forms of CSC, defined as a persistent choroid anomaly demonstrated on ICGA, are not the rule. In those cases, PEDs do not always accompany a SRD.<sup>56</sup> ICGA has demonstrated the presence of “multiple presumed occult” PEDs in both acute and chronic stages.<sup>57</sup>

Chronic CSCR often resembles age-related macular degeneration (AMD) or can be complicated by CNV. Enhanced visualization of the choroid with spectral-domain optical coherence tomography (SD-OCT) has facilitated the assessment of the role played by the choroid in CSCR. Based on these observations, it was proposed that “pachychoroid pigment epitheliopathy” could be a subclinical phenotype potentially complicated by serous detachments and/or choroidal vasculopathy, including subepithelial CNV and polypoidal vasculopathy.<sup>58</sup> Although the possible occurrence of subepithelial CNV complicating the course of chronic CSC should not be ignored, all cases of flat irregular PED should not be mistaken for active CNV and systematically treated with anti-vascular endothelial growth factor (VEGF) drugs. Nevertheless, in some cases with worsened vision not responding to usual CSC therapy, use of anti-VEGF drugs could be considered as a therapeutic test to rule out the presence of secondary CNV.<sup>59</sup>

There are multiple theories on the origin of CSC, none of which has been proven. Neither RPE nor choroidal dysfunction can be effectively pointed out as the sole causative mechanism. The leakage rate corresponds to bulk fluid flow, rather than secretion and diffusion,<sup>60</sup> which indicates that the underlying choroid is

possibly responsible and not the RPE. Focal areas of hyperpermeability visualized as tiny punctuate spots in the inner choroid may be involved in the development of SRD.<sup>61</sup> During the period of time in which the retina remains detached, many events occur that have to do with the change in metabolism and intercellular processes. The outer segments of photoreceptors overlying the detached area are no longer phagocytosed, the photoreceptors elongate,<sup>62</sup> and finally, outer segments begin to accumulate, resulting in the deposit of multiple dot-like yellow precipitates and material. This material is demonstrated by high reflectivity on OCT and hyperautofluorescence.<sup>63</sup> The autofluorescent fluorophores in the photoreceptor outer segments may be concentrated in precipitates or settled into the inferior SRD.<sup>64</sup> This could correspond to the described acute hypertrophic outer retinal changes.<sup>65</sup>

The structure of the detached NSR in eyes with CSC remains preserved.<sup>66</sup> Photoreceptor apoptosis may be implicated in visual function in CSC, since apoptosis has been reported in experimental retinal detachment and human retinal detachment within a few days.<sup>67</sup>

Upon resolution the fluid will be reabsorbed rapidly for water and ions, whereas macromolecules will remain in the SRS and precipitate. After resolution of a long lasting episode, a hyperautofluorescent aspect remains on retinal imaging.<sup>68</sup>

Recently, significant progress has been made in the understanding of the molecular events triggering choroidal vasodilation in CSC. Inappropriate activation of the mineralocorticoid receptor (MR) by glucocorticoids, induces upregulation of the vasodilator potassium channel KCa2.3 (calcium-dependent channel) and smooth muscle cells relaxation in the choroidal vasculature.<sup>69</sup>

## **Serous Retinal Detachment in Idiopathic Polypoidal Choroidal Vasculopathy**

Idiopathic polypoidal choroidal vasculopathy (PCV) is a distinct exudative disorder in which the SRD is thought to be of choroidal origin.<sup>70</sup> PCV is a disease in which the primary abnormality involves the inner choroidal circulation,<sup>71,72</sup> where thin capillary

vessels dilate within Bruch's membrane, immediately under the RPE, where they form cavernous vascular channels.<sup>73</sup> It is distinguishable from more typical proliferations of abnormal choroidal vessels.<sup>74</sup>

These lesions cause serosanguineous RPE detachments via damage to the overlying Bruch's membrane and/or RPE. The histopathologic findings suggest that these lesions can be more accurately considered as a degenerated RPE–Bruch's membrane–choriocapillaris complex and inner choroid dilated venules and arterioles, rather than an intra-Bruch's fibrovascular membrane.<sup>75–77</sup>

## **Age-Related Macular Degeneration**

In the early stages of AMD, inflammation may help keep the RPE barrier intact by preventing RPE proliferation and migration, and, at the same time, choroidal cell growth may increase blood flow to the retina and the clearance of pathogens or drusen.

In chronic inflammatory diseases such as in AMD, the IFN-induced dehydration of the SRS would increase the activity of already accumulating chemokines and, thereby, help draw monocytes and neutrophils across the RPE to the SRS. Inhibition of RPE proliferation and migration by IFN also protects and maintains the RPE barrier. However, over long periods of unresolved inflammation, chronic exposure to IFN and other cytokines (e.g., IL-1 and tumor necrosis factor) could induce a significant decrease in transepithelial paracellular resistance and the loss of transport potential (fluid absorption).

These persistent changes, coupled with an IFN-driven increase in choroidal cell proliferation, suggest a pathway for the entry of choroidal neovascular blood vessels into the SRS via the RPE. Neovascular AMD results in an alteration of the outer BRB. These mechanisms provide a possible basis for understanding the role of inflammation in CNV and AMD.

Presently, fluid accumulation under the RPE, under and within the NSR, evidenced on OCT examination is considered clinically as an indicator of CNV activity. Its presence results in treatment indication.<sup>78</sup>

## **Serous Retinal Detachment in Uveitis: Exudative**

## Retinal Detachment

During inflammation, loss of the BRB and a diminished outflow of the choroid and choriocapillaris result in the accumulation of liquid in the SRS. The sustained pressure exerted from the choroid is responsible for the accumulation of fluid between the RPE and the retina and then may evolve into edema of the inner retinal layers.

Later, when more inflammatory damage develops and/or fluid volume increases, retinal resistance may become insufficient, and the fluid may enter the neuroretinal tissue and form cysts. The transient aspect of a subfoveal SRD in uveitis and favorable response to treatment support this hypothesis. A subfoveal SRD may also be documented in patients with normal neuroretinal tissue and without intraretinal edema.<sup>79</sup> In the acute phase of Vogt–Koyanagi–Harada disease, fluorescein angiography has shown increased permeability of the chorioretinal vessels and of the BRB, and delayed circulation of choroidal arteries, veins, and choriocapillaris.<sup>80,81</sup> This delayed perfusion has been related to massive infiltration of the choroid, resulting in the thickening of the choroid and delayed arterial choroidal flow.

NSR serous detachment of the macula resulting from focal retinochoroiditis has been reported previously in patients with *Bartonella*-associated neuroretinitis. SRD may precede the formation of a macular star in a minority of patients with neuroretinitis.<sup>82</sup> The macular exudates may take months to resolve.<sup>83</sup>

## Detachment of Retinal Origin

### Serous Retinal Detachment in Diabetic Retinopathy

Diabetic macular edema (DME) is thought to be caused by hyperpermeability in the retinal vasculature, leading to dysfunction of the neuroglial cells and concomitant visual disturbance. Macular SRD occurs in 15–30% of patients with diabetic maculopathy.<sup>84,85</sup> SRD in DME is diagnosed on OCT even when the neuroretinal tissue above the SRD is normal.<sup>86</sup> Retinal functionality in these types of SRD is controversial.<sup>87</sup> It has been reported that macular SRD in diabetic patients is more often correlated with high levels of HbA1c, and that this might break both the inner and the outer BRB.<sup>88</sup>

Transient SRD may represent a step in the process of macular edema resorption. Its evolution is not related to the severity of DME, and it sometimes disappears before resorption of retinal fluid. The elongation of the photoreceptors is not visualized in diabetic retinopathy-associated SRD, suggesting that the pathogenesis of this disease might be different.<sup>89</sup> The high protein content of the fluid in these SRDs could alter the oxygenation and elimination of metabolites from the photoreceptor layer, thus decreasing retinal sensibility.

The involvement of the RPE is also thought to play a role in the hydrodynamics of fluid accumulation into the SRS, where hypoxia might impede its normal pump function. RPE impairment has already been proven in human and experimental diabetes.<sup>90</sup> Thus SRD in diabetic maculopathy is linked not only to the limited drainage of the vascular system (both retinal and choroidal) but also to impairment in the function of the RPE.

## **Severe Retinal Detachment in Central or Branch Retinal Vein Occlusion**

Severe retinal vein occlusion may be accompanied by extensive SRD.<sup>91</sup> The occurrence of SRD has been related to inflammatory reaction that is associated with hyperreflective material on OCT. SRD can be demonstrated in approximately 80% of central retinal vein occlusion patients with cystoid macular edema.<sup>92</sup> It appears that SRD is more frequent in major branch retinal vein occlusion (BRVO) than in macular BRVO.<sup>93</sup> In cases of major BRVO, a positive correlation with VEGF and the presence of SRD has been reported.<sup>94</sup> The major complication of serous detachment is the deposit of macular hard exudates, which may result in poor visual outcome.<sup>95</sup>

## **Other Causes**

A large number of diseases, both ocular and systemic, have been associated with SRD. Different immunogammopathies have been associated with serous macular detachments: multiple myeloma, Waldenström macroglobulinemia, and immunoglobulin M paraproteinemia. SRD has been described in patients with acute leukemias while on chemotherapy or during a relapse.<sup>96</sup> The

mechanism of SRD in hypertensive choroidopathy as well as in eclampsia is more linked to renal failure and subsequent uremia.<sup>97</sup>

Choroidal effusion syndrome is thought to be due to the reduced porosity of the sclera and to the compression of the vortex veins by a rigid sclera, impeding the normal outflow of fluid within the choriocapillaris. Choroidal melanomas and retinoblastoma have been associated with SRD.<sup>98</sup> Vascular malformations such as retinal capillary hemangioma, phacomatoses, and carotid–cavernous fistula have all been associated with SRD.

## Conclusion

Detachment of the neuroretina and/or of the pigment epithelium is not pathognomonic of a single disease. Detachments may result either from a primary choroidal alteration, with or without RPE secondary disturbances, or from an abnormality of the retinal circulation. The triggering mechanism remains, however, unknown most of the time, requiring not only the dissection of the biochemical cascades but in addition a detailed analysis of all clinical data available.

## **Introduction**

The purpose of this chapter is to provide an overview of concepts underlying our current understanding of the genetic basis of inherited retinal diseases (iRDs). iRDs are perhaps the best understood of human hereditary disorders. In part this is because diseases that affect vision are easily recognized and the retina is an accessible and well-characterized tissue. In many ways, though, we are still at an early stage of understanding the causes and consequences of these diseases. In fact, the causes of iRDs are highly varied: many different types of retinal disease are known, many different genes are involved, and there may be dozens of disease-causing mutations reported within a single gene. For example, currently at least 256 genes are known that can cause one or another form of retinal disease,<sup>1</sup> and over 12,000 mutations have been reported, in total, in these genes.<sup>2</sup> In spite of the underlying complexity, it is now possible to identify the disease-causing gene and mutation, or mutations, in a substantial fraction of affected individuals and families.<sup>3,4</sup>

A useful concept in medical genetics is the distinction between single-gene diseases and multifactorial diseases. Inherited diseases such as retinitis pigmentosa (RP) are considered to be single-gene because there is a specific, underlying cause in each affected individual, that is, an inherited difference in DNA sequence that has a direct cause-and-effect relationship to the disease. There may be one DNA difference for dominant diseases, or two for recessive diseases, but only one gene is involved. These are also referred to as monogenic or Mendelian diseases. In contrast, for diseases such as age-related macular degeneration (AMD), genetic differences play a role in lifetime risk and/or clinical expression, but the differences are merely contributory and do not have a clear cause-and-effect relationship to the disease. These are “multifactorial” diseases because multiple factors, genetic, environmental, and stochastic, play a role in determining who is affected and who is not.

Therefore the cause of disease in an individual with an inherited condition such as RP is “simple,” in the sense that only one gene is affected (and usually affected in an obvious way), whereas there may be multiple contributory factors in an individual with AMD and the differences may be subtle. We already know exceptions to this rule – for example, there are digenic forms of RP with two affected genes<sup>5</sup> – but the exceptions are rare.

This chapter focuses on genetic differences that are single-gene in nature and have a direct cause-and-effect relationship with disease, that is, inherited diseases of the retina. Genetic factors contributing to AMD are discussed in [Chapter 66 \(Epidemiology and risk factors for age-related macular degeneration\)](#).

## Basic Concepts in Human Genetics

### Inheritance

[Fig. 33.1](#) shows pedigrees illustrating autosomal dominant, autosomal recessive, and X-linked recessive inheritance (see Nussbaum et al.<sup>6</sup> for details).

Autosomal dominant inheritance

Autosomal recessive inheritance

X-linked recessive inheritance

**FIG. 33.1** Pedigrees illustrating autosomal dominant, autosomal recessive, and X-linked recessive inheritance.

iRDs follow textbook patterns of Mendelian inheritance: autosomal dominant, autosomal recessive, or X-linked. However, real families are often more complicated, especially for late-onset, progressive forms of retinal disease. This section reviews the conventional modes of inheritance and possible complexities.

## Autosomal Dominant Inheritance

Autosomal dominant inheritance occurs when a single copy of a mutation on an autosomal chromosome is sufficient to cause disease. That is, an affected individual is heterozygous for the

mutation. Diseases caused by dominant mutations pass from generation to generation, i.e., most families have affected individuals in multiple generations. Males are as likely to be affected as females, and approximately 50% of children of an affected individual will be affected. Forms of retinal disease that are often autosomal dominant include maculopathies such as Best disease.

Two phenomena that can confuse the picture of autosomal dominant disease are variable expression and incomplete penetrance.

Variable clinical expression means that individuals with the same mutation may vary in onset, progression, or severity of disease or, in some cases, may have distinctly different clinical findings. Autosomal dominant RP is notoriously variable in expression. For example, mutations in one autosomal gene, *PRPH2* (also known as *RDS*), can cause dominant RP, dominant macular degeneration, or dominant panretinal maculopathy, even among members of the same family.<sup>7-11</sup>

Variable expression is a problem in determining mode of inheritance because some individuals may not show symptoms until late in life, and individuals with different symptoms may be diagnosed with different diseases even if the underlying cause is the same.

Incomplete penetrance, or nonpenetrance, means that some individuals with a disease-causing mutation will not be affected. For instance, 20% of individuals with a dominant-acting mutation in *PRPF31* will have normal vision by age 60 even though relatives with the same mutation may have RP by age 20.<sup>12-15</sup> One indicator of nonpenetrance in a multigenerational family is a “skipped generation,” that is, an unaffected individual with an affected parent and an affected child. This is often seen in families with *PRPF31* mutations.<sup>16,17</sup>

Although variable expression and incomplete penetrance are seen as distinct phenomena, they are actually part of a continuum, with nonpenetrance just the extreme. The difference between late onset and no onset may simply be the age of the patient when examined. Whatever the terminology, the underlying finding is that dominant retinal disease mutations may have highly variable

consequences, confounding diagnosis.

An additional rare but confounding possibility has been observed in large, multigenerational families with inherited retinal disease: mutations in more than one gene may be segregating independently in the family. This occurs because families with late onset, nonlethal diseases are likely to meet and socialize with similar families. Descendants of these families are at risk of inheriting mutations in more than one gene. This is “assortative mating.”

## **Autosomal Recessive Inheritance**

Autosomal recessive inheritance occurs when both copies of an autosomal gene must be affected to cause disease. An affected individual can be either homozygous for a single mutation or heterozygous for two distinct mutations. An individual with two distinct recessive mutations is also called a compound heterozygote. Note that a pair of recessive mutations must be on opposite chromosomes. If two variants are in the same gene on the same chromosome, they are in *cis* to each other; if they are on opposite chromosomes, they are in *trans*. Recessive mutations must be in *trans* to cause disease

Examples of autosomal recessive retinopathies include Leber congenital amaurosis and Usher syndrome.

Unless one of the two mutations in a recessive case is a new mutation, the parents must be carriers of the mutation or mutations, that is, they must be heterozygous. Carriers are usually not affected. Approximately one-fourth of children of carrier parents are affected and one-half of children are carriers. Many recessive cases are isolated or simplex cases, i.e., one affected family member only. Families with multiple affected sibs are “multiplex.”

Finally, in consanguineous families with marriage between relatives, an identical recessive mutation may be passed to multiple family members. Affected individuals may occur in more than one generation and in more than one branch of these families. Two identical mutations that derive from a recent ancestor are identical by descent (IBD). Marriage between relatives is more common in some cultures than others, hence IBD inheritance of retinal diseases is more frequent in those societies.

Because carriers are not self-evident, the mode of inheritance is often hard to assign in recessive families.

## **X-Linked or Sex-Linked Inheritance**

X-linked or sex-linked inheritance is a single mutation on the X chromosome that causes disease. Males, who are hemizygous for the X chromosome, are always affected, often severely affected. For many inherited diseases, female carriers of an X-linked mutation are not affected. Since females have two Xs, this implies that most X-linked mutations will be recessive in females. For a truly recessive X-linked mutation, one-half of the sons of a carrier female are affected, one-half of her daughters are unaffected carriers, and none of the sons of an affected male are affected. This produces a notable pattern of inheritance, with the salient feature that male-to-male transmission of an X-linked mutation is not possible.

The disease status of female carriers is more complex. Although females have two Xs, one of the Xs, selected at random in each cell, is inactivated in most tissues. This is X-inactivation or Lyonization, named for Mary Lyon, who first described the phenomenon.<sup>18,19</sup> Lyonization increases the likelihood that a female carrier will be affected since some cells will express only the mutant protein. In fact, many female carriers of X-linked RP mutations show clinical symptoms. Females are less severely affected than males with the same mutation, but female carriers of X-linked RP mutations may have significant loss of vision by midlife or earlier.<sup>20-24</sup>

One consequence of clinical disease in carrier females is that families with X-linked RP may appear to have autosomal dominant RP if several females are affected.<sup>25</sup> This is an example of complexities that arise in determining the mode of inheritance of iRDs.

## **Isolated Cases**

Isolated cases deserve an entry of their own because the mode of inheritance is often unclear. A practical definition of an isolated case is an affected individual with no affected first-degree relatives (parents, sibs, and children) and no reports of more distant affected relatives. One immediate concern is that there may be other affected family members but the person describing the family is unaware of

the disease status in these individuals. Clinical examination of first-degree relatives is often informative in these cases.

Assuming a case is genuinely isolated, there are several possibilities. The most likely prospect is that this is an autosomal recessive case and the parents are carriers. Or, perhaps one parent is a carrier but the other mutation is *de novo* (new). Alternatively, this may be a new dominant-acting or X-linked mutation. Another possibility is autosomal dominant or X-linked inheritance with nonpenetrance in prior generations. Ultimately, for most isolated cases the mode of inheritance must be determined at a molecular level by genetic testing.

## Digenic and Polygenic Inheritance

Nearly all iRDs are monogenic, with only one gene affected per person. This is based on empirical observation, but it may be misleading since more complex forms of inheritance are hard to prove. Two counterexamples are known for iRDs. First, one form of RP is caused by a combination of one mutation in the *PRPH2* (*RDS*) gene and another mutation in the *ROM1* gene.<sup>5,24</sup> These two mutations are benign alone but pathogenic in combination. This is digenic inheritance. Secondly, Bardet–Biedl syndrome (BBS), a form of RP combined with congenital abnormalities, is in most instances a recessive disease with mutations in any one of at least 22 known BBS genes.<sup>1,26</sup> Some cases of BBS, though, require a third mutation in a second BBS gene for disease expression.<sup>27,28</sup> This is called trigenic or triallelic inheritance. Whether these examples of polygenic inheritance of iRDs are just rare anomalies or hint at greater complexity of retinal diseases is uncertain.

## Chromosomes

Chromosomes are dark-staining bodies seen in the nucleus of dividing eukaryotic cells. In diploid organisms, such as humans, the earliest diploid cell before division results from fusion of a haploid cell from the male parent and a haploid cell from the female parent. That is, the first human cell has a diploid count of 23 pairs of chromosomes ( $n$ ), or 46 total chromosomes ( $2n$ ), and derives from fusion of a haploid sperm and haploid ovum. This is

the primary germline cell and contains the germline genetic information in the nucleus. All subsequent cells, known as somatic cells, contain a nearly perfect copy of the original chromosomes and genetic information. Exceptions in humans are sperm- and ovum-producing cells (also known as germline cells), which produce haploid cells, and certain blood cells that do not contain a nucleus.

Eukaryotic chromosomes have been referred to as “information-carrying organelles” because they are highly structured, ultra-compressed complexes of proteins, RNAs, DNA, and other factors, with the primary function of transmitting genetic information from one generation to the next, or from a parent cell to a daughter cell. However, at the heart of each chromosome is a single, double-stranded DNA molecule. DNA length is measured in basepairs (bp): each single strand of DNA is composed of nucleotide bases, and each base interacts (pairs) with an alternate base in double-stranded DNA, so bp are the natural units. DNA is also measured in kilobases (kb), megabases (Mb), and gigabases (Gb). The DNA molecule within a chromosome may be hundreds of Mb in length. This is, by far, the largest single biomolecule known. One reason for the chromosomal superstructure may simply be to keep this giant molecule intact. However, chromosomes also participate directly in DNA duplication and expression.

## DNA, RNA, and Proteins

Fig. 33.2 shows the steps in DNA duplication, RNA translation, and protein synthesis.<sup>29</sup>

**FIG. 33.2** Steps in DNA duplication, RNA translation, and protein synthesis. (Reproduced from Nussbaum RL, McInness RR, Willard HF. Thompson and Thompson's Genetics in medicine. 7th ed. Philadelphia, PA: Saunders Elsevier; 2007. p. 31. With permission from Elsevier.)

DNA is deoxyribonucleic acid, a linear molecule composed of four monomers: adenine (A), thymine (T), guanine (G), and cytosine (C). Two antiparallel DNA strands pair through hydrogen bonds to form a double-stranded molecule that carries genetic information.

RNA is ribonucleic acid, a linear molecule, like DNA, composed of adenine, uracil (U), guanine, and cytosine. RNA is single-stranded in most circumstances, but it can form complex folded shapes by pair bonding within the linear strand. Messenger RNA (mRNA) transfers genetic information within cells, but other RNA molecules play diverse roles in many biologic processes.

Proteins, composed of various combinations of 20 amino acids, are linear molecules that can fold into many shapes, and can play essential and highly diverse roles in all biologic processes.

DNA function is called the central dogma of DNA in recognition of the landmark explanation of DNA structure and function by

Watson and Crick in 1953, and subsequent unraveling of the genetic code over the next decade.<sup>30,31</sup> DNA is comprised of a phosphate backbone with nucleotide bases, A, T, G, or C, in linear array along the backbone. The backbone is conventionally drawn from the 5' phosphate on one end to the 3' phosphate on the other end. The opposite strand forms by pairing of cognate bases, A to T and G to C, on the parent strand. The opposite strand naturally aligns in a helical, antiparallel fashion, from 3' to 5' phosphates. This arrangement essentially explains inheritance in all living things.

In DNA *duplication*, the two antiparallel strands unwind, and a nearly exact antiparallel copy is synthesized on each single strand. The principal enzyme involved is DNA polymerase, but additional enzymes are involved in unwinding, patching, and repairing the DNA. DNA duplication occurs in the nucleus of cells only.

In DNA-RNA *transcription*, the DNA strands unwind, and a single-stranded RNA molecule is synthesized as an antiparallel copy of one of the DNA strands, pairing each DNA nucleotide with the corresponding RNA nucleotide. The primary enzyme involved is RNA polymerase, and the first steps occur in the nucleus. Thereafter the RNA molecule is processed through many steps and eventually exported from the nucleus to the protein-forming machinery. The final molecule in this process is mRNA since it carries the DNA message to the cytoplasm.

In protein *translation*, mRNA is read by the protein-forming machinery and the corresponding protein is built by adding one amino acid to the next in succession, from the amino (NH<sub>2</sub>-) end of the protein to the carboxy terminus (-COOH). Each amino acid is coded for by three RNA bases, that is, a nucleotide triplet or codon. After synthesis, most proteins are further modified through posttranslational modification, then the linear protein folds into its active shape, often with the assistance of proteins known as chaperones.

It is now recognized that RNA plays many additional roles than simply carrying genetic information through mRNA. Functional RNA that does not code for a protein is called nontranslated (or noncoding) RNA and is a major focus of contemporary research.

## Gene Structure

Fig. 33.3 shows gene structure based on the relationship between the protein sequence, mRNA intermediate, and original DNA gene sequence.<sup>29</sup>

**FIG. 33.3** (A,B) Gene structure based on the relationship between the protein sequence, mRNA intermediate, and original DNA gene sequence. (Panel B, reproduced from Nussbaum RL, McInness RR, Willard HF. Thompson and Thompson's Genetics in medicine. 7th ed. Saunders Elsevier; 2007. p. 29. With permission from Elsevier.)

The modern concept of a gene is clouded by arguments as to where a gene starts and stops, and whether segments of DNA that do not code for proteins but still influence traits are “genes.” The discussion here is limited to defining a gene in terms of proteins while acknowledging the broader complexities, e.g., noncoding RNAs.

Gene expression is principally the steps from DNA transcription

to protein translation. Gene expression starts with separation of double-stranded DNA, exposing a single-stranded sequence on which DNA-to-RNA transcription can occur. This is accompanied by binding of a complex set of proteins, “expression factors,” that facilitate binding and activity of RNA polymerase.

The primary RNA strand begins at the start of transcription and ends far beyond the length sufficient to code for a protein. The first RNA-processing steps add a methyl cap to the first RNA nucleotide, trim the 3' end, and add a polyadenosine tail (poly-A tail). Next the RNA moves to a complex assembly of proteins and small, functional RNAs, known as a spliceosome. The spliceosome then removes anywhere from one to many internal segments of the RNA transcript and reassembles the remainder. This is, largely, the finished mRNA, which is then exported from the nucleus to the protein synthesis machinery in the cytoplasm.

RNA splicing has profound consequences for gene structure and protein variation. Splicing occurs in nearly all eukaryotes, and almost all human genes are spliced. The spliced-out segments are called introns, and the remaining, reassembled segments are exons. The splice sites are defined by short, canonical sequences, highly conserved across species, known respectively as splice-donor and splice-acceptor sites.

The evolutionary significance of splicing is still disputed, but its functional consequence is clear: it vastly increases the number of distinct proteins. This is because when splicing occurs, alternate combinations of introns may be removed. Alternate splicing is the norm in human genes, not the exception, and usually results in alternate mRNAs and alternate protein isoforms – all from a “single” gene. There are many examples of alternately spliced retinal genes producing multiple protein isoforms.<sup>32,33</sup>

Following splicing and export from the nucleus, mRNA is translated into protein by ribosomes in the endoplasmic reticulum. The start of translation is usually not at the beginning of the mRNA, and the end is not at the end. The segment upstream of the start of translation is the 5' untranslated region (5'-UTR). Similarly, the segment downstream of the end of translation is the 3' untranslated region (3'-UTR). The 5' and 3'-UTRs may sit within the first and last exons, respectively, or may stretch across exons.

In addition to alternate splicing and alternate protein isoforms, there are alternate starts of transcription, alternate starts of translation, alternate ends of translation, and alternate poly-A sites.

## **Mitosis, Meiosis, and Linkage**

Fig. 33.4 shows the steps in meiosis.<sup>6</sup>

**FIG. 33.4** The steps in meiosis. (Reproduced from Nussbaum RL, McInness RR, Willard HF. Thompson and Thompson's Genetics in medicine. 7th ed. Philadelphia, PA: Saunders Elsevier; 2007. p. 19. With permission from Elsevier.)

In normal cell division, in which a somatic cell divides to produce a daughter cell, the DNA in all 46 human chromosomes is copied and a complete copy is passed to each of the two resulting cells. This is mitosis, and it provides a nearly perfect copy of the DNA sequence to each somatic cell.

Chromosome distribution and DNA processing are substantially different in meiosis. Meiosis occurs in cells producing sperm and ova. In the first phase of meiosis chromosomal DNA is duplicated as in mitosis, but the duplicated DNA strands do not separate. Then, in subsequent phases, homologous chromosomes bind to each other and exchange DNA strands. Homologous chromosomes are pairs of similar chromosomes from each parent, e.g., the maternal and paternal chromosome 1. The result of homologous exchange or recombination is to produce novel DNA sequences that are mixed linear combinations of chromosomal segments from each parent. The resulting duplicated, recombined chromosomes are then separated into four haploid-containing cells, which eventually become sperm or ovum.

The result is, first, that each sperm or ovum contains only a haploid set of chromosomes. However, when a sperm fertilizes an ovum, the resulting cell has the full diploid set of chromosomes. Second, each chromosome in the offspring is a recombined mix of the chromosomes of each parent. Thus the chromosomes in each individual are a unique, one-of-a-kind combination of previous generations (excepting identical twins).

As a result, genes on different chromosomes segregate independently, but genes that are close together on a chromosome segregate together. More generally, the further a pair of genes are apart on a chromosome, the more likely a recombination will have occurred between them during meiosis. Two loci that are close enough on a chromosome such that recombination is unlikely are "linked." The phenomenon of genes that do not segregate independently is linkage.

To put this in context, the average chromosome is 100 Mb in length. Genes that are 50 Mb apart are unlinked, and genes within 10 Mb of each other show linkage. If genes are within 1 Mb of each other, the chance of recombination is less than 1% per generation.

There are roughly 5–20 genes per Mb in the human genome, so hundreds of contiguous genes on a chromosome may show linkage to each other.<sup>34</sup>

Linkage has significant evolutionary and functional consequences, but its importance in medical genetics is as a tool to locate disease-causing genes. If a neutral genetic variant is found in association with an inherited disease in a family, then the variant, called a marker in this case, may be physically close to the disease gene, that is, they may be linked. If so, then knowing the location of the marker fixes the location of the disease gene.

## Evolution

Theodosius Dobzhansky said “nothing in biology makes sense except in the light of evolution.”<sup>35</sup> This observation serves to emphasize the fundamental organizing principle of biology. Without evolution, biology is largely a random collection of facts and principles; with evolution, biology (and medicine) is a coherent science. Evolution explains why the central dogma is true for all species, why all eukaryotic cells share a common architecture, why animal models are useful in understanding and treating human diseases, why human DNA variants are evaluated by comparison to other species. Evolution is so central to biology and medicine that we often forget its impact, but modern, 21st-century biomedicine is unimaginable without it.

## The Human Genome

### Overview

The human genome is the combined DNA sequence of the haploid set of all chromosomes. Humans have 23 pairs of chromosomes; these consist of 22 pairs shared by males and females (autosomes) and a pair of Xs in females or an X and Y in males (sex chromosomes). Autosomes are labeled from the largest, 1, to the smallest, 22. Thus the human genome is the sequence from the top of chromosome 1 through the bottom of chromosome 22, plus the X and Y chromosomes.

In one of the greatest scientific achievements in modern history, the Human Genome Project produced the first human genome sequences in 2001.<sup>36,37</sup> Since then thousands of complete human genomes have been sequenced, and the genomes of thousands of other species are known.<sup>38</sup>

There is a distinction between the generic human genome and the genome of a specific person. “The” human genome, or “the” genome of any species, is neither an average nor a consensus. It is simply a sampling of the first individuals sequenced. Therefore the reference human sequence and reference gene sequences are just examples, not definitive sequences. In contrast, the genome of a specific human would cover all 46 chromosomes and be unique to that person. Thus, in this sense, there are billions of human genomes and no two are alike.

Nonetheless, both the generic human genome sequence and the many specific sequences are extremely valuable contributions to medicine and biology.

The human haploid genome is 3.3 Gb in length; the complete genome of an individual is 6.6 Gb. There are 21,000–25,000 protein-producing genes in the generic human genome. This is far fewer than expected, but the discrepancy is partly explained by alternate splicing and multiple protein isoforms.

Most genes, including introns, exons, and regulatory elements, are 10–100 kb in length. Therefore the portion of the genome devoted to genes is less than 10% of the total. Considering exons only, the fraction of the genome actually coding for proteins is only 1.5% of the total.

Roughly 50% of the human genome consists of thousands or millions of short, repetitive DNAs. For example, there are more than one million copies of *Alu* sequences dispersed throughout the genome. *Alu*'s are short retrotransposon-related sequences that have the capacity to copy themselves into new locations in the genome. Some repetitive DNAs are functional in that they play a role in chromosome structure and protein activity. However, it is fair to say that this is principally “junk DNA,” at least in relation to actual genes.

The remaining 50% consists of single-copy DNA (that is, not repetitive), including coding sequences. Most of this single-copy

DNA is transcribed into RNA but not translated into proteins. This noncoding RNA (ncRNA) must play a role in normal biologic processes, and probably contributes to human diseases, but it is poorly understood at present.

## Polymorphisms

Humans are 99.9% identical to each other at a DNA level. Since there are 6.6 Gb in the human diploid genome, this means that one person differs from another at millions of sites. Some of these differences contribute to diseases, both simple and complex, but the vast majority are neutral or only slightly advantageous or disadvantageous. This is the extremely varied “genetic background” that distinguishes one individual from another.

An identifiable site in a genome, usually a gene, is called a locus, and any variant at this site is an allele. If there is more than one allele at a locus in a group of people, and the second most common allele has a frequency of 1% or greater, then this is called a genetic polymorphism. If there are only two alleles at a locus, then the less common allele is the minor allele. Note that locus and allele apply to an individual, whereas polymorphism only makes sense in the context of a population in which more than one allele is found.

The 1% criterion is arbitrary. A specific allele may occur only once in one individual or may range up to 100% of all chromosomes in a population. One percent was chosen because this frequency can be measured in a realistic survey and it was presumed that any more common allele must be largely benign. (The latter is definitely not true; for instance, the sickle-cell and cystic fibrosis mutations are both polymorphic in their respective populations.) Polymorphism is a useful concept, though, despite the arbitrary definition.

A person who has identical alleles at a locus is homozygous at that site; a person with two different alleles is heterozygous. (This applies to autosomal chromosomes and the Xs in a female. Alleles on the male Y are hemizygous.) The frequency of heterozygotes in a population is predicted from Hardy–Weinberg equilibrium: if there are two alleles with frequencies  $p$  and  $q$ , then the frequency of the two homozygote types is  $p^2$  and  $q^2$ , respectively, and the

heterozygote type is  $2 \times p \times q$ . The total fraction of heterozygotes at a locus in a population is heterozygosity, basically the sum of all heterozygote combinations.

Several broad classes of polymorphism are found in the human genome.

## Single Nucleotide Polymorphisms

Single nucleotide polymorphisms (SNPs) are sites at which more than one nucleotide is found in a population. There are usually only two alleles at a SNP locus, e.g., an A or a T. Millions of SNP sites have been identified in humans.<sup>39</sup> Some are found in only one major population, such as Africans, but many are polymorphic in all major human groups. A SNP site at which the nucleotide substitution leads to an amino acid substitution, or otherwise affects a protein, is a coding SNP (cSNP). There are tens of thousands of cSNPs, at least one in almost every gene.

If a pair of human chromosomes are compared base by base, each of us is heterozygous for a nucleotide substitution roughly every 1000 bp. Not all of these are at polymorphic sites; some are private or rare variants (often called single nucleotide variants). However, most are true SNPs.

## Short Tandem Repeats

Another type of polymorphism is short tandem repeats (STRs). STRs are short stretches of DNA, typically 2–5 bp in length, which are repeated a variable number of times, say from 10 to 20 times. Alleles differ in the number of repeats. Because many different lengths are possible, there are usually several or many alleles at a locus. These are also called microsatellites.

## Copy Number Variants (CNVs)

The number of copies of a gene or genetic region may also differ between individuals and the differences may be polymorphic. These are copy number variants (CNVs). CNV differences may range between zero copies up to several copies in tandem. An absent or deleted gene may have obvious functional consequences, but multiple copies of a gene may also have consequences, through

overexpression, for example. CNVs are not as numerous as SNPs, but there are at least 100s of sites in humans.<sup>40</sup>

## Other Polymorphisms

There are many other human DNA polymorphisms. There are large polymorphic elements called minisatellites or VNTRs (variable number tandem repeats); *Alu* insertions may be polymorphic; chromosome deletions and rearrangements are polymorphic in humans. The extent of polymorphic variation in humans is exceptional, reflecting our high mobility, heterogeneous habitats, and variable mating patterns.

Finally, in addition to polymorphic variants, there are many private or rare variants. Some, but not all, of these are deleterious, e.g., mutations causing retinal diseases. The extent of rare variants is not well known, and it is often difficult to determine which are benign and which are pathogenic. However, it is clear that each of us harbors millions of variants in our genomes that are rare or unique to us or our families, some of which affect our health and wellbeing.

## Mutations

Fig. 33.5 illustrates several of the types of mutation that cause iRDs.

Effect on a protein of a nucleotide substitution in a coding region

A

1. Native unaffected sequence										
DNA:	ATG	TCT	CCT	CGT	ATG	GAA	GTT	TAA	TGG	TAA
protein:	met	- ser	- pro	- arg	- met	- glu	- val	<ter>		
2. Wobble codon (silent/or synonymous substitution)

new DNA:	ATG	TCT	CCT	CTG	GAA	GTT	TAA	TGG	TAA	
protein:	met	- ser	- pro	- leu	- glu	- val	<ter>			

**FIG. 33.5** Types of mutation that cause inherited retinal diseases.

Technically, a mutation is a change in DNA from one generation to the next. In practice, the word often refers to any damaging, deleterious DNA variant, one that acts in either a dominant or

recessive fashion. This chapter uses the word largely in the second sense, that is, a mutation is “bad.” However, it is important to recognize that a rare, novel variant is not necessarily pathogenic and a polymorphic variant with an allele frequency of 1% or greater is not necessarily benign.

Most disease-causing mutations affect a protein, either directly or indirectly. However, this observation may simply reflect the fact that only proteins have been well studied.

A mutation may eliminate a protein, reduce or eliminate its function, alter or add to its function, or convert the protein into a toxic factor. One way of describing mutations is by their consequences: an absent protein, a functional null, a gain or loss of function, or a toxic protein. Dominant mutations may also be described as dominant negative: the mutant protein interferes with the wild-type protein. As a sweeping generalization, with many exceptions, autosomal recessive mutations often lead to an absence of a protein or a functional null, and autosomal dominant mutations often result in a gain of function, toxic protein, or dominant negative effect. X-linked mutations are less predictable because of the differential effect in males and females.

Another way to categorize mutations is to work from DNA to mRNA to proteins:

1. DNA deletions or rearrangements may result in the absence of a protein or a critical part of a protein. Surprisingly, humans harbor large, polymorphic deletions, some 100 kb in length or longer.<sup>40</sup> In apparently healthy people, these are in a heterozygous state: one chromosome segment is deleted, and the matching segment on the homologous chromosome is intact. Large, homozygous deletions are severely deleterious. Smaller deletions, usually the size of a gene or less, affecting one or a few proteins, may cause autosomal dominant, autosomal recessive, or X-linked retinal diseases.<sup>14,41,42</sup>

2. DNA changes 5' to the start of transcription may block synthesis of mRNA or may affect timing or amounts of mRNA. These are promoter or expression mutations. Further, any changes to the canonical nucleotides that define the donor or acceptor splice sites of introns may profoundly affect mRNA splicing. These are splice site mutations. Splice site mutations typically result in a structurally

abnormal protein or no protein at all.

3. Finally, mutations can alter proteins directly in a myriad of ways. Mutations in DNA that directly affect proteins are broadly classed into nucleotide substitutions in contrast to small insertions or deletions, typically 1–15 bp in length, called indels. A nucleotide substitution that causes replacement of one amino acid with another is a missense mutation. Missense mutations may alter protein function or produce a toxic protein or a dominant negative protein. (A nucleotide substitution that changes a codon but does not alter an amino acid is a silent substitution. Most silent substitutions are benign.) An indel that alters the order of codons is a frameshift mutation or an in-frame amino acid deletion. A nucleotide substitution that introduces a signal to stop translation of a message prior to the normal stop is a nonsense mutation or a premature-stop mutation. Indels and premature-stop mutations produce a severely abnormal protein or no protein.

It is likely that new ways in which mutations can cause disease will be revealed in the future as the complexity of the human genome and inherited diseases is better understood.

## Genetic Testing Methods

The primary purpose of genetic testing for iRDs is to determine the underlying cause of disease in an affected individual and in his or her family. A broader goal is to use genetic testing for research purposes, e.g., to find novel mutations, to discover new disease-causing genes, to identify patients for clinical trials, or to study the natural history of disease. There is no clear demarcation between diagnostic testing and research, but there are practical distinctions. Diagnostic testing is often limited to testing affected individuals, screening known genes only, and is usually conducted in a certified laboratory. (Diagnostic laboratories in the USA have Clinical Laboratory Improvement Amendments (CLIA)<sup>43</sup> and/or College of American Pathologists (CAP)<sup>44</sup> certification.) Research testing may involve other family members, may screen novel genes, and is often conducted in facilities that are not certified.

However, for this section, no distinction is made between diagnostic testing and research testing, in part because the boundary between them is frequently shifting. In general, diagnostic testing and research are highly interdependent activities.

Current methods for genetic testing can be grouped into three categories: (1) screening known genes and mutations; (2) mapping to localize the disease-causing gene; and (3) high-throughput DNA sequencing. However, the essential first step is an informed clinical examination, which must precede testing.

## Informed Clinical Examination

The clinical examination is critical in selecting the correct tests and in making sense of the results. An effective examination and good family history are necessary to establish the mode of inheritance, may identify subtle clinical findings suggesting possible causes, and may rule out certain genes and diseases. The examination may involve additional affected and unaffected family members, which will facilitate follow-up studies. Finally, without good clinical and family information it may be difficult or impossible to interpret and explain the testing results.

## Screening Known Genes and Mutations

For each category of disease there is a set of known, possible disease-causing genes and a set of known mutations within each gene. Among the known genes and mutations, some are more common causes of disease than others. For example, mutations in 27 genes are known to cause autosomal dominant RP,<sup>1</sup> and more than 1000 mutations have been reported in these genes.<sup>2</sup> However, mutations in one gene, rhodopsin, account for at least 25% of cases of autosomal dominant RP in the United States.<sup>4</sup> Also, more than 195 mutations have been reported in rhodopsin alone, but six of these mutations account for more than half of all cases.<sup>24</sup>

As a consequence, the natural next step is to test the most likely disease-causing genes in an affected individual, based on clinical findings and family history. One approach uses polymerase chain reaction-based di-deoxy chain termination cycle sequencing, also called Sanger sequencing.<sup>45,46</sup> Sequencing laboratories and services

in the United States for iRDs include commercial facilities, university-based services, and federally supported programs.<sup>47</sup> A current list of testing facilities in Europe and the United States is maintained by GeneTests.<sup>48,49</sup>

An alternative to DNA sequencing is to detect known mutations only. One approach is to use microarrays with short single-stranded DNA sequences that bind to the region containing the targeted mutation and detect the presence or absence of the mutation. An example of this technology is arrayed primer extension.<sup>50,51</sup> The advantage of DNA sequencing is that it detects both known and unknown mutations in the genes tested. The advantage of testing known mutations only is that it is much less expensive than sequencing.

Additional possible tests include sequencing all the known disease-causing genes, even the rare causes of disease, and using methods other than sequencing to detect mutations. An example of the latter is the use of multiplex ligation-dependent probe amplification to detect large deletions.<sup>14,52,53</sup>

## Linkage and Homozygosity Mapping

If sequencing known genes fails to detect a disease-causing mutation in an affected individual, then an alternative approach is to determine the chromosomal site of the disease locus using linkage mapping. This does not immediately identify the disease gene, but it can reduce the location harboring the gene from the entire genome to a region containing, at most, a few hundred genes. From this information, other methods can be used to find the specific gene.

Linkage testing is the principal approach used to map disease genes. This involves determining whether a neutral allele at a polymorphic site is tracking with disease in a family, taking into consideration the proposed mode of inheritance. A large number of polymorphic sites are assayed, and alleles at each locus are tested for association with the putative disease mutation or mutations in each family member. If a particular allele is segregating with disease in the family, then the polymorphic locus and the disease gene are linked, that is, close together on the same chromosome.

The chromosomal location of each polymorphic site is known exactly (an outcome of the Human Genome Project), so the location of the disease gene is also fixed.

In practice, linkage testing is most useful in large families with autosomal dominant or X-linked disease since more affected family members are available for testing. Currently, linkage testing is often done using microarrays that assay up to a million SNPs, made by Affymetrix, among others.<sup>54,55</sup> Several computer programs are available for analysis of linkage data.<sup>56-58</sup> Once linkage is established, genes in the linkage region are sequenced, by a variety of methods, looking for mutations. Determining whether a rare variant in the linkage region is pathogenic can be challenging.<sup>54</sup>

In some cases, linkage can be useful in small recessive families, too. One effective approach is homozygosity mapping (also called autozygosity mapping).<sup>59</sup> If the mutations in a family with recessive disease are IBD, then not only are the mutations themselves identical, but DNA sequences within thousands of basepairs of the mutations are also identical, because of linkage. This manifests as long chromosomal segments surrounding the disease gene that contain no variant sites, for example, no heterozygous SNP sites. Long, homozygous DNA sequences are rare in humans and often indicative of IBD. They can be detected using the same SNP-testing arrays used for conventional linkage testing. Once the region containing the disease gene is located by homozygosity mapping, strategies to identify mapped genes can be applied. This has been a fruitful approach to finding genes causing recessive iRDs.<sup>60,61</sup>

## High-Throughput DNA Sequencing

In recent years, novel methods for very rapid DNA sequencing have become available. This is referred to as next-generation sequencing (NGS) or deep sequencing.<sup>62,63</sup> These approaches can be up to 10,000 times as fast as conventional di-deoxy cycle sequencing. The principle is to shear human DNA into short fragments and to sequence these fragments, up to 1 million simultaneously, in micron-sized wells or slots. The isolated sequences are then assembled computationally by comparison to the reference human genome. This is called “shotgun sequencing”

because many short, random fragments are sequenced and later assembled into long, useful sequences. Next-generation sequencing is more error-prone than conventional sequencing, but it more than compensates by the extremely high sequencing rate.

With next-generation sequencing it is practical and inexpensive to sequence large tracts of the genome in individual patients. One application is to sequence the coding regions of all human genes. This is referred to as whole-exome sequencing – the “exome” is all known exons. Another application is whole-genome sequencing, that is, sequencing the entire genome of an individual. Since exons are only 1.5% of the genome, whole-exome sequencing is currently faster and cheaper than whole-genome sequencing, but whole-genome sequencing will be common within a few years. Already, whole-exome and whole-genome sequencing have shown promise in finding novel iRD genes and mutations.<sup>54,64–66</sup>

A variant of whole-exome sequencing is to target only genes known to cause disease followed by next-generation sequencing. For retinal diseases this is retinal targeted-capture NGS.<sup>67</sup> This has the advantage of limiting analysis to known causes only, increasing the likelihood of identifying truly pathogenic mutations, but perforce excludes detection of novel disease-causing genes.

## Future Prospects

Currently, high-throughput sequencing, and even faster sequencing methods, are beginning to dominate genetic testing. One problem now, and for the foreseeable future, is distinguishing pathogenic mutations from the exceptional number of rare variants in each of us – variants that help define our individuality. Also, the sheer amount of DNA sequence data per patient is potentially overwhelming. At the same time, though, robust computational methods are under development to address these problems. The divide between diagnostic testing and research is likely to fade further. Genetic testing will play an increasingly important role in the diagnosis and treatment of iRDs, with clinical ophthalmology serving as the indispensable link between patients, families, and testing facilities.

## Mitochondrial Origins

It is now accepted that the origin of mitochondria within eukaryotes is the result of an endosymbiotic relationship and that mitochondrial (mt) DNAs can be traced to an  $\alpha$ -proteobacterial genome.<sup>1,2</sup> This theory has been supported by phylogenetic patterns of gene arrangements, small subunit ribosomal RNAs (rRNA) and protein data.<sup>3,4</sup> The DNA sequencing studies have shown that tremendous variations still remain, with the genome of the protozoan *Reclinomonas americana* having the most bacteria-like mitochondrial genome and *Rickettsia prowazekii* the most mitochondria-like eubacterial genome.<sup>1</sup> The mtDNA from eukaryote species show remarkable differences in size, ranging from 6 kb to 60 kb. They also vary in shape, with some eukaryotes having linear mtDNA while others have circular mtDNA. Although there is no recombination of mtDNA in humans, mitochondrial genomes of some plant species, such as *Arabidopsis thaliana*, have become recombinantly active.

## Mitochondrial Structure

Depending on the energy requirement of each cell, the number of mitochondria varies from one to several thousand. Each mitochondrion is divided into compartments that are contained within the outer membrane and include the intermembrane space, the inner membrane, cristae, and the matrix (Fig. 34.1). The outer

membrane is permeable to molecules smaller than 5000 Daltons, which pass through the lipid bilayer through channels called porins (voltage-dependent anion channel, VDAC) into the intermembrane space. It also contains a translocase of the outer membrane (TOM) complex that is involved in the import of resident mitochondrial proteins that are encoded by the nuclear genome and produced in the cytosol.<sup>5</sup> The inner membrane has a high content of cardiolipin, and its selective permeability allows only specific molecules into the matrix. The surface area is greatly expanded as a result of the numerous invaginations of the inner membrane, known as cristae. Embedded within the inner membrane are many of the enzyme complexes required for adenosine triphosphate (ATP) production and the translocase of the inner membrane (TIM) complex that is responsible for the import of nuclear-encoded proteins into the matrix. The matrix contains numerous proteins, ribosomes, tRNA, and the mtDNA.

## Mitochondrial DNA (mtDNA)

Mitochondria are unique in that they have their own DNA that is inherited through the maternal lineage. The human mtDNA forms a closed circle of double-stranded DNA, with 16,569 nucleotide pairs, comprised of two strands that are differentiated by their nucleotide content. The heavy strand is guanine-rich and encodes for 28 genes while the light strand is cytosine-rich and encodes for nine genes. Unlike the nuclear genome, mtDNA contains a unique noncoding Control Region but no introns. The noncoding mtDNA D-loop has within it the 1121 nucleotide control region that is important for replication and transcription. The coding region of mtDNA codes for 37 genes including 13 protein subunits essential for oxidative phosphorylation (OXPHOS), 2 ribosomal RNAs, and 22 transfer RNAs (Fig. 34.2A).<sup>6-8</sup> Recently, small biologically active mitochondrial derived peptides (MDPs) that are encoded from the mtDNA genome have been reported. The vast majority of mitochondrial proteins (~1500–2000), many of which contribute to energy biogenesis,<sup>4,9</sup> are encoded by nuclear DNA and imported into the mitochondria.

**Human mtDNA Migrations**  
<http://www.mitomap.org>

**FIG. 34.2** Haplogroups' associated mt single nucleotide polymorphisms (SNPs) and global origins of mtDNA. (A) Schematic of circular mtDNA showing noncoding D-loop region and coding genome. SNPs that define the H haplogroup (73A>G, 7028C>T), the J haplogroup (13708 G>A, 16126 C>T, 16069 C>T), T haplogroup (4917 A>G, 13368 G>A), UK haplogroup (12308 A>G), and K haplogroup (9055 G>A) are shown. Note that some are nonsynonymous SNPs that lead to amino acid changes that may alter bioenergetic functions. The 4977 bp common deletion spans coding regions for subunits of complexes I, IV, and V. Cells that have this common deletion will have decreased bioenergetic efficiency. (B) Map of the haplogroup origins showing mtDNA distribution worldwide. *MYR*, million years; *YBP*, years before present. (Panel A modified from [www.mitomap.org](http://www.mitomap.org); illustration by S. Atilano. Panel B image from [www.mitomap.org](http://www.mitomap.org).)

Within a cell there is a single DNA copy of the nuclear genome (nDNA) but multiple copies of mtDNA because there can be thousands of mitochondria per cell, and within each mitochondrion, 1 to 10 copies of mtDNA. With aging and exposure to oxidative stress, mtDNA molecules can be damaged, which results in a mixture of nonmutated (wild-type) and mutant mtDNA within the same cell. This mixture of damaged and undamaged mtDNA is termed heteroplasmy. When cells with heteroplasmic mitochondria divide, the two types of mtDNA are randomly or in some instances nonrandomly distributed into the daughter cells.<sup>10-14</sup> Alternatively, cells may have either a pure mutant mtDNA or pure nonmutant (wild-type) mtDNA population, in which case it is referred to as homoplasmic mtDNA.<sup>15</sup> Homoplasmy within a cell indicates that all mtDNA copies are identical. Cells can function only with relatively low levels of heteroplasmy, but once this threshold is breached, abnormal function and disease can occur. Although low levels of heteroplasmic mtDNA defects may have an effect on function, the mtDNA changes are not always obvious and special technical approaches are required to ensure their detection. Correlating a phenotype with mtDNA defects can be difficult

because the complexity of the phenotype can be influenced by when (time during embryogenesis) and where (tissue-type) the mutation arises.<sup>16-18</sup> In addition, environmental factors, such as oxidative stress, can modulate the expression of the phenotype. mtDNA is particularly susceptible to oxidative damage because it resides in the matrix in close proximity to sites of ROS formation. In addition, the mitochondrion has a poor DNA repair process and a high transcription rate. Oxidative damage to mtDNA is especially prevalent in very metabolically active tissues such as the retina, brain, and muscle.

## Mitochondrial Function

The mitochondria perform many essential roles, such as heme biosynthesis, calcium buffering, iron homeostasis, and regulation of apoptosis. The mitochondria are also the major site of cellular energy production, which includes contributions from beta-oxidation of fatty acids, the tricarboxylic acid (TCA) cycle, and OXPHOS. The initial molecular processes occur within the intermembrane space and mitochondrial matrix to produce acetyl CoA, which is then taken up into the TCA cycle. In addition to producing ATP, the TCA cycle also supplies reducing equivalents for OXPHOS via enzymes of the electron transport chain (ETC). The ETC consist of five multi-subunit respiratory complexes (complexes I–V) that are embedded in the mitochondrial inner membrane. Thirteen critical protein subunits of the respiratory complexes I, III, IV, and V are encoded by mtDNA and produced within the mitochondria. The remaining ETC subunits, including the four subunits of respiratory complex II, are encoded by the nuclear genome, produced in the cytosol, and imported into the mitochondria.

## Electron Leakage and ROS Formation

Under normal conditions, ATP is produced via a series of oxidation-reduction reactions that involve the flow of electrons through complex I to IV of the ETC. Electron transfer generates the energy required to transport protons across the inner mt membrane

into the inner membrane space. The flow of the protons down their concentration gradient from the inner membrane space into the matrix through complex V, also known as the ATP synthase, provides the energy to generate ATP from ADP. Under optimal conditions, each molecular oxygen captures two electrons released from complex IV to form water. However, partial reduction of oxygen can produce potentially harmful intermediates, such as superoxide, peroxide, and hydroxyl radicals, collectively known as reactive oxygen species (ROS). Additionally, ineffective transfer of electrons between ETC complexes can permit partial reduction of oxygen and production of ROS as byproducts during normal oxidative metabolism. In fact, approximately 2% to 5% of the oxygen we consume is only partially reduced and forms ROS.<sup>19</sup>

## Localization of Mitochondria Within the Retina and Optic Nerve

The retina has one of the highest oxygen consumption rates in the body due, in part, to the high concentration of mitochondria in nearly all cells. Mitochondria are distributed toward the source of oxygen, which in the outer retina are toward the choriocapillaris and for the inner retina toward the inner retinal vessels. To meet the energy demand for vision, the photoreceptor cells have a high concentration of mitochondria within the inner segments and at the axon terminals, thus receiving oxygen from both the choriocapillaris and the deep capillaries of the inner retinal vasculature (Fig. 34.3). In RGCs, the mitochondria are present in the soma around the nucleus and along the axons, but they tend to accumulate just anterior to the lamina cribrosa (Fig. 34.3).<sup>20</sup> For Müller cells, mitochondria congregate along the outer limiting membrane toward their oxygen source from the choriocapillaris. Mitochondria in the RPE cluster at the basal surface of the cell, which is adjacent to the choriocapillaris.

**FIG. 34.3** Mitochondrial localization within retinal cells. Schematic showing sites with high density of mitochondria within retinal ganglion cells, cone photoreceptors, and rod photoreceptors. (Illustration by S. Atilano.)

## Influences of mtDNA on Cell Function

Influences of mtDNA upon cell function can be classified into hereditary (ancient adaptive polymorphism changes/haplogroups versus recent mutations) and somatic mtDNA changes.<sup>21</sup> Examples of each are presented below.

### Ancient Inherited mtDNA Variants Representing Populations (Haplogroups)

#### Definition of Haplogroups

Haplogroups are mtDNA sequence polymorphism variations that have occurred over more than 150,000 years and correlate to the

geographic origins of populations traced through the maternal lineages (Fig. 34.2B). The oldest haplogroups are from Africa, and with migration and climate adaptations, European, Asian, and Native American haplogroups have evolved.<sup>4</sup> Each haplogroup has related patterns of mtDNA sequences (haplotypes) that represent that population. If the specific single nucleotide polymorphism (SNP) variants representing the haplogroup are found in the mtDNA D-loop, it can affect the replication and transcription rates. If within the coding region, the SNP variants can be nonsynonymous (amino acid changing), which can alter efficiencies of energy production, causing ROS formation, apoptosis, and cell death. This means that each haplogroup, with its different set of SNPs, can produce unique bioenergetic properties.

### **Association of Haplogroups With Retinal Diseases**

Haplogroups increasingly are being correlated to a broad spectrum of age-related diseases, such as Parkinson's disease and Alzheimer's disease.<sup>22-32</sup> Additionally, there are a number of ocular diseases that exhibit an increased disease risk among individuals in a specific haplogroup. For example, AMD is associated with specific mtDNA SNPs that define northern European haplogroups.<sup>33-36</sup> Studies of European mtDNA variants have revealed that J, T, and U haplogroups are associated with AMD,<sup>33-38</sup> while the H haplogroup has a protective effect.<sup>37</sup> Large soft drusen and retinal pigment abnormalities, which are characteristics of AMD retinas, have been associated with J and U haplogroups.<sup>33</sup> The haplogroup T-associated SNP A4917G located in the NADH dehydrogenase subunit 2 of complex I is an independent predictor of AMD.<sup>34</sup> Udar and coworkers found that patients with late AMD showed strong association with noncoding mtDNA D-loop SNPs (Fig. 34.2A).<sup>35</sup> Two variants of the T2 haplogroup, A11812G of MT-ND4 and A14233G of MT-ND6 located in respiratory complex I, are 2.5 times more likely to be associated with advanced AMD than the age-matched control subjects.<sup>36</sup>

Multiple studies have shown that a person's mtDNA background can play a role in the clinical phenotype of diseases, such as diabetes and glaucoma. In an Austrian cohort, type 2 diabetic patients with the mtDNA T haplogroup background have a higher

prevalence of diabetic retinopathy.<sup>39</sup> In an Italian population, the H haplogroup was associated with diabetic retinopathy, the H3 subgroup with neuropathy, U3 haplogroup with nephropathy, and the V haplogroup with renal failure.<sup>40</sup> In an American population, diabetic subjects who had the H haplogroup were more likely to develop proliferative diabetic retinopathy, while the UK haplogroup patients were protected.<sup>41</sup> In addition, the mtDNA haplogroups were a strong predictive risk factor for those that had elevated HgbA1c.<sup>41</sup> The manifestation of glaucoma has also been linked to specific haplogroups. Recent studies have reported that susceptibility to pseudoexfoliation glaucoma is decreased in patients with a U haplogroup but increased with T or L2 haplogroups.<sup>42,43</sup> In a Saudi Arabian population, the African L haplogroups, excluding L2 haplogroup, have been associated with increased risk of primary open angle glaucoma.<sup>44</sup>

Haplogroups may also influence diseases via interaction with nuclear genes to increase the severity of or protect against disease. It has been shown that an individual harboring the milder Leber hereditary optic neuropathy (LHON) mutations at positions 11778, 14484, and 10663 has increased probability of blindness if they have a J haplogroup background.<sup>45,46</sup> In contrast, human immunodeficiency virus (HIV)-infected patients with a J haplogroup background were protected against progression of neuroretinal disorder (NRD).<sup>47</sup>

The mechanism behind how mtDNA haplogroups influence disease risk is an area of active investigation. One of the prominent ideas is that mtDNA variants alter cellular bioenergetics. This idea is supported by results showing that mtDNA SNPs defining haplogroups can cause partial uncoupling of OXPHOS and decreased efficiency of ATP production.<sup>31,32,48</sup> If mitochondrial energy production levels fall below a specific bioenergetic threshold, the mitochondrial permeability transition pore (mtPTP) can be activated and photoreceptors or RGCs destroyed through apoptosis. This scenario of mitochondrial dysfunction playing a role in retinal or neuronal diseases may offer an array of new therapeutic approaches targeted toward increasing mitochondrial energy production, decreasing mitochondrial ROS, and stabilizing the mtPTP.

Our knowledge for understanding the effects of mtDNA upon cellular homeostasis has been advanced through the use of the transmitochondrial cybrid model, which are cell lines with identical nuclei, but the mtDNA from different subjects. Using human retinal pigment epithelial cell cybrids, it has been demonstrated that mtDNA can greatly affect growth rates of cells, bioenergetics and expression levels of complement, inflammation, and angiogenesis genes, pathways which are important in human retinal diseases.<sup>49–55</sup> In addition, cybrids with H (protective against AMD) versus J (high risk for AMD) mtDNA haplogroups have different responses to heat stress, hydrogen peroxide, and ultraviolet (UV) radiation.<sup>49,54,56,57</sup> Osteosarcoma cybrids with K mtDNA have lower mitochondrial potential, consistent with decreased endogenous leaking and uncoupled respiration compared to the H cybrids.<sup>58</sup> These studies support the hypothesis that an individual's mtDNA background sets up baseline cellular homeostasis, making the cells differentially susceptible to identical stressors.

## Recent Maternally Transmitted mtDNA Mutations Associated With Retinal Diseases

This category refers to true pathology-creating mtDNA mutations that are inherited over recent generations rather than mtDNA adaptation (haplogroups) that occur over thousands of years in response to environmental challenges. Defects or mutations in the mtDNA genes can decrease OXPHOS and ATP production, which results in energy deficiency diseases. Tissues that are very metabolically active, such as brain, heart, muscle, retina, kidney, and the endocrine organs, can be significantly affected by these changes. Therefore, many of these patients have not only retinal abnormalities but also neurologic, cardiac, metabolic, and skeletal muscle dysfunctions related to damage in these high-energy requiring organs systems. It is now apparent that patients with mtDNA mutations that cause mitochondrial dysfunction can have a wide range of clinically abnormal ocular and systemic phenotypes.<sup>59</sup> Table 34.1 lists mtDNA defects that result in diseases involving the retina and optic nerve. While there are many diseases caused by nuclear gene defects encoding mitochondrial proteins,

they are not addressed here but are covered in an excellent review by Yu-Wai-Man and coworkers.<sup>60</sup>

**TABLE 34.1**

**Mitochondrial DNA Defects That Result in Diseases Involving the Retina**

Disease	Mutation	OMIM#	Site of Action	Retinal Phenotype
Cytochrome c oxidase deficiency	T7587C, G7896A, <i>MT-CO2</i> gene	516040	Complex IV deficiency	Pigmentary retinopathy, decreased color vision, bilateral optic atrophy
Kearns–Sayre syndrome (KSS)/chronic progressive external ophthalmoplegia (CPEO)	Large mtDNA deletions	530000	Depends on site of deletion	Pigmentary degeneration of retina, altered electroretinogram, ophthalmoplegia
Leber hereditary optic neuropathy (LHON)	G11778G, <i>MT-ND4</i> gene; G3460A, <i>MT-ND1</i> gene; T14484C, <i>MT-ND6</i> gene; and others <sup>a</sup>	516003	Complex I deficiency	Acute-optic disc hyperemia, pseudoedema, circumpapillary telangiectatic microangiopathy, swollen nerve fiber layer, temporal optic nerve pallor, optic atrophy
Maternally inherited diabetes and deafness (MIDD)	A3243G, T14709C, <i>MT-TE</i> gene; mtDNA, deletions, duplication, point mutations	520000	tRNA-glu	Salt and pepper retinopathy, pigmentary degeneration, diabetic retinopathy, macular pattern dystrophy
Mitochondrial encephalopathy lactic acidosis and stroke-like episodes (MELAS)	T3271C, C3256T, A3243G <i>MT-TL1</i> gene	590050	tRNA-leu	Retinal pigment epithelium atrophy
Myoclonic epilepsy and ragged red fibers (MERRF)	C3256T, <i>MT-TL1</i> gene; G8313A, <i>MT-TK</i> gene	590060	tRNA-leu tRNA-lys	Pigmentary retinopathy
Neuropathy, ataxia, and retinitis pigmentosa (NARP)/Leigh syndrome	T8993G, T8993C, <i>MT-ATP6</i> gene	516060	Complex V deficiency	Retinitis pigmentosa, bone spicules, loss of foveal reflex, optic atrophy, ophthalmoplegia, strabismus, nystagmus
Renal tubulopathy, diabetes mellitus, and cerebellar ataxia	mtDNA duplication between ATPase6 and cytochrome b genes	560000	Complex III deficiency	Pigmentary deposits of the retina, extinguished electroretinogram

<sup>a</sup>There are 18 other allelic variants with varying phenotypes.

# Somatic mtDNA Variations Associated With Retinal Diseases

## Mechanisms of mtDNA Damage

The hydroxyl radical is most reactive with mtDNA and can produce multiple DNA modifications, such as strand breaks, cleavage of bases from the deoxyribose backbone to form abasic sites, and addition of oxygen to DNA forming many different mutagenic molecules (e.g., 8-hydroxydeoxyguanosine [8-OHdG] and thymine glycol). Compared with nuclear DNA, mtDNA is particularly susceptible to oxidative damage due in part to its close proximity to the ETC, the major cellular source of ROS.

Additionally, mtDNA lacks protective histones and has a limited capacity for repair, which includes only a mechanism for base excision repair.<sup>61</sup> Enzymes involved in base excision repair that are present in the mitochondria include glycosylases, endonucleases, and GTPases. Of great importance for ocular tissue, proteins involved in nucleotide excision repair that repair UV damage are abundant in the nucleus but are absent from the mitochondria.<sup>61</sup>

The most frequent oxidative damage to mtDNA is 8-hydroxylation/oxidation of a guanine base to 8-OHdG<sup>62,63</sup> (Fig. 34.4). This oxidative modification is mutagenic because it inhibits methylation and can pair with adenosine (rather than cytosine) during DNA replication, leading to a GC to AT conversion, which is the most frequent type of spontaneous mutation. In postmitotic tissue, such as skeletal muscle, neurons, and retina, 8-OHdG accumulates with age and disease.<sup>64–66</sup> Abasic sites, which have neither purines (adenine and guanine) nor pyrimidines (cytosine and thymine), are also produced due to DNA damage and can lead to somatic mutations. Thymine is also susceptible to oxidative modification and produces a variety of modified thymines that are mutagenic.

**FIG. 34.4** Common mtDNA base modifications caused by oxidative damage. (A) Oxidation of guanine to 8-OHdG results in the mispairing of guanine with adenosine during DNA replication. (B) An abasic site can be either an apurinic site (missing the A or G base) or apyrimidinic site (missing the C or T base). (C) Oxidation of thymine can produce multiple forms of modified thymine.

In addition to DNA mutations, oxidative damage to mtDNA can also lead to mtDNA deletions by causing double-strand breaks in the DNA.<sup>67,68</sup> Damage from UV light can also cause double-strand breaks.<sup>69</sup> In general, mtDNA deletions occur more frequently than somatic mutations in aged postmitotic tissue.<sup>70,71</sup> There is a frequently encountered 4977 bp deletion known as the “common deletion.” It is located in the major arc between the two origins of replication ( $O_H$  and  $O_L$ ) and is flanked by short direct repeats (Fig. 34.2A). This region of the mtDNA genome is eliminated with increasing frequency in aged postmitotic cells, such as neurons, muscle, cochlear tissue, retina, and retinal pigment epithelium (RPE) and thus is considered a hallmark of aging.<sup>64,70,72–75</sup> In a comparison of the amount of common deletion 4977 in ocular tissue, the occurrence is highest in the cornea > iris > retina and accumulates with age.<sup>76</sup> The common deletion encompasses the coding region for subunits of complex I (ND3, ND4, ND4L, ND5),

complex IV (cytochrome oxidase III), and complex V (ATPase 6, ATPase 8). Therefore, high levels of common deletion should have a functional impact on the cell. However, each cell contains multiple mtDNA copy numbers, which may be a mixture of damaged and undamaged mtDNA (heteroplasmic). As the damaged mtDNA continues to accumulate, a “critical threshold” is reached, whereby extensive mitochondrial dysfunction causes detrimental consequences for the cell. Importantly, the “critical threshold” is tissue-specific. For example, the abundance of mtDNA deletions must reach >85% in muscles of Kearns–Sayre syndrome patients for disease phenotype to manifest.<sup>77</sup> In aged substantia nigra neurons, the critical threshold for functional defects is between 48% and 67%.<sup>66</sup> In RPE from elderly donors, deletion levels of ~40% were tolerated since the donors had no clinically obvious signs of retinal degeneration.<sup>75</sup> This may explain why clinical signs of diseases (such as drusen and RPE cell loss) may take decades to present in AMD patients. Of note, the content of RPE mtDNA deletions was not significantly increased in age-related macular degeneration (AMD) eyes compared with age-matched controls, suggesting that the presence of the common deletion does not contribute to AMD pathology.<sup>75</sup>

Two opposing models involving either replication or repair have been proposed as the mechanism for deletion formation.<sup>78</sup> While both models are supported by strong evidence, the presence of high levels of deletions in postmitotic cells compared with actively replicating mitotic cells favors defects in the process of repair as the mechanism responsible for generating deletions. In brief, double-stranded breaks that occur as a consequence of oxidative or UV damage stimulates activation likely of a 3'-5' exonuclease that removes base pairs that are directly adjacent to the double-stranded break.<sup>78</sup> This action exposes homologous regions of 10–15 bp and allows them to anneal with direct repeats on the opposite strand. The unbound single strands are degraded and double strands are ligated. This results in production of mtDNA containing a partially deleted sequence. Thus, the age-dependent accumulation of mtDNA deletions is likely a byproduct of a lifetime of ongoing repair.

In vitro studies show that oxidative stress leads to preferential

damage of mtDNA compared to nuclear DNA.<sup>79</sup> There are numerous reports of mitochondrial abnormalities, including mtDNA damage, in aging, and AMD retinas.<sup>75,79-84</sup> Animal models also support the idea that mtDNA is particularly vulnerable to damage, as demonstrated by increased mtDNA deletions and damage in aging and degenerating retinas.<sup>82,85</sup> In some studies, specific regions of damage have been identified. In diabetic retinas and in retinas from donors with AMD, the mtDNA D-loop region has increased levels of damage compared to other regions.<sup>84,86</sup> The retinal ganglion cells (RGC) with their long axons are also susceptible to mitochondria damage. The numbers of RGCs and their axons are significantly decreased in Leber hereditary optic neuropathy and glaucoma.<sup>87,88</sup> This may be related to lower energy production caused by mtDNA damage and dysfunction.

### **mtDNA Damage and AMD**

Three studies using a long-extension polymerase chain reaction technique testing for mtDNA damage in the RPE from human donor eyes provided evidence that mtDNA damage is increased with AMD. Karunadharma and colleagues showed marked differences in damage accumulation with aging and disease.<sup>75</sup> Age-related damage in the RPE appeared to be limited to the common deletion, whereas AMD was associated with global damage, which includes deletions and oxidative damage to mtDNA, throughout the mt genome. Corroborating data was also provided by Lin and colleagues, who showed that the increased DNA damage in RPE cultured from donors with AMD was accompanied by a fivefold increase in somatic mutations compared with age-matched controls.<sup>89</sup> Terluk and colleagues showed increased mtDNA damage with AMD progression occurred in the RPE but not the neural retina, and also localized the damage to specific regions of the mt genome, including the regulatory D-loop.<sup>84</sup> This result was consistent with a previous study where the sequence analyses of the mtDNA D-loop showed a significantly greater number of SNPs per person in the AMD population compared to either older or younger normal groups.<sup>80</sup> Increased oxidative DNA damage in retinas from donors with AMD was also shown from immunohistochemical staining with antibodies that recognize 8-OH-dG.<sup>35</sup> These results

support the hypothesis that defects in the mitochondria are hallmark, and most probably pathologic, events in AMD and other retinal diseases.

The potential consequences provoked by mtDNA damage has been suggested from studies using an animal model, where increased accumulation of mtDNA deletions and mutations impaired the cellular function and left the cells more susceptible to external stresses.<sup>90</sup> Additionally, damaged cells can release mtDNA, eliciting an inflammatory reaction because mtDNA contains “damage-associated molecular patterns,” or DAMPs, that bind to toll-like receptors and activate the NLRP3 inflammasomes,<sup>91</sup> alter innate immunity, and generate chronic, low-grade inflammation.<sup>92</sup> Inflammation and inflammasome activation play an important role in several retinal diseases, including AMD.

## Epigenetics and mtDNA

“Epigenetics” describes mechanisms by which gene expression and cellular functions are modified without alterations in the gene sequence. Epigenetic changes can be inherited but are also subject to environmental factors and are reversible. The most common epigenetic modification occurs at CpG dinucleotides where the 5' position cytosine becomes methylated to become 5-methylcytosine (5-mc). Another epigenetics event includes histone modifications through methylation, acetylation, phosphorylation, ubiquitylation, and SUMOylation, which ultimately activates or inhibits transcription, thereby regulating gene expression.<sup>93</sup>

Recent studies have shown that altered epigenetic profiles play a role in human retinal diseases including AMD, diabetic retinopathy, retinitis pigmentosa, proliferative vitreoretinopathy, retinoblastoma, and uveal melanoma.<sup>94-98</sup> There is a close association between mitochondria and methylation status. For example, DNA methylation levels are affected if mitochondria are depleted from cells.<sup>99</sup> High glucose levels, as seen in diabetes, lead to hypermethylation of mtDNA and mitochondrial dysfunction.<sup>95</sup> In addition, cybrids with the J mtDNA haplogroup have elevated total global methylation levels and higher expression levels of genes associated with acetylation and methylation compared to cybrids

with H mtDNA.<sup>100,101</sup> Furthermore, methylation inhibitor studies show the mtDNA variants can influence transcription for inflammation, signaling and angiogenesis genes, which are important pathways in retinal diseases.<sup>101</sup> It has been suggested that epigenetic changes of the nDNA and mtDNA leads to long-term “metabolic memory,” which causes pathologic conditions leading to retinal diseases.<sup>102</sup> Investigating the role of epigenetics in retinal diseases has provided a new area for developing therapeutics and drugs that target this malleable condition within the human genome.

## Mitochondria as a Target for Retinal Diseases

The importance of mtDNA damage and mitochondrial dysfunction to the development and progression of retinal diseases has become increasingly recognized. This is true not only for eye diseases but also for neurodegenerative diseases, cancers, diabetes, obesity, and cardiovascular diseases. Therefore, the mitochondria have become a target for a new field of drug development. While there are currently no ongoing clinical trials using mitochondrial-targeting drugs for retinal diseases, this represents an exciting, novel area of research with great therapeutic potential.

Two different approaches to protecting the mitochondria included either capitalizing on endogenously produced compounds (i.e., mitochondrial derived peptides) or targeting specific pathways that are involved in maintaining mitochondrial function.

Mitochondrial-derived peptides (MDPs) are recently identified biologically active, short peptides (20–27 AAs) that are encoded from short open reading frames (sORF) in the mtDNA genome.<sup>103–106</sup> In 2001, Humanin (MT-RNR2), a 24 amino acid peptide, was the first MDP described,<sup>107</sup> is encoded from the 16S rRNA region of the mtDNA and has been shown in vitro and in vivo to have antiapoptotic, neuroprotective properties supporting cell survival.<sup>103,105,106,108,109</sup> Humanin levels decline with aging, and it has been associated with many age-related and metabolic diseases.<sup>103,110</sup> A second MDP, called MOTS-c, is coded from the 12S rRNA region of mtDNA and plays a role in regulation of metabolic

homeostasis and insulin sensitivity.<sup>111</sup> The MDPs represent a new class of biologically active molecules with tremendous potential to protect retinal cells from aging and oxidative stress associated with retinal pathology.

Another approach for maintaining mitochondrial function includes targeting specific pathways that are altered with aging and disease. The decrease in mitochondrial function is often paralleled by increased oxidative stress and high levels of ROS. Therefore antioxidant drugs, (e.g.,  $\alpha$ -lipoic acid,  $\alpha$ -tocopherol, genistein, resveratrol, memantine, MitoQ, and Mito-CP) have been tested in vitro and in vivo for their protective effects with some encouraging results.<sup>112-114</sup> However, the positive outcome of a vitamin/mineral supplement in slowing the progression to blindness in some AMD patients support the notion that suppressing ROS damage is a viable therapeutic approach for AMD.<sup>115-118</sup> Attempts to attenuate the decrease in energy production have been to supplement with substrates or regulators of energy metabolism (e.g., creatine, EPI-743, coenzyme Q10, and its analogs such as Idebenone, or quinone analogs, such as SkQ1, SkQR1).<sup>119-121</sup> Some positive results have been obtained with this approach. In a small open-label trial for five patients with Leber hereditary optic neuropathy, EPI-743 arrested disease progression and reversed vision loss in all but one participant.<sup>122</sup> Preventing apoptosis by stabilizing the mitochondrial permeability transition pore with cyclosporine A or by inhibiting the mitochondrial fission protein Drp1 with the drug MDIV-1 or molecular manipulation have shown protective effects in the in vitro and in vivo models.<sup>123-127</sup> Another promising drug, known as MTP-131, was effective in reversing the visual decline associated with diabetes induced by either streptozotocin or a high fat diet in mice and protecting ocular cells against oxidative stress in vitro.<sup>128,129</sup> MTP-131(SS-31) is a soluble peptide that has high affinity for cardiolipin and selectively partitions into the inner mitochondrial membrane.<sup>130,131</sup> Some of these drugs have been tested clinically for cardiovascular and neurodegenerative disorders, but none has been performed on a large-scale clinical scale for retinal diseases.<sup>112,113,119,120,126,132,133</sup> The field of mitochondria-targeting drugs to treated retinal and other ocular diseases has shown tremendous promise and will be expanding in the future.

**Perspectives and Challenges of Epigenetics**

Treatment of Retinal Disease With Epigenetic-Modifying Drugs

## Introduction

The term “epigenetics” was coined by C.H. Waddington in the 1940s, fusing the word “genetics” with “epigenesis,” the latter indicating the theory by which the adult form develops from the embryo through gradual steps, as opposed to being fully preformed as a zygote.<sup>1,2</sup> Epigenetics refers to the modifications of external factors to DNA that turn genes “on” or “off” by which the functions and behaviors of an organism are modified, these modifications do not cause a change of the DNA sequence but are inheritable. Since

the 1990s, with the expansion of epigenetic research, several new concepts and terms such as the epigenome, epigenetic epidemiology, epigenetic pathology, epigenetic disease, epimutation, and epigenetic therapy have been created. In order to promote epigenetic research, the Association for the Study of the Epigenome in Europe was established in 1999, and launched the Human Epigenome Project (HEP) in 2003. The Genome Research Institute (NHGRI) launched a public research consortium named ENCODE, the Encyclopedia of DNA Elements, in September 2003 to carry out a project to identify all functional elements in the human genome sequence. In 2010, the International Human Epigenome Consortium (IHEC) was launched to coordinate international collaborative efforts to produce reference maps of epigenomes for cellular states relevant to human health and disease. Recent reports from the ENCODE project consortium show that 80% of the genome is functional; the significance of research into epigenetic mechanisms has become even more important. With the inspiration of genome-wide association studies (GWAS), epigenome-wide association studies (EWAS), primarily focused on evaluating DNA methylation across the entire genome, are identifying associations between variation in DNA methylation and common diseases or related traits.<sup>3</sup> Most recently, scientists from NIH have summarized epigenome studies and published their data from mature cells from healthy human tissues, various stem cell populations, cancer cells, and patients with neurodegenerative diseases and autoimmune diseases.<sup>4</sup> Mapping of epigenomic marks in healthy and diseased human tissues may provide new understanding into epigenetic variation and disease. Notably, the possibility of predicting the human epigenome from DNA motifs has been published.<sup>5</sup> The field of epigenetics has garnered increasing attention over recent years; therefore, the importance of epigenetic research to human health has coined the term “the epigenetic era.”

## Major Factors of Epigenetic Regulation

## DNA Methylation

Traditionally, DNA methylation involves the addition of a methyl group to the 5' position of the cytosine pyrimidine ring or the number 6 nitrogen of the adenine purine ring, and typically occurs in a CpG dinucleotide context. Recently, 5-(hydroxymethyl) cytosine (5-hmc), the sixth base of the genome, and 5-formylcytosine and 5-carboxylcytosine, the seventh and eighth bases, were discovered. CpG islands are regions with high frequency of CpG sites often at or near transcription start sites of genes. Lower CpG density regions are termed CpG "island shores."

The CpG dinucleotide is the most important site of DNA methylation. In general, CpG methylation silences genes while demethylation activates them; however, recent studies have shown that the functional effects of DNA methylation can vary according to the genomic context. In mammals, 60–90% of all CpGs are methylated in the nonpromoter area.<sup>6</sup> DNA methylation may affect the transcription of genes in two ways. First, the methylation of DNA may itself physically impede the binding of transcriptional factors to the gene, and second, and likely more important, methylated DNA may be bound by proteins known as methyl-CpG-binding domain (MBD) proteins. MBD proteins then recruit additional proteins to the locus, such as histone deacetylases (HDACs) and other chromatin remodeling proteins that can modify histones, thereby forming compact, inactive chromatin. This process has been termed silent gene expression.<sup>7</sup> On the other hand, more recently methyl CpG binding protein 2 (MeCP2), a reader of DNA methylation, has been found to bind not only methylated CpG islands related to gene silencing but also to sites of active gene transcription. MeCP2 may act as a transcriptional repressor or as a gene activator depending on its specific modification and the microenvironment.<sup>8</sup>

Although CpG dinucleotides are the primary site of DNA methylation in mammals, there is new evidence to show that up to 7.5% of all non-CpG cytosines (CPA, CPT, and CPC) exist in the tissue of many mammals.<sup>9</sup> Importantly, non-CpG methylation plays a unique role in the regulation of gene expression for genes such as *PGC1*, *IFN*, and *SYT11*.<sup>10</sup> Genome-wide analysis showed that non-CpG methylation is abundant in the adult brain.

## Histone Methylation

Histone methylation is the modification of certain amino acids in a histone protein by the addition of one, two, or three methyl groups, and is catalyzed by histone methyltransferases (HMTs). The regulation of gene expression by histone methylation is bifunctional and can either increase or decrease transcription of the gene, depending on the location of the histone protein. Histone lysine methylation has been well studied at the K4, K9, and K27 residues. These lysine residues can be monomethylated, dimethylated, or trimethylated. Generally, trimethylation of lysine 4 on histone H3 (H3K4me3) is associated with a fully activated promoter, which correlates with gene transcription activities, whereas dimethylation (H3K4me2) occurs at both inactive and active euchromatic genes. H3K9 is a major negative regulator of the H3K4 mark. Dimethylation at lysine 9 (H3K9me2) marks the silence of gene expression in euchromatin, whereas H3K9me3 is enriched in regions of “gene-poor” pericentric heterochromatin. Methylation at lysine 27 on histone H3 (H3K27me) is associated with transcriptional repression in many developmental processes.

## Histone Acetylation and Deacetylation

The histones can also be acetylated on lysine residues in the N-terminal tail, and this serves as an important regulatory factor of gene expression. Steady-state levels of histone acetylation are maintained by a balance between the opposing activities of histone acetyltransferases (HATs) and HDACs. Acetylation brings in a negative charge, which acts to neutralize the positive charge on the histones and decreases the interaction of the N termini of histones with the negatively charged phosphate groups of DNA. As a consequence, the condensed chromatin is transformed to a more relaxed structure, which allows transcription factors access for DNA binding and gene transcription. Aberrant histone acetylation/deacetylation and other epigenetic modulations have been implicated in cell division, growth, DNA damage, genome stability, cell fate determination, higher-level cognitive behaviors such as learning and memory<sup>11</sup> and many pathologic conditions, including inflammatory diseases characterized by expression of

inflammatory factors such as nuclear factor-kappa B (NF- $\kappa$ B) and activator protein (AP)-1 transcription factor, wound healing, degenerative and neurologic disease, cancer development, and multiple sclerosis.

Histone acetylases are broadly classified in two different types: types A and B, based on their functional localization. While type A HATs are nuclear and catalyze transcription-related acetylation events, type B HATs are cytoplasmic and catalyze acetylation events linked to the transport of newly synthesized histones from the cytoplasm to the nucleus for deposition on to newly replicated DNA. There are five main classes of HATs (GNAT, MYST, p300/CBP, transcription factor, and nuclear hormone-related), which are characterized by specific functions controlled by its specific structural folding.

The process of histone acetylation is reversed by the HDACs, which catalyze acetyl group removal, and there are four main classes (I–IV) of HDACs. HDAC1–3 and 8 are members of class I, and are located in the nucleus and involved in epigenetic regulation. HDAC4–6, 7, 9, and 10 are members of class II, and are characterized by nucleocytoplasmic shuttling. Class III HDACs are characterized by their NAD dependence. HDAC 11 has been categorized into its own group, a class IV deacetylase. These molecules have been implicated in aging and calorie restriction as well as disease.

## Noncoding RNA

A noncoding RNA (ncRNA) is a functional RNA molecule that is not translated into a protein. ncRNA genes include highly abundant and functionally important RNAs such as transfer RNA (tRNA) and ribosomal RNA (rRNA), as well as RNAs such as miRNA, siRNAs, piRNAs, and long noncoding RNAs (lncRNAs). Recently, roughly 1300 short RNA sequencing datasets from 13 distinct human tissues have documented 3707 novel mature miRNAs arising from 3494 novel precursors. The current estimates are that the human genome likely has over 25,000 miRNAs.<sup>12</sup>

miRNAs are a class of small (on average 22 nucleotides long), ncRNA molecules that regulate gene expression and are implicated

in many cellular processes, including development, tissue morphogenesis, apoptosis, and tumor growth. Genes encoding primary miRNAs are scattered throughout the genomes of eukaryotes and are transcribed to generate RNA species that are cleaved to 60–70-nucleotide stem–loop miRNA precursors (pre-miRNAs) by a microprocessor complex containing the nuclear RNaseIII Drosha and DiGeorge syndrome critical region protein. After export from the nucleus, the pre-miRNAs are cleaved by a cytoplasmic RNase III (Dicer). After strand selection and separation, mature 22-basepair miRNAs are incorporated into an RNA-induced silencing complex to act as target recognition sequences. miRNAs may contain target sequences and can undergo cleavage.

miRNAs have been implicated in the regulation of growth and development, cell differentiation and diseases by modification of chromatin structure, and regulation of transcription.<sup>13</sup>

## Epigenetic Factors in the Retina

### DNA Methylation in Mammalian Retina

DNA methylation is catalyzed by DNA methyl transferases (DNMTs), a five-member family consisting of DNMT1, 2, 3a, 3b, and 3L. Among these, DNMT1, 3a, and 3b are the catalytically active enzymes. While DNMT3a and 3b are de novo enzymes, DNMT1 is a maintenance enzyme important in regulating tissue-specific patterns of methylated cytosine residues DNMT3a methylates CpG sites at a rate much slower than that of DNMT1 but greater than that of DNMT3b. DNMT1 is expressed in human retinal pigment epithelium (RPE) cells and in endothelial cells, and DNMT3a is weakly expressed in some inner nuclear layer cells in the adult mouse retina.<sup>14</sup> DNA methylation regulates the expression of genes in mammalian retina; the gene encoding interphotoreceptor retinoid-binding protein (IRBP), a major soluble component of the interphotoreceptor matrix, which is secreted into this matrix by both rods and cones, and is hypomethylated in retinas. Methylation of IRBP promoter suppresses transcription in nonphotoreceptor cells by precluding specific DNA protein-binding events, whereas the lack of methylation in photoreceptors allows

for its transcription. In the retina of the adult mouse, EphA5, a member of the ephrin receptor subfamily of the protein-tyrosine kinase family, mediates  $1.2 \pm 0.3\%$  of CpG methylation.<sup>15</sup> This represents a relatively low level of promoter methylation. Although methylation of major CpG sites results in the silencing of EphA5 promoter activity, lower levels of methylation can produce differential activation or repression of EphA5 promoter activity, depending on the sites methylated. Methyl-CpG binding protein 2 (MECP2), a protein that specifically binds methylated DNA, thus regulating transcription and chromatin organization, is expressed in all retinal neurons, except rods, and the onset of its expression coincides with neuronal differentiation, in particular, with massive formation of neural synapses in the inner and outer plexiform layers.<sup>16</sup>

In the adult murine retina, H3K4me3, a mark associated with active transcription, is observed in all layers of the neural retina, including rhodopsin-positive photoreceptors, Müller glia, and retinal ganglion cells (RGCs). H3K27me3, a mark associated with transcriptional repression, is enriched in the inner nuclear layers and in a subset of outer nuclear layer in the adult murine retina. However, H3K9me2, another repressive mark, is not observed in the inner layers of the adult retina. Histone methylation, a dynamic and reversible process, is maintained by the balance between HMTs and histone demethylases (HDMs). Although the majority of HMTs contain a Su(var)3-9, Enhancer of Zeste, Trithorax (SET) domain, which catalyzes the addition of methyl groups to lysine residues, a small group consists of non-SET domain-containing enzymes. The Ezh2 and G9a HMTases are the two best-characterized HMTases, which catalyze H3K27me3 and H3K9me2 modifications, respectively, and are found in the fetal murine retina,<sup>17</sup> suggesting a crucial role of gene transcription by Ezh2- and G9a-mediated histone lysine methylation in retinal neuronal differentiation and survival. Although the enzymes responsible for demethylation are not well defined, a lysine-specific histone demethylase, LSD1, which specifically removes methyl group from H3K4me and H3K9me, is shown to be present in the retina and its capillary cells.<sup>18</sup>

As with histone methylation, a group of enzymes with opposing

functions maintain the required acetylation status; while HATs insert acetyl groups on the lysine residues, HDACs remove them.<sup>19,20</sup> Acetylated histone 3 and 4 are found in fetal and adult retina; however, their levels are reduced in dry age-related macular degeneration (AMD). HATs and HDACs are expressed in mammalian retina, and in contrast to the decrease of acetylated histones, HDAC1 is highly upregulated in human AMD retinal sections. In addition, exposure of adult murine retina to trichostatin A (TSA) induces upregulation of apoptotic genes. Activation of HDAC may decrease the retina's resistance to ischemic injury.<sup>21</sup>

## miRNA in Mammalian Retina

Gene regulation by miRNAs has been associated with normal retinal development and function and with many retinal diseases, and more than 250 miRNAs have been identified in the retina. Retinal miRNAs have different levels of expression across different layers, and some are regulated directly by light.<sup>22</sup> The most highly expressed adult mouse retinal miRNAs are miR-181a, 182, 183, 204, 125b, 126a, and 124a. Among these, miR182 is expressed throughout all layers of the retina, miR-181 is in the ganglion cell, inner plexiform and inner nuclear layers; and miR-183 is expressed only in the outer nuclear layer. Strong expression of miR-204 is detected in the RPE and the ciliary body, and miR-124a is expressed in all layers of the neural retina except the RPE. miRNA-132, miR-204, and 211 are also expressed in the RPE. Transforming growth factor-beta (TGF- $\beta$ ) receptor-2 and SNAIL2 are direct targets of miR-204. Notably, anti-miR-204/211 decreases transepithelial resistance and reduces cell membrane voltage and conductance, suggesting a critical role of miR-204/211 in maintaining epithelial barrier function and cell physiology.

## Epigenetic Mechanisms in Retinal Development

Although epigenetic mechanisms have been shown to regulate neural stem cell renewal and differentiation, it was not until recent

years that their involvement in retinal development has been realized. The retina is composed of specialized glia and neuronal cells which are generated from multipotent retinal progenitor cells in a highly conserved temporal sequence with overlapping phases during development. RGCs, horizontal cells, and cone photoreceptors appear in the early phases, while rod photoreceptors, bipolar cells, and Müller glial cells appear in the late phases. The cell fate decision of the progenitor cells depends on both intrinsic and environmental cues, and these are regulated by specific networks of transcription factors. Through covalent modifications of DNA and histone, chromatin remodeling regulates the interactions of these transcription factors and their effector genes, and is an important epigenetic mechanism in retinal development.

## DNA and Histone Methylation in Retinal Development

DNA and histone methylation are mediated by DNMT and HMTases. In zebrafish retina, antisense-based morpholino knockdown of DNMT3 and H3K9 HMTases Suv39h1 and G9a lead to defects in retinal cell differentiation, supporting a role of both DNA and histone methylation in zebrafish retinal development. In mice, immunohistochemical analysis shows changing patterns of histone methylation marks in the developing retina. Specifically, the transcriptionally activating H3K4me3 and repressive H3K27me3 histone marks are found in differentiated neurons from embryo to adulthood, corresponding to the expression of the HMTase Ezh2 that catalyzes the H3K27me3 mark. In contrast to Jmjd3, Ezh2 is expressed in the embryonic retina, but its expression decreases rapidly after birth, suggesting an important role for histone H3K27me3 modification in regulating the proliferation and maturation of certain subsets of interneurons in the retina.<sup>23</sup> In contrast, the repressive H3K9me2 mark and the corresponding HMTase G9a are seen primarily in early differentiating RGCs, and decrease after birth. These changing patterns of histone methylation may, at least in part, account for the temporal sequence of retinal progenitor cell differentiation during development. Evidence also

implicates DNA methylation in regulating the expression of genes involved in the topographic patterning of RGC axons, such as EphA5 receptor.<sup>15</sup> These studies have suggested that DNA and histone modifications may regulate both temporal and spatial expression of these genes in different populations of retinal progenitor cells to orchestrate the precise timing of cell proliferation and differentiation during development.

## Histone Acetylation in Retinal Development

During photoreceptor differentiation, HAT-containing coactivators, such as general control nondepressible 5 (Gcn5) and CREB-binding protein (Cbp), interact with cone-rod homeobox (Crx) transcription factor to promote the transcription of opsin genes. The role of the histone acetyltransferase-containing Tip60 is shown in the developing mouse retina by acting as a coactivator in the Nrl-dependent transcriptional regulation of the rhodopsin and Ppp2r5c gene.<sup>24</sup> In addition to HATs, HDACs have been also studied extensively and are implicated in retinal development. HDAC1 is recruited by the retinoblastoma protein (Rb) and related family members to promoters with E2F-binding sites, resulting in transcriptional repression of cell cycle genes and suppression of cell growth. In zebrafish, *hdac1*-deficient mutants exhibit retinal cell proliferation and differentiation defects, resulting in severe reduction in the inner and outer plexiform layers and absence of RGC, rod and cone photoreceptors, and Müller glia. These defects result from failure in downregulation of cyclin D and E transcription and the canonical Wnt and Notch signaling pathways, which are necessary for retinal progenitor cells to exit the cell cycle, suggesting that histone deacetylation may be a regulatory mechanism to switch off stem cell proliferation and initiate a program for retinal differentiation. In mouse retinal explants, pharmacologic inhibition of HDAC with TSA also results in defects in rod differentiation, but unlike in zebrafish, causes a reduction in retinal progenitor cell proliferation. In vivo knockdown of HDAC4 by RNA interference leads to apoptosis of rod photoreceptors and bipolar cells, and overexpression of HDAC4 reduces naturally occurring cell death of bipolar cells, supporting a role of HDAC4 in

promoting the survival of developing retinal neurons as well.<sup>25</sup> Further work is needed to help clarify the specific downstream effectors regulated by HATs and HDACs during the various stages of retinal development.

## Chromatin Remodeling Complexes in Retinal Development

While covalent DNA and histone modifications decondense chromatin and promoter regions, adenosine triphosphate (ATP)-dependent displacement from promoters and enhancer regions requires the action of chromatin-remodeling complexes. These include the SWItch/Sucrose NonFermentable (SWI/SNF) and the Imitation SWItch (ISWI) families. Zebrafish mutants lacking the brahma-related gene 1 (*BRG1*), the catalytic ATPase subunit of SWI/SNF chromatin remodeling complex, show defects in retinal differentiation, suggesting that *BRG1* is involved in triggering retinal cell differentiation. In mice, however, loss of *BRG1* in neural stem cells results in precocious neuronal differentiation, suggesting that it represses differentiation and maintains neural stem and progenitor cells. These differences may be related to changes in the composition of accessory units known as BRG1-associated factors (BAFs) in the SWI/SNF complexes in different cell states. Nevertheless, chromatin-remodeling complexes are likely to be critically involved in regulating retinal cell differentiation during development.

## microRNAs in Retinal Development

Recently, miRNAs have also been implicated in retinal development. Early studies using a conditional knockout mouse lacking the RNA endonuclease Dicer in the retina has shown no defects in the retina before the second postnatal week, suggesting that miRNAs are not required for mouse retinal development. However, subsequent research using a different strain of Dicer conditional knockout mouse have documented increased production of early generated cell types such as RGC and horizontal cells, and failure to generate late-born cell types such as

rod photoreceptors and Müller glia. This is also supported by data from *Xenopus* morpholinos, where Dicer inactivation results in defects in cell cycle, lamination, and timing of retinal differentiation. Thus Dicer and miRNAs may provide a common regulatory mechanism to signal changes in retinal progenitor cell competence.<sup>26</sup>

Microarray analysis of the miRNA transcriptome in mouse retina has revealed at least 78 miRNAs, 21 of which are potentially retina-specific.<sup>27</sup> The miRNA transcriptome of the mouse retina is similar to that of humans, and shows dozens of miRNAs that are differentially expressed during different stages of development. In *Xenopus*, miRNAs have been found to inhibit the translation of homeodomain transcription factors (Xotx2 and Xvsx1) involved in bipolar cell differentiation by binding the 3' untranslated region of mRNAs. Inactivation of these miRNAs in vivo releases the inhibition and supports the generation of additional bipolar cells. Another miRNA, miR-24a, negatively regulates proapoptotic factors caspase-9 and apoptotic protease-activating factor 1 (apaf1) in *Xenopus* retina. Inhibition of miR-24a leads to increased apoptosis during retina development and reduction in eye size. miR-7a is shown to regulate Müller glia differentiation, possibly, via attenuation of Notch3 expression, and miR410 in RPE differentiation program.<sup>28,29</sup> Target prediction and in vitro functional studies have indicated that the microphthalmia-associated transcription factor (MITF), a transcription factor necessary for the development and function of RPE, is directly inhibited by miR-96 and miR-182, supporting a role of miRNAs in RPE maintenance also. MiR-124a, which is expressed in all neuronal subtypes in the adult retina, has also been shown to repress retinol dehydrogenase 10 (Rdh10), which is selectively expressed in Müller glia and RPE. Hence, some miRNAs may impact retinal development not by affecting neuronal proliferation and differentiation, but via effects on supporting glial and RPE cells. MicroRNA research is still in its infancy, and more work is necessary to determine the landscape of noncoding RNAs in different retinal cell populations.

# Epigenetic Mechanisms in Retinal Diseases

## Epigenetic Factors in Retinal Fibrosis

It is known that RPE cells are key players in the pathogenesis of proliferative vitreoretinopathy (PVR). In PVR, RPE cells undergo epithelial–mesenchymal transition (EMT) characterized by an increase in mesenchymal cell components and the manifestation of a migratory and proliferative phenotype. Transdifferentiation of RPE cells into myofibroblast-like cells has been exclusively demonstrated in tissue repair during several retinal pathologic conditions, including choroidal neovascularization, diabetic retinopathy, and PVR. A major feature of RPE transdifferentiation is the increased expression of alpha smooth-muscle actin ( $\alpha$ -SMA), and  $\alpha$ -SMA-positive RPE cells have been shown to be the major cells that promote contraction and induce retinal detachment in PVR. Although a variety of inflammatory cytokines and growth factors (in particular, TGF- $\beta$  and PDGF) are involved in the regulation of RPE transdifferentiation, the basic mechanisms of the RPE transdifferentiation from an epithelial cell to a myofibroblast-like cell is still under investigation. TGF- $\beta$  is the major inducer of  $\alpha$ -SMA expression in transdifferentiated cells,<sup>30</sup> and increased TGF- $\beta$  activity is associated with the downregulation of the genes of transdifferentiation inhibitors such as Smad7, I $\kappa$ B $\alpha$ , and peroxisome proliferator-activated receptor-gamma (PPAR- $\gamma$ ).<sup>31</sup>

## DNA Methylation

Recent studies suggest that the wound-healing process is also regulated by epigenetic factors, including DNA methylation and histone acetylation.<sup>32</sup> In terms of DNA methylation, MeCP2 has been demonstrated to be an orchestrator of epithelial myofibroblastic transdifferentiation and play a pivotal role in EMT and/or fibrosis.<sup>32</sup> We have recently shown that RPE EMT and the pathogenesis of PVR are tightly regulated by MeCP2.<sup>33</sup> MeCP2 is highly expressed in human PVR membranes (Fig. 35.1) and MeCP2 colocalized with cytokeratin and  $\alpha$ -SMA in human PVR

membranes. Knockdown of MeCP2 by specific siRNA inhibits TGF $\beta$ -receptor 2 and Smad2/3 activation and  $\alpha$ -SMA, fibronectin expression induced by TGF- $\beta$ . The regulation of  $\alpha$ -SMA by MeCP2 is mediated through the Ras GTPase activating-like protein (RASAL1). 5-aza-2'deoxyctidine (5-AZA, a DNA methylation inhibitor) suppressed *RASAL1* gene promote methylation while increasing the gene expression of *RASAL1*.<sup>33</sup> More importantly, we have shown that PPAR- $\gamma$  expression is almost absent in human PVR membranes; the upregulation of PPAR- $\gamma$  is associated with the decreased expression of MeCP2 after methylation inhibitor 5-AZA exposure. These observations support the suggestion that MeCP2 is an important factor in the regulation of fibrosis in general and that the pathogenesis of PVR may be under complex epigenetic regulation. More importantly, EMT is reversible from mesenchymal-to-epithelial transition (MET). MeCP2 and DNA methylation may be targets for therapeutic intervention in PVR (Fig. 35.1).

**FIG. 35.1** MeCP2 expression in human proliferative vitreoretinopathy (PVR) membranes. Negative control without primary antibody (A), abundant MeCP2 expression was seen within cellular regions of a

human PVR membrane (B). *Black arrows* indicate MeCP2 staining in nuclei and *white arrows* show cytoplasmic MeCP2 immunoreactivity. (C) MeCP2 is increased in human PVR membranes, which is associated with retinal pigment epithelium (RPE) epithelial–mesenchymal transition (EMT). Application of 5-AZAdc inhibits the RPE EMT by the following mechanisms: (1) Inhibition of the expression of MeCP2 leads to increased expression of RASAL1; (2) reduction of methylation level of the RASAL1 promotor leads to upregulation of RASAL1 expression; (3) inhibition of TGF $\beta$ -R2 expression leads to decrease of TGF $\beta$  Smad2/3 phosphorylation; (4) increased RASAL1 expression and decreased Smad2/3 phosphorylation both lead to inhibition of RPE EMT.

Inhibition of DNA Methylation and Methyl-CpG-Binding Protein 2 Suppresses RPE Transdifferentiation: Relevance to Proliferative Vitreoretinopathy. Invest Ophthalmol Vis Sci 2015;56:5579-89. © Association for Research in Vision and Ophthalmology.)

## Histone Acetylation/Deacetylation

Besides DNA methylation, the other epigenetic mechanism that regulates EMT or fibrosis is histone acetylation/deacetylation. Although there are few reports of the effect of histone acetylation on RPE EMT and retinal fibrosis, the involvement of histone acetylation has been extensively studied in a number of systemic diseases.<sup>34</sup> Recent reports reveal that histone acetylation and HDAC activity are also correlated with the development and progression of some fibrotic diseases, such as cardiac hypertrophy, kidney fibrosis, idiopathic pulmonary fibrosis, and liver fibrosis. Hyunjin et al. found that HDAC inhibition suppressed both diabetes- and TGF- $\beta_1$ -induced renal fibrosis.<sup>34</sup> Inhibition of HDAC activity by TSA decreased platelet-derived growth factor (PDGF)-induced fibroblast proliferation; importantly, it was found that activation of STAT3 is required for the induction of HDAC activity; renal fibroblast activation also is blocked by the inhibition of STAT3 pathway. Interestingly, TSA is able to inhibit the TGF- $\beta$ -mediated transdifferentiation of corneal stromal cell. Furthermore, silencing

of matrix metalloproteinase (MMP) genes is under epigenetic regulation, especially by HDAC-4 during liver cell fibrogenesis. More specifically, Hyunjin et al. have demonstrated an important role of HDAC-2 in the development of EMT, and extracellular matrix (ECM) accumulation in diabetic kidney.<sup>34</sup> In the laser-induced model of choroidal neovascularization (CNV) systemic administration of TSA significantly reduces expression of vascular endothelial growth factor (VEGF), and smooth muscle actin in CNV lesions.<sup>35</sup>

Finally, alterations in DNA methylation and histone acetylation/deacetylation are required for the development and progression of tissue fibrosis. It seems that manipulation of DNA methylation and histone acetylation may suppress major profibrotic growth factors such as TGF- $\beta$ . However, the mechanisms of epigenetic-mediated EMT and fibrosis formation remain largely under investigation. Further study is required to establish the profile of DNA methylation and HDAC-mediated genes in the initiation of EMT and fibrosis, especially, the regulation of the expression of NF- $\kappa$ B, Snai1, and Twist by epigenetic factors in the process of development of RPE EMT and how the RPE EMT could be reversed to MET by increases of the MET inducer factors such as BMP7, OCT4, and SOX2 expression because the switch between EMT and MET is a dynamic process.<sup>36</sup> This knowledge is not only important for further understanding of the mechanism by which DNA methylation and histone acetylation regulates tissue fibrosis, but also is critical for the potential pharmacologic epigenetic approach for the treatment of PVR and other fibrotic retinal diseases.

## Epigenetic Factors in Retinitis Pigmentosa

Retinitis pigmentosa (RP) is an inherited retinal degeneration that is characterized by selective cell death of photoreceptors. At least 40 gene mutations involved in human RP have been identified so far,<sup>37</sup> although the metabolic pathways leading to photoreceptor cell death remain unknown, and no cure is as yet available. In the well-studied retinal degeneration 1 (rd1) mouse model for RP, where a rod photoreceptor cGMP phosphodiesterase-6 mutation leads to

cGMP accumulation and photoreceptor cell death, increased HDAC activity was found to precede photoreceptor degeneration. More importantly, pharmacologic inhibition of HDAC activity reduces photoreceptor cell death, an effect that may be mediated by transcriptional regulation through the poly-ADP-ribose-polymerase family of proteins, or through upregulating peroxisome proliferator-activated receptor-gamma in an animal model.<sup>38</sup>

Interestingly, overexpression of HDAC4, which regulates retinal neuronal survival, can prolong photoreceptor survival in *rd1* mouse retina,<sup>25</sup> suggesting different roles of HDAC family members in the pathogenesis of retinal degeneration. Beside the abnormal histone acetylation/deacetylation, Farinelli et al. have demonstrated that cytosine hypermethylation is revealed in dying photoreceptors in the rodent models of RP; importantly, inhibition of DNA methylation suppressed photoreceptor death.<sup>39</sup> Recently, valproic acid, an HDAC inhibitor, has been used for treating patients with retinitis pigmentosa.<sup>40</sup> Although encouraging preliminary results are available, the benefit of this drug in RP needs to be confirmed in a placebo-controlled clinical trial.

Studies in recent years are beginning to unveil a role for miRNAs in retinal degenerative diseases. miRNAs typically enriched in the mouse retina, such as miR-96, miR-182, and miR-183, are reduced several fold in *rd1* mice where rod photoreceptors have degenerated.<sup>27</sup> A mouse model of RP carrying a mutant Pro347Ser rhodopsin transgene demonstrates altered expression of miR-96, miR-183, miR-1, and miR-133 in the retina when compared with wild-type animals. A similar miRNA signature is confirmed in three other mouse models of RP. Predicted targets of these miRNAs include antiapoptotic factors such as Fas apoptotic inhibitor molecule, which offers a possible mechanism whereby defects in miRNAs expression may lead to photoreceptor degeneration through apoptosis.

## Epigenetic Factors in Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is a leading cause of vision loss among people age 50 and older. Though AMD is an age-

related disease, several genetic components have also been identified, and the extent to which epigenetic modifications contribute to the phenotype heritability remains unclear. Emerging evidence has clearly suggested that epigenetic changes could be playing an important role in the disease process and is implicated in various aspects of the disease, including inflammatory responses and gliosis.<sup>41</sup> In addition, significant DNA methylation differences are observed in the blood of neovascular AMD patients near age-related maculopathy susceptibility 2, a top-ranked GWAS locus preferentially associated with neovascular AMD, and also in the promoter region of protease serine 50.<sup>42</sup> Clusterin (also known as apolipoprotein J), a major component of drusen that accumulates with age, has a promoter with a CpG-rich methylation domain that may be epigenetically regulated.<sup>43</sup> In human RPE cell culture, pharmacologic induction of DNA hypomethylation or histone hyperacetylation leads to increased expression of clusterin. Another recent study showed that Dicer may also be involved in the pathogenesis of geographic atrophy in AMD. Dicer is reduced in the RPE of human patients with geographic atrophy, and conditional knockout of Dicer reproduces the RPE degeneration phenotype in mice. Surprisingly, the role of Dicer in the pathogenesis of macular degeneration does not appear to involve miRNAs, but instead the degradation of *Alu* elements, common noncoding, repetitive DNA sequences in the human genome which may be toxic to the RPE.<sup>44</sup> miRNAs are implicated in various aspects of the disease pathogenesis; miR-22, miR-26, miR-30, miR-92, miR-124, and let-7 families are associated with the survival of rods.<sup>45</sup> miR-23a is considered to serve as a regulator of macular RPE cell survival in response to oxidative stress, and miR-31 and -150, that code for proteins that have proangiogenic activity, have altered in AMD, and are associated with choroidal neovascularization. Although how much epigenetic changes contribute to AMD is still unknown, there is a great need to study the role of epigenetics in its pathogenesis in the future. If similar findings can be demonstrated in vivo, epigenetic mechanisms may potentially be exploited as targets for treating this chronic eye disease.

## Epigenetic Factors in Retinoblastoma

Retinoblastoma is the most common intraocular tumor of childhood. Although the disease is initiated by the loss of both alleles of the prototypic tumor suppressor gene, *RB1*, subsequent changes in other tumor suppressor and DNA repair genes have been implicated in the pathogenesis of the disease. The retinoblastoma protein (pRb) is the founding member of the pocket protein family of tumor suppressors, including p107 and p130, which have been implicated in numerous cellular processes, including cell cycle regulation, DNA repair, DNA replication, differentiation, and apoptosis. *RB1* has been shown to regulate numbers of epigenetic events, such as miRNA, DNA methylation histone acetylation, and chromatin remodeling. The inactivation of *RB1* gene in retinoblastoma and other tumor genesis is found to be the major force of tumor development without other genetic abnormal. pRb regulates cell cycle progression by binding to the E2F family of transcription factors and inducing repression of E2F-regulated cell cycle genes.<sup>46</sup> The action of this repression involves two mechanisms – direct binding and blockage of the transactivation domain of E2F, and recruitment of chromatin-modifying molecules. All three pocket protein family members have been shown to associate with HDAC1 through the “pocket” domain to repress cell cycle genes by E2F-regulated promoters.<sup>47</sup> In addition, pRb associates with the HMTase Suv39H1, DNMT1, and heterochromatin protein 1 (HP1) via its pocket domain.<sup>48</sup> Finally, pRb also influences the accessibility of chromatin through interactions with the ATP-dependent helicase *BRG1*, the catalytic subunit of the SNF/SWI chromatin remodeling complex. Together, DNMT1, HMTases, HDACs, HP1, and *BRG1* are all recruited by pRb to form a multiprotein chromatin remodeling complex that can heterochromatinize promoters regulated by the E2F family, and epigenetically silence transcriptional activation of cell cycle genes.

There is increasing evidence that, in addition to mutations in the *RB1* gene, epigenetic changes involving aberrant DNA methylation of other tumor suppressor gene promoters may be involved. Researchers found that there is hypermethylation in *RB1* promoter which is associated with suppression of *RB1* gene expression.<sup>49</sup> Besides *RB1*, examination of the promotor methylation of other tumor suppressor genes such as *p16INK4A*, *MGMT*, *GSTP1*, *APC*,

*DAPK*, *RARB*, *CDH11*, and *CDH13* in retinoblastoma have also been revealed.<sup>50</sup> It is found that 118 genes are differentially expressed in their promoter methylation from 19 primary retinoblastoma tumor samples by a genome-wide analysis.<sup>46</sup> In retinoblastoma tissues there is promoter hypermethylation of O<sub>6</sub>-methylguanine-DNA methyltransferase,<sup>51</sup> which encodes a DNA repair enzyme and is also hypermethylated in breast and prostate cancer, lymphoma, and gliomas. *RASSF1A* (the RAS-association domain family 1, isoform A, tumor suppressor gene involved in microtubule stability, apoptosis, and cell cycle regulation), is also methylated and inactivated in multiple pediatric tumors, including retinoblastoma. Finally, promoter methylation of caspase 8, which is involved in Fas-mediated apoptosis, and *MLH1*, a DNA mismatch repair gene, may provide mechanistic explanations for loss of cell cycle regulation in retinoblastoma tumors. It remains unclear to what degree aberrant methylation contributes to the pathogenesis of tumor growth in patients with retinoblastoma. For example, does hypermethylation of tumor suppressor genes represent the second or third “hit” required for tumor genesis, or are they merely compensatory changes that occur in response to tumor growth? Furthermore, the involvement of miRNA in the pathogenesis of retinoblastoma is also being studied. It was found that the level of miRNA-17 92a is high in retinoblastoma, which means it may be a therapeutic target.<sup>49</sup> Further work will be necessary to delineate the roles of complex epigenetic factors including single nucleotide polymorphisms (SNPs) of p53 rs1042522 involved in this childhood cancer.<sup>52</sup>

## Epigenetic Factors in Uveal Melanomas

Uveal melanoma is the most common primary intraocular tumor in adults, with a high mortality rate and frequent metastases. Similar to retinoblastoma, aberrant DNA methylation of the *RASSF1A* promoter has also been implicated in uveal melanoma.<sup>53</sup> In addition, there are a number of tumor suppression genes silenced by promoter methylation, including *pINK4a*, *TIMP3*, *RASEF*, and *EFS*.<sup>54</sup> Interestingly, the expression of a number of histone-modifying genes and polycomb family members are decreased in

the tissues of uveal melanoma with monosomy 3/class 2, and more importantly abnormality of those epigenetic modifiers is associated with a worse prognosis.<sup>55</sup> However, other investigations of promoter methylation in several tumor suppressor genes in uveal melanoma tissues identified only the human telomerase reverse transcriptase (*hTERT*) gene, but not *RASSF1A*, to be abnormally methylated. Such discrepancies may be related to the genetic heterogeneity of uveal melanomas in humans, and additional research is needed to identify these different patterns of DNA methylation.

The involvement of histone acetylation in uveal melanoma remains unclear. In vitro, inhibition of HDAC activity in both primary and metastatic uveal melanoma cell lines results in inhibition of cell growth and induction of apoptosis, an effect likely mediated by Fas-dependent pathways.<sup>56</sup> It is not known, however, whether HDACs are involved in the pathogenesis of the disease in humans. Nevertheless, these findings implicate a potential role of HDAC inhibitors in the treatment of this devastating cancer.

Recent evidence also points to a role of microRNAs in uveal melanoma. miRNAs such as miR-34a and miR-137, which have been implicated in tumor suppression, are expressed in melanocytes, but not in uveal melanoma cells.<sup>57,58</sup> Transfection of miR-34a or miR-137 into uveal melanoma cells led to decreased cell growth and migration. miR-34a is a potential key effector of the p53 tumor suppressor gene, while miR-137 is involved in downregulation of MITF, a master regulator of melanocyte cell growth, maturation, apoptosis, and pigmentation.<sup>59</sup> miR-144 acts as a tumor suppressor in uveal melanoma. Identifying other miRNAs involved in tumor suppression may provide novel targets for uveal melanoma therapy.

Notably, application of DNA methylation inhibitor-5-AZA can suppress the migration and proliferation of uveal and cutaneous melanoma cells,<sup>60</sup> suggesting the involvement of a methylation mechanism in the pathogenesis of uveal melanoma.

## Epigenetic Factors in Retinal Angiogenesis

Angiogenesis is controlled by a balance between pro- and

antiangiogenic factors. Epigenetic changes caused by aberrant DNA methylation or histone acetylation of antiangiogenic molecules have been shown to control angiogenesis. Initial studies revealed a crucial role for miRNAs in stimulating or reducing angiogenesis. These research efforts improved our understanding of how epigenetic factors control angiogenesis. Importantly, these epigenetic insights may also be of important clinical relevance for the use of antiangiogenic strategies in diabetic retinopathy or AMD.

## Diabetic Retinopathy

Diabetes is now considered as the epidemic of the 21st century, and diabetic retinopathy is emerging as a major public health concern. The vasculature and neuronal cells components of the retina are damaged, but the exact mechanism responsible for the pathogenesis of this blinding disease, however, remains unclear. A cross-sectional study with over 1000 type 2 diabetic patients has identified a possible genetic and epigenetic basis for the development of diabetic retinopathy. Diabetic patients have shown a strong association between the polymorphism in the gene that encodes histone methyltransferases, *SUV39H2*, and retinopathy.<sup>61</sup> Experimental studies have shown a role of increased H4K20 methylation at the promoter and enhancer regions of *SOD2*, the gene that encodes mitochondrial superoxide dismutase in its downregulation in diabetes.<sup>18,20,62</sup> Increased histone methyltransferase Set7 recruitment at the promoter of NF- $\kappa$ B in hyperglycemic milieu is associated with its increased transcription.<sup>61,63</sup> Altered histone acetylation machinery (HATs and HDACs) is observed in the in vitro and in vivo models of diabetic retinopathy. Increased acetyl H3K9 at the promoter of matrix metalloproteinase-9, an enzyme implicated in retinal mitochondrial damage in diabetes, is considered to facilitate its binding with NF- $\kappa$ B, resulting in its increased expression in diabetes, but that at the promoter of *SOD2*, is implicated in its downregulation.<sup>64,65</sup> In addition, hypoxia is a major stimulus for the retinal neovascularization observed in diabetes;<sup>66</sup> ischemia and hypoxia also stimulate HDAC activity, thus the activation of retinal HDAC by increased retinal hypoxia in diabetes remains a strong

possibility. In addition, in the development of diabetic retinopathy, epigenetic modifications are considered to play a significant role in the decreased transcriptional activity of the master regulator Nrf2.<sup>67</sup> The modification of histone H3 at lysine 9 (H3K9) at the proximal Cox2 promoter bearing the NF- $\kappa$ B-binding site has been shown to modulate hyperglycemia-induced thioredoxin-interacting protein-mediated inflammation in retinal capillary endothelial cells. The mechanism of histone modification in diabetes may include increased oxidative stress and hypoxia, as in diabetes the retina experiences increased oxidative stress, and hyperglycemia-induced superoxide overproduction activates the major pathways in the development of diabetic retinopathy.<sup>18,20,62</sup> Global DNA methylation status in a case-control study of 168 patients with type II diabetes has shown a strong correlation with the progression of retinopathy<sup>68</sup> and 19 potential CpG sites undergoing methylation have been identified in the blood cells from type 1 diabetic patients that undergo DNA methylation in diabetes. Animal models have shown the role of DNA methylation in retinal mitochondrial homeostasis in diabetes: hypermethylation of the mitochondrial DNA biogenesis enzyme, DNA polymerase-gamma, downregulates its expression, impairs mtDNA transcription, and compromises the electron transport system.<sup>14,69</sup> The role of miRNAs in diabetic retinopathy is still in its incipient stage. miRNA-expression profiling and established miRNA transcriptomes of the retina have shown dysregulation of many miRNAs associated with the pathogenetic pathways of diabetic retinopathy, especially upregulation of a NF- $\kappa$ B-responsive miRNA, miR-146, in the retina and retinal endothelial cells of diabetic rats. Altered levels of miR-21, miR-181c, and miR-1179 are observed in the serum of patients with proliferative and nonproliferative diabetic retinopathy. Models of diabetic retinopathy have shown an association between downregulation of miR-126, miR-146a, and miR-200b and the upregulation of VEGF, and upregulation of miR-29b and protection of apoptosis of the retinal ganglion cells.<sup>62,70</sup> Thus, epigenetic modifications appear to play an important role in the development of diabetic retinopathy (Fig. 35.2), and could be targeted to combat this blinding disease.

**FIG. 35.2** Diabetes increases oxidative stress, and this, by altering the expression of genes involved in histone (LSD1, KDM5A, HDACs) and DNA (Dnmts) modifications, brings about a number of epigenetic changes. Due to alterations in histone methylation (e.g., H3K4, H3K9, and H4K20) and acetylation (H3K9-Ac, p300), the binding of transcription factor (Nrf2, Sp1, NF- $\kappa$ B-p65) is altered resulting in dysregulation (*GCLC*, *Keap1*, *MMP-9*, *Sod2*, *TXNIP*). Activation of DNMTs methylates *POLG1* promoter, suppressing its expression and altering mtDNA biogenesis. In addition, the levels of number of microRNAs (miR-200b, miR-129b, miR-149) are also changed, dysregulating transcription of various genes (*Oxr1*, *VEGF*, *Rax*, *NF-kB*). These epigenetic modifications, by altering the gene expressions of proteins associated with the oxidative damage and antioxidant defense and miRNA levels, also dysfunction mitochondria and impair mtDNA transcription, and the vicious cycle of ROS continues to fuel in. Although a number of modifications are

shown here, there are many other, yet unidentified, epigenetic modifications, that could also be contributing to the development of diabetic retinopathy.

Cox2, cytochrome c oxidase subunit 2; Dnmt1, DNMT1: DNA methyl transferase 1; Gclc, glutamate cysteine ligase, catalytic subunit; GSH, glutathione-reduced form; H3K4me1, histone H3 lysine 4 monomethyl; H3K4me3, histone H3 lysine 4 trimethyl; H3K9Ac, histone H3 lysine 9 acetylation; H3K9me2, histone H3 lysine 9 dimethyl; H4K20me3, histone H3 lysine 20 trimethyl; HDAC, histone deacetylases; KDM5A, lysine-specific demethylase 5A; Keap1, Kelch-Like ECH-associated protein 1; LSD1, lysine specific demethylase 1; MMP-9, matrix metalloproteinase 9; NF- $\kappa$ B, nuclear transcriptional factor- $\kappa$ B; NRF2, nuclear factor-erythroid 2-Like 2; Oxr1, oxidation resistance protein 1; POLG1, polymerase gamma 1; Rax, retina and anterior neural fold homeobox; Sod2, superoxide dismutase 2; SP1, specificity protein 1.

## Choroidal Neovascularization (CNV)

CNV describes the growth of new blood vessels that originate from the choroid through a break in Bruch's membrane into the sub-RPE or subretinal space.<sup>71</sup> CNV is a major cause of central visual loss.

The pathogenesis of CNV is mediated by a multitude of factors. Epigenetics can potentially participate in various pathologic aspects of CNV. miR-155, which is expressed in immune cells, was demonstrated to activate macrophages. Macrophages facilitate the inflammatory response that promotes angiogenesis, for instance, through the production of tumor necrosis factor, which induces the expression of VEGF and MMPs.<sup>72</sup> However, retinal production of tumor necrosis factor and its stimulatory effects on MMPs can be reversed by an HDAC inhibitor.<sup>21</sup> The expression of pro- and antiinflammatory genes, such as interleukin genes *IL2*, *IL8*, and *IL10*, can also be regulated by HDAC activity.<sup>72</sup> Furthermore, oxidative stress can also induce expression of the major player in angiogenesis, VEGF, as well as expression of HIF-1 $\alpha$ , which stimulates VEGF production. HIF-1 $\alpha$  can also be downregulated by

the HDAC inhibitor,<sup>73</sup> TSA, whereas the antiangiogenic and neuroprotective molecule pigment epithelium-derived factor is upregulated by TSA.<sup>73</sup> TSA can also inhibit the proliferation and migration of RPE cells, implying the potential regulation of pro- and antiproliferative, ECM-modifying genes by HDACs.

In a study mapping promoter DNA methylation in AMD and age-matched normal RPE/choroid samples, the antioxidants glutathione S-transferase isoforms mu1 and mu2 have been shown to be downregulated and heavily methylated in their promoter regions in AMD samples. Additionally, the proangiogenic angiopoietin-like protein 2 had less methylation in its promoter in the AMD samples.<sup>74</sup> Notably, hypomethylation of the interleukin-17 receptor C (IL17RC) promoter has recently been identified in peripheral blood cells from patients with AMD and was associated with increased expression of IL17RC in their peripheral blood and affected retina and choroid. These results suggest that epigenetic regulation of IL17RC may play a role in the pathogenesis of AMD.<sup>75</sup>

Previous studies described the key role of SIRT1 as a critical regulator of angiogenesis. The expression of SIRT1 was found more frequently in human CNV membranes than non-AMD donor eyes. Another experiment revealed that the SIRT1 pathway is involved in the mechanism of resveratrol inhibiting hypoxic-induced choroidal vascular endothelial cells proliferation through downregulating the levels of HIF-1a. Thus, RSV inhibits the HIF-1 $\alpha$ /VEGF/VEGFR2 signaling axis in choroidal neovascularization-related cells, at least in part, through SIRT1.<sup>76</sup> The discrepancy of effects of SIRT1 may be due to the different activators or inhibitors used in the experiments. Further studies should be performed to identify the accurate effect of SIRT1 on CNV formation.

## Perspectives and Challenges of Epigenetics

The epigenome plays a pivotal role as the interface between genome and environment, and over years, an individual may accumulate various intrinsic insults caused by chronic diseases such as diabetes mellitus or accumulate environmental alterations that

could affect the epigenome, and participate in the induction of age-related diseases. Understanding the pathologic epigenetic alterations should help reveal additional insights into their etiology and how possible environmental modulations may contribute to the disease process and may be targeted through pharmacologic intervention on chromatin-modifying enzymes. The class III family of HDACs, sirtuins, specifically SIRT1, has been demonstrated to inhibit cell death.<sup>77</sup> It acts to prevent the overactivation of p53 in causing apoptosis due to DNA damage, resulting in DNA repair and cell survival.

Epigenetics has become an important area of biomedical research and it may be able to explain phenotypic changes in many complex retinal diseases. Epigenetic therapies may offer additional options for the treatment of some retinal diseases. However, there are some important challenges, including nonspecific activation of imprinted genes, which are normally regulated by methylation, unwanted expression of transposable elements, which may contribute to pathology, persistence of the reversible nature of methylation patterns after drug treatment, and remethylation and resilencing issues. Due to the dynamic nature of epigenetics, and lack of detailed knowledge about its role in retina, some critical questions need to be addressed:

1. What is the detailed mechanism of epigenetic regulation of retinal development?
2. In the physiologic condition, how do epigenetic factors contribute to normal retinal function?
3. How is retinal inflammation regulated by epigenetic factors?
4. How much of a role does epigenetics play in the pathogenesis of retinal angiogenesis and fibrosis?
5. How do cytokines and growth factors regulate epigenetic factor expression and vice versa?
6. How is epigenetics involved in the process of retinal degeneration, including AMD?

7. What is the role of epigenetics in mitochondrial, endoplasmic reticulum, and Golgi stress in retinal disease?
8. What is the role of crosstalk among epigenetic factors in retinal development and disease?
9. What is the epigenome of retinal cells in the normal and diseased condition?

## Treatment of Retinal Disease With Epigenetic-Modifying Drugs

As detailed above, ongoing research has clearly documented a major role of epigenetics in the retinal development and diseases. Since the epigenetic modifications are dynamic and can be reversed, they are evolving as attractive targets for therapeutic interventions. Many small molecule compounds have been designed to modulate the activity of histone modifying enzymes and DNMTs, and some of them are in clinical trials. Preclinical studies using epigenetic modifying drugs are in progress and some epigenetic modifying drugs, such as 5-AZA and suberoylanilide hydroxamic acid, are in clinical trials.<sup>78-80</sup> However, the major concern about epigenetic drugs is lack of target specificity. The DNA methylation inhibitors result in global demethylation; similarly, the HDAC inhibitors can affect many isoforms of HDAC and nonhistone proteins. Since miRNAs are considered as potential diagnostic biomarkers for disease, double-stranded miRNA mimics and anti-mRNA antisense oligo-deoxyribonucleotide could be used to target specific miRNAs. But one miRNA can act on multiple targets, so the development of compounds with higher specificity and greater efficacy is essential, and the possibility of their access to the posterior part of the eye is another important aspect that needs major consideration.

Although several epigenetic inhibitors have been approved, or are in clinical trials, for cancer treatment, the use of combinations of inhibitors targeting different regulatory components of the epigenetic machinery, and/or with other traditional therapies, may be considered to improve therapeutic efficacy for patients suffering

from retinal diseases.

Generic Strategies for Reversing Blindness in  
“Dead” Retinas

**Conclusion**

State of the Art of Retinal Gene Therapy

## Background: Preclinical Gene Therapy Studies

Gene therapy holds great promise for the treatment of inherited and acquired blinding retinal diseases. There has been much progress over the past two decades in identifying disease-causing genes in humans and in animal models and this, in turn, has expedited our understanding of disease pathogenesis. For diseases that lack naturally occurring animal models, additional models have been generated through genetic-engineering techniques or through somatic gene transfer. Simultaneous with the increase in knowledge of the genetic bases of retinal diseases, there have been great technical developments in delivering genes efficiently and stably to retinal cells. Because of its ease of access, its favorable immunologic response to gene transfer, and the ability to perform noninvasive functional and structural studies, the mammalian eye has been intensely studied as a target for gene therapy. Gene transfer strategies have been used in both small- and large-animal models to demonstrate proof of concept. These preclinical studies have allowed the field to reach the point where gene therapy to treat several forms of inherited blindness have been tested in clinical trials. A phase III trial (aimed at obtaining approval of a gene therapy reagent as a drug) is also underway for one of these diseases. Tremendous challenges lie ahead to extrapolate these results to other retinal diseases. These challenges include the need to develop individualized treatment strategies for a vast array of different genetic diseases, studies of the natural history of the disease so that appropriate outcome measures/timing of studies can be planned, identification of appropriate candidates for clinical trials through genetic testing and phenotypic characterization, and development of outcome measures appropriate for identifying a therapeutic benefit in a reasonable period of time. Despite the challenges, these efforts bring hope for patients with a variety of blinding diseases which, until recently, have been considered to be untreatable and incurable.

## Definitions

Nucleic acids do not readily cross cell membranes due to their charge and size. Vectors are therefore used to deliver DNA or RNA into the cell, where they can then access the cell nucleus. Over the past two decades, there has been great progress in developing vectors with which to deliver nucleic acids to a variety of retinal cell types. Delivery of genes by a virus and subsequent expression of the gene is termed “transduction” and the infected cells are described as “transduced.” Usually the complementary deoxyribonucleic acid (cDNA) is delivered with a recombinant virus due to the large size of genomic DNA. The DNA is not expressed unless the appropriate regulatory elements are present. The transgene cassette generally consists of regulatory elements (promoter, etc.), the cDNA, and a poly(A) sequence. There are both physicochemical methods for delivering genes as well as a large toolkit of recombinant virus vectors, complete with modifications of capsids, envelopes, and surface proteins designed to achieve the desired transduction parameters.

## Nonviral Gene Delivery

There are several nonviral methods of delivering nucleic acids to cells, and those include use of physicochemical agents to compact the DNA and/or transport it across the membrane lipid bilayer.<sup>1,2</sup> There are several potential advantages of nonviral approaches: First, they can be used to deliver DNA of unlimited size. Second, there is a smaller chance of detrimental immune response since the only antigen would be the nucleic acid itself plus any protein that is used as a condensation agent. The main obstacle faced with most physicochemical methods is the difficulty in applying the technique to *in vivo* conditions and in achieving an extended duration of gene expression. Several studies have demonstrated proof of concept of retinal gene therapy using nonviral DNA delivery<sup>1,3,4</sup> and additional studies will reveal the long-term safety, stability, and efficacy of this approach.

## Viral Vector-Mediated Gene Delivery

Recombinant viruses are genetically engineered so that they cannot reproduce and cause an infectious disease once they infect a target

cell. There is a host of recombinant viruses that have been tested in the retina ([Table 36.1](#)). Different viruses have varying attributes and challenges, including cargo capacity, ease of purification, cellular specificity, and immune response. However, a large cohort of these have been used to demonstrate efficacy in animal models of retinal disease (see [Table 36.2](#)).

**TABLE 36.1**

**Vectors Tested for Transduction Characteristics in Animal Models<sup>a</sup>**

Delivery Approach	Cargo Limits	Integration	Stability (Large-Animal Models)	Retinal Cell Targets	Risk of Toxic Immune Response	Used in Human Ocular Studies	Requires Further Development Prior to Human Application
Electroporation	Unlimited	No	Unknown (unlikely)	RPE, PRs; BP	Low	No	Yes
Compact nanoparticles; POD	Unlimited	No	Unknown	PRs, RPE; GC, IR	Low	No	Yes
Adenovirus	7.5 kb	No	No	RPE, Müller	High	Yes	No
Helper-independent (“guttet”) adenovirus	36 kb	No	Unknown	RPE, PRs	Unknown	No	No
Adeno-associated virus	4.8 kb	No	Stable	RPE, Müller, PRs, GCs	Low	Yes	No
Lentivirus	7.5 kb	Yes	Stable	RPE, PRs	Low	Yes	No

<sup>a</sup>Various retinal cell targets are listed; however, the exact targets depend on the route of administration, dose, species, and modifications to the vector.

BP, bipolar cells; GC, ganglion cell; IR, inner retinal cells; Müller, Müller cells; POD, peptide for ocular delivery; PRs, photoreceptor cells; RPE, retinal pigment epithelium. References for the use of these vectors are provided in [Table 36.2](#).

<sup>a</sup>This list highlights many of the recent studies aiming to treat animal models of retinal degeneration, retinal development anomalies, and retinal neovascularization. Several of these studies have been carried forward to human clinical trial, and those references are listed as well.

AAV, recombinant adeno-associated virus vector; ACHM, achromatopsia; AD, autosomal dominant; Adeno, recombinant adenovirus vector; AR, autosomal recessive; CD, cone dystrophy; CNV, choroidal neovascularization; CRD, cone-rod dystrophy; EIAV, equine infectious anemia virus; IM, intramuscular; IV, intravitreal; LCA, Leber congenital amaurosis; Lenti, recombinant lentivirus vector; MPS, mucopolysaccharidosis; NP, not published; NXNL1, nucleoredoxin-like 1; P-O, periocular; POD, peptide for ocular delivery; Ret NV, retinal neovascularization; RP, retinitis pigmentosa; SR, subretinal; STGD1, recessive Stargardt disease; VEGF, vascular endothelial growth factor; XL, X-linked: strategies aiming at treating glaucoma or optic nerve disease are not included.

The first recombinant adenovirus vectors, generated from the common respiratory virus, carried deletions in the adenoviral E1, E3 genes, and these Ad type 5 (Ad5) vectors were the first to be evaluated for retinal gene transfer in the differentiated retina.<sup>5,6</sup> Adenovirus vectors result in high levels of gene expression within 24–48 hours. When injected subretinally, they target retinal pigment epithelial (RPE) cells efficiently in the adult eye and also Müller cells.<sup>5,6</sup> When injected intravitreally, they target Müller cells and cells in the anterior segment, including corneal endothelium, lens and iris epithelium, and cells in the outflow tract (such as trabecular meshwork cells).<sup>7</sup> Similar results are found when recombinant adenovirus is injected into the undifferentiated (early postnatal) retina; however, in addition to RPE cells, progenitor cells are targeted in the neonatal mouse eye.<sup>8,9</sup> Additional manipulations of adenovirus vectors have yielded reagents that target photoreceptors more efficiently.<sup>10–13</sup>

A disadvantage of the early generations of E1, E3-deleted

adenovirus is that it still carries viral open reading frames. These can enhance its immunogenicity, even in the immune-privileged environment of the eye. This characteristic of adenoviral vectors has in fact been utilized to probe the nature of the intraocular immune response. When these vectors were injected subretinally, transgene expression persisted for several weeks to months. However, when injected intravitreally, transgene expression ceased within 2 weeks. Expression could be prolonged by incorporating immune-suppressant molecules, however.<sup>14,15</sup>

Adeno-associated virus (AAV) vectors do not carry any virus open reading frames (and thus encode any virus-specific proteins) and therefore are generally more favorable from an immunologic standpoint than adenovirus vectors (Table 36.1). There is abundant safety data related to AAV administration in animals and in humans, both systemically and intraocularly. Recombinant AAV (rAAV) vectors have an added benefit in that they target a more diverse set of cell types than adenoviral (or other) vectors. Unlike lentiviral vectors, AAV vectors do not integrate into host cell genomic DNA, or do so only rarely (Table 36.1). However, since the transgene persists in episomal fashion in the target retinal cells, rAAV vectors result in stable transgene expression. Expression persists for the life of small animals (mice and rats) and at least for many years in large animals and humans.<sup>16-20</sup> rAAV vectors are useful for delivering genes efficiently to many types of retinal cells. A major disadvantage of these vectors is their relatively limited cargo capacity (a maximum of 4.8 kb) (Table 36.1).

AAV vectors can be modified in several ways in order to optimize their behavior for specific gene therapy applications. In AAV vectors, the transgene cassette is bordered by the inverted terminal repeats (ITRs) from an AAV2 genome. The original AAV vectors were generated by packaging the transgene cassette ITRs into an AAV serotype 2 capsid and this resulted in "AAV2/2" vectors, i.e., ITRs of an AAV serotype 2 genome packaged into an AAV2 serotype 2 capsid. Often, investigators skip the reference to the ITR serotype and refer to the capsid serotype alone as will be done henceforth in this chapter (i.e., AAV2 vectors instead of AAV2/2 vectors.) More than a dozen AAVs of different serotypes have been described. Many cross-packaged AAVs differ

significantly from rAAV2 vectors with respect to cellular specificity, efficiency of transduction, and onset of transgene expression. While rAAV2 targets RPE cells efficiently (and photoreceptors less efficiently), it takes up to 6 weeks for transgene expression mediated by this vector to plateau.<sup>21-23</sup> In comparison, rAAV5 and rAAV8 vectors transduce photoreceptors with much higher efficiency and result in transgene expression within 5–10 days of delivery.<sup>21,22</sup> This information is helpful in selecting vectors for particular applications. For example, in a relatively slowly progressive retinal degenerative disease (Leber congenital amaurosis (LCA) due to *RPE65* mutations), rAAV2 performs well in delivering a therapeutic transgene to RPE cells. For an animal model with a much faster rate of degeneration (e.g., LCA due to *AiPL1* mutations<sup>24,25</sup>), it is necessary to use a vector with a much faster onset of expression and which targets photoreceptors efficiently (such as a rAAV5 or 8 vector; [Table 36.2](#)). Efforts have also been made to reengineer the virus by altering specific molecules in the capsid or by “directed evolution.” The latter strategy screens large numbers of variants for desirable properties such as the ability to reach the outer nuclear layer from the vitreous or the ability to transduce specific cells (such as ON-bipolar cells).<sup>26,27</sup> More recently, two different groups have reconstructed ancestral AAVs as an approach to generate novel gene therapy vectors.<sup>28,29</sup>

Vectors originally based on the human immunodeficiency virus, lentiviral vectors, have been shown to be safe in animal models and their safety in humans is currently being tested ([Table 36.2](#)). A number of groups have since generated vectors based on viruses that were identified in nonhuman species, such as equine lentivirus.<sup>30,31</sup> Transgene expression is stable after lentiviral administration, because these vectors mediate integration into the host chromosome ([Table 36.1](#)). Lentiviral vectors target RPE cells efficiently after subretinal injection and, in undifferentiated retina, also target neural progenitor cells. They have thus been used to demonstrate efficacy in animal models of RPE disease, such as LCA-RPE65 or autosomal recessive (AR) retinitis pigmentosa (RP) due to *PDE6B* mutations<sup>32</sup> ([Table 36.2](#)). Lentiviral vectors are also attractive in that they can carry a relatively large cargo of up to 7.5

kb (Table 36.1). Specific modifications also allow lentiviral vectors to target mature photoreceptors.<sup>23,33</sup> Since lentiviral vectors are integrating vectors, there is a concern about the potential for insertional mutagenesis. To date there has been no report of such an effect after retinal administration in animal models.

## Surgical Delivery

With the exception of the engineered AAV, AAV7m8, which penetrates the retina efficiently after intravitreal injection (at least in the mouse),<sup>26</sup> the currently available viral vectors used in retinal gene therapy have very limited ability to diffuse across tissue interfaces. While intravitreal administration by pars plana injection may be adequate to transduce cells of the inner retina and uveal tract, this simple technique is inadequate for treatment of the outer retina and RPE. In animals with anatomically large eyes such as canines and primates, viral vectors must come into direct contact with photoreceptor and RPE cells to result in successful transduction. In this case, gene therapy agents need to be delivered to the subretinal space.

There are several methods whereby subretinal delivery can be achieved. First, diffusion may potentially occur across the choriocapillaris and RPE layers after systemic administration. This has not been observed, however, and has several theoretical disadvantages, including the need for increased dosing due to larger volumes of distribution, as well as exposure of nontarget tissues to immunogenic and potentially toxic viral vectors or transgene products. Delivery to the subretinal space can be achieved using a transchoroidal approach. This requires manipulations through the choriocapillaris layer which lacks the diffusion barrier present in retinal vasculature. Presence of immunogenic material in this area may be undesirable due to increased exposure to the systemic vasculature. In addition, visualization of the injection procedure is problematic using this surgical approach since it is often difficult to monitor the position of the injection apparatus through several intervening tissue layers.

Most investigators have employed a transvitreal, transretinal approach to subretinal injection in large-animal eyes. This approach

has several practical and theoretical advantages. First, there is a wealth of experience with three-port pars plana vitrectomy for human retinal surgery. This approach allows direct visualization of the retina throughout the procedure and real-time monitoring of the injection. The instrumentation for subretinal injection is easily available having been developed for other subretinal applications. Additional maneuvers such as fluid–gas exchange and laserpexy can be employed with the pars plana approach in order to manipulate the subretinal bleb or to manage potential complications.

When a subretinal injection is performed through a small retinotomy, a retinal detachment or “bleb” is raised (Fig. 36.1). Most if not all of the volume of injected material is trapped between the outer retina and RPE as a localized retinal detachment. There is negligible escape of material back through the retinotomy site into the vitreous, as evidenced by the fact that, initially, the size of the bleb does not change once it is formed. There is apparently little pressure differential between the subretinal space and vitreous once the bleb is established and this is especially so when the scleral incisions are closed. In addition, the small-gauge cannulas used for the subretinal injection appear to be self-sealing, especially when a gas tamponade or formed vitreous is present. Since a bleb raised by subretinal injection tends not to expand beyond the border of the initial injection, the volume of distribution of the administered agent is limited, especially when compared to an intravitreal injection or systemic administration. The concentration of the compound contained in the bleb remains high and may even increase as the RPE cells extract free water from the vehicle used to dilute the agent. Limiting the volume of distribution in this manner may serve both to increase the efficiency of drug delivery and to decrease local and systemic toxicities by restricting diffusion of the drug. The location of the original subretinal detachment cannot be appreciated in most species (including humans) after it has flattened, though occasionally the most dependent border of a bleb is later outlined by pigment fallout.<sup>18,34</sup> (The location of a bleb raised in the tapetal retina of dogs is often visible years after the injection, however, because of alterations in reflectivity of the underlying tapetum due to the procedure; see Fig. 36.1.)

**FIG. 36.1** Subretinal injection of gene therapy vector results in a “bleb,” the position of which is often visible in the dog retina years after the injection has occurred, due to alterations in the reflective properties of the underlying tapetum. Such changes are not observed in the human retina.

Since the RPE and Bruch's membrane are typically not violated when subretinal injection is performed by the pars plana approach, there is further protection against systemic exposure of antigens via the highly vascular choroidal circulation. In addition, there is minimal disruption of retinal vasculature since the placement of the injection cannula is done under direct visualization. Therefore, the integrity of the blood–ocular barrier remains intact when subretinal delivery is performed in this manner. There is in addition an immunologic compartmentalization when antigenic material is delivered to the subretinal space. Limiting exposure to this area may result not only in characteristic immunoprivileged behavior evident with intraocular delivery but, when delivery is confined to the subretinal space, antigenic tolerance can be induced due to immune-deviant response.<sup>35,36</sup> This unique property of the subretinal space is of great significance in the delivery of biologics and in gene therapy in particular as the development of antibody/immune response to both viral antigens and foreign transgene products may limit the effectiveness of treatment.

While several methods for subretinal injection of gene therapy agents have been described in human clinical trials, the basic elements of the procedure are similar. All surgical maneuvers are

done using standard three-port pars plana vitrectomy techniques and instrumentation. In all instances, a core vitrectomy is performed and subretinal injection is delivered using a small-gauge cannula. Spontaneous resorption of the subretinal bleb is allowed to occur without the need for laser or tamponade for posterior retinotomy sites.

The major differences in surgical methods between various investigators who have carried out gene transfer in humans so far<sup>15,18,34,37-39</sup> involve (1) use of perioperative systemic corticosteroid therapy; (2) the removal of posterior cortical vitreous prior to subretinal injection; and (3) placement of a gas (air) bubble after the injection is performed. With regard to systemic corticosteroid use, there appears to be no important difference in efficacy. It should be noted that all studies employ the use of topical and periocular corticosteroid to suppress surgical inflammation.

The surgical protocols for the phase I/II and III Children's Hospital of Philadelphia (CHOP) gene therapy trial for LCA2 and the phase I University of Pennsylvania (UPenn)/CHOP trial for choroideremia specify removal of the posterior hyaloid.<sup>18,34</sup> In many instances, a complete posterior vitreous detachment (PVD) is already present despite the young age of the subjects enrolled in the LCA2 trial. This is not unexpected as vitreous abnormalities, including the presence of debris or posterior separation, are characteristic features of eyes with retinal degeneration. In cases without PVD, the posterior cortical vitreous is engaged with active suction and the hyaloid face is gently separated to create a complete PVD, as evidenced by the presence of a glial ring separating from the optic nerve head (Weiss ring). Once the presence of a PVD is confirmed, the mobilized vitreous is removed as completely as possible, with special attention to pare back any gel in the vicinity of the active sclerotomy sites. This is done both to avoid vitreoretinal traction induced by instruments passing into and out of the eye, and also to prevent vitreous traction which can bend the tip of the 39-gauge (and smaller) subretinal injection cannula. Most investigators recommend the removal of epiretinal membrane (ERM) if present in the macular area in order to prevent interference with the injection cannula and to avoid late-occurring complications such as macular hole resulting from membrane

contraction.

Prior to subretinal injection, the infusion pressure is reduced in order to accommodate the additional intraocular volume added by the injection. Removal of vitreous gel from the vicinity of the infusion cannula allows reflux of infusate during the injection, though a small amount of fluid may escape around the active instruments at the other sclerotomy sites.

When directing the injection into the posterior pole or macula, the cannula tip is usually placed in the vicinity of the papillomacular bundle. Even in eyes with advanced retinal degeneration, the retina in this area is usually thick enough to allow for successful placement of the cannula tip and the injection into the subretinal space. The cannula tip is positioned so as to avoid direct injury to retinal arterioles. The UPenn/CHOP protocols specify that the site of injection be a minimum of 3 mm from the foveal center in order to avoid development of a foveal dehiscence from fluid tracking directly to the central macula in a fistula-like manner. In addition, a small bubble of perfluoro-octane liquid is placed over the fovea to counteract the hydrodynamic force created during the subretinal injection in the CHOP LCA2 trial, thereby buttressing this anatomically vulnerable area (Fig. 36.2; Video 36.1 online). In contrast, injection directly under the fovea is clearly necessary to treat diseases such as choroideremia (CHM) where the remaining viable tissue is in the central macular area. Typically, an area at the border of atrophic and intact retina is chosen as the entry site for the subretinal cannula.

**FIG. 36.2** Subretinal injection with protection to the fovea. (A) Subretinal injection cannula is apposed to the retina. Perfluoron had already been layered over the fovea. (B) The injection was initiated. A few small bubbles were expressed initially from the cannula (and

are in the subretinal space). (C) The bleb has expanded. (D) The cannula has been removed and the Perfluoron is being removed. The inferior border of the bleb is visible. (See Video 36.1 online, showing subretinal injection of AAV2-hRPE65v2 in a human.<sup>34</sup>)

The subretinal injection is performed in two steps. First, the cannula is positioned so as to indent the retina over the tip. When the cannula is inserted near a blood vessel, the vessel can be used as a landmark to visualize the tip as it passes underneath. Blanching of the choroid is sometimes observed as the retina is imbricated by the cannula. This indicates significant downward force being exerted on the RPE and the need to avoid further advancement of the cannula tip. At this point, the surgeon directs the assistant to inject a small amount of the gene therapy agent. If a small bleb is raised during the test injection, the remainder of the material is injected. If no bleb is created during the test injection, the cannula tip is repositioned and the sequence is repeated until a bleb is created. If a volume of 0.15 mL or more is placed in the subretinal space near the macula, a smooth-domed retinal detachment is created which typically encompasses the temporal posterior pole extending just beyond the major vascular arcades. As mentioned above, the injection site is self-sealing and reflux of the injected material is not observed.

The retina is inspected with indirect ophthalmoscopy. Any retinal breaks identified are treated with retinopexy prior to fluid–air exchange. If bleeding is seen at the injection site, intraocular pressure is raised with closed sclerotomy sites until hemostasis is achieved.

The CHOP/UPenn protocols specify that fluid–air exchange is performed, carefully avoiding draining through the retinotomy created for the subretinal injection. Air exchange is principally done to compartmentalize the subretinal injection so that the vector does not come into contact with anterior uveal structures and remains central to the area of the retina-RPE. A 55% exchange is adequate for this purpose. In cases where it is desirable to change the position of the bleb, a more complete air exchange can be performed. The subretinal fluid in the bleb then migrates in a gravity-assisted fashion to settle in the most dependent region of

retina. Head positioning is instituted in the postoperative period to orient the eye such that the desired area of retina-RPE treatment is placed in the most dependent position. A complete air exchange also serves to tamponade the posterior retinotomy site if any reflux of the subretinal injection is observed.

One unique feature of subretinal injection in retinal gene therapy when compared to other surgical indications is that the subretinal fluid, i.e., gene therapy agent, is not evacuated and the retina flattened at the time of fluid–air exchange. This is done in order to maximize the time of exposure to the subretinal injection, something that is not necessary, for example, after the extraction of a subretinal hemorrhage or translocation of the macula. Indeed, the creation of retinal detachment by subretinal injection is of itself a concern with respect to possible retinal toxicity. Fortunately, the extent of injury after acute retinal detachment created by injection of physiologic solutions appears to be small based on both laboratory and clinical data. Resorption of volumes less than 0.45 mL typically occurs in less than 24 hours.<sup>15–18,34,40,41</sup> In the CHOP trial, resorption of 0.3 mL of fluid was observed within 6 hours of injection. Bainbridge et al.<sup>37</sup> reported a longer period of detachment >24 hours after subretinal injection using a two-step injection technique where vector was administered into a bleb raised first with a physiologic solution. The longer period required for reattachment is likely due to the large volume of injection, i.e., 1.0 mL.<sup>37</sup>

Development of macular hole is a complication that appears to be unique to the subretinal injection procedure. Although creation of macular hole has been described in subretinal surgery for choroidal neovascularization (CNV), this typically occurs as a CNV is extracted in the presence of an adhesion to the overlying retina. In the phase I CHOP trial for LCA2, macular hole developed in one patient not during the surgical manipulation but rather several days postoperatively. Although ultimately the ophthalmoscopic appearance of the defect was typical for an idiopathic macular hole, several key differences were noted. First, prior to the development of a full-thickness defect, inner lamellar thinning was demonstrated on optical coherence tomography.<sup>18</sup> In addition, intraretinal edema or cystoid macular edema was never present either during

evolution of the hole or after hole formation. Finally, a subretinal fluid cuff was never apparent before or after hole formation. In the absence of inflammation, vasculopathy, or acute tissue injury, it was felt that the macular hole was unlikely to have been caused by drug toxicity. The appearance of the lamellar defect was reminiscent of pseudohole caused by ERM contracture. Since the ERM was recognized preoperatively and the posterior cortical vitreous was removed at surgery, it was thought that surgery-induced contraction of the pre-existing ERM was the most likely cause of macular hole formation. A second patient was observed to develop a foveal dehiscence at the time of subretinal injection as fluid channeled directly from the cannula through the fovea through a fistula-like tract.<sup>34</sup> This phenomenon has been observed to occur infrequently during subretinal injection in nonhuman primates.<sup>42</sup> Occurrence of a foveal dehiscence is presumably induced by intense hydrodynamic stress from injection in the vicinity of the fovea. No ERM was present in this case. Air tamponade with face-down positioning resulted in complete resolution of this induced hole within days. Since instituting a protocol modification specifying a minimum distance from the fovea for injection and use of perfluorocarbon liquid prior to injection, intraoperative foveal dehiscence has not occurred. In addition, foveal complications were not reported in CHM patients who received subretinal injection in the macular center.<sup>43</sup> This latter finding suggests that the foveal changes that can occur after creating a subretinal bleb may in fact be disease-specific and less likely to occur when the remaining tissue is relatively normal in thickness.<sup>34</sup>

## **History of Retinal Gene Therapy**

### **Preclinical Studies: Retinal Transduction Characteristics of Different Vectors**

Initial gene transfer studies in animals generally evaluated the safety and stability of delivery of “reporter genes,” genes whose activity in terms of protein products can be evaluated noninvasively or in tissue samples through either

histochemical/immunohistochemical measures or through a bioassay. A popular reporter gene encodes enhanced green fluorescent protein (EGFP), a bioluminescent, intracellular protein normally produced by the jellyfish *Aequorea victoria*. EGFP's absorption/fluorescence characteristics are very similar to those of fluorescein, which is used in the clinic to measure blood vessel integrity in the eye. Thus, EGFP can be measured using the same instruments/optics that are used in the clinic to measure fluorescein (Fig. 36.3). The only difference is that fluorescence with EGFP is not transient (as in the case with fluorescein angiography) as intracellular EGFP does not wash out with time.

**FIG. 36.3** Green fluorescent protein (GFP) is visible through illumination with blue light with an ophthalmoscope in this nonhuman primate that had received subretinal injection of  $1E11$  vector genomes (vg) AAV2/8.CMV.EGFP in its right eye. The left eye had received subretinal injection of the same material but with a dose that was 2 log units lower than the right eye.<sup>44</sup>

## Evaluation of Different Vectors

Numerous studies in small and large animals have relied on vector-mediated delivery of reporter genes to elucidate the characteristics of one vector versus another.<sup>21-23,44</sup> The transduction characteristics

are affected by dose and age (or stage of development) of the animal. In the fetal mouse, one can deliver vector to retinal progenitor cells and carry out “birthday studies” by looking later in adulthood at which types of photoreceptor cells were being “born” at the time of injection.<sup>45,46</sup> This led to an approach that reversed blindness in utero in LCA-rpe65 mice.<sup>47</sup>

The majority of studies published to date involve postnatal delivery. Transduction characteristics are dependent on the surgical approach and the dose. Intravitreal injection of particular recombinant viruses can lead to transduction of ganglion cells and/or Müller glia. For example, intravitreal injection of AAV2 leads to ganglion cell transduction (and expression in the optic nerve, optic chiasm, and brain) in species ranging from mouse to dog to human, whereas intravitreal injection of AAV5 does not.<sup>48,49</sup> Except for AAV7m8, intravitreal injection of recombinant viral vectors does not usually result in transduction of the photoreceptors in the outer retina or the RPE (Table 36.1).<sup>7,16,17,22,26</sup>

Most vectors target RPE cells efficiently even at low dose (Table 36.1). As the dose is increased and depending on the vector, photoreceptors and Müller cells can also be transduced (Fig. 36.4).<sup>44</sup> Cellular transduction characteristics can also differ from species to species. A very active area of research continues to involve engineering of AAV capsids in order to expand their cargo capacity and enhance their transduction properties.<sup>23,50,51</sup>

**FIG. 36.4** Histologic section from a monkey injected subretinally in the macula with  $1E11$  vg AAV2.CMV.EGFP. This shows very strong enhanced green fluorescent protein (EGFP) expression in retinal pigment epithelium cells and also (lesser) expression in photoreceptors (including inner-segment, outer nuclear layer, and outer plexiform layers). There are also occasional inner retinal cells which express EGFP. Nuclei are labeled blue and background fluorescence is shown with red.

## Proof-of-Concept Studies

With progress in delineating the molecular genetic bases of inherited retinal degenerations in humans and in animals and the development of recombinant viral vectors with which to deliver

transgenes to different retinal cell types, the logical next step is to determine how this information can be used to correct the diseases. Gene augmentation strategies, whereby a wild-type copy of a gene is delivered, have been tested successfully now in animal models of more than a dozen different conditions (Table 36.2). The animal model conditions have included AR RP, autosomal dominant (AD) RP, LCA, cone–rod dystrophy, macular dystrophy, oculocutaneous albinism, Leber hereditary optic neuropathy (LHON), X-linked retinoschisis (XLRS), mucopolysaccharidosis VI, AR Stargardt disease, choroideremia, and RP found in syndromes such as Bardet–Biedl and Usher syndrome (Table 36.2).<sup>3,8,14,16,17,24,25,32,33,30,52–89</sup> Gene augmentation therapy has also been used to restore function to a nonhuman primate model of red–green color blindness (Table 36.2).<sup>90</sup> There are a number of details that affect the success of retinal gene augmentation, including selection of the appropriate vector (see above), and when and where to deliver the vectors. The outcome measures used in the various studies include physiologic assays such as electroretinograms (ERGs), evaluations of pupillary light reflexes and optokinetic responses, visual behavior (ability to swim through a water maze or to select light or dark areas and, in the monkey model of color blindness, to identify specific colors),<sup>90</sup> and histology (including immunohistochemical demonstration of expression of the appropriate transgenic protein).

There has also been success with strategies aimed at rescuing disease due to toxic gain-of-function mutations.<sup>91–99</sup> Such strategies are necessarily more complex than gene augmentation strategies. The best-studied examples of intervention with gain-of-function gene defects include rhodopsin mutations found in AD RP. Such defects result in abnormal cellular trafficking as well as altered functional properties. Deleterious effects of the endogenous mutant genes can be minimized by a knockdown or knockdown/gene augmentation strategy. The mutant messenger ribonucleic acid (mRNA) can be specifically targeted, leaving the wild-type mRNA (either endogenous or delivered via gene augmentation) intact. Knockdown has been achieved successfully by using ribozymes, RNA interference (RNAi), delivery of microRNAs, and use of zinc finger nucleases (Table 36.2 part A).

Gene therapy strategies have also been used successfully to target

specific genes/proteins which may not be the primary cause of disease, but which are known to be involved in downstream pathways. An example involves manipulation of the vascular endothelial growth factor (VEGF) pathway implicated in ocular neovascularization (Table 36.2 part A).

Several groups have evaluated the possibility of ameliorating neovascularization by delivery of a gene that encodes a soluble decoy VEGF receptor, s-FLT.<sup>100-105</sup> Such an approach has been used successfully in animal models of both retinal and CNV. These studies led to two different phase I human clinical trials to test the safety and efficacy of intraocular delivery of an AAV2-sFLT vector in humans with CNV (Table 36.2 part A).

There are gene therapy strategies that can be used that are not specific to the disease-causing gene and could potentially be applied to a diverse set of conditions. One approach that has been used to evaluate development of a “generic” strategy with which to treat RP has been to use growth or neurotrophic factors or hormones to maintain the health of the diseased photoreceptors (Table 36.2 part B). Because growth factor proteins have very short half-lives (some as short as seconds), generation of a constant supply through a gene therapy approach is attractive. A growth factor could potentially be used to maintain the health of these cells until a disease-specific vector can be developed. Alternatively, such factors could be delivered as part of a cocktail.<sup>106</sup> An additional set of factors that has attracted interest in recent years consists of molecules that could protect against oxidative stress. Protection using a variety of different growth factors has been tested through direct viral gene transfer in animal models, including brain-derived neurotrophic factor, basic fibroblast growth factor, ciliary neurotrophic factor (CNTF), glial cell-derived neurotrophic factor, pigment epithelium-derived factor (PEDF), and X-linked inhibitor of apoptosis (Table 36.2 part B).<sup>4,106-122</sup> The majority of these have ameliorated structure and function, although CNTF, while ameliorating structure, has been shown to diminish retinal function at high doses in some animal models.<sup>114,117,123</sup> Sustained delivery of CNTF through use of a device that encapsulates CNTF-transfected cells (encapsulated cell therapy) has resulted in structural improvement without adverse functional effects (and in some cases,

improvement in function), both in animals and in humans (Table 36.2 part B).<sup>112,124–129</sup> The encapsulated cell therapy approach entails placement of a capsule containing a grid occupied by cells, transfected with a CNTF-encoding plasmid, into the vitreous. Another neurotrophic factor that has attracted great interest due to data showing that it rescues cone photoreceptors in animal models is rod-derived neurotrophic factor (RdCVF, whose gene is known as *NXNL1*).<sup>130</sup> Alternative splicing of *NXNL1* results in two isoforms of RdCVF, and the two isoforms appear to have distinct protective properties. This long isoform appears to protect against hyperoxia and the short form appears to protect cones from degeneration through stimulation of aerobic glycolysis.<sup>131,132</sup> Evaluation of the results in all of these growth/neurotrophic factor therapies reveals that, with the majority of these factors, efficacy is dependent on them being expressed in/by the retina. Interestingly, there is a hormone, erythropoietin, that can also delay retinal degeneration in certain animal models through gene therapy-mediated delivery, but this is only effective if it is delivered outside the eye (intramuscularly: Table 36.2 part B).<sup>110</sup> Finally, there are a number of factors that appear to reduce reactive oxygen and resultant oxidative stress and these are also “generic” candidates for therapy of retinal degeneration. Such factors include the transcription factors NRF2 and PGC1a, which regulate a network of genes involved in oxidative stress pathways, and superoxide dismutase 2 (SOD2) or catalase, enzymes which break down oxidants.<sup>111</sup>

Approaches using a generic gene therapy strategy to bring vision to retinas in which photoreceptor cells have been lost or severely damaged are also under investigation. These involve delivering light-sensitive channels, originally isolated from single-celled organisms, to either inner retinal neurons or remaining diseased cone photoreceptors. The gene encoding channel rhodopsin-2 (*ChRd*), originally identified in the algae *Chlamydomonas reinhardtii*, has been delivered to either bipolar cells or ganglion cells; Halorhodopsin (*NpHR*), originally identified in halobacteria, has been delivered to diseased cone photoreceptors (Table 36.2 part B). Unlike mammalian opsins, however, these light-activated proteins directly form ion channels that polarize (*NpHR*) or depolarize (*ChRd*) upon photostimulation in a single molecule. Other groups

have developed synthetic optogenetic molecules, including a light-gated excitatory mammalian ion channel light-gated ionotropic glutamate receptor (LiGluR). A second generation of the LiGluR receptor was recently tested in both mice and dogs.. With all of these molecules, optogenetic gene therapy rendered animals that were previously insensitive to light responsive to light as judged by retinal/visual behavior.<sup>51,133–138</sup>

## **Current Status of Retinal Gene Therapy Trials: Retinal Diseases Evaluated in Human Clinical Trials**

### **Studies That Were Completed, but Discontinued**

#### **Retinoblastoma**

Gene therapy has been used for treating tumor cells in the eye with the ultimate goal of avoiding the need to perform enucleation (and then chemotherapy and radiation therapy) in young children. If gene therapy were used to reduce the tumor burden, this would allow more control. Such an approach could potentially spare the patient disfigurement and loss of vision. Hurwitz and colleagues transduced murine retinoblastomas in vivo with an adenoviral vector containing the herpes simplex thymidine kinase gene followed by treatment with the prodrug ganciclovir (Table 36.2 part B).<sup>139,140</sup> This resulted in a complete ablation of detectable tumors in 70% of animals and a significant prolongation of progression-free survival compared with untreated controls. The study proceeded to clinical trial: seven patients had resolution of their vitreous tumors and one patient remained free of active vitreous tumors 38 months after therapy.<sup>139,141</sup>

#### **CNV Using AdPEDF**

Campochiaro and colleagues<sup>142</sup> carried out a phase I clinical trial in individuals with advanced neovascular age-related macular degeneration (AMD). In this dose escalation study, a serotype 5

(Ad5), E1, partial E3-, E4-deleted adenoviral vector carrying human *PEDF* (AdPEDF.11) was injected intravitreally into one eye of each of 28 individuals (Table 36.2 part B). PEDF is an endogenous protein with potent antiangiogenic activity. It also has antiapoptotic activity. There were no serious adverse events or dose-limiting toxicities through the highest dose. There was evidence that injection of doses greater than 10E8 particle units of AdPEDF.11 resulted in antiangiogenic activity persisting for several months.

## Encapsulated Cell Therapy

Results of a phase I study of delivery of CNTF through encapsulated cell therapy (see above) were reported by Sieving et al.<sup>129</sup> in 10 subjects with retinal degeneration. The implants were removed after 6 months. The delivery was safe save for one surgically related choroidal detachment. Three of the individuals showed improved visual acuity. A phase II study followed and results showed the outer retinal layers were thicker in CNTF-treated eye, and cone spacing and density increased as judged with adaptive optics scanning laser ophthalmoscopy.<sup>128</sup> The results of a multicenter, dose-ranging phase II study followed selected subjects with geographic atrophy and the results indicated that the implant slowed the progression of vision loss.<sup>125</sup> In a recent study individuals with achromatopsia due to *CNGB3* mutations were tested for efficacy of CNTF-encapsulated cell therapy after promising results were found in *CNGB3* mutant dogs.<sup>126</sup> Although the subjects reported beneficial changes of visual function in the treated eyes, no objectively measurable enhancement of cone function was found.<sup>127</sup>

## Studies in Progress

### Gene Augmentation Therapy for Leber Congenital Amaurosis

Three different clinical trials involving gene augmentation therapy for LCA due to *RPE65* mutations were initiated near simultaneously in 2007. The disease in LCA-RPE65 is due to lack of a function of RPE 65 kDa (RPE65) protein in the RPE. RPE65 is an isomerohydrolase and breaks down retinyl ester, thereby allowing

production of 11-*cis* retinal, the chromophore which contributes to the visual pigment rhodopsin.<sup>143</sup> Each of the three studies used an AAV serotype 2 vector delivering the wild-type human *RPE65* cDNA subretinally to the RPE in one eye, but the studies differed in terms of dose, inclusion criteria, type of promoter, location of injection, and outcome measures. The early reports from all three trials revealed a high degree of safety and demonstrated efficacy as judged by increase in light sensitivity, improved visual acuity and visual fields, improved pupillary light reflex, and improved mobility.<sup>18,37,144</sup>

The entire set of results of the phase I/II study were reported from the group at CHOP and indicated that not only was the AAV delivery safe, but also each one of the 12 clinical trial subjects, ages 8–45 years, showed evidence of improved retinal and visual function as judged by any of several different test paradigms.<sup>34</sup> The children in the study showed particularly large improvements, now being able to read books and play sports.<sup>15</sup> The older individuals also showed evidence of gain in function but not surprisingly (since this is a degenerative disease), had worse vision outcomes compared to the younger cohort. A follow-on study reported the results of readministration of the AAV to the contralateral eye in the first three subjects. There was no inflammation and there were no safety concerns with readministration and there was evidence of benefit.<sup>145</sup> The safety and efficacy data from these phase I/II studies prompted initiation of a phase III clinical trial at CHOP. Enrollment has been completed in this phase III study and the initial results show robust improvement in the primary endpoint (a multi-luminance mobility test) as well as secondary endpoints (<http://ir.sparktx.com/phoenix.zhtml?c=253900&p=irol-newsArticle&ID=2211949>). The full set of results will be reviewed by the Food and Drug Administration (FDA) in 2017. This could potentially lead to the first approved gene therapy in the United States and the first approved gene therapy for retinal disease in the entire world.

The set of results from a second phase I (single eye) study were recently reported and were complementary yet did not describe any age-related effects of treatment.<sup>146</sup> The authors also described retinal sensitivity testing in 3 of the 16 subjects and showed

significant benefit of retinal and visual function, but the authors believe there is in focal retinal sensitivity in the injected areas of the retina, although sensitivity was still significantly higher than it was at baseline.<sup>147</sup> The set of results from the third phase I (single eye) study initiated in 2007 were published in 2015, and the authors concluded that it will be important in the future to use more efficient delivery of RPE65 at an early stage of the disease.<sup>148</sup>

Two other clinical trials for LCA-RPE65 were initiated several years ago ([www.clinicaltrials.gov](http://www.clinicaltrials.gov)) but neither has provided results (except for one report from one patient).<sup>15</sup>

## **CNV and AAV-sFLT**

Wet AMD is currently under consideration as a target for development of gene therapy. In this disease people can go blind overnight due to leakage in blood vessels. Anti-VEGF therapies have been shown to be effective for the treatment of neovascular AMD. The downside of anti-VEGF therapies is that they must be readministered frequently, with the result that doctors are overburdened and patients must return frequently to receive intravitreal injections. There is a clear need for long-lasting production of a VEGF decoy in the eye – a stable product that could be delivered through a one-time injection. A strategy with which to interfere with proangiogenic activities of VEGF involves intravitreal delivery of an AAV-carrying soluble VEGF receptor (sFLT). This strategy is currently being tested in two different dose escalation studies in individuals with AMD (Table 36.2 part A). Recent results of one of the phase IIa studies (run by Avalanche Biotechnologies) indicated that the test compound, AVA-101, met its 12-month primary endpoint, based on ophthalmic and systemic safety. AVA-101 also showed an improvement on best corrected visual acuity (BCVA) compared with the control group and a positive trend in response rate (stable vision with few rescue injections; <http://investors.avalanchebiotech.com/>).

## **CNV and Lentivirus-Mediated Delivery of Angiostatin and Endostatin**

Another strategy that is being tested in clinical trial for wet AMD is

subretinal delivery of RetinoStat, a lentiviral vector delivering angiostatin and endostatin.<sup>30,149</sup> Both angiostatin and endostatin have strong and well-documented antineovascularization effects.

## **Gene Augmentation Therapy for X-Linked Juvenile Retinoschisis (XLRS)**

Mutations in the *RS1* gene cause abnormal function of the retina protein, retinoschisin. A lack of retinoschisin causes the layers of the retina to split apart, resulting in the loss of vision. Studies in rodent models have shown that delivery of the normal copy of the *RS1* cDNA can improve retinal structure and function.<sup>82-85</sup> A clinical trial evaluating safety and efficacy of intravitreal delivery of AAV2.RS1 in adults with XLRS is in progress at the National Eye Institute, National Institutes of Health, USA.

## **Gene Augmentation Therapy for Choroideremia (CHM)**

Two different phase I/II trials are underway to test safety and efficacy of subretinally delivered AAV2 carrying the wild-type human *CHM* cDNA. Both studies enroll affected men, aged 18 years and older ([www.clinicaltrials.gov](http://www.clinicaltrials.gov)). The ultimate goals of a CHM gene augmentation trial are different than those of an LCA2 trial. CHM have fairly good vision early in life whereas individuals with LCA2 do not. Retinal degeneration proceeds in CHM in a peripheral-to-central fashion, leaving few viable cells in the periphery late in the disease. Central vision is the last to remain intact. Gene augmentation therapy requires that viable cells be present (even if dysfunctional) in order of having a chance of benefitting, and so there is little hope that peripheral vision can be rescued late in the course of CHM. The goal in CHM is thus to preserve central vision (and to halt further progression of the disease). Ultimately, it may be possible to treat the entire retina of a boy affected with CHM and prevent any disease symptoms.

## **Gene Augmentation Therapy for Leber Hereditary Optic Neuropathy (LHON)**

Two different phase I/II trials are underway and one additional trial is planned to test safety and efficacy of intravitreally injected AAV2

carrying a synthetic nuclear DNA encoding one of the three NADH dehydrogenase mitochondrial genes implicated in LHON, the *ND4* gene. LHON is caused by mitochondrial defects in retinal ganglion cells, which are efficiently transduced through intravitreal injection of AAV2. A challenge inherent with mitochondrial disorders, such as those implicated in LHON, is that the mitochondrial DNA encodes proteins localized to this organelle. Since viruses deliver genes to the cell's nucleus, a challenge is how to intervene to target the gene/protein to the mitochondria. One solution is to deliver the corrective gene to the nucleus, but to tag it with a mitochondrial targeting sequence, a signal that guides the cell to shuttle proteins into the mitochondrion. This approach was used to develop proof-of-concept data to support clinical trials run by two different groups targeting the G11778A *ND4* mutation.<sup>150,151</sup> Interestingly, the rodent models were generated by injecting either DNA (followed by electroporation) or AAV encoding the mutant G11788A human *ND4* cDNA.<sup>150,151</sup> A second injection allowed the allotopically expressed wild-type *ND4* to ameliorate the phenotype induced by the G11778A mitochondrial DNA. A third group, directed by Dr. G. Farrar, generated the disease model by giving animals a drug that inhibits Complex I proteins normally encoded by mitochondrial DNA.<sup>152</sup> This team tested a novel strategy for intervening with LHON by delivering a gene from yeast, *ND11*, which encodes a protein that functions similarly as mammalian Complex I. The therapeutic protein compensated for the dysfunctional Complex I in the rodent mitochondria.<sup>152</sup> Whether the synthetic mitochondrial targeting sequence or the yeast-derived protein may result in a harmful immune response in the primate retina is unknown. Additional challenges include the fact that most affected individuals are initially unaware that they are affected until they experience loss of vision in the first eye and it is difficult to predict when there will be vision loss in the second eye, although the delay is usually only a few months. Thus, one of the current goals of LHON gene therapy is to develop a rational strategy to prevent vision loss in the second eye after symptoms initially manifest in the first eye.

# Promises and Challenges of Bringing Retinal Gene Transfer From Bench to Bedside

## Safety/Efficacy/Stability Issues

Numerous studies have been carried out showing that retinal gene transfer can be both safe and effective. The successes of the first human gene augmentation therapy studies involving LCA-RPE65,<sup>15,18,34,37,144,145,147,148,153</sup> provide the foundation for gene therapy approaches for the treatment of other forms of inherited retinal degenerative diseases. LCA-RPE65 may well be the easiest target for study as it is slowly progressive, is caused by a gene whose cDNA fits within the limited AAV cargo capacity, and is caused by a defect in RPE cells. The latter are easy to target using AAV vectors. In predicting what other disease(s) could be targeted using a similar approach, one confronts the following challenges:

1. Not all transgene cassettes fit within the cargo confines of the AAV vector (Table 36.1). Studies in progress aim to modify AAV capsids so that they can carry larger cargo or, alternatively, deliver different portions of large transgenes in multiple AAVs so that, after infection has taken place, the cargo recombines in the target cell and leads to the production of a full-length therapeutic protein. Alternative strategies to packaging large transgene cassettes into rAAVs include delivery of a cDNA encoding a truncated but functional protein, or delivering the cDNA in segments through a “trans-splicing” approach. For the latter approach, the cDNA is split into two separate rAAV vectors using an engineered intron to mediate splicing of the two cDNA segments within the cell. Feasibility of this approach has been demonstrated in vivo in the mouse retina.<sup>154</sup> With new gene editing techniques using CRISPR/CAS, it may also be possible to correct the specific source of the disease.<sup>155</sup> There are concerns with this approach, however, about potential “off-target” effects<sup>156</sup> that could lead to additional malfunction or even oncogenesis.
2. Photoreceptors – not RPE cells – are the primarily diseased cells

in many retinal degenerative diseases and those cells are not targeted as efficiently by AAV2 or by most forms of lentivirus (Table 36.1). Fortunately, a number of hybrid vectors are now available that can target these cells efficiently and this work continues (Fig. 36.4; see above). Further, some of them result in transgene expression using 10-fold less vector than AAV2.<sup>44</sup> Additional modifications of capsids, envelopes, and surface proteins will continue to provide improved toolkits with which to deliver these large genes efficiently to photoreceptors and other retinal cell types.

3. Some diseases progress very quickly and there will be challenges making sure that the gene is delivered before the cells have died. In some cases (such as in diseases that involve mutation in a gene expressed early in development), the optimal result will likely require delivery early in infancy, or even prenatally. In those cases, besides the need to identify the disease early in life, there will be difficult ethical issues to consider, in addition to risk-to-benefit ratios.

4. There are formidable economic challenges. For many of the potential disease targets, very few patients have been identified. Even though the cost of carrying out genotyping has decreased considerably over the years, it is still expensive. It would be possible to establish widespread genetic screening programs to identify the disease-causing gene in every individual with retinal degeneration, but who will pay for this? Another challenge involves unavailability or lack of an appropriate animal model. It is possible to engineer rodent models but, again, this is costly and time-consuming. Also, rodent models do not mirror some of the unique issues of the primate (human retina), for example, presence of a macula. It may be possible to carry out proof-of-concept studies in cell models for which animal models are unavailable or irrelevant, and then carry out safety studies in animals with normal vision. Such a strategy was used successfully by Vasireddy et al.<sup>89</sup> Finally, the costs of establishing and running clinical trials will limit the number of therapies that can be tested. It is possible, however, that once the first gene therapy reagent is designated as a FDA-approved drug in the USA or in Europe, the regulatory (and thus

financial) burden for developing additional drugs will decrease. For example, data from development of one particular vector could be used to support the development of another.

5. Gene therapy is not going to be effective for every retinal disease. There are some diseases in which the efficiency of transduction and/or levels of gene expression are going to be critical. Delivery of either too much or too little of the reagent will be either ineffective or possibly even toxic. There may also be immune responses to particular vectors/gene products that could limit efficacy. The recent successes in retinal gene therapy are very exciting but we have much to learn about the safety limitations not only with respect to type of gene, route of delivery, and dose, but also with respect to readministration.

## **Outcome Measures in Human Clinical Trials**

A number of outcome measures (visual acuity, visual field, color vision, and area of nonseeing retina) have been used or accepted in the development of drugs for ophthalmologic indications. Except for visual acuity, however, there is no generally accepted level of improvement considered “clinically meaningful” in FDA parlance. For visual acuity, the precedent of 15 letters, or three lines on an ETDRS eye chart corresponding to 0.3 logMAR or 50% improvement, has been accepted as clinically meaningful. For some of the diseases that are being considered for treatment with gene therapy, individuals may only have light perception vision and so an ETDRS chart is irrelevant. In addition, there are many diseases, e.g., choroideremia, where visual acuity remains intact long after patients become severely disabled from nyctalopia and legally blind from visual field loss. Furthermore, endpoints that are used in adults may not be applicable for small children, who do not have the attention span or cognitive abilities to participate in the study procedures. Some endpoints may not have enough sensitivity to detect a change in clinical status. While it has been argued that improvement on visual field testing can be considered clinically meaningful when results of multiple points in the visual field meet specific criteria, this test cannot be completed accurately by an individual who cannot fixate due to nystagmus, such as individuals

with LCA or cone-rod dystrophy. Thus, it will be essential to do correlation analyses that will provide surrogate measures for clinically meaningful outcomes and thus expand and validate additional efficacy outcome measures such as pupillometry (Fig. 36.5) for particular target populations.

**FIG. 36.5** Example of improvement of the pupillary light reflex after a unilateral subretinal injection of AAV2-hRPE65v2. There is minimal response to light in either eye in the subject prior to injection. After injection, there is a brisk pupillary response after the (treated) right eye (but not the untreated left eye) is illuminated. This gives the appearance of a relative afferent pupillary defect except that this reflects correction of the defect in the treated eye. Shown for comparison is the pupillary light reflex of a normal-sighted individual.

## Window of Opportunity

In order to attain the maximal therapeutic effect for any retinal disease, it is important that the transgene be delivered within the appropriate timeframe. In the case of degenerative diseases, gene augmentation therapy will only be effective if the target cells are still present. For example, gene augmentation strategies for RP will only be effective if the photoreceptors are still present (even if they are dysfunctional).

There is also the issue of whether the goal is to reverse blindness or simply to prevent the disease from worsening (i.e., to hold it in place). For a disease such as LCA due to *RPE65* mutations, there is a biochemical deficit that can be remedied and thus allow previously functional photoreceptors to respond to light. In AR Stargardt disease, however, there may be toxicity due to the disease-associated accumulation of toxic byproducts of the retinoid cycle. Delivery of the normal version of the Stargardt disease gene, *ABCA4*, may prevent additional toxic byproducts from accumulating but will not remove those that have already accumulated. In other diseases, the gene mutation may affect a structural component in photoreceptor cells and thus may affect the development of the retina and prevent formed vision very early in life. In such cases, the disease initiates and thus must be corrected very early in life (i.e., it has a developmental component). In addition, there is the significant risk that if the retina is “corrected” too late in life, the individual will not be able to benefit from vision because of amblyopia. In cases where there is formed vision early in life, this may not be as significant a concern (see below).

## Plasticity of the Visual System

Nearly 40% of the human brain is involved with the processing and perception of vision.<sup>157</sup> Of all sensory systems, vision provides the most information to the human brain. Both laboratory and clinical studies have demonstrated that early onset of blindness can lead to structural and functional brain changes. Severe impairment of the visual pathway early in life due to developmental or retinal degenerative diseases is likely to limit the responsiveness of neurons in the visual cortex. Thus, while gene therapy for some early-onset retinal degenerative diseases may be able to rescue

retinal function, it may not necessarily allow vision. The limits to restoration of the retinal-cortical pathways are not well defined, however, as shown by recent results from a functional magnetic resonance imaging (fMRI) study in children and young adults who had been treated at CHOP with gene therapy for LCA-RPE65 mutations. Ashtari and colleagues<sup>158</sup> carried out an fMRI study in such patients to investigate how the cortex responds to the recovery of function after gene therapy in specific areas of the retina after prolonged visual deprivation. That study employed only dim light stimuli, since it is known that young LCA-RPE65 patients are able to see and function (albeit poorly) when their environment is brightly lit. Functional analyses were carried out separately for each individual patient to account for disease stage and treatment area in each of the subjects. The untreated eyes served as an internal control for each subject. The results showed that the visual cortex could become responsive to visual input, even after prolonged (up to 35 years in the oldest patient) visual deprivation (Fig. 36.6).<sup>158</sup> Treatment of the retina also resulted in myelination of the corresponding visual tracts in the brain.<sup>159</sup> The plasticity data provide hope for being able to use gene therapy to resuscitate not just the retina (and potentially also other sensory organs) but also the visual cortex even after chronic visual deprivation.

**FIG. 36.6** The visual cortex of individuals with Leber congenital amaurosis due to *RPE65* mutations

responds to visual stimuli as predicted by the site of injection of AAV2-hRPE65v2. Cortical activations are appreciated after presentation of stimuli to the injected, but not the uninjected, eye. Subject 1 had received an injection in his left macula; subject 2 had received a superotemporal injection in his right retina. (For full details, see Ashtari M, Cyckowski LL, Monroe JF, et al. The human visual cortex responds to gene therapy-mediated recovery of retinal function. *J Clin Invest* 2011;121:2160–8.)

## Genotyping Issues

Over the past two decades, more than 238 different genes have been identified which, when mutated, cause retinal disease (<http://www.sph.uth.tmc.edu/RetNet>). Molecular diagnostics of inherited retinal diseases is performed in order to provide a definitive disease diagnosis and to be able to provide prognostic information to patients as well as genetic counseling. With the progress in developing gene therapy for retinal diseases, genotyping has become increasingly more important as patients want to know whether they are eligible for certain trials. In addition, genotype/phenotype data have become very important in planning ahead for other clinical trials. This information is invaluable for determining the optimal age for intervention, selecting appropriate outcome measures, and predicting how long it would take to document an improvement in the phenotype given the appropriate gene therapy intervention.

While genetic testing has become more commonplace, there is still not a routine, standardized test. There are large technologic and economic challenges associated with genetic testing because of allelic and genetic heterogeneity, and further, we still do not know the genes responsible for a large number of the diseases. As a result, only a minority of patients know their genetic defect. The decision as to what path to take in order to obtain a genetic diagnosis is often guided by economic issues, including insurance coverage. Good phenotype analysis can shorten the list of suspect genes on a differential diagnosis list considerably. That, the initiation of other retinal gene therapy trials for genetic disease, and the development of cost-effective strategies for identifying and sequencing disease-

causing genes will continue to transform the clinical workup of retinal degeneration and other patients.

## A Treatment Versus a Cure?

One of the questions that is being and continues to be evaluated in various clinical trials is whether gene therapy can result in a permanent improvement in retinal and visual function. Results reported by two of the groups carrying out human clinical trials for LCA2 show long-lasting (on the order of 3–6 years so far) improvements in retinal and visual function,<sup>20,145,153</sup> although one group reported on 3 of the 15 subjects treated and found large improvements followed after 3 years by a slow decline.<sup>147</sup> In that study, even with the decline, retinal sensitivity is increased significantly over baseline at the 6-year timepoint. The phase I clinical trials in which the data were collected using different doses of AAV are complicated by numerous additional variables, including stage of degeneration, volume of AAV injected, area of retina injected, complications, age of the subject, surgical details, type of outcome measures used, etc. With time, it should be possible to determine the optimal parameters for intervention and to determine whether a cure is possible. In the meantime, even with a slow decline in retinal sensitivity over years, the improvements could be meaningful to the subjects suffering from these otherwise untreatable conditions (see also [http://www.medscape.com/viewarticle/844151#vp\\_2](http://www.medscape.com/viewarticle/844151#vp_2)). It may be possible to further boost efficacy by readministration to additional portions of the retina, however safety of such strategies will need to be tested in animal models prior to testing in humans.

## Generic Strategies for Reversing Blindness in “Dead” Retinas

A major challenge for retinal gene therapy is, who will pay for the costs of generating and validating clinical vectors, carrying out preclinical safety studies, screening potential clinical trial candidates for the relevant gene defect, conducting the appropriate regulatory oversight, and paying for the clinical trial itself –

particularly if potentially over 230 different gene therapy products (each specific for a different retinal gene) could be developed? Studies involving proof of concept of a given gene therapy often can be covered by conventional funding mechanisms – government grants, private foundations. It is much more difficult, however, to find funding for the costlier clinical trials. Safety data from one approach and then applied to another may provide shortcuts for some portions of product development but still, the economic challenges alone are enormous.

It is for that reason that generic strategies to treat retinal disease are appealing. As described above, there has long been an interest in using growth factors or neurotrophic factors to maintain the health of the retina for longer (Table 36.2 part B). In many diseases, a stabilization of the disease progression would be clinically meaningful. In “dead” retinas, it may be feasible to harness the remaining circuitry to provide some useful vision using “optogenetic therapy”. There are many technical challenges associated with this endeavor, including the desirability of engineering the molecules so that they would be useful with typical indoor lighting parameters. There are also potential biologic challenges with this approach. Will the mammalian retina recognize optogenetic (algal or bacterial) proteins produced in inner retinal cells as foreign? Nevertheless, the ability to deliver clinically meaningful vision to individuals who have none is very exciting and could supply hope to millions of patients with endstage retinal or macular degeneration.

## Conclusion

### State of the Art of Retinal Gene Therapy

There has been a huge amount of progress in developing proof-of-concept of retinal gene therapy and proof-of-concept data for several approaches that have led to the initiation of clinical trials. It may not be long before the first gene therapy product is approved for human use in the Western world and this may be a product intended for use in the retina. The early successes will likely fuel the development of gene therapy for other retinal disease targets.

With the rapid development of engineered vectors, the swift progress in our understanding of the genetics of retinal diseases, and finetuning of surgical delivery procedures, this field has never been more promising. With continued successes with ocular gene therapy, there may be a day when gene-based approaches can be used to treat blinding diseases which are currently untreatable.

Concluding Remarks**

## **Stem Cells as Therapeutics to Treat Retinal Disease**

Nothing more dramatically captures the imagination of visually impaired patients or the ophthalmologist treating them than the possibility of rebuilding a damaged retina using stem cells. Since many retinal neuro- and vasculodegenerative diseases progress slowly, it may be possible to use stem cell-derived “replacement cells” to prevent visual loss if such therapies are performed at an early stage of disease. Stem cells are defined as cells that are able to self-renew (i.e., create more stem cells) and differentiate into (i.e., become) specialized, more mature cell types. The three main types of stem cells that will be explored in this chapter, and that are of most interest as potential therapeutics to treat retinal disease, are human embryonic stem cells (hESCs), human induced pluripotent stem cells (hiPSCs), and adult stem cells. hESCs are derived from early embryos, specifically called blastocysts, and are pluripotent, which means they can differentiate into all of the mature cell types in the human body, including retinal cell types. hiPSCs are also pluripotent stem cells, making them similar to hESCs in appearance and behavior, but hiPSCs can be derived from adult somatic tissues, which makes it possible to create patient-specific pluripotent stem

cells when autologous replacement tissues for treating ocular, and other, diseases is desirable. Many different subtypes of adult stem cells have been identified and isolated; these adult stem cells presumably represent a pool of progenitor cells in the specific tissues in which they are found and may supply cells to maintain those tissues as well as repair the tissue following injury or stress. Overall, there are now several populations of stem cells that have been described and each may have relative benefits for the treatment of different diseases.<sup>1</sup> Readers are referred to [Chapter 128](#) (Transplantation frontiers) for further discussion of clinical applications of retinal progenitor and adult transplantation therapies.

## Definitions

Stem cells can be generally divided into those that are isolated from early embryonic cell populations (i.e., embryonic stem cells [ESCs]) and those that are isolated from adult tissue (i.e., adult stem cells). (hiPSCs are often grouped together with ESCs based on their behavioral similarities.) ESCs are typically isolated from blastocysts, which are at an early embryonic stage of development, and exhibit pluripotency, meaning they have the ability to differentiate into any of the mature cell types of the adult body (when cultured under appropriate conditions). Adult stem cells typically reside in adult tissues in a quiescent, undifferentiated state and, under appropriate stimuli, will divide and differentiate into the cell type of the tissue in which they reside or, if appropriately stimulated, into other cell types.<sup>2</sup> The mechanism whereby an undifferentiated, quiescent stem cell can give rise to a multitude of differentiated, postmitotic cell types is an area of active investigation, and large-scale genomic analysis<sup>3</sup> and transcriptional profiling<sup>4</sup> of stem cells have led to the discovery that different types of stem cells have varying degrees of “stemness,” or potency (i.e., limitations on the types of cells that they can differentiate into).<sup>5</sup> For example, while truly pluripotent ESCs can give rise to a multitude of differentiated cell types, adult stem cells are more limited in their differentiation potential and are usually considered “multipotent,” meaning they can typically differentiate into more than one mature cell type, but the variety of

cell types is usually restricted to an interrelated group.

## Embryonic Stem Cells

ESCs are derived from cells in the early embryo, specifically at the late blastocyst stage, and are characterized by being pluripotent and having the capacity to self-renew indefinitely. Pluripotency is defined as the ability to differentiate into cell types belonging to the three germ layers (ectoderm, endoderm, and mesoderm; the three different tissue types that exist during development in the embryo and that later, together, comprise the adult body). Their pluripotency is the reason why ESCs are theoretically able to become any of the mature cell types found in the adult body.

The first ESCs created were murine ESCs (mESCs), derived and cultured from mouse blastocysts in 1981,<sup>6,7</sup> and have become important research tools for the creation of transgenic and knockout mice, and for the study of early development in mammals ([Table 37.1](#)).<sup>8</sup> In 1995, James Thomson's team generated nonhuman primate ESCs for the first time – cultured from rhesus monkey blastocysts<sup>9</sup> – and then later, in 1998, Thomson's group was also the first to derive hESCs.<sup>10</sup> hESCs are generated from late-stage human blastocysts that are allowed to develop for approximately 4–5 days post-fertilization. At this point, the blastocyst has not yet been implanted in the uterus and consists of a hollow sphere made up of approximately 150 cells in total and three distinct areas: the trophoblast (the surrounding outer layer that later becomes the placenta), the blastocoel (a fluid-filled cavity within the blastocyst), and the inner cell mass (also known as the embryoblast; it has the potential to become the embryo proper, or fetus). hESCs are created from cells taken from the inner cell mass, which consists of 20–50 cells at days 5 and 6 ([Fig. 37.1](#)).<sup>11</sup> In 2006, a method for deriving hESCs from single blastomeres without destruction of the embryo was reported.<sup>12</sup> Methods for culturing hESCs have typically utilized a feeder layer of inactivated mouse embryonic fibroblasts (MEFs) to facilitate the growth and survival of the stem cells, although in recent years there has been a transition towards employing feeder-free and serum-free culture methods, which are more ideal for generating cells in xenogeneic-free (xeno-free) conditions for use in

cellular transplantation therapies.<sup>8</sup>

The National Institutes for Health (NIH) has developed guidelines to establish policy and procedures under which hESC-based research will be funded to ensure that NIH-sponsored research in this area is ethically responsible, scientifically worthy, and conducted in accordance with applicable law. These guidelines were developed in response to Executive Order 13505, were issued on March 9, 2009, and became effective on July 7, 2009. As of September 2016, there were 369 hESC lines eligible for use in NIH-supported research, as listed in the NIH Human Embryonic Stem Cell Registry (<http://stemcells.nih.gov/research/registry/>). The National Academy of Sciences has also released extensive guidelines for the ethical conduct of hESC research (<http://nas-sites.org/stemcells/>).

## Induced Pluripotent Stem Cells

The creation of induced pluripotent stem cells (iPSCs) – pluripotent stem cells that are similar in appearance and function to ESCs but that can be generated from adult tissues – was one of the most significant advances in the field of stem cell biology. The idea that an adult, somatic cell could become a reprogrammed embryonic-like cell gained more attention in the scientific community after the creation of the first cloned animal in 1997 (i.e., Dolly the sheep) and the cloning of several other animals in the late 1990s. These cloned animals were generated using somatic cell nuclear transfer, a technique wherein the nucleus from a somatic cell is inserted into an enucleated egg cell, which is then implanted into, and develops in, a surrogate mother.<sup>13</sup> Similarly, the creation of iPSCs came with the finding that forcing adult somatic cells (e.g., skin keratinocytes, fibroblasts, or T or B cells from blood) to produce key ESC transcription factors could induce, or reprogram, the adult cells to a pluripotent state. In 2006, Shinya Yamanaka's group created the first iPSCs this way using mouse fibroblasts.<sup>14</sup> Expression of these embryonic transcription factors was accomplished by transducing the fibroblasts with a viral vector encoding the factors. Only a year

later, the same principles were independently applied by Thomson's and Yamanaka's teams to generate the first human iPSCs (hiPSCs; using human fibroblasts).<sup>15,16</sup> Yamanaka utilized the same transcription factors that were used for mice (Oct-4, Sox2, Klf4, and c-Myc), while Thomson used a different, but overlapping, set of factors (Oct-4, Sox2, Nanog, and Lin28). Since the creation of hiPSCs, researchers have found ways of making hiPSCs using nonintegrating vectors and systems that deliver the key reprogramming proteins to cells without directly altering the cell's genome. The creation of hiPSCs may enable the production of grafts that are autologous or donor-matched (i.e., human leukocyte antigen [HLA]-typed to assure immune system compatibility) for use in treating a variety of diseases, including those of the retina.<sup>14,17</sup> This is discussed in greater detail below.

## Adult Stem Cells

The concept that adult tissues contain stem cells that can serve as a source of regenerative tissue is an important advancement in our way of thinking about normal mechanisms for repairing aging adult organ systems and how to apply these processes in the field of regenerative medicine.<sup>18</sup> While adult stem cells (specifically hematopoietic stem cells [HSCs]) were first used to treat patients during World War II – in the form of bone marrow transplants for people who had received lethal doses of radiation – these adult stem cells were not identified and characterized until decades later. Today, while there is an extensive literature on adult stem cells giving rise to nervous,<sup>19</sup> muscle,<sup>20</sup> vascular,<sup>21,22</sup> and hematopoietic tissue, work on retinal stem cells is more limited. Nonetheless, a literature has emerged over the past decade that strongly supports the potential for exploiting progenitor cells to maintain, and perhaps regenerate, abnormal retinal tissue. These studies describe four basic populations of cells that may contain dormant progenitor cells which, under appropriate circumstances, may have therapeutic application in the treatment of retinal disease: (1) retinal stem cells that can give rise to photoreceptors and other retinal neurons; (2) Müller glial stem cells that can differentiate into retinal neurons; (3) retinal pigment epithelial (RPE) stem cells that can not

only serve to replace diseased RPE but perhaps also be stimulated to differentiate into photoreceptors; and (4) endothelial progenitor cells (EPC) that can contribute to the retinal vasculature and exert a neurotrophic effect. Since there are a large number of reviews on retinal stem cells, this topic will not be discussed in great detail here. Müller glial cells, RPE stem cell biology, and adult bone marrow-derived HSC containing EPCs have great therapeutic potential, and are discussed below in more detail.

## Retinal Stem and Müller Glial Cells

It has long been known from classic studies in developmental biology that the retina of amphibians and chick embryos regenerates after injury and that this regenerative capacity derives from quiescent stem cells that reside in the adult retina of these species.<sup>23,24</sup> Given that such potential exists in lower vertebrates, there have been numerous efforts to demonstrate similar regenerative capacity in the mammalian retina. For a population of retinal stem cells to exist in the adult retina, it would be necessary for such a cell population to remain quiescent after the retina has fully differentiated. Studies that give us a better understanding of gene expression during retinal development, such as by employing large-scale genomic analysis<sup>25</sup> or serial analysis of gene expression in combination with in situ hybridization<sup>26</sup> to localize gene expression temporally and spatially to individual retinal cell types, have assisted in the search for adult retinal progenitor cells by providing a kind of “molecular atlas.” Such efforts have served as a starting point for the evaluation of numerous genes and their potential roles – as they are progressively switched on and off in an orderly manner – in the regulation of retinal cell developmental determination. The regulation of cell proliferation,<sup>27</sup> various transcription factors and signaling molecules,<sup>28</sup> and the surrounding microenvironment<sup>29</sup> have all been found to play roles during this process, providing insight into putative mechanisms whereby the mammalian retina holds in reserve a subset of progenitor cells that theoretically could be used to regenerate damaged tissue in the adult. Transcriptional profiling studies of retinas at different states of development coupled with in vitro

studies of progenitor cell populations<sup>30</sup> should continue to be important for providing information necessary to analyze and determine what conditions help maintain quiescence and what conditions stimulate proliferation and subsequent differentiation of retinal progenitor cell populations.

Retinal progenitor cells are purported to exist in the ciliary margin; single pigmented epithelial cells can be isolated from the ciliary margin (but not the central or peripheral pigmented epithelium) and clonally expanded in culture. However, the potential utility of these cells and their characterization have come under scrutiny and are discussed extensively in a number of excellent recent reviews and book chapters.<sup>31-34</sup> Retinal neuronal phenotypes<sup>35</sup> and neuroepithelial-like clusters of retinal progenitors<sup>36</sup> have also been generated via the differentiation of ESCs using factors including insulin-like growth factor (IGF)-1 and retinoic acid or the formation of self-organizing, 3-D optic vesicle-like structures from hESCs and hiPSCs. The development of such 3-D structures is explored in further detail later in this chapter.

Müller glial cells hold particular interest as an endogenous cell source due to their ability to potentially convert to a progenitor state under certain conditions, usually related to disease or injury.<sup>33</sup> In lower vertebrates (e.g., chickens), adult, differentiated Müller glia can, in response to injury or exogenously added cytokines or transcription factors, dedifferentiate, proliferate, and redifferentiate into additional glial cells or neurons.<sup>37-39</sup> Müller glia are also known to be activated in a variety of retinal vascular and neurodegenerative diseases, and in response to similar vascular changes.<sup>40,41</sup> Further supporting their role as stem cell-like cells are molecular profiling studies of developing mammalian retinas that show a high degree of similarity between the gene expression profiles of Müller glia and mitotic retinal progenitor cells in the mouse.<sup>26</sup> One study has expanded this concept significantly: amacrine, horizontal, and photoreceptor phenotypes have been found to be expressed by Müller glial cells following toxic injury to the adult mammalian retina in the presence of extrinsic factors (e.g., retinoic acid) or activation of intrinsic genes.<sup>39</sup> Similarly, Müller glial cells have also been shown to be capable of transdifferentiating to retinal interneurons after the introduction of a proneural

transcription factor (i.e., *Ascl1*) in a damaged mammalian retina.<sup>38</sup> These studies provide additional insight into retinal regeneration in mammals and potential rationale for targeting Müller glia in certain inherited and acquired retinal degenerative disorders. Additional studies are needed to improve our understanding of the development of mammalian Müller glial cells and their ability to revert to a stem cell-like state.

Müller glial cells may also be utilized for the targeted delivery of certain factors in the retina. These are the only cells that span the entire neurosensory retina; Müller cell processes extend anteriorly to the ganglion cell layer as well as posteriorly to the RPE. These processes form intimate contacts with retinal blood vessels, photoreceptors, and other retinal neurons. In animal models of outer retinal neovascular disease, the appearance and location of activated Müller glial cells precisely correlate, both temporally and spatially, with subretinal neovascularization and associated neuronal degeneration in the outer retina.<sup>42</sup> Activated Müller cell-targeted adeno-associated viral vectors containing a transgene encoding a neurotrophic molecule have been shown to target the outer retina in vasculodegenerative<sup>42</sup> and neurodegenerative disorders<sup>43</sup> characterized by photoreceptor degeneration. This strategy could be useful clinically to avoid the need for subretinal injections of the viral vector, a procedure that can have deleterious effects on already diseased retinas.

## Differentiation of hESCs and hiPSCs Into Photoreceptors

Studies evaluating the *in vivo* efficacy of photoreceptors derived from pluripotent stem cells are at an early stage of development. Differentiation of hESCs into retinal progenitor cells has been achieved, as has further *in vitro* differentiation into photoreceptor-like cells.<sup>44,45</sup> However, while enrichment of RPE derived from human pluripotent stem cells is relatively straightforward, no equivalent protocol for purifying photoreceptors from these stem cell sources exists yet, and contamination of multiple retinal and perhaps other cell types is a significant concern.<sup>46</sup> Initial differentiation studies showed that *Noggin* (inhibitor of BMP

pathway) or Dickkopf (Dkk)-1 (an antagonist of the Wnt signaling pathway) promote anterior neural identity and then IGF-1 promotes the formation of retinal progenitor cells.<sup>45,47</sup> Tom Reh's lab reported differentiation of retinal and photoreceptor-like cells from hESC-derived embryoid bodies grown in suspension culture, through addition of Noggin, Dkk-1, and IGF-1 into neuronal differentiation medium in adherent culture<sup>44,48</sup> that, after 21 days of differentiation, expressed retinal progenitor cell-related transcription factors such as Rx, Otx2, Pax6, Chx10, and Crx.<sup>48</sup> When further cultured, these cells formed neural rosettes that, when allowed to self-aggregate, formed retinal progenitors and differentiated cells expressing photoreceptor and RPE markers.<sup>48</sup> Microarray analysis of hESC-derived retinal cells showed a very high correlation between genes expressed in human fetal retina and hESC-derived retinal cells.<sup>49</sup> Thereafter, investigators from the RIKEN Research Institute reported the successful derivation of retinal progenitor cell and photoreceptors from both mouse and human ESC using an even more highly defined stepwise method.<sup>50,51</sup> The final steps included use of retinoic acid and taurine to induce photoreceptor differentiation. With this induction method, they found that hESCs can be differentiated into photoreceptors showing both rhodopsin and recoverin immunoreactivity in 150 days.<sup>51</sup> The Gamm lab subsequently found that retinal differentiation from hESCs and hiPSCs can also occur through a near default pathway due to endogenous production of appropriate proanterior neuroectoderm and proteinogenic factors.<sup>45</sup>

Most recently, the Gamm, Sasai, and Canto-Soler labs have shown that photoreceptors can be generated from 3D retinal cultures using hESCs and hiPSCs, and these cells possess typical electrophysiologic features as well as primitive inner and outer segments, and are also light-responsive,<sup>36,46,52,53</sup> making such 3D approaches a promising route for generating photoreceptors derived from human pluripotent stem cells. These 3D structures are further explored in the following section of this chapter.

As compared to RPE, photoreceptor transplants would likely require integration into – or reformation of – the existing outer nuclear layer and establishment of functional synapses to act as a replacement therapy. Conversely, there may be some therapeutic

benefit by providing neurotrophic support to adjacent cells without true synaptic integration. When hESC-derived retinal progenitor cells were co-cultured with explants from retinal degeneration mice (*Aipl1*<sup>-/-</sup>), they showed incorporation into the retinas, had morphologic characteristics of photoreceptor cells, and were immunoreactive for recoverin – a finding that was only rarely found when cells were cocultured with wild-type retinas.<sup>44</sup> Subsequent experiments showed that when these cells were injected into the subretinal space of adult *Crx*<sup>-/-</sup> mice (a model of Leber congenital amaurosis), the hESC-derived retinal cells differentiated into photoreceptor-like cells that were immunoreactive for recoverin and rhodopsin and restored light responses with an electroretinogram-like signal in the transplanted eye.<sup>54</sup> While the integration of hESC-derived photoreceptors may be a relatively rare event, these results demonstrate in principle that hESCs can be used as a source of cells for photoreceptor replacement therapy. Rod precursor cells generated from mESCs have also been transplanted into various mouse models in multiple studies.<sup>55–58</sup> Integration of the transplanted precursor cells in the investigated mouse models was found to depend upon disease progression and the specific genetic defect in the model, although significant integration was possible even in some late-stage models.<sup>55</sup> Integration of these cells was also shown to lead to the development of mature outer segment-bearing photoreceptors.<sup>56</sup> Of particular note, in a mouse model of severe retinitis pigmentosa that had no remaining rod cells, transplantation of precursor cells resulted in a polarized outer nuclear layer with mature rods and light-sensitive outer segments that restored visual function.<sup>57</sup> Fewer retinal integration and functional studies have been performed using photoreceptors derived from hiPSCs.

## Differentiation of hESCs and hiPSCs Into Three-Dimensional Retinal Tissues

In 2003, murine ESCs were shown to be able to differentiate into eye-like structures with cells that have properties of the crystalline lens, neural retina, and RPE.<sup>59</sup> Later, in 2008, dissociated cells from these eye-like structures were shown to integrate into the retina,

especially after retinal injury.<sup>60</sup> Then, in 2011, investigators reported the remarkable discovery that murine ESC aggregates grown in the presence of added basement membrane components formed hollow spheres that underwent evagination into vesicles and then invagination into 3-D, optic cup-like structures containing RPE and neural retinal domains, and stratified neural retinal tissues<sup>61</sup> (Fig. 37.2). Later in 2011, populations of human retinal progenitor were isolated from 3-D optic vesicle-like structures (OVs) derived from hESCs and hiPSCs.<sup>36</sup> Since this discovery, several studies have reproduced and characterized human pluripotent stem cell-derived OVs.<sup>46,52,53</sup> These OVs, which are separated from early forebrain neurospheres, have been shown to be able to differentiate into all neuronal retinal cell types, including RPE and photoreceptors.<sup>36</sup> The timeframe for the generation of different cell types in human OVs is similar to human retinogenesis, with cones being the earliest photoreceptor cell type to appear and rods being produced in greater numbers later.<sup>52</sup> In addition, these OVs possess clearly delineated apical-basal orientation and self-organized tissue layers mimicking those found in the developing human retina, having a neuroblastic layer that gives rise to an inner ganglion layer, an intermediate layer containing retinal interneurons, and an outer layer comprised of photoreceptor cells.<sup>52,53</sup> Human OVs hold much potential for use in retinal disease research (such as by creating patient-specific hiPSC-derived OVs as retinal models) and clinical applications to regenerate diseased retinas.

**FIG. 37.2** (A) Murine embryonic stem cells can self-assemble into optic cup-like structures. These complex primitive retinal structures are engineered to express green fluorescence protein. (B,C) Similarly, hESCs and hiPSCs can differentiate and self-organize into optic vesicle-like structures, as shown here in phase-contrast (B) and immunostained (C) images that reveal structures that, over time, spontaneously organized into primitive retina-like tissues. ## RPE Cells

RPE cells enjoy an intimate relationship both anatomically and functionally with their neighboring cells in the retina, forming a monolayer of pigmented, hexagonal cells situated between the overlying photoreceptors and the underlying choriocapillaris (which comprise part of an extracellular matrix layer called the

Bruch's membrane). The RPE cells are highly polarized, with their apical sides interacting with photoreceptor outer segment tips and their basal sides attaching to the Bruch's membrane.<sup>62a</sup> This interdependence has historically contributed to the difficulty in determining where the principal defect lies in many inherited retinal degenerations – the photoreceptor or underlying RPE cell. With the advent of molecular genetics this confusion has lessened, but the interdependence between these two cell types remains, and there is often concomitant degeneration of both cell types observed in a variety of inherited and acquired degenerative diseases of the retina. In this regard, RPE cell transplantation has been evaluated both for its potential to replace diseased RPE as well as to provide a source of cells whose phenotypic differentiation may be manipulated by various cytokines and trophic substances. Thus, RPE cell lines have been developed for use as RPE cell transplants, and as cell-based drug delivery platforms.

Because the RPE cells are unable to self-renew, replenishing diseased RPE cells with various sources of healthy RPE cells has been explored. In a number of macular and retinal degenerative disorders there is atrophy of the RPE and associated malfunctioning in the phototransducing cellular machinery. Damaged RPE cells and associated atrophy are hallmarks of age-related macular degeneration (AMD). Heroic surgical approaches have been undertaken in individuals with healthier, RPE-rich regions of the retina to translocate and insert such autologous extramacular RPE sheets below the fovea, and these efforts have been associated with visual improvement, serving as a proof-of-principle that such cell sheet transplantations are a potential treatment strategy.<sup>62a</sup> A limitation of this approach is the availability of cell sources; autologous peripheral RPE cells may be non-ideal due to sharing the same genetic defects.

Allogeneic adult RPE cells, some of which have been shown to have stem cell characteristics, are also being pursued for use in therapy.<sup>62b,62c</sup> Methods have been developed for expansion of adult RPE cells from donor eyes, which could be used to replace dysfunctional or dying RPE cells in patients. One limitation of using adult and fetal RPE is their limited ability to expand, however. Consequently, deriving RPE cells from potentially unlimited stem

cell sources is an appealing option.

## RPE Cell-Based Delivery of Trophic (and Other) Factors

Immortalized human RPE cell lines have been created by stable transfection with a plasmid encoding the simian virus 40 large T antigen and many of the trophic (derived from the Greek word for “nourishment”) or growth factors expressed by functional RPE cells *in vivo* are observed to be expressed by these transformed cell lines.<sup>63</sup> When these cells are transplanted subretinally into a rat model of retinal degeneration (the Royal College of Surgeons (RCS) rat), loss of visual function is attenuated<sup>64</sup> and cortically dependent visual function is preserved long-term.<sup>65</sup> These RPE cell lines can be transfected with plasmids encoding a variety of trophic factors shown to have protective effects on photoreceptors<sup>66,67</sup> and then encapsulated into polymer devices that permit diffusion of cell products into the tissue into which they are transplanted. When transformed RPE cell lines are transfected with a plasmid encoding one such factor, ciliary neurotrophic factor (CNTF), and transplanted directly into the vitreous of dogs with retinal degeneration, photoreceptor degeneration is reduced.<sup>68</sup> While multiple human clinical trials have been performed using transplantation of CNTF-transfected encapsulated RPE cells to treat different retinal degenerative diseases, the efficacy of this approach is unclear; patients with retinitis pigmentosa (RP) who received the implant showed no improvement in two clinical trials and some patients experienced reduced visual field sensitivity that was reversed upon removal of the implant.<sup>62a,69</sup> In contrast, vision was found to be significantly improved in a trial to treat AMD.<sup>62a,70</sup> Overall, implanted encapsulated cell devices utilizing trophic factors may provide factors critical to the prevention of, or recovery from, retinal degenerative disease.

## Differentiation of hESCs and hiPSCs Into RPE

Over the past decade, a number of methods have been reported to

achieve the differentiation of hESCs and hiPSCs into retinal cells.<sup>44,51,71-73</sup> Some of these methods were developed for the differentiation of these stem cells into one type of retinal cell, such as the RPE<sup>51,71-73</sup> or photoreceptors,<sup>51,72,73</sup> while other methods have focused on the efficient generation of retinal progenitor cells.<sup>44</sup>

Spontaneous differentiation of hESCs and hiPSCs into RPE is the simplest and most commonly used method to produce RPE from these pluripotent stem cells.<sup>72</sup> hESC colonies are first allowed to overgrow in growth factor-supplemented hESC medium until the borders of the colonies contact each other. The medium is then changed to basic hESC medium without basic fibroblast growth factor supplementation and is changed every other day for several months until the RPE cells appear (visible as small pigmented colonies in the culture dish) and are then mechanically enriched (Fig. 37.3). RPE cells can also be derived from hESCs and hiPSCs using a two-stage induction method: the stem cells are first differentiated towards a neuroectodermal fate in suspension culture (i.e., embryoid bodies) using neural differentiation medium, and then differentiated into RPE through adhesive culture on cell culture plates.<sup>36</sup> During these stages of induction and differentiation, the RPE cells appear as early as 4 weeks and reach a large enough number of cells for subculture at approximately 8–10 weeks.<sup>72</sup> Nicotinamide and Activin A (a member of the transforming growth factor-beta superfamily) can also be used to direct the induction of RPE from hESCs.<sup>36,74</sup> Additionally, while RPE differentiation protocols have typically employed culture on MEFs and the addition of animal-derived soluble factors, efforts have been made to explore and adopt feeder-free and serum-free culture methods, as generating cells in such xeno-free conditions may be more ideal for use in cellular transplantation therapies.<sup>62a,75</sup>

**FIG. 37.3** Spontaneous differentiation of pigmented retinal pigment epithelium from human embryonic stem cells after withdrawal of basic fibroblast growth factor. In dish on left (A), multiple foci of pigmented cells are seen. These colonies can be picked, enriched, and expanded to pure populations of retinal pigment epithelium, as shown on right (B). (Panel A courtesy of Dennis Clegg, PhD, University of California Santa Barbara.)

RPE cells can be relatively easily identified, isolated, and enriched apart from other differentiated cells in these cultures because of their unique pigmentation, hexagonal shape, and pattern of growth. The RPE patches can be either mechanically incised out of the cultures through microdissection or enzymatically dissociated from the cultures. The enriched cells can then be grown to confluence, passaged, and retain typical pigmentation and morphology (Fig. 37.3).<sup>76</sup>

## Characterization of hESC- and hiPSC-RPE in Vitro

The characteristics that define human RPE cells have been outlined in Chapter 18 (Cell biology of the retinal pigment epithelium) and reviewed by others.<sup>71</sup> hESC- and hiPSC-derived RPE (hESC-RPE and hiPSC-RPE, respectively) develop a typical hexagonal shape and become highly pigmented when they attain confluence (Fig. 37.3B). The cells can further differentiate and become highly polarized when grown for extended periods of time on Transwell

inserts and other substrates (Fig. 37.4).<sup>76–78</sup> Polarized hESC-RPE show apical microvilli, are joined in the apical regions by tight junctions, show apically distributed sodium/potassium ATPase ( $\text{Na}^+/\text{K}^+\text{ATPase}$ ), and have a high transepithelial resistance.<sup>78</sup> hESC-RPE express a host of characteristic RPE genes, including visual cycle genes (*RPE65*, *RDH 11*, *CRALBP*); RPE membrane channel and transporter genes (*BEST1*, *SLC*); pigment biosynthesis and melanin biosynthesis genes (*GPR143*, *TYRP1*, dopachrome tautomerase gene *DCT*, *SILV*); and phagocytosis-associated genes (*LAMP2*, *VDP*, *Mertk*, *GULP1*).<sup>72,79</sup> hiPSC-RPE cells have been found to express RPE markers similarly to hESC-RPE cells, and both hESC-RPE and hiPSC-RPE can perform RPE functions as well, including being able to phagocytose rod outer segments.<sup>72,79,80,81</sup> However, transcriptomic studies have revealed significant differences in gene transcription between pluripotent stem cell-derived RPE and native human RPE,<sup>82</sup> emphasizing the importance of analyzing the functional consequences of transcriptional activity through metabolomic-based analyses (which can quantitatively measure the activities of endogenous biochemical pathways)<sup>83–85</sup> and sophisticated in vivo imaging techniques, such as scanning laser ophthalmoscopy, optical coherence tomography, and adaptive optics, coupled with focal electroretinography, which will altogether permit the detailed evaluation of therapeutic stem cell treatments.

**FIG. 37.4** Human embryonic stem cell-derived retinal pigment epithelium can be differentiated into a polarized monolayer. These monolayers show tight junction proteins (ZO-1), as shown by confocal microscopy (A), apical microvilli, as shown by scanning electron microscopy (B), and apical microvilli, apical melanosomes, and tight junctions, as shown by transmission electron microscopy (C,D). MV, microvilli.

## Efficacy of hESC- and hiPSC-RPE in Vivo

The most commonly used model to evaluate therapeutic efficacy of hESC-RPE and hiPSC-RPE is the RCS rat. The primary defect in the RCS rat is in the RPE; thus this model provides the ability to evaluate the effectiveness of RPE cell replacement therapy. The RCS rat has a recessively inherited mutation in the receptor tyrosine kinase gene *Mertk*, leading to impaired phagocytosis of shed photoreceptor outer segments with buildup of outer-segment

material in the subretinal space, and subsequent secondary degeneration of photoreceptors between postnatal days 20 and 60.<sup>86</sup>

The two main transplantation approaches being pursued in the RCS rat, other model animals, and human trials are injecting a suspension of stem cell-derived RPE cells into the subretinal space and implanting the cells as a monolayer cultured on a membrane.<sup>62a</sup> Using subretinal injections of cell suspensions of hESC-RPE, several groups have shown reproducible survival of the transplanted hESC-RPE in the subretinal space of the RCS rat (>220 days in one study), and positive labeling of these cells with human-specific markers and RPE-specific genes (e.g., *RPE65*).<sup>74,80,87-89</sup> The cells appear to disperse in the subretinal space and, while clumps of cells or multilayered grafts are often formed, in some cases they were arranged in an apparent monolayer. Cells showed focal rhodopsin staining, suggesting that they are phagocytosing photoreceptor outer segments.<sup>74,88,89</sup> The transplanted hESC-RPE were associated with histologic and functional rescue of the photoreceptors, as measured by delay in the loss of nuclei in the outer nuclear layer, and retention of electroretinogram and optomotor responses in the treated eye compared to untreated eye.<sup>74,87-89</sup> Each of these studies utilized immune suppression (typically systemic cyclosporine, with or without systemic corticosteroid) to prevent immune rejection of the xenograft. Although the subretinal space is thought to be an immune-privileged site, such privilege may be compromised at the time of surgery or by the disease process.<sup>90,91</sup> hiPSC-RPE cell suspensions have also been injected into the subretinal space of RCS rats with similar in vivo results: they phagocytose photoreceptor outer segments, functionally rescue photoreceptors, and maintain long-term visual function.<sup>72,80</sup>

The main alternative approach to the use of hESC-RPE cell suspensions is to transplant monolayer sheets of highly differentiated and polarized RPE resting on a biodegradable or biostable scaffold. The reasoning for such an approach is that it is essential for RPE cells to become a polarized monolayer to carry out their normal functions, and implanting these cells as a monolayer should allow them to better integrate with the host photoreceptor outer segments and thus improve the functionality of the graft.<sup>77</sup> It has been shown that hESC-RPE can be polarized in vitro to develop

tight junctions with high transepithelial resistance and elaborate extensive apical microvilli (Fig. 37.4) and that highly polarized hESC-RPE show increased secretion of pigment epithelial-derived growth factor (a factor with neurotrophic and antiangiogenic activity).<sup>78</sup> hESC-RPE are capable of phagocytosing photoreceptor outer segments,<sup>79</sup> and polarized hESC-RPE specifically show increased phagocytosis of bovine rod outer segments in vitro compared to nonpolarized cultures.<sup>78</sup> Studies implanting polarized hESC-RPE grown on a nonbiodegradable substrate (e.g., parylene) show retention of an intact monolayer in vivo and prominent integration with host photoreceptors (Fig. 37.5).<sup>77</sup>

**FIG. 37.5** Human embryonic stem cell (hESC)-derived retinal pigment epithelium (RPE) can be grown to confluence and polarized on a nonbiodegradable substrate. In (A), the pigment cells form an intact monolayer. The cells with substrate can be implanted in the subretinal space of Royal College of Surgeons

rats where they survive and protect host photoreceptors from degeneration. In (B) (hematoxylin and eosin stain), the hESC-RPE sitting on the nonbiodegradable membrane integrate into the host retina. Note the interface between the transplanted RPE and the host photoreceptor outer segments (*arrows*). In (C), the transplanted hESC-RPE can be identified using the human-specific marker TRA-1–85 (immunofluorescence microscopy with human marker TRA-1–85 in green, and nuclear counterstain 6'-diamidino-2-phenylindole hydrochloride (DAPI) in blue). *ONL*, outer nuclear layer.

The relative efficacy of hESC-RPE cell suspensions versus polarized sheets is under active investigation by several groups. Injections of subretinal suspensions have been shown to rescue photoreceptors and preserve visual function, although problems and concerns have been reported with cell survivability, placement, and formation of a polarized monolayer. For example, hiPSC-RPE suspension injections into the subretinal space of monkeys created blebs of accumulated cells that compromised monolayer formation. At the same time, reflux of the injected hiPSC-RPE into the vitreous can result in severely damaging proliferative vitreoretinopathy.<sup>92</sup> On the other hand, some studies have shown that monolayer transplantations may improve photoreceptor function and survival compared to cell suspension injections.<sup>80</sup> For example, when hiPSC-RPE sheets were transplanted into the subretinal space of monkeys, the sheets were found to remain in place after implantation.<sup>92</sup>

The effect of the local tissue microenvironment on transplant survival is an important issue when considering how best to deliver stem cells and cells derived from stem cells. Cross-talk between cells and extracellular matrix is critical to maintaining the differentiated cell type as well as insuring appropriate function. Many studies, in the retina as well as other tissues, have identified a number of factors that may be critical to the successful engraftment of stem cell-derived, and other, cell types, including cardiomyocytes,<sup>93</sup> spinal cord,<sup>94</sup> and brain<sup>95</sup> neurons and photoreceptors.<sup>96</sup>

Pivotal safety studies are necessary prior to receiving approval from the FDA for a specific clinical trial, although there has been

increasing evidence that short-term safety of implanting pluripotent stem cell-derived RPE is not a major concern.<sup>62a</sup> Studies using hESC-RPE cell suspensions under good manufacturing practices and good laboratory practice have been performed to establish karyotypic stability in the cells, lack of infectious and adventitious agents in the product, and lack of teratoma and/or tumor formation by the cells in immune-deficient mice.<sup>88</sup> It should be noted that G-banding karyotypic analysis may not show any significant abnormalities while high-resolution DNA analysis may show culture-induced copy number changes and loss of heterozygosity; the significance of these changes for the purpose of cell therapy is unknown.<sup>12</sup> Importantly, none of the studies that utilized highly differentiated hESC-RPE in immune-deficient animals found evidence of teratoma formation.<sup>74,87-89</sup> However, long-term survival, function, and safety studies are still needed to achieve clinical application of stem cell-based therapeutics for AMD.<sup>62a</sup>

## Using hiPSCs as a Source of RPE Grafts

Although it is possible that patients with hiPSC-derived autologous transplants may not require immunosuppressive treatment to prevent graft rejection, there are still major safety concerns regarding using hiPSC-RPE in transplantations. Post-translational modifications in hiPSCs may occur during dedifferentiation and/or differentiation, which may cause even autologous hiPSC-RPEs to elicit an immune reaction. However, studies investigating multiple hiPSC lines have detected only negligible immune responses following transplantations of hiPSC-derived cells, including hiPSC-RPEs.<sup>62a,92</sup> There have also been concerns that transplanted hiPSC-derived cells could undergo malignant transformation resulting from reactivation of the reprogramming transcription factors (e.g., *c-MYC*) that can be randomly integrated into the genome at multiple loci following retroviral transduction,<sup>97-101</sup> although this situation may be circumvented by using efficient, high-fidelity reprogramming methods that do not cause the reprogramming factors to become integrated into the genome. Such nonintegrating reprogramming systems – including sendai-viral, episomal, and mRNA transfection methods – are becoming more commonly

employed, and are thoroughly reviewed elsewhere.<sup>102</sup> Additionally, while epigenetic markers (some associated with cancer and/or pluripotency) may remain on both hiPSC- and hESC-derived cells after differentiation,<sup>103</sup> hiPSCs have been found to differ from hESCs by retaining additional epigenetic patterns that are typical of the somatic cells from which the hiPSCs were reprogrammed.<sup>104</sup> These epigenetic remnants may cause cells to undergo dedifferentiation, or drift away from the final, target cell type. To overcome this, efforts have been made to modify differentiation protocols<sup>105</sup> and screen the final cell product to detect and eliminate cells that are not the desired cell type, such as undifferentiated cells or cells that resemble ones from the hiPSCs' somatic origins (via flow cytometry and/or qRT-PCR).<sup>62a,106</sup>

It is also debated whether hiPSC-derived autologous cells are actually ideal or not for use in transplantations to treat a disease with a genetic basis, such as retinitis pigmentosa, because the derived cells would still contain the genetic abnormality (or abnormalities) that predispose the individual to the disease. While several genetic risk alleles for AMD have been identified,<sup>107</sup> manifestation age of AMD even in the presence of these risk alleles is above 55 years. Hence, hiPSC-RPE cell grafts from AMD patients would be expected to represent younger, and presumably healthier, RPE that have not yet themselves become damaged by the aging processes. Furthermore, patient-derived hiPSCs could be modified genetically to “fix” or replace the faulty genes, and then be differentiated into the desired hiPSC-RPE cells for use in transplantation.<sup>62a</sup> With the rapid development and continual improvements of the CRISPR/Cas9 gene-editing technique, such approaches are becoming more feasible, although it may not be a practical approach for the near future.<sup>108</sup> New methods to combine somatic cell reprogramming with gene correction offer a more time- and cost-effective means to harness the potential benefits of autologous hiPSC therapies.<sup>109</sup> Alternatively, the production of homozygous HLA-matched banks of hiPSCs could provide an off-the-shelf supply of partially immune matched stem cells for therapeutic use.

Exhaustive comparative analyses of multiple human hiPSCs and hESC lines reveal that, while many hiPSCs and hESCs lines share

very similar transcriptomic and epigenetic profiles, others are heterogeneous. The differences observed are randomly distributed and limit the differentiation capacity of the cells.<sup>110</sup> Furthermore, recent evidence shows that, in hiPSCs, reprogramming and selection pressure to obtain rapidly proliferating cell lines may induce chromosomal aneuploidy in nonrandomly distributed loci that may further limit the differentiation capacity and promote tumorigenicity of hiPSCs.<sup>111-113</sup> Genetic instability in hiPSCs is correlated with higher passage numbers, so reprogramming methods that are inefficient and require multiple passages may increase the risk of tumorigenesis.<sup>111,112</sup>

Generating patient-specific hiPSC-RPE is more time- and resource-intensive compared to creating hESC-RPE, which represents an economical challenge for patients and healthcare systems. To generate patient-specific hiPSCs, a cellular sample (commonly a skin fibroblast punch biopsy or, increasingly, a blood sample) must first be collected and cultured from patients, then the somatic cells are reprogrammed into hiPSCs, and finally the resultant hiPSC clones undergo careful screening, with all of this happening prior to RPE differentiation, which in itself is a time-consuming process. Therefore, to generate any tissue of interest, including RPE from hiPSCs, one or two specific reprogramming protocols may need to be adopted and optimized to ensure reliable, safe, and efficient derivations of that cell type.

## **Adult Bone Marrow-Derived Endothelial Progenitor Cells**

Emerging evidence suggests an important role for endothelial cells in promoting interactions, self-renewal, and possibly the “rescuing” of severely stressed cells, all in surrounding vascular networks. The vast majority of diseases that lead to vision loss in industrialized nations, such as AMD, diabetic retinopathy, and neovascular glaucoma, do so at least in part as a result of abnormalities in the retinal or choroidal vasculature (i.e., macula edema, retinal and vitreous hemorrhage, and fibrovascular scarring). Most inherited retinal degenerations, such as retinitis pigmentosa, exhibit vascular

abnormalities traditionally attributed to the loss of neuronal elements and accompanying decreased metabolic demand, leading to vascular atrophy. “Cross-talk” between local vascular networks and the tissues they supply almost certainly helps maintain a functional state in a variety of organ systems.<sup>114-116</sup> Endothelial cells specifically are known to provide trophic substances that greatly stimulate self-renewal and expand neural differentiation of neural stem cells,<sup>117</sup> which has led to the idea of using EPCs to rescue surrounding tissues in the face of severe stress, such as hypoxia or cellular degenerations.

Adult bone marrow-derived EPCs, which consist of a lineage-negative ( $\text{Lin}^-$ ) population of HSCs,<sup>118</sup> mobilize from the bone marrow in response to a variety of signaling molecules.<sup>119,120</sup> These EPCs can specifically target sites of angiogenesis in induced ocular injury,<sup>121</sup> where they can incorporate into forming blood vessels and potentially help relieve ischemia. While there is strong evidence supporting the concept that bone marrow contains progenitor cells capable of participating in the repair of a variety of injured tissues,<sup>21</sup> there is significant controversy as to how commonly such developmental plasticity is observed in adult HSCs<sup>122</sup> and even whether these EPCs are derived from HSCs or, in fact, are derived from an entirely distinct population of bone marrow-derived stem cells. While many reports in the literature demonstrate that HSCs can differentiate into a variety of cell types other than hematopoietic cells, including neurons, glia, and muscle, depending on their microenvironment,<sup>123</sup> the precise identity of the precursor cell remains unclear.<sup>124,125</sup>

The potential clinical utility of bone marrow-derived EPCs<sup>21</sup> falls into three broad categories. First, if these cells target sites of ischemia during circulation and, thus, contribute to pathologic neovascularization, it seems reasonable to inhibit their targeting or differentiation, thereby inhibiting angiopathies of the type seen in retinal and choroidal neovascularization. Second, and alternatively, enhancing their participation in functional, ischemia-relieving angiogenesis may be of benefit in ischemic retinopathies such as diabetes. Third, if EPCs do, indeed, target to sites of neovascularization, it should be possible first to transfect these cells *ex vivo* with plasmids encoding angiostatic or angio/neurotrophic

proteins and, thus, inhibit abnormal angiogenesis or enhance trophic activity of EPCs through a form of cell-based therapy. Each of these approaches will be explored below.

## Potential Clinical Utility of Bone Marrow-Derived EPCs

Several groups have recently demonstrated that HSCs contain a pool of EPC capable of incorporating into areas of retinal and choroidal neovascularization. The study by Grant and colleagues was the first direct demonstration that systemically administered HSC can function as hemangioblasts during hypoxia-stimulated retinal neovascularization.<sup>126</sup> In these studies, GFP-expressing HSCs were injected intravenously into mice that had been sublethally irradiated (to destroy host bone marrow), mouse retinal neovascularization was stimulated (via thermal laser), and the injected GFP-expressing HSCs were found to contribute to the neovascularization. Other studies using the same irradiation/bone marrow reconstitution model have shown that circulating stem cells can also contribute to choroidal neovascularization.<sup>127–129</sup> This work shows that circulating, undifferentiated HSCs can be recruited to sites of retinal or choroidal neovascularization and, along with proliferation of local endothelial cells, can contribute to new blood vessel growth and development. While the experiments of Grant and colleagues demonstrate that circulating cells can incorporate into laser-stimulated retinal neovascularization, the relative contribution of circulating HSCs and endogenous retinal vascular endothelial cells to newly forming vasculature in normal conditions – when the proliferation of local cells is not impaired by irradiation – remains unknown.<sup>121</sup>

If circulating EPCs contribute to pathologic neovascularization in ischemic and inflammatory retinopathies, such as diabetic retinopathy and AMD, would inhibition of their targeting to these sites reduce abnormal angiogenesis? One study found that when R-cadherin (an adhesion molecule suspected to be involved in the targeting of HSCs to the retinal vasculature) was functionally blocked in HSCs prior to intravitreal injection, the cells did not target sites of angiogenesis.<sup>130</sup> However, all of the molecular signals

involved in HSC “homing” have not yet been identified (although R-cadherin is clearly involved); identification of these signals would be of immense benefit for exploiting the potential use of HSCs in therapeutic angiogenesis and directed cell therapy. Other adhesion molecules, such as integrins, likely play roles in targeting circulating EPC to sites of abnormal angiogenesis (e.g., tumor vascularization), and these molecules may be potential therapeutic targets if circulating EPCs do indeed contribute to pathologic ocular angiogenesis. Unfortunately, inhibition of neovascularization under ischemic conditions may serve to promote ongoing ischemia: would it be better to coax the newly forming vessels into functional ones that could alleviate hypoxia, or make the endogenous vasculature and neurons more resistant to hypoxic damage?

To address the potential utility of these cells in relieving hypoxia and exerting a vasculotrophic rescue of a damaged retinal vasculature, HSCs have been injected directly into the eyes of newborn mice while they were forming their retinal vasculature (Fig. 37.6); in this environment, these cells can target activated astrocytes, a hallmark of many ocular vascular and degenerative diseases, and participate in normal developmental angiogenesis in both neonatal mice and injury-induced neovascularization in adult mice.<sup>131</sup> An HSC fraction has also been found to “stabilize” degenerative, abnormal retinal vasculature by inhibiting angiogenesis when engineered to express an antiangiogenic and rescuing degenerating vessels.<sup>131</sup> More surprisingly, it was also observed that by preventing vascular degeneration there is a trophic rescue effect on the photoreceptors themselves,<sup>115</sup> suggesting that autologous bone marrow grafts of HSC fractions containing EPCs may provide trophic effects that go beyond simple nutrition, providing a rationale for the use of HSCs in treating a variety of inherited retinal degenerations, such as retinitis pigmentosa.

**FIG. 37.6** Bone marrow-derived endothelial progenitor cells target sites of retinal gliosis and incorporate into developing blood vessels to form mosaic vessels. When these cells are taken from the bone marrow of adult mice transgenic for enhanced green fluorescent protein (eGFP, yellow) and injected into mice transgenic for GFP-gliial fibrillary acidic protein (a marker of astrocytes, green), the stem cells selectively target to the underlying astrocytes (A). This also happens when these cells are injected into adult mice (B), in which a needle or laser is used to scar the retina and stimulate a focal gliosis (red), suggesting that these cells (green) may also be useful to treat injured adult retinas. Two weeks after injection of adult bone marrow-derived stem cells into the neonatal mouse retina (C), mosaic blood vessels (orange–yellow) consisting of stem cells and endogenous retinal vascular endothelial cells are observed along with vessels consisting only of endogenous vessels (red). (Adapted with permission from Otani A, Kinder K, Ewalt K, et al. Bone marrow-derived stem cells target retinal astrocytes and can promote or inhibit retinal angiogenesis. *Nat Med* 2002;8:1004–10.)

The use of EPCs and other stem cells as drug delivery vehicles has the potential to deliver drugs selectively and potently to the back of the eye in physiologically meaningful doses. Thus, genetically modified, autologous EPCs transplanted into ischemic or abnormally vascularized eyes may stably incorporate into new vessels and continuously deliver therapeutic molecules locally for prolonged periods of time.

Lastly, bone marrow-derived EPCs can exert a neurotrophic rescue in retinal degeneration and inhibit abnormal angiogenesis.

Despite having identified mutations in over 110 different genes involved in inherited degenerations of the retina,<sup>132-137</sup> there are still no effective treatments to slow or reverse the progression of these diseases. Recent advances in gene therapy have led to successful reversal of the *rds*<sup>138</sup> and *rd*<sup>139</sup> phenotypes in mice and the *RPE65* phenotype in dogs<sup>140</sup> when the wild-type transgene is delivered to photoreceptors or the RPE in animals with a specific mutation. The potential use of calcium channel blockers,<sup>141</sup> trophic factors,<sup>142</sup> and dietary supplements<sup>143</sup> has also been explored. Most inherited human retinal degenerations have concomitant loss of cones, the principal cellular component of the macula. Consequently cone-specific survival factors have been described<sup>144</sup> and may facilitate cone survival in mouse models of retinal degeneration. In addition to the vasculotrophic properties described above, these cells have also been reported to prevent retinal vascular degeneration, which correlates with neuronal rescue (Fig. 37.7). The inner nuclear layer remains nearly normal and the outer nuclear layer containing photoreceptors is significantly preserved, with the rescued cells being predominantly cones. This rescue effect is also observed when human bone marrow-derived Lin<sup>-</sup> HSCs are used to treat severe combined immunodeficient mice with retinal degeneration. Large-scale genomic analysis of rescued and nonrescued eyes revealed significant upregulation of antiapoptotic genes. Of note, the injected (GFP-labeled) bone marrow-derived progenitor cells were not observed anywhere but in or near blood vessels. The fact that the neurotrophic effect correlates with preservation of the vasculature suggests that autologous bone marrow-derived EPCs may be useful in treating retinal degenerative diseases in which abnormal angiogenesis is the cause of vision loss. Furthermore, other reports support the concept that tissue-specific vasculature has trophic effects that go beyond that expected from simply providing vascular “nourishment”,<sup>114,116</sup> in individuals with retinal degeneration, the presence of EPCs may make the vasculature more resistant to degeneration and at the same time facilitate retinal neuronal survival, potentially slowing the rate of degeneration to provide years of additional sight.

**FIG. 37.7** Adult bone marrow-derived stem cells rescue degenerating blood vessels and retinal function, and exert a profound neurotrophic rescue effect in a mouse model of retinal degeneration. (A,B) Representative cases of rescued and nonrescued retinas 2 months after injection. Retinal section of stem cell-injected right eye (A) and control cell-injected left eye (B) of the same animal are shown (green: CD31-

stained vasculature, red: 6'-diamidino-2-phenylindole hydrochloride (DAPI)-stained nuclei). (C,D) Electroretinographic recordings were used to measure the function of stem cell- or control cell-injected retinas from the same eyes shown in panels A and B. (E–H) Rescued outer nuclear layer (ONL) in a mouse model of retinal degeneration (rd1/rd1) following intravitreal injection of adult bone marrow-derived stem cells consists predominantly of cones. Control (CD31 hematopoietic stem cell-injected) eyes are identical to noninjected rd1/rd1 retinas, without any staining for cone (E) or rod (G) opsin. Stem cell-treated contralateral eyes in the same animals have a markedly reduced, but clearly present, ONL that is predominantly comprised of cones, as evidenced by positive immunoreactivity for cone red/green opsin (F). A small number of rods are also observed (H). *GCL*, ganglion cell layer; *INL*, inner nuclear layer. (Adapted with permission from Otani A, Kinder K, Ewalt K, et al. Bone marrow-derived stem cells target retinal astrocytes and can promote or inhibit retinal angiogenesis. *Nat Med* 2002;8:1004–10 and Otani A, Dorrell MI, Kinder K, et al. Rescue of retinal degeneration by intravitreally injected adult bone marrow-derived lineage negative hematopoietic stem cells. *J Clin Invest* 2004;114:765–74.)

Overall, adult bone marrow-derived stem cells may have wide utility in the treatment of retinal vascular diseases and perhaps even inherited retinal degenerations. Potential applications of these cells include not only use as cell-based therapeutic delivery vehicles, but also possible use as stabilizing elements in an otherwise unstable neovasculature of the type observed in ischemic retinopathies. In fact, these cells will selectively target sites of hypoxia-driven neovascularization, as demonstrated in mouse models of these diseases. While current retinal vascular disease therapy is based largely on ablating the new vessels with angiostatics or thermal and nonthermal lasers, a novel paradigm would include the use of these stem cells to target, incorporate into, and stabilize neovasculature.

## Human Clinical Trials Using Stem Cells for the Treatment of Retinal

## Diseases

In recent years, many groups<sup>62a,145–147</sup> have proposed using hESC- and/or hiPSC-derived cells for the therapy of retinal diseases such as retinitis pigmentosa, Usher syndrome, AMD and Stargardt disease. Human trials using hESCs became a reality in 2009 (Table 37.1) with the approval by the FDA for a phase I trial (NCT01217008). In this trial, hESCs differentiated into oligodendrocyte precursor cells (GRNOPC1) were injected into the spinal cord of patients with acute, severe spinal cord injury.

In November 2010, FDA approval was given for a phase I/II clinical trial to treat Stargardt disease using subretinal injection of cell suspensions of hESC-derived RPE (NCT01345006). Then, in January 2011 FDA approval was granted for a phase I/II clinical trial (NCT01344993) to treat advanced dry AMD using subretinal injection of cell suspensions of hESC-derived RPE (50,000–200,000 cells/eye). No evidence of adverse reaction or serious safety issues related to the transplanted RPE tissue itself, including tumor formation or rejection, was reported although adverse events possibly related to immunosuppression were apparent in nearly all patients. Modest visual benefits for some study subjects were also claimed, although different interpretations of those results have been put forth.<sup>62a,148</sup>

Several other stem cell-based clinical trials for treating AMD and other retinal diseases – including retinitis pigmentosa, optic nerve disease, retinal vein occlusion, and diabetic retinopathy – are also being pursued. As of early 2015, there are at least 14 ongoing clinical trials registered in the International Clinical Trials Registry Platform of the World Health Organization for treating macular degeneration alone. A clinical trial using hiPSC-RPE sheets to treat patients with advanced wet AMD has begun in Japan, after approval by Japan's Ministry of Health in July 2013, which is the first approved clinical study for using hiPSC-RPE for the treatment of AMD (JPRN-UMIN000011929). This trial utilizes cell sheets cultured on a collagen-based scaffold that is enzymatically dissolved prior to implantation, creating a sheet of cells without a potentially immunogenic scaffold. For certain eligible patients with wet AMD, a phase I clinical trial (NCT01691261) to test the safety

and efficacy of hESC-RPE sheets (on a polyester membrane<sup>149</sup>) was initiated by Pfizer/University College London.<sup>62a</sup> This group is also investigating hiPSC-RPE on the same scaffold system.<sup>62a</sup> For treating patients with geographic atrophy involving the central fovea, a human phase I/IIa clinical trial using hESC-RPE monolayer implants (on a Parylene membrane) was initiated at the University of Southern California Eye Institute. This trial, supported by funding from the California Institute for Regenerative Medicine (CIRM), is the result of a collaboration between researchers at USC and researchers at the University of California, Santa Barbara, the City of Hope, and Caltech. Other stem cell types – including bone marrow-derived stem cells, human umbilical tissue-derived cells, human central nervous stem cells, human fetal retinal cells, and adipose-derived stromal cells – are being pursued in clinical trials to treat retinal diseases. Many of these rely on paracrine effects rather than cell replacement, as is discussed elsewhere in this volume<sup>62a,150</sup> In current clinical trials so far, patients are placed on a thorough systemic immunosuppressive regimen, involving pre- and postoperative immunomodulatory therapy along with oral and topical corticosteroids.<sup>62a,148,151</sup> For a more detailed review of recent and current clinical trials, see Nazari et al., 2015.<sup>62a</sup>

## Discerning the Legitimacy of A Human Stem Cell Treatment

When approached by a patient inquiring about the legitimacy of a specific human stem cell-based treatment, it can be a challenge to investigate the treatment and address the many concerns that naturally accompany such a treatment. [Table 37.2](#) provides a list of the basic questions that should be initially answered to help evaluate the legitimacy of a human stem cell-based treatment, although this list should only be used as a starting point for further investigation. For additional information, the International Society for Stem Cell Research (ISSCR) provides several useful resources online, including the “Patient Handbook on Stem Cell Therapies,” “Stem Cell Treatments: What to Ask,” and “Guidelines for Stem Cell Research and Clinical Translation” (<http://www.isscr.org/>).

**TABLE 37.2****Initial Questions for Discerning the Legitimacy of a Human Stem Cell Treatment**

<b>Oversight and Safety</b>	<b>Scientific Evidence</b>	<b>The Treatment</b>
<ul style="list-style-type: none"> <li>• Is the treatment part of an approved clinical trial?</li> <li>• If the treatment is “approved,” is the approving body official? For example, has approval been received from a national or regional regulatory agency, such as the European Medicines Agency (EMA), the US FDA, or Japan's PMDA?</li> <li>• Is the clinic conducting the treatment accredited?</li> <li>• What independent oversight is there for the clinic conducting the treatment and the facility that will prepare the cells?</li> <li>• Is there an ethics committee that has independent oversight of the treatment?</li> </ul>	<ul style="list-style-type: none"> <li>• What peer-reviewed scientific data supports the validity of the treatment?</li> <li>• Were there earlier preclinical or clinical trials?</li> <li>• What were the findings of earlier preclinical or clinical trials?</li> <li>• How many people have already been successfully treated at the clinic? ## Concluding Remarks

The potential use of stem cells in the treatment of a variety of human retinal diseases remains tremendously exciting, with multiple potential approaches. Recently initiated clinical trials using RPE derived from human pluripotent stem cells to treat patients with Stargardt disease and AMD are first steps in taking this technology into the clinics and will continue to be followed very closely while treatments for other retinal diseases, including optic nerve disease, retinal vein occlusion, and diabetic retinopathy, are nearing clinical trials. The recent development of 3D optic vesicle-like structures (OVs) from human pluripotent stem cells is of particular interest because of the ability of these OVs to generate a wide variety of retinal cell types and self-organize into the layers found in the human retina. hiPSCs may be of particular interest for generating autologous, patient-specific retinal cell types for disease modeling or regenerative therapeutics, in situations where this is desirable. Even if such tissue reconstruction from stem cells could be successfully completed, reestablishing functional visual pathways will be an even greater challenge. Clearly, prevention of retinal degeneration and vascular abnormalities would preserve established visual pathways and provide a better chance of preserving vision. In this regard, vasculo- and neurotrophic rescue effects of adult bone marrow and neonatal cord blood-derived progenitor cells may offer great promise, and the potential involvement of bone marrow-derived EPCs in the progression of

retinal neovascularization warrants additional study. Challenges remain in successfully identifying clinically useful progenitor cell types, optimizing differentiation protocols using these cells as well as human pluripotent stem cells to generate target retinal cell types, and developing strategies to surgically deliver and integrate healthy retinal cells into patient retinas to safely rescue and improve visual functionality.

## Acknowledgments

TR: I am very grateful for my time spent in the laboratory of Dennis O. Clegg, where I became exposed to and passionately interested in the stem cell field, with a particular focus on how the microenvironment affects the differentiation of hESCs and hiPSCs into RPE cells.

DMG: I would like to recognize the Foundation Fighting Blindness Wynn-Gund Translational Research Award, NIH R01 EY021218, UW-Madison McPherson Eye Research Institute (Emmett A. Humble Distinguished Directorship and the Sandra Lemke Trout Chair in Eye Research), David Walsh Family Foundation, Reeves Foundation, Choroideremia Research Foundation, and Muskingum County Community Foundation (DMG) for supporting this work.

DOC: I would like to recognize the Garland Initiative for Vision, the California Institute for Regenerative Medicine (CIRM; grants DR1-01444, CL1-00521, TB1-01177, and TG2-01151) Fight for Sight, the Foundation Fighting Blindness Wynn-Gund Translational Research Acceleration Program, the University of California Santa Barbara Institute for Collaborative Biotechnologies from the US Army Research Office (Grant W911NF-09-0001), CIRM Major Facilities Grant (FA1-00616), The Vermont Community Foundation, the Breaux Foundation, and the Wilcox Family Foundation for supporting this work.

We would like to thank Dr. Lyndsay Leach for her comments on the chapter.

## Introduction

Nanotechnology provides an important new set of tools for the diagnosis and treatment of ocular diseases. Miniaturization of devices, chip-based technologies, and novel nanosized materials and chemical assemblies already provide novel tools that are contributing to improved healthcare in the 21st century and will impinge directly on ophthalmology.<sup>1-4</sup> In this chapter, we review general principles of nanotechnology and nanomedicine as well as properties of nanomachines. We also consider specific and potential applications of nanotechnology to ophthalmology, including drug, peptide, and gene delivery; imaging; minimally invasive physiologic monitoring; prosthetics; regenerative medicine; and surgical technology. Finally, we consider obstacles to incorporation of nanotechnology into ophthalmology. Each of these topics has been reviewed in detail previously.<sup>5-7</sup>

## General Principles of Nanotechnology and Nanomedicine

### Nanotechnology

Nanotechnology involves the creation and use of materials and devices at the size scale of intracellular structures and molecules. The systems and constructs deployed typically are on the order of <100 nm. (Recall that an average man is 1.6 meters [1.6 billion nanometers (nm)] tall; an erythrocyte is 7  $\mu\text{m}$  [ $7 \times 10^3$  nm] wide; and a strand of deoxyribonucleic acid [DNA] is 2 nm wide.) Transformational opportunities in information storage, computation, and mechanical efficiency are available through nanotechnology.

Regarding information storage, Richard Feynman, who is credited with conceiving the field of nanotechnology, calculated

that it was possible to write the entire 24 volumes of the *Encyclopedia Britannica* on the head of a pin.<sup>8</sup> If one did not simply etch the letters on to the surface of the pin but used the interior of the material also, he calculated that one could fit all the information that humans had accumulated up to December 1959 (estimated at  $10^{15}$  bits) in a cube of material 1/200 inch wide, comparable to the size of a piece of dust.<sup>8</sup> Today, through nanotechnology-based precision assembly of matter, storage densities of  $10^{11}$  bits per  $\text{cm}^2$  have been demonstrated, which closely approximates Feynman's vision.<sup>9</sup> Efficient information storage is crucial for the complexity of biological systems, as each eukaryotic cell stores an enormous amount of information. A retinal pigment epithelial (RPE) cell has a diameter of approximately  $4 \times 10^{-4}$  inches ( $1 \times 10^{-3}$  cm), and each cell stores the blueprint to create an entire human in DNA molecules (3 billion chemical basepairs, ~25,000 genes).

Regarding computation, Feynman also noted that biological systems do not simply store information, they create measurable outputs. The human brain has the capacity to make judgments, e.g., recognize a person's face (even if shown at different distances, under different lighting conditions, at different angles), or play chess. Feynman reasoned that if computers could have as many computational elements as our brains, they could make judgments as well.<sup>8</sup> Today sophisticated facial recognition can be accomplished with a powerful laptop computer (versus poorly in 1959, with a much larger computer), due to the development of microprocessors and sophisticated software. Defeating a grand master at chess, however, requires a supercomputer. A Cray XT5 supercomputer uses ~40 kW power/cabinet, and each cabinet measures  $\sim 81 \times 23 \times 57$  inches<sup>3</sup> (larger than a refrigerator) and weighs ~1530 lb (694 kg) (<http://www.cray.com/downloads/CrayXT5Blade.pdf>). It is remarkable that the “computer” in our cranium does not require the amount of rare elements, generate the heat, or have the energy requirements of a supercomputer. Thus, the evolution of our cognitive capacities from infancy to adulthood (derived from the interaction between a DNA template-guided, manufactured neuronal network and the external environment) is one demonstration that it is possible to develop nanoscale mechanical systems that create complex, measurable outputs.

Nanomachines are highly efficient.<sup>10</sup> When organized in massively parallel structures, for example, nanomotors can generate large forces (e.g., muscles that move massive animals such as whales) or large electrical currents (e.g., those generated by the Hunter's organ of electric eels). Nanomotors also can direct delicate processes such as ion transport and chromosomal migration during mitosis. Nanomachines are not only highly efficient, they typically have long operational half-lives and are mass-produced easily.

## Nanomedicine

The aim of nanomedicine is the comprehensive monitoring, control, construction, repair, defense, and improvement of human biological systems at the molecular level, using engineered nanodevices and nanostructures, operating massively in parallel at the single-cell level, performing “single-cell medicine,” ultimately to achieve medical benefit.<sup>11</sup> Integration of nanoscale technologies with the practice of medicine will alter profoundly our approach to the diagnosis, treatment, and prevention of disease.<sup>12</sup> We will begin to diagnose and treat diseases at the single-cell level, for example, rather than just at the organ level.

General principles of nanotechnology as applied to nanomedicine include:

1. Biomimicry: the approach that cells use to direct molecules within a cell and/or direct molecules/machines to the proper cells in the body.
2. Size and location drive biocompatibility and biological efficacy.
3. Engineer feedback control into therapeutic systems (e.g., therapeutic gene synthesis).<sup>3,4,13-15</sup>
4. Molecules as machines: engineer molecules to perform specific physical tasks, such as opening ion channels, to alter cell and organism behavior.<sup>16-18</sup>
5. “Pseudointelligence” resulting from intelligent design, e.g., self-assembly of extracellular matrix (ECM) molecules.<sup>15,19-23</sup>

6. Highly interdisciplinary undertaking: development of nanotechnologies typically involves expertise in biology, engineering, chemistry, and physics.<sup>18,24–26</sup>

The functional properties of living systems arise not only from their component parts, but also from how these parts are assembled, which dictates interactions between the parts, the nature and flow of information within the system, and the outputs that the system produces.<sup>6</sup> Thus, one concept from biology that may be important for development of nanomachines in medicine is that spatial control of the distribution of nanomachines directly affects the efficiency of the macromolecular assembly and nature of this assembly's work product.<sup>27</sup> Spatial control can be achieved through the use of membranes and anchoring molecules that place enzymes and substrates in proximity (e.g., as occurs in the endoplasmic reticulum for synthesis of ECM proteins, in the mitochondrial membrane for electron transport, and on the cell surface for ECM ligand integrin-mediated changes in intracellular signaling).<sup>28</sup> This concept is exploited in the area of neural prosthetics, as described later in this chapter. Conversely, this engineering approach also permits segregation of molecules (e.g., segregation of lysosomal enzymes from the cytoplasm). Microelectromechanical systems (MEMS) or nanoelectromechanical systems (NEMS)-based techniques can be used to create engineered scaffolds (see next paragraph) that achieve this spatial control. One might also use a synthesized lipid bilayer or block co-polymer membranes to create artificial organelles as occurs in nature.

One can produce nanomachines by assembling naturally occurring ones.<sup>10,29–32</sup> M/NEMS-based engineering, however, permits the construction of small devices using computer-aided design and by the repeated application of a number of procedures, including oxidation, photolithography, etching, diffusion, sputtering, chemical vapor deposition, ion implantation, and epitaxy, as illustrated by the devices described later in this chapter. Control of features down to the submicron level permits production of mechanical structures at length scales ranging from 100 nm or less to greater than 1 cm. The ability to create complex microfabricated biomaterial substrates using these techniques enables one to define

surface microarchitecture, topography, and feature size. By engineering the microenvironment, one can control individual cell responses utilizing structures at the micro- and nanoscale to alter cellular attachment and motility, attenuate the foreign-body response, simulate tissue organization, and promote cell differentiation.<sup>33–40</sup>

A straightforward application of nanomachines to nanomedicine is the use of error-prone polymerase chain reaction and transposons to nanoengineer novel structures (e.g., viral capsids) as vectors for gene and drug delivery (as discussed later in this chapter). A somewhat less obvious application of nanomachines exploits their capacity for energy transduction. Motor proteins, for example, transduce the following forms of energy: (1) optical and electroosmotic; (2) optical and electronic; (3) chemical and electroosmotic; (4) chemical and electronic; (5) mechanical and electroosmotic; and (6) mechanical and chemical. By exploiting the transducing properties of nanomotors, one might be able to develop nanomachines that measure biological variables: oxygen tension, pH, glucose concentration, the redox state of a cell or subcellular organelle, temperature, intraocular pressure (IOP), or blood pressure. Alternatively, one can use nanomachines to induce energy sensitivity where it does not normally exist, e.g., creation of light-sensitive retinal ganglion cells (RGCs) or bipolar cells (described later in this chapter) or to provide therapeutic molecules to cells, e.g., wild-type alleles of retinal proteins to blind mutants (described later in this chapter). Finally, one might couple the measuring and therapeutic capacity of nanomachines to create devices that measure critical biological variables (e.g., redox state) for diagnostics and provide therapy (e.g., antioxidant therapy) at the appropriate time and place and in the appropriate quantity, a concept termed theranostics (discussed later in this chapter).

## Properties of Nanomachines<sup>8</sup>

### Physical Properties

Feynman noted that, at the size scale of intracellular structures and molecules, materials acquire seemingly surprising properties that

are predictable based on the principles of quantum physics.<sup>8</sup> For instance, carbon becomes stronger than steel; gold melts at room temperature, and aluminum becomes highly explosive. Quantities such as weight and inertia are of relatively little importance.

Inhomogeneity of materials (e.g., metals versus plastics) might limit their utility.<sup>8</sup> Magnetic properties on a very small scale are not the same as on a large scale. Lubrication is not needed if the machine is small enough because heat loss is rapid (due to the large surface area : volume ratio). Some of these properties produce unexpected results. For example, rapid heat loss might prevent gasoline from exploding, which would make a nanoscale internal combustion engine impossible.<sup>8</sup>

The influence of gravity on the function of true nanomachines is negligible because their mass is that of atoms ( $F_g = Gm_A m_B / r^2$ ).<sup>8</sup> On the other hand, the distance between the elements is in nanometers. Because of van der Waals forces, parts of nanomachines might adhere to each other, which might not be desirable. Electrical resistance may be very large with nanocircuits, a feature that might be useful in biological systems. Another problem with nanocircuits is the inverse relationship between the size of the device and the amount of noise generated (Hooge's rule). The development of stacked graphene sheets may provide a solution to this problem and facilitate the development of circuits much smaller than those in conventional silicon-based computer chips.<sup>41</sup> However, when working on the scale of atoms, circuits might not be needed, and quantized energy levels might be manipulated for energy transfer according to the laws of quantum mechanics. This property is exploited in some nanoparticle-based imaging technologies.

Axial ratio is the ratio of the magnitude of the axes (e.g., length and width in the case of a two-dimensional object), the greater being divided by the lesser. Nanotubes and nanofibers have very large axial ratios. Synthetic methods exist to alter the length-to-volume ratio and thus the physical properties of the material. Conductivity, for example, is enhanced as the diameter of semiconducting nanotubes is reduced.

A key property of nanomaterials is that they are surface-rich objects in relation to volume. The following analogy illustrates this concept. A baseball filled with membrane surface-active enzymes

would have only a minimal number of these extending to the surface of the ball, so the vast majority would be inactive. A pea filled with enzymes would have a greater proportion extending to the surface. A sphere 100 nm in diameter would have the majority of the enzymes it contains in an active state. This property results in a situation in which there is relatively limited unutilized surface area on to which one might attach molecules to the nanoparticle surface. The net effect is to create structures that accelerate many chemical reactions at their surfaces and act in some ways like very active enzymes.

Vacancy-engineered mixed-valence state cerium oxide ( $\text{CeO}_2$ ) nanoparticles (nanoceria) illustrate the useful properties that materials can develop at the nanoscale. Alteration in the oxidation state of  $\text{CeO}_2$  creates defects in its lattice structure via loss of oxygen or its electrons. As their size decreases, nanoceria (3–5 nm diameter) demonstrate formation of more oxygen vacancies in the crystal structure.<sup>42,43</sup> As described later in this chapter, vacancy-engineered nanoceria may function as a highly effective treatment for ocular conditions associated with oxidative damage.

## Manufacture

At each step in the process of manufacturing smaller and smaller machines, one must improve the accuracy of the equipment.<sup>8</sup> Feynman speculated that if devices are built on the scale of 5–10 atoms, then it should be possible to mass-produce them such that they are perfect copies of each other.<sup>8</sup> One useful outcome of a “nanomanufacturing” process is that the material costs of billions of these machines would be minimal since each is so small that minimal material is used. Nanomachines can have the capacity to repair and build themselves. Indeed, most nanoparticle structures are self-assembling under the proper thermodynamic conditions, allowing for production of a large number of virtually identical nanostructures.

Some properties of nanomachines are illustrated by the design and manufacture of an axon surgery platform. Using microtechnology, electrokinetic axon manipulation (i.e., dielectrophoresis), and cell fusion (i.e., electrofusion), Sretavan et

al.<sup>24</sup> developed a paradigm of direct axon repair involving the substitution of damaged axon regions with healthy segments from donor axons. This multidisciplinary group developed a multifunctional axon surgery platform that is  $\sim 1 \text{ mm}^3$  (Figs. 38.1 and 38.2). The cutting device consists of a silicon nitride knife with an ultrasharp knife-edge mounted on to a silicon-based compliant knife suspension (Fig. 38.1). The knife edge's radius of curvature ( $\sim 20 \text{ nm}$ ) is similar to the diameter of a single microtubule. Because the knife is manufactured from a silicon nitride membrane, it is nearly transparent, which permits visualization of axons during the cutting procedure. The mechanical compliance of the suspension can be varied to deliver sufficient force for cutting different tissues (e.g., single axons) or for harvesting specific cell populations from histologic tissue sections. The authors envision future improvements such as sensors as well as force-generating actuation mechanisms that automatically deliver a controlled cutting stroke, and they indicate that both piezoelectric and thermal expansion actuation mechanisms can deliver forces in the range needed for axon cutting. A femtosecond laser might also be used for axotomy.<sup>44</sup> The goal is to develop a microcutting device with on-board sensing and actuation that can function as a semiautonomous instrument, requiring only initiating commands from the surgeon. Important limitations to the practical application of this invention remain. The authors estimate, for example, that  $\sim 20$  seconds are required to repair a single axon using dielectrophoresis and electrofusion.<sup>24</sup> Cutting and fusing multiple axons simultaneously might enable relatively rapid repair of several thousand axons.

**FIG. 38.1** Microfabricated axon surgery platform, an example of a nanomachine. (A) Axon knife assembled within a compliant suspension frame. The pyramidal structure in the center is an optically transparent axon knife with a 10- $\mu\text{m}$  cutting edge. *f*, silicon suspension flexures; *k*, axon knife; *h*, handle to micromanipulator. The footprint of the frame is 1  $\text{mm}^2$ . Scale = 200  $\mu\text{m}$ . Devices with substantially smaller footprints can be fabricated. (B) Detail of the silicon suspension flexure on each side of the axon knife that provides mechanical compliance during cutting. The number of switchbacks in the flexure can be modified to obtain devices with different mechanical compliances that deliver a range of cutting forces. The compliance of the flexures allows it to act as a suspension, maximizing the durability of the knife edge. (C) Oblique view of the silicon nitride knife. Knives with edges from 5 to 200  $\mu\text{m}$  have been fabricated and tested. A 200- $\mu\text{m}$ -long knife is shown. (D) Scanning electron micrograph showing a cross-section of the silicon nitride knife at its very edge. The radius of curvature at the edge is roughly 20 nm. # Applications to Ophthalmology

Nanomedicine will foster revolutionary advances in the diagnosis and treatment of disease. Nanomedicine is likely to have a major impact on biopharmaceuticals (e.g., drug delivery, drug discovery),<sup>45</sup> implantable materials (e.g., tissue regeneration scaffolds, bioresorbable materials), implantable devices (e.g., IOP monitors,<sup>46</sup> glaucoma drainage valves<sup>47</sup>), and diagnostic tools (e.g., infectious disease diagnosis, genetic testing, imaging, IOP monitoring). Nanotechnology will bring about the development of regenerative medicine (i.e., replacement and improvement of cells, tissues, and organs), ultrahigh resolution in vivo imaging, microsensors and feedback devices, and artificial vision.

“Regenerative nanomedicine,” a new subfield of nanomedicine, uses nanoparticles containing gene transcription factors and other modulating molecules that allow reprogramming of cells in vivo.

## Delivery of Drugs, Peptides, and Genes

### General Considerations Regarding Nanoparticles

Nanoparticles are colloidal carrier systems that can improve the efficacy of drug delivery by overcoming diffusion barriers, permitting reduced dosing (through more efficient tissue targeting) as well as sustained delivery (Fig. 38.3). These features are attractive for drug treatment of chronic conditions such as glaucoma,<sup>48</sup> uveitis,<sup>49</sup> or retinal edema (due to venous occlusion or choroidal neovascularization [CNV]) as well as for treatment of intraocular tumors and other conditions associated with cell proliferation such as capsular fibrosis after cataract surgery, ocular neovascularization, and proliferative vitreoretinopathy. Nanoscale-engineered cell substrata (e.g., nanowires) and carbon nanotubes also can be used for gene and drug delivery.<sup>50-52</sup>

Ligand conjugated ZnS-capped CdSe quantum dots

Ferrofluid conjugated to ligand

**FIG. 38.3** Schematics of different nanotechnology-based drug delivery systems. Nanoparticles are small polymeric colloidal particles with a therapeutic agent either dispersed in polymer matrix or encapsulated in polymer. Polymeric micelles are self-assembled block copolymers, which in aqueous solution arrange to form an outer hydrophilic layer and an inner hydrophobic core. The micellar core can be loaded with a water-insoluble therapeutic agent. Liposomes are lipid structures that can be made “stealth” by PEGylation

and further conjugated to antibodies for targeting.

Dendrimers are monodispersed symmetric macromolecules built around a small molecule with an internal cavity surrounded by a large number of reactive end groups. Quantum dots are fluorescent nanocrystals that can be conjugated to a ligand and thus can be used for imaging purposes. Ferrofluids are colloidal solutions of iron oxide magnetic nanoparticles surrounded by a polymeric layer, which can be further coated with affinity molecules such as antibodies.

*PEG*, poly(ethylene glycol). (Reproduced with permission from Sahoo SK, Labhasetwar V. Nanotech approaches to drug delivery and imaging. *Drug Discov Today* 2003;8:1112–20 with permission from Elsevier; and from Zarbin MA, Montemagno C, Leary JF, et al. Nanomedicine in ophthalmology: the new frontier. *Am J Ophthalmol* 2010;150:144–62.)

Strategies in the design of nanoparticles for therapeutic purposes have been reviewed thoroughly by Petros and DeSimone,<sup>53</sup> Moghimi et al.<sup>54</sup> and Kompella et al.<sup>55</sup> Particle size, shape, and surface properties influence nanoparticle biodistribution. Particle size, for example, affects whether the particle is internalized via phagocytosis, macropinocytosis, caveolae-mediated endocytosis, or clathrin-mediated endocytosis, which in turn results in exposure of the nanoparticle to different intracellular environments.<sup>56</sup> The cell surface receptor, nucleolin, transports compacted polylysine DNA nanoparticles into cells and directly to the nucleus.<sup>57</sup>

One can target nanoparticles to specific cells by attaching to the particle surface ligands/antibodies/peptides/aptamers for receptors/molecules that are abundant on the surface of the target cell/tissue.<sup>53</sup> This approach can have complications. Receptor aggregation on the cell surface, for example, can induce unintended events, such as apoptosis.<sup>58</sup> One can engineer the nanoparticle for a particular mode of intracellular entry depending on the choice of nanoparticle targeting molecules, e.g., cholesterol favors uptake via caveolin-mediated endocytosis, and transactivating transcriptional activator peptide favors macropinocytosis.<sup>59,60</sup> Nanoparticle surface chemistry also can be manipulated to trigger cargo release under specific circumstances. For example, when exposed to a reducing environment such as is present in the cytosol, reductively labile disulfide-based crosslinks between the carrier and cargo are

broken.<sup>61,62</sup> Approaches for targeting nanoparticles to particular subcellular organelles, e.g., mitochondria<sup>63</sup> or the nucleus,<sup>64</sup> also have been developed.

Liposomes and polymer–drug conjugates are among the most frequently used nanoparticles for therapeutic purposes. Liposomes, which carry hydrophobic or hydrophilic cargo, can be coated with ligands that direct them to specific cell surface receptors for cell targeting as well as with polymers that prolong their half-life in the circulatory system. Poly(ethylene glycol) (PEG) can be conjugated with different molecules to enhance their solubility and stability in plasma and to reduce immunogenicity.<sup>53</sup> Opsonization by immunoglobulin and/or complement proteins can lead to recognition of the nanoparticle as foreign and induce a hypersensitivity reaction.<sup>65,66</sup> Coating a nanoparticle with albumin and/or PEG can create a hydrophilic surface that temporarily resists protein adsorption, thus prolonging the particle's bioavailability.<sup>53,67,68</sup> This approach allows for much longer drug circulation and concomitant lowering of therapeutic-level drug doses, which in turn can reduce many unintended side-effects.

Dendrimers are synthetic, highly branched polymers that have precisely controllable nanoscale scaffolding and nanocontainer properties, which in some senses mimic the properties of macromolecules such as DNA and ribonucleic acid (RNA).<sup>69</sup> The diameter of poly(amidoamine) dendrimer ranges from 1.5 to 14.5 nm.<sup>70</sup> As generation (G) number increases, the number of active terminal groups doubles. G3 dendrimers, for example, contain 32 terminal groups, and G4 dendrimers contain 64 terminal groups. In poly(amidoamine) dendrimers, full generations (e.g., G3) have terminal amine or hydroxyl groups while half-generation dendrimers (e.g., G3.5) have carboxylic acid terminal groups. Dendrimers have been explored as vehicles for controlled drug delivery, including cancer therapy, pilocarpine, gatifloxacin, and for vascular endothelial growth factor (VEGF) inhibition.<sup>71–74</sup> Marano et al.,<sup>72</sup> for example, used a lipophilic amino acid dendrimer to deliver an anti-VEGF oligonucleotide into rats' eyes with laser-induced CNV. The dendrimer–oligonucleotide conjugate inhibited CNV development for 4–6 months by up to 95%, whereas eyes injected with oligonucleotide alone showed no treatment benefit compared

to vehicle-injected controls at these times. The dendrimer–oligonucleotide conjugate was well tolerated in vivo. Ideta et al.<sup>75</sup> used dendrimer porphyrin encapsulated by a polymeric micelle to treat laser-induced CNV in rodents and found significant enhancement of photodynamic therapy efficacy with less light energy required for CNV occlusion.

### **Antibiotic Therapy**

Typically, only a small fraction (<5%) of topically administered medications is biologically available due to limited ocular penetration and rapid clearance from the aqueous humor. Because dendrimers contain surface functional groups as well as void spaces within and between their branches, they can serve as delivery vehicles for therapeutic modalities such as carboplatin.<sup>74</sup>

Dendrimeric polyguanidylated translocators (DPT) are nanosized dendrimers that translocate molecules across biological barriers efficiently. Durairaj et al.<sup>71</sup> used a six-guanidine group-containing dendrimer to enhance gatifloxacin solubility (fourfold) and delivery to the anterior and posterior segment of rabbits. The DPT–gatifloxacin complexes (346 nm) enhanced tissue concentration in the conjunctiva (13-fold) and cornea (twofold). A single dose resulted in sustained aqueous humor levels ( $t_{1/2} = 9$  hours), potentially allowing decreased frequency of administration (e.g., once-daily dosing). After multiple dosing, DPT–gatifloxacin achieved therapeutic levels in the vitreous humor for 12 hours (versus no drug levels detectable at 12 hours after topical gatifloxacin alone).

### **Antimetabolite Therapy**

Shaunak et al.<sup>76</sup> used anionic, polyamidoamine, generation 3.5 dendrimers to make novel water-soluble conjugates of D(+)-glucosamine and D(+)-glucosamine 6-sulfate with immunomodulatory and antiangiogenic properties, respectively. Dendrimer glucosamine inhibited Toll-like receptor 4-mediated lipopolysaccharide-induced synthesis of proinflammatory chemokines (i.e., macrophage inflammatory protein (MIP)-1 $\alpha$ , MIP-1 $\beta$ , interleukin (IL)-8) and proinflammatory cytokines (i.e., tumor

necrosis factor- $\alpha$ , IL-1 $\beta$ , IL-6) primarily from immature human monocyte-derived dendritic cells and monocyte-derived macrophages, but allowed upregulation of the costimulatory molecules CD25, CD80, CD83, and CD86. Dendrimer glucosamine 6-sulfate blocked fibroblast growth factor-2-mediated human umbilical vein endothelial cell proliferation, but not VEGF-mediated proliferation, and neoangiogenesis in human Matrigel and placental angiogenesis assays. When dendrimer glucosamine and dendrimer glucosamine 6-sulfate were used together in a validated, clinically relevant rabbit model of scar tissue formation after glaucoma filtration surgery,<sup>77,78</sup> they increased the long-term success of the surgery from 30% to 80% ( $p=.029$ ). A clinical trial of this modality to reduce scarring after trabeculectomy, however, was not successful (P Khaw, R Ritch, personal communication).

## Neurotrophic Factor Therapy

Nanoparticles can deliver growth and neurotrophic factors to cells.<sup>79</sup> Intravitreal nanoparticle-based basic fibroblast growth factor (bFGF) delivery, for example, provides sustained retinal rescue in Royal College of Surgeons (RCS) rats.<sup>80</sup> In RCS rats, the RPE cells have a mutation that prevents proper outer-segment phagocytosis, with secondary rod and cone photoreceptor degeneration.<sup>81</sup> Some patients with retinitis pigmentosa (RP) have this same mutation.<sup>82-84</sup> Sakai et al.<sup>80</sup> prepared bFGF nanoparticles using gelatin isolated from bovine bone collagen and human recombinant bFGF. The nanoparticle diameter, assessed using dynamic light scattering, was ~585 nm.

Glaucoma, a leading cause of blindness worldwide, is associated with progressive RGC death and optic nerve atrophy.<sup>85</sup> Intravitreal glial cell line-derived neurotrophic factor (GDNF)-loaded biodegradable (poly)lactic-co-glycolic acid (PLGA) microspheres provide sustained RGC protection in a rodent model of glaucoma.<sup>86</sup> Microspheres (~8  $\mu\text{m}$  diameter) containing GDNF were fabricated using a modification of a spontaneous emulsion technique.<sup>87</sup> Since adeno-associated virus (AAV)-mediated GDNF secretion from glia delays retinal degeneration in a rat model of RP,<sup>88</sup> it is possible that nanoparticle-mediated GDNF delivery can be applied to treating RP-like diseases.

Optic nerve injury (crush) has been treated using nanoparticles to deliver neurotrophic factors. Kim et al.<sup>89</sup> demonstrated that human serum albumin nanoparticles (150 nm diameter) conjugated with brimonidine released brimonidine for 5 days and improved retinal ganglion cell density after injury by almost 400% compared to control 14 days after optic nerve injury in rats. Brimonidine was loaded into the hydrophobic pockets of the human serum albumin nanoparticles. The nanoparticles seemed to reduce amyloid-beta deposition in the retinal ganglion cell layer. In view of the pore size of the internal limiting membrane (10–20 nm) and the outer limiting membrane (3–4 nm), it seems likely that the nanoparticles penetrated the retina by a receptor mediated endocytosis mechanism, possibly the transforming growth factor-beta receptor.<sup>89</sup>

## Antioxidant Therapy

Age-related macular degeneration (AMD), RP, diabetic retinopathy, and retinopathy of prematurity are characterized, in part, by the presence of oxidative damage.<sup>90–95</sup> As noted above, alteration in the oxidation state of CeO<sub>2</sub> nanoparticles creates defects in its lattice structure via loss of oxygen or its electrons. Chen et al.<sup>96</sup> posited that engineered nanoceria can scavenge reactive oxygen intermediates because the large surface area-to-volume ratio at 5 nm diameter enables CeO<sub>2</sub> to regenerate its activity and thereby act catalytically. (Unlike nanoceria, most free-radical scavengers require repetitive dosing.) Chen et al.<sup>96</sup> showed that intravitreal injection of nanoceria prevents light-induced photoreceptor damage in rodents, even if injected after the initiation of light exposure. Vacancy-engineered nanoceria also inhibit the development of and promote regression of pathologic retinal neovascularization in the *Vldlr* knockout mouse, which carries a loss-of-function mutation in the very low-density lipoprotein receptor gene and whose phenotype resembles a clinical entity known as retinal angiomatous proliferation (Figs. 38.4 and 38.5).<sup>97,98</sup> This regression occurs even if nanoceria are injected intravitreally after the mutant retinal phenotypes are established (Fig. 38.6). Because nanoceria are a catalytic and regenerative antioxidant, a single injection has a prolonged effect (measured in weeks).

Nanoceria inhibition of increased VEGF levels in this model<sup>97</sup> may mean that CeO<sub>2</sub> nanoparticles will be effective in treating macular edema in diabetic eyes and CNV-induced retinal edema in AMD eyes.<sup>99-101</sup>

**FIG. 38.4** Nanoceria reduce oxidative stress in the *Vldlr*<sup>-/-</sup> retina. Retinal sections from saline-injected wild-type (WT) mice (panels A, D, G, J); saline-injected *Vldlr*<sup>-/-</sup> mice (panels B, E, H, K), and CeO<sub>2</sub>-injected (panels C, F, I, L) *Vldlr*<sup>-/-</sup> mice are shown as imaged by confocal microscopy. The 2',7'-dichloro-dihydro-fluorescein-diacetate (DCF) assay (A–C) visualizes reactive oxygen species (ROS) as punctuate fluorescence and demonstrates a very low level of ROS in the normal retina (A), a considerable amount in

the *Vldlr*<sup>-/-</sup> retina (B), and a greatly reduced amount in the retina of the *Vldlr*<sup>-/-</sup> mice injected with CeO<sub>2</sub> (C).

Similar results were obtained with the other three assays. NADPH-oxidase (P47-phox; D–F), a major producer of ROS, was very high in the *Vldlr*<sup>-/-</sup> retina and almost reduced to control levels in the CeO<sub>2</sub>-injected mice. Nitrotyrosine (G–I), a reflection of oxidative activity due to increases in nitric oxide concentration, was highest in the *Vldlr*<sup>-/-</sup> retina and significantly reduced in the nanoceria-injected mice. ROS-mediated damage to DNA was indicated by the labeling of the retina with an antibody against a DNA adduct, 8-hydroxy-29-deoxyguanosine (8-OHdG; J–L), which showed little labeling in the control, significant labeling in the saline-injected *Vldlr*<sup>-/-</sup> retina, and a greatly reduced amount in the nanoceria-treated retina. DAPI (blue) was used to visualize the nuclei. (Reproduced with permission from Zhou X, Wong LL, Karakoti AS, et al. Nanoceria inhibit the development and promote the regression of pathologic retinal neovascularization in the *Vldlr* knockout mouse. PLoS One 2011;6:e16733; and from Zarbin MA, Montemagno C, Leary JF, et al. Regenerative nanomedicine and the treatment of degenerative retinal diseases. Wiley Interdiscip Rev Nanomed Nanobiotechnol 2012;4:113–37.)

**FIG. 38.5** Nanoceria inhibit the development of pathologic intra- and subretinal vascular lesions in the *Vldlr*<sup>-/-</sup> retina. Photomicrographs of whole-mount

retinas (A–C) and eyecups (retinal pigment epithelium, choroid, and sclera) (D–F) from P28 animals are shown. All retinal blood vessels were labeled green by the vascular filling assay. Wild-type (WT) retinas (A) showed the normal web-like retinal vasculature whereas those from the *Vldlr*<sup>-/-</sup> mice (B) showed numerous intraretinal vascular lesions or “blebs.” See *white arrows* for examples. A single injection of nanocerium at P7 (C) inhibited the appearance of these lesions. Eyecups from WT mice (D) showed no subretinal neovascular (SRN) “tufts” but those from *Vldlr*<sup>-/-</sup> mice (E) had many bright SRN tufts. A single injection of nanocerium on P7 inhibited the appearance of these SRN tufts (F). (Reproduced with permission from Zhou X, Wong LL, Karakoti AS, et al. Nanocerium inhibit the development and promote the regression of pathologic retinal neovascularization in the *Vldlr* knockout mouse. PLoS One 2011;6:e16733; and from Zarbin MA, Montemagno C, Leary JF, et al. Regenerative nanomedicine and the treatment of degenerative retinal diseases. Wiley Interdiscip Rev Nanomed Nanobiotechnol 2012;4:113–37.)

**FIG. 38.6** Retinal vascular lesions in the *Vldlr*<sup>-/-</sup> retinas require continual production of excess reactive oxygen species. *Vldlr*<sup>-/-</sup> mice were injected at P28 with saline or nanocerium and killed 1 week later on P35. Analysis of vascular endothelial growth factor (VEGF) levels by Western blots (A) showed a fourfold reduction (B) within 1 week of nanocerium injection. The numbers of

intraretinal neovascular (IRN) blebs (C) and subretinal neovascular (SRN) tufts (D) were also dramatically reduced. \* $p=.05$ ; \*\* $p=.01$ . (Reproduced with permission from Zhou X, Wong LL, Karakoti AS, et al. Nanoceria inhibit the development and promote the regression of pathologic retinal neovascularization in the *Vldlr* knockout mouse. PLoS One 2011;6:e16733; and from Zarbin MA, Montemagno C, Leary JF, et al. Regenerative nanomedicine and the treatment of degenerative retinal diseases. Wiley Interdiscip Rev Nanomed Nanobiotechnol 2012;4:113–37.)

C-60 fullerenes are cage-like structures (truncated icosahedron) of carbon atoms with antioxidant properties.<sup>102</sup> Malonic acid C-60 derivatives (carboxyfullerenes) can eliminate superoxide anion and  $H_2O_2$ , and inhibit lipid peroxidation.<sup>8</sup> Systemic administration of the C-3 carboxyfullerene isomer delayed motor deterioration and death in a mouse model of familial amyotrophic lateral sclerosis.<sup>92,103</sup> It might be useful in the treatment of retinal diseases associated with oxidative damage.

Iron is an essential element for enzymes involved in the phototransduction cascade, in outer-segment disc membrane synthesis, and in the conversion of all-*trans*-retinyl ester to 11-*cis*-retinol in the RPE.<sup>104–106</sup> Free  $Fe^{2+}$  catalyzes the conversion of hydrogen peroxide to hydroxyl radical, which is a highly reactive species that causes oxidative damage (e.g., lipid peroxidation, DNA strand breaks).<sup>107</sup> Increased intracellular iron causes oxidative photoreceptor damage.<sup>108</sup> Polymeric nanoparticles can be used to chelate metals. Liu et al.<sup>109</sup> showed that a chelator-nanoparticle system complexed with iron, when incubated with human plasma, preferentially adsorbs apolipoprotein E and apolipoprotein A-I, which should facilitate transport into and out of the brain via mechanisms used for transporting low-density lipoprotein. Iron accumulation in the RPE and Bruch's membrane is greater in AMD eyes than in controls, including cases with early AMD and late stages of the disease (i.e., geographic atrophy, CNV).<sup>110</sup> Some of this iron is chelatable.<sup>110</sup> Although it is not proven that iron overload is a cause of AMD,<sup>111–114</sup> iron chelation might have a therapeutic effect. Thus, the technology developed by Liu et al.<sup>109</sup> might have utility for treating AMD eyes.

## Immune-Suppressive Therapy

Cell-based therapy might be sight-restoring for patients with degenerative retinal diseases such as RP and AMD. An immune response to transplanted cells may depend upon the cell types included in the cellular therapy.<sup>115</sup> Nanotechnology provides immune-suppressive therapy (local or systemic) in selected cases where its need is anticipated.<sup>115-117</sup> In preclinical models, for example, nanoparticles are helpful in managing corneal allograft rejection. Yuan et al.<sup>118</sup> manufactured 300-nm-diameter rapamycin-loaded chitosan/poly(lactic acid) nanoparticles and demonstrated that they extended median allograft survival by 17% in rabbits compared with aqueous rapamycin eye drops. Topical chitosan particles were well tolerated in this study, but intraocular chitosan nanoparticles may not be well tolerated.<sup>119</sup>
