Animal models are useful in reproducing the findings observed in ocular trauma in humans; and furthermore, these models are valuable for evaluating surgical techniques and therapeutic drugs.<sup>29,30</sup> For instance, the morphology of the wound and the efficacy of vitrectomy have been studied in this animal model of a contusion injury. Because of initial uveal engorgement and inflammatory swelling, early surgical intervention was hazardous. The findings support the clinical impression that vitrectomy in traumatized eyes with a substantial contusive component is best delayed for 1 or 2 weeks.<sup>26,27</sup> (This is discussed in more detail in [Chapter 114](#), Surgery for ocular trauma.)

A human RPE culture system is another useful means of investigating the RPE cell's behavioral patterns, such as the migration, proliferation, and alteration of its phenotype, and the growth factors and cytokine-secreting patterns in order to understand the process of PVR.<sup>31–36</sup>

## Wound Healing and Traumatic Proliferative Vitreoretinopathy

Wound healing in the eye is similar to that in other bodily tissues, consisting of three phases: exudation/inflammation, proliferation, and regeneration.<sup>37</sup> The typical wound healing response in the anatomic setting of the eye and the vitreoretinal relationship explain the development of tractional retinal detachment after penetrating ocular injury.

Open-globe injury results in a breakdown of the blood–retinal barrier and allows the entry of a variety of cells into the intraocular milieu, causing the expression of a variety of chemokines, inflammatory cytokines, and growth factors that affect the adjacent RPE, fibroblasts, and glial cells. In response, these previously resting cells undergo proliferation and migration as they change their pattern of gene expression, resulting in alterations of their own cytokine, extracellular matrix, and receptor profiles. Some cells – myofibroblasts, for example – proliferate and produce strong contractile forces that oppose the physiologic forces that normally keep the retina attached and a tractional retinal detachment occurs. Following the natural course, proliferation is accompanied by a progressive accumulation of extracellular collagen and by a decrease in inflammation and inflammatory mediators.<sup>18,20</sup> This wound healing process is central to the final common pathway that leads to tractional retinal detachment and posttraumatic PVR in open-globe injury (Fig. 102.3).

**FIG. 102.3** Traumatic proliferative vitreoretinopathy pathway. Abbreviations: *BRB*, blood–retinal barrier; *RPE*, retinal pigment epithelium; *PDGF*, platelet-derived growth factor; *HGF*, hepatocyte growth factor; *VEGF*, vascular endothelial growth factor; *TGF*, tissue growth factor; *CTGF*, connective tissue growth factor; *ECM*, extracellular matrix; *MMP*, matrix metalloproteinase; *TRD*, tractional retinal detachment.

Accordingly, when interpreting human tissues, it is important to emphasize the stage of the wound healing response: the early stage is characterized by many cells, including a range of inflammatory cells, myofibroblasts, RPE, etc. The late stage is characterized by fewer cells of a chronic variety and more extracellular matrix, e.g., collagen.

## Cellular Constituents

Epiretinal membranes removed during vitreous surgery for PVR after injury have been analyzed to gain an understanding of the origin and characteristics of their cellular constituents.<sup>38-40</sup>

Depending on the nature of the injury and the stage of the response, these membranes contain variable numbers of cells that are phenotypically identified as inflammatory cells, RPE cells, glial cells, fibroblasts, and myofibroblasts.

Inflammatory cells are among the earliest cell types to appear in the wound healing response. They may be attracted to the wound by chemokines upregulated in traumatized retinal tissue, by breakdown of the blood-retinal barrier, or as a response to intraocular blood.<sup>31,41-45</sup> The cytokine products of these cells may be critical for the activation of other retinal cell types, further recruitment of inflammatory cells, and formation of collagen. Macrophages are a constant feature of experimental tractional retinal detachment.<sup>42,43</sup> In the primate model of posterior penetrating injury, macrophages are present before the invasion and proliferation of fibroblast or RPE cells.<sup>19,20</sup> The finding of cellular and humoral immune responses to retinal antigens following retinal detachment and experimental PVR has suggested the possibility of an autoimmune component in PVR, although the evidence for a pathogenic role of such a response is incomplete.<sup>45-48</sup>

The RPE cell is central to the pathophysiologic response seen in posttraumatic PVR. The RPE cells have critical characteristics, including migration and proliferation.<sup>32,33,38</sup> The posttraumatic stimuli that are specifically responsible for RPE changes are not completely understood. RPE cell growth appears to be regulated by both paracrine and autocrine stimulation. RPE cells were shown to proliferate and form multilayered colonies of dedifferentiated RPE cells within 24 hours of retinal detachment in cats.<sup>49</sup> They were also consistently found in the membranes of animal models of penetrating injury.<sup>20,22,26</sup> Additionally, cultured RPE cells, just like RPE cells under the detached retina, produce mitogenic and chemotactic growth factors, such as platelet-derived growth factor (PDGF) and hepatocyte growth factor (HGF), and possess receptors for each of these growth factors. RPE cells respond not only to growth factors from RPE cells (autocrine) but also to those from surrounding tissue or from serum (paracrine), resulting in

recruitment of additional RPE cells, and thus augmenting the process.<sup>34-36,50-56</sup> In response to these stimulations, RPE cells may undergo epithelial-to-mesenchymal transition (EMT) altering their phenotype to cells with a macrophage, fibroblast, or myofibroblast morphology.<sup>32,33,38</sup> This fibroblastic RPE may synthesize and remodel the matrix on the retinal surface, contributing to the formation of the membrane. It was demonstrated that the proportion of RPE in human membranes varies according to the age of the membrane. The number of RPE cells is greater in early (<4 months) specimens and declines progressively as the membranes mature with more advanced extracellular matrices.<sup>57</sup>

Glial cells, identified by their typical morphologic characteristics and immunoreactivity to glial fibrillary acidic protein (GFAP), were found in neurosensory retina and membrane from full-thickness retinectomy specimens obtained at surgery for PVR, with increased expression correlated to the severity of degeneration after trauma.<sup>57-60</sup> Glial cells appear to be involved in PVR formation through migration onto the surface of the retina and may be involved in remodeling of intraretinal synapses, possibly contributing to visual recovery after retinal injury.

Fibroblastic proliferation is critical to the progression of the posttraumatic proliferative response. Although fibroblasts are typically derived from RPE and glial cells, the immunohistochemical markers for these cells are missing in some fibroblasts, making their derivation uncertain.<sup>38,61,62</sup> In studies using an animal model of globe perforation with long posterior wounds and injection of intravitreal blood, where membranes extended from the wounds and  $\beta$ -galactosidase-labeled Tenon fibroblasts were identified in the vitreous and membrane, it was determined that at least some of the fibroblasts may have originated from Tenon layer at the wound edge (Fig. 102.4).<sup>20,24,25,63,64</sup>

**FIG. 102.4** Tenon fibroblasts in proliferative vitreoretinopathy membranes in an experimental ocular trauma model. Fibroblasts were transduced using a retroviral vector to express beta-galactosidase. These labeled cells were injected into Tenon's capsule of rabbits, and 2 days later a double perforation was performed. Animals developed funnel retinal detachment with vitreous membranes extending between the wounds at 30 days. Staining of the specimen with X-gal resulted in a blue color in labeled cells. (A) The vitreous strand from the posterior Tenon wound is blue, indicating that it contains labeled cells from the Tenon's capsule. (B) A microscopic section shows many labeled (blue) cells within the membrane. (Reproduced with permission from Santos RO, Murata T, Cui JZ et al. The role of Tenon fibroblasts in the pathogenesis of proliferative vitreo-retinopathy due to perforating eye injury. ARVO abstract 1998;517.)

Myofibroblasts are an important component of wound contraction in granulation tissue. Similarly, although the origin of these cells is unknown, RPE cells, fibroblasts, and other cell types have been implicated.<sup>38,61,62</sup> Ultrastructural analysis showing that myofibroblasts contain myofibrils and smooth muscle actin suggests that these myofibroblasts may produce contractile forces that cause contraction of the vitreous, retina, and membrane in PVR.<sup>65–67</sup> This force of cellular traction may be transmitted directly by cellular attachment to the adjacent tissue or indirectly through traction on collagen fibrils that are attached to the tissue. Experimental work suggested an alternative mechanism of membrane contraction involving the interaction of RPE cells and collagen.<sup>14</sup> Collagen fibers are pulled by the RPE cells by alternating extension and retraction of their lamellipodia. Collagen is piled up adjacent to the RPE cell with subsequent tissue shortening.

## Growth Factors

Several growth factors appear to play critical roles, including platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF), transforming growth factor- $\beta$  (TGF- $\beta$ ) and connective tissue growth factor (CTGF). The abundance of these growth factors in both vitreous and PVR membranes suggests that they play an important role in the wound healing response.<sup>31,34–36,55,56,68</sup>

The PDGF signaling network is comprised of five ligands (PDGF-AA, PDGF-BB, PDGF-AB, PDGF-CC, and PDGF-DD) and two receptors (PDGFR- $\alpha$  and PDGFR- $\beta$ ). Platelet-derived growth factor may be released from platelet  $\alpha$ -granules after tissue damage or from endogenous retinal cells such as RPE cells. As a potent mitogenic and chemotactic stimulant for RPE and glial cells, PDGF receptor (PDGFR) signaling seems to play a central role in the development of PVR.<sup>36,69</sup> Analysis of epiretinal membranes from patients with PVR shows that PDGFRs are activated in these membranes.<sup>70</sup> Experimental studies using an organ culture model showed that RPE cell-mediated retinal contraction can be inhibited by neutralizing antibodies against PDGF, and studies using a mouse fibroblast-induced model of PVR showed that PVR was

diminished when fibroblasts isolated from PDGF-receptor knockout mice were used.<sup>71,72</sup> However, recent evidence suggests that experimental PVR depends on PDGFR- $\alpha$ , which can be activated by a much larger spectrum of growth factors rather than the concentration of PDGF only. Neutralizing PDGF does not effectively attenuate experimental PVR, however inhibition of PDGFR $\alpha$  activation prevents the development of PVR.<sup>73</sup> Non-PDGF growth factors such as epidermal growth factor (EGF), fibroblast growth factor (FGF), insulin, HGF, and VEGF-A can indirectly activate PDGFR $\alpha$  without engaging its ligand-binding domain.<sup>74-76</sup> Indirect activation of PDGFR $\alpha$  by non-PDGF family growth factors appears to promote PVR by chronic activation of Akt and suppression of p53.<sup>77</sup>

Vascular endothelial growth factor also has been localized to PVR membranes. Recent study showed that VEGF-A competitively blocks PDGF-dependent PDGFR- $\alpha$  activation.<sup>76</sup> Further study showed that neutralization of VEGF-A inhibits non-PDGF-mediated activation, which protects against PVR.<sup>78</sup>

Hepatocyte growth factor is also mitogenic and chemotactic for RPE cells and was found in the vitreous of patients with PVR.<sup>34,50,51,53</sup> Experimentally, cultured human RPE cells responded to HGF by epithelial-to-mesenchymal shape change and by cell migration response that increased with increasing concentrations of HGF.<sup>34,50,51,53</sup> Activation of mitogen-activated protein kinases (MAPK) is a component of the HGF-induced RPE change.<sup>54</sup> This response was reduced in the presence of neutralizing antibody.<sup>51</sup> In vivo studies in rabbits have shown that overexpression of HGF in RPE leads to subretinal proliferation of RPE.<sup>55</sup>

Transforming growth factor- $\beta$  is known to play a crucial role as a potent fibrotic factor in EMT and is overexpressed in the vitreous of patients with PVR.<sup>79-80</sup> The contractile effect of hyalocyte-containing collagen gels correlates with vitreal concentration of activated TGF- $\beta$ 2.<sup>81</sup> Similarly, there is strong immunoreactivity for CTGF in human PVR membranes, and CTGF N-terminal fragment accumulates in the vitreous of patients with PVR.<sup>82</sup> CTGF functions as a downstream mediator of TGF- $\beta$  action on fibroblasts and RPE where it stimulates cell migration and cell matrix deposition.<sup>34,82</sup> In vivo studies have shown that CTGF promotes the development of

highly fibrotic PVR membranes in rabbits.<sup>82</sup> Recently, CTGF has been shown to promote the profibrotic activities of TGF- $\beta$  by regulating fibronectin-extra domain A (EDA) through protein–protein interactions between CTGF and both TGF- $\beta$  and TGF- $\beta$  receptor II.<sup>83</sup>

In addition to various growth factors, proinflammatory cytokines such as tumor necrosis factor- $\alpha$  and interleukin appear to have dramatic effects on many cell types, including RPE, and may alter cellular function by stimulating proliferation, migration, and expression of cell surface integrin and cell adhesion molecule, as well as extracellular matrix production and invasiveness.<sup>35,84–85</sup> It was also shown that infiltrating macrophages or resident RPE or glial cells may be the source of these cytokines.<sup>35,68</sup> A strong association has been found between a polymorphism in the tumor necrosis factor locus and PVR in a case–control study.<sup>86</sup>

The stage specificity of growth factor expression during PVR development has been described, where PDGF-AA is expressed uniformly throughout all stages of PVR, while HGF expression peaks during mid-stage, and CTGF expression is highest during late-stage PVR. These results may be applicable to a stage-specific therapeutic approach for PVR.<sup>87</sup>

## Extracellular Matrix

In addition to cellular response, extracellular matrices (ECM) are important components of human PVR membranes, similar to the wound healing process in other organs. Initially, the formation of a fibrin-rich membrane can be observed.<sup>88–89</sup> Intraocular fibrin may provide a structure for the formation of complex membranes by stimulating the migration of RPE cells along the fibrin sheets.<sup>90</sup> Subsequently, membrane is characterized by the presence of interstitial collagens I and III and fibronectin within the membranes.<sup>57,84,91–92</sup> The collagens and fibronectin may be derived from RPE, glial cells, or macrophages, although the most consistent association is with RPE. Similar patterns of ECM expression are found in experimental PVR produced by injection of fibroblasts in the rabbit.<sup>93</sup> Provisional ECM components (collagen I, fibronectin) in PVR membranes may play important roles in the progression of

the wound healing response by stimulating the RPE and glial cells through activation of integrin receptors, resulting in altered cell behavior, including chemotaxis and migration.<sup>85,94</sup>

The wound healing process of PVR involves the unbalanced action of matrix metalloproteinases (MMPs) and tissue inhibitors of MMPs in the degradation and contraction of extracellular matrix.<sup>95-98</sup> MMP-9 and MMP-2 are the major MMPs that have been detected in vitreous samples and proliferative membranes of PVR patients.<sup>96-97,99</sup> In in vitro models of collagen contraction mediated by the RPE, synthetic MMP inhibitors have shown an anticontraction effect in a dose-dependent manner.<sup>100</sup>

## Special Conditions

### Traumatic Endophthalmitis

Endophthalmitis is a particularly devastating complication of open-globe injury, with a higher reported rate of infection after open-globe injuries (from 3.1% to 31%) in the absence of intraocular foreign body (IOFB) when compared with intraocular surgery (up to 0.1%).<sup>101</sup> Approximately 75% of all posttraumatic culture-positive endophthalmitis cases are infected by gram-positive organisms, with *Bacillus* species causing about 20% of the infections.<sup>102</sup> Risk factors associated with the development of endophthalmitis include the presence of an IOFB, lens rupture, delayed timing of primary repair, age >50 years, female gender, large wound size, location of wound, ocular tissue prolapse, placement of a primary intraocular lens, and rural location.<sup>103-105</sup>

The incidence of infectious endophthalmitis after penetrating injury with IOFB was reported higher, varying from 1.3% to 60%.<sup>101,105-106</sup> A delay in IOFB removal or primary repair of the wound more than 24 hours after the injury have been associated with the increased risk of endophthalmitis<sup>107</sup> (see also [Chapter 90](#), Endogenous endophthalmitis).

### Intraocular Foreign Body

The presence of an IOFB affects visual prognosis in three ways: (1)

in the structural damage induced by the IOFB (e.g., retinal tear); (2) as a vehicle for delivery of infectious agents; and (3) in the chemistry of the IOFB (e.g., pure copper is very inflammatory).

Preoperative retinal detachment, the location and the size of IOFB, and scleral or corneoscleral entry wound are predictive of a postoperative retinal detachment.<sup>102,106,108</sup> IOFBs also have a related higher risk of endophthalmitis, which increases dramatically when the IOFB is of a non-metallic material.<sup>106</sup> A chronically retained iron IOFB results in an extinguished electroretinogram and blindness, referred to as ocular siderosis, when there is progressive deposition of iron in the ocular tissues. Collections of dense ferritin particles are seen in the cytoplasm and organelles of ocular cells, and it has been hypothesized that these large accumulations cause physical damage that kills retinal cells.<sup>109</sup> Copper IOFBs are of particular concern because they can rapidly elicit a sterile endophthalmitis-like reaction with hypopyon and retinal detachment. Ionization of copper causes changes in the neurosensory retina that, if left untreated, can lead to loss of vision within a few hours.<sup>110</sup>

Posttraumatic infection and the presence of an IOFB are likely to increase the risk of PVR. Definitive treatment involves vitrectomy, removal of the IOFB, and intravitreal as well as systemic antibiotic therapy.<sup>111</sup>

## Combat Ocular Injury

The main mechanism of open-globe injury in the military population is secondary to blast explosions, e.g., from improvised explosive devices (IEDs). Blast-associated injuries have been demonstrated to result in poor functional outcomes despite surgical intervention because of the surgical complexities and extensive blunt ocular concussive damage.<sup>112-113</sup>

Intraocular foreign bodies in combat-related ocular injury may have a reduced risk of endophthalmitis since they are usually propelled with high velocity from the explosion and may attain high temperatures, leading to self-sterilization. Predictably, visual outcomes were substantially associated with the depth of penetration of the IOFBs rather than with the timing of removal.<sup>113</sup>

# Therapeutic Aspects

## Surgical Approach

Throughout the literature on the pathophysiology of ocular trauma and related wound healing processes, vitrectomy is shown to be beneficial in that it removes the blood, vitreous scaffolds, and other stimuli for PVR (see [Chapter 114](#), Surgery for ocular trauma, for a description of trauma principles and treatment techniques).

Although progress in instrumentation and surgical techniques has provided dramatic improvements in anatomic repair, including repairing the laceration, reattaching the retina, and removing IOFBs after open-globe injury, a variety of late complications may develop, including new or recurrent retinal detachment and progressive proliferative membranes.<sup>114–115</sup> Therefore, pharmacologic approaches have been studied to modify the wound healing process by inhibiting the development of PVR.

## Pharmacologic Approach

Corticosteroids reduce intraocular inflammation and adversely affect wound healing.<sup>116</sup> Machemer and Tano et al. suggested intravitreal application of steroids to suppress inflammation locally and to reduce proliferation of cells in patients with aggressive PVR.<sup>117,118</sup> Since soluble cortisone is washed out of the eye within approximately 24 hours after a single intravitreal injection, the use of crystalline triamcinolone has been described for the treatment of PVR. As part of its wide utilization for a number of other retinal diseases, intravitreal triamcinolone is now commonly used in PVR.<sup>119</sup> However, posttraumatic PVR is a long-term complication that may require drug release over months, and long-term injections of triamcinolone are associated with complications, such as elevated intraocular pressure, cataract formation, and endophthalmitis.<sup>120</sup>

Antiproliferative drugs have been considered for the treatment of PVR, and a wide spectrum of drugs such as 5-fluorouracil, daunomycin, cyclosporine, mitomycin C, hypericin, and Taxol have been tested in experimental models or human clinical trials to decrease uncontrolled mitogenic activity of the cells at the

vitreoretinal interface.<sup>30,121-128</sup> However, none of these drugs was entirely satisfactory because their inhibitory effects were transient, and most have a narrow therapeutic window.<sup>127-128</sup>

Agents that block growth factors and their signaling also have been considered to modify the wound healing process. Targeting PDGFR- $\alpha$ , HGF, and protein kinase C through approaches such as direct-binding blockers, receptor blockers, and gene therapy seem to have potential in experimental models but further tests in humans are required prior to clinical use.<sup>129-132</sup> The recent study demonstrated non-PDGF-mediated activation of PDGFR- $\alpha$  involves the development of PVR and the inhibition of this pathway via neutralization of VEGF-A using ranibizumab resulted in a protection for the development of PVR in rabbit models.<sup>78</sup> These findings suggest that inhibitors of PDGFR- $\alpha$  and the related pathway would be a potential target to prevent development of PVR, but it needs to be further studied for the treatment of PVR.

Various MMP inhibitors have been suggested to reduce the severity of PVR because cell-mediated collagen contraction and cell migration and invasion in PVR are mediated by MMPs, and these inhibitors may be adjunctive to other pharmacologic approaches.<sup>95-97,100</sup>

Although these therapies would likely be of no use in the treatment of an established membrane, their possible use in the prevention of intraocular proliferation in specific high-risk populations with ocular trauma is being explored. Recent advances in drug delivery to the vitreous and retina including injectable particles and implantable devices may be even more helpful for these pharmacologic approaches for the treatment of PVR.<sup>133</sup>

## Conclusion

Severe open-globe injuries continue to be a major cause of ocular morbidity. The advent of vitrectomy with adjunct procedures in the 1970s has led to more successful anatomic results and a decreased rate of enucleation. Functional success, however, remains limited. In addition to the nature of the injury and the location and extent of the initial damage, the subsequent wound healing process contributes further anatomical and functional damage. Wound

healing in the eye occurs in a manner and with processes and cell cycles similar to that of other bodily tissues. Injury to the vitreous and breakdown of the blood–retinal barrier are major risk factors for the development of PVR with the expression of a variety of cytokines and growth factors that exert effects on the RPE, fibroblasts, and glial cells. These cells proliferate, migrate, change their pattern of gene expression, and develop preretinal membranes. The contractile properties of these cells may overcome the normal adhesion between the neurosensory retina and the RPE, causing a traction retinal detachment to occur.

Vitreous surgery and adjunct procedures remain the primary mode of therapy as these treatments eliminate stimulating factors and remove the scaffold for proliferation. Future progress may include pharmacologic approaches. There are theoretical reasons to favor strategies that emphasize the inhibition of cellular proliferation, inhibition of growth factors and cytokines, or inhibition of intracellular signaling pathways, or possibly the alteration of cellular function through gene therapy. For the future, these approaches need to be further studied, not only to moderate wound healing but to restore functional vision loss.

**Conclusion**

## Introduction

The use of scleral buckles in conjunction with chorioretinal adhesions around retinal breaks forms the basis of therapy for some uncomplicated rhegmatogenous retinal detachments. Other techniques for retinal reattachment, such as the use of vitrectomy and a gas bubble or pneumatic retinopexy, are described in other chapters. Understanding the biomechanics of scleral buckles helps the surgeon to choose when their use is most appropriate for retinal

detachment repair. This chapter examines the physical effects of scleral buckles on the eye and the mechanism of action of scleral buckles in promoting retinal reattachment.

## Effects of Scleral Buckles on the Geometry of the Eye

The scleral buckle alters the shape of the eye, depending primarily on the type of buckling material used, the location and tension of the scleral sutures, and the circumferential tightening of an encircling buckle. The changes in the geometry of the eye may have a number of secondary effects that may be clinically important to the patient. These include changes in the axial length of the eye, induced spherical equivalent and astigmatic refractive errors, changes in the volume of the eye, and altered compliance (ocular rigidity) after scleral buckle placement. Some of these effects are also beneficial in helping to reattach the retina.

### Axial Length Changes After Scleral Buckles

The axial length of the eye may change after placement of a scleral buckle. Radial soft silicone sponges appear to induce little change in the axial length of the eye. Segmental scleral buckles may cause a hyperopic shift while encircling scleral buckles may produce increases or decreases in axial length, depending on the scleral buckle material, the location of the buckle, and the height of the buckle.<sup>1,2</sup> Hard silicone encircling buckles most commonly increase the axial length of the eye,<sup>3-5</sup> although some eyes show no apparent change in axial length after placement of an encircling buckle.<sup>6,7</sup> Occasionally, high encircling silicone buckles may decrease the axial length of the eye.<sup>4,8</sup>

The changes in axial length induced by circumferential scleral buckles can be understood by analyzing the geometry of the eye with an encircling buckle in place. If a circumferential buckle is tightened around the equator of the eye, the first effect is to decrease the circumference of the eye in coronal cross-section, causing the eye to assume an elliptical shape in horizontal cross-

section. The normally spherical human eye acquires the shape of a prolate spheroid after placement of a broad circumferential buckle (Fig. 103.1). The eye is still circular in coronal cross-section, because the encircling buckle constricts the equator of the eye into a circle of smaller circumference. The eye becomes more elliptical in sagittal and horizontal cross-section. A decrease in the circumference of the eye caused by indentation from a scleral buckle in the coronal plane is accompanied by an increase in the anteroposterior dimension of the eye (Fig. 103.1) in the sagittal and horizontal planes as the eye becomes elongated by the equatorial constriction from the encircling scleral buckle. This change from a sphere to a prolate spheroid occurs primarily because of the relative inelasticity of the sclera at physiologic intraocular pressures in the fluid-filled eye. If the circumferential buckle is tightened high enough, the eye will assume the shape of a dumbbell. The anteroposterior axial length of the eye decreases at very high circumferential buckle heights because part of the circumference of the sclera in the horizontal and sagittal cross-sections is used to create the dumbbell-shaped indentation in the sclera (Fig. 103.1).

**FIG. 103.1** (A) The normal spherical shape of the eye. (B) The spherical eye acquires the shape of a prolate spheroid after placement of a moderately high circumferential buckle. Horizontal and sagittal cross-sections of an eye with a broad circumferential buckle at moderate buckle heights show an ellipse. Coronal cross-section of an eye with a circumferential buckle shows a circle. The anteroposterior axial length of the eye increases at moderate buckle heights. (C) The eye acquires a dumbbell shape at very high circumferential buckle heights. Coronal cross-section of an eye with a very high circumferential buckle still shows a circle, but the sagittal and horizontal cross-sections show a

dumbbell shape. The axial length of the eye decreases at very high buckle heights.

Placement of two mattress sutures per quadrant to invaginate the sclera beneath a circumferential buckle has additional effects on the geometry and axial length of the eye. Indentation of the sclera by tightening mattress sutures around a circumferential hard silicone exoplant causes a decrease in the axial length of the eye if there is no concomitant circumferential shortening of the encircling buckle.<sup>4</sup> The mattress sutures pull together the anterior and posterior sclera where the suture bites are anchored, decreasing the axial length of the eye. As the mattress sutures are tightened, the sclera is indented by the circumferential buckle beneath the mattress sutures, causing the eye to acquire a dumbbell shape in horizontal and sagittal cross-sections.

These two effects, circumferential shortening and scleral invagination by mattress sutures, must be considered in understanding the geometry of the eye after placement of an encircling scleral buckle. The first effect, circumferential shortening, increases the axial length by changing the shape of the eye from a sphere to a prolate spheroid with mild to moderate circumferential tightening of an encircling buckle. The second effect, invagination of the sclera around a broad encircling element with mattress sutures, contributes to a decrease in the axial length of the eye.

The increases in axial length from circumferential shortening of the eye predominate over decreases in axial length from scleral invagination at low to moderate buckle heights, producing a shift toward myopia. The decreases in axial length from scleral invagination tend to predominate over increases in axial length at very high buckle heights. Some eyes with moderate to high circumferential buckles have no net change in axial length when the circumferential shortening and scleral invagination precisely balance. It would be desirable to try to adjust circumferential buckle to minimize axial length changes, but this is difficult to achieve, since other factors, such as support of the retinal breaks and relief of vitreoretinal traction, are more important surgical goals.

A geometric model to explain the effects of circumferential scleral buckles on the axial length and to predict these axial length changes was developed to improve the predictability of these axial length

changes. The geometric model of the effects of scleral buckles on axial length is based on the following assumptions: First, the overall contour of the eye with a scleral buckle is assumed to be an ellipse. Second, the circumference of the eye is constant, because the buckle does not stretch or shrink the sclera substantially. Fig. 103.2 gives a gross estimate of the circumference of the indented eye wall (which equals  $\pi$  times axial length) after a scleral buckle, based on the preoperative perimeter of the eye and the amount of indentation of the eye wall by the scleral buckle at the equator. The axial length of the eye can then be calculated following placement of the scleral buckle, using the formula to solve for the axial length to predict the effect of the scleral buckle on refraction.

**FIG. 103.2** (A) The axial length changes induced by a circumferential scleral buckle may be estimated grossly by this formula by solving the equation for 'a' if the original circumference of the eye, the amount of buckle indentation, and equatorial shortening of the eye are known. (B) Geometric model relating circumferential buckle shortening, scleral indentation, and axial length.

## Refractive Errors Caused by Scleral Buckles

Three primary types of refractive error can be induced by scleral buckles used for retinal reattachment. The first type is an astigmatic error caused by changes in the corneal curvature; the second type is a change in the spherical equivalent induced by changes in axial length, anterior chamber depth, or position of the crystalline lens. The third are higher-order aberrations that were found to be greater

when segmental scleral buckles are used rather than circumferential buckles.<sup>9</sup> The higher-order aberrations persist at least 3 months but may improve over time.

## **Astigmatic Errors**

Regular and irregular corneal astigmatism are most likely to result from placement of segmental or radial explants.<sup>8,10-13</sup> Some astigmatic errors may be persistent, requiring correction,<sup>1</sup> although many astigmatic errors improve within several months following surgery.<sup>14</sup> Corneal astigmatism usually results when a high, anterior radial buckle is placed. The indentation of a radial buckle in the anterior sclera can be transmitted to the cornea because of the inelasticity of both the sclera and the cornea. If the eye were highly elastic like a balloon, indentation of the eye from a radial buckle would be present only directly under the buckle. The radial buckle would have no effect on the surrounding sclera. Because the sclera is less elastic than the rubber skin of a balloon, the radial buckle causes some indentation in the surrounding sclera beyond the extent of the buckle itself. The greatest astigmatic errors occur in eyes in which a segmental buckle spans one to two quadrants.<sup>15</sup> Encircling circumferential buckles of uniform width rarely produce substantial astigmatism.

## **Spherical Equivalent Errors**

Changes in refraction from scleral buckles caused by changes in axial length and lens position are more common than astigmatic errors. Most eyes with encircling buckles have a small shift toward myopia; this is associated with an increase in axial length.<sup>5,8,16</sup> Shallowing of the anterior chamber associated with displacement of the lens anteriorly in phakic eyes with an encircling buckle may also contribute to a shift toward myopia.<sup>8</sup> Anterior displacement of the lens becomes less pronounced several months after retinal reattachment in most eyes.<sup>16</sup> The buckle height decreases substantially in eyes with radial buckles over a period of months, while buckle height does not decrease as much in eyes with circumferential buckles.<sup>17</sup> Some eyes with high circumferential scleral explants have a shift in refraction toward hyperopia.<sup>7</sup> The changes in axial length and refractive error with different scleral

buckles are reported in the literature and are summarized in [Table 103.1](#). When scleral buckles are placed in children, the scleral buckle may retard growth-related increases in the axial length of the eye, causing the eye to develop less myopia than the fellow eye.<sup>21</sup>

**TABLE 103.1**

**Changes in Axial Length and Refractive Error with Different Scleral Buckles**

Authors	Buckle Type	Axial Length (mm)	Refraction (diopter)
Jacklin <sup>18</sup>	Narrow band	-1.3	
Rubin <sup>8</sup>	2-mm band, low buckle	+0.44	-1.25
	2-mm band, moderate buckle	+1.09	-1.89
	2-mm band, high buckle	-0.35	+0.47
Burton et al. <sup>19</sup>	Implant + explant	No net change	
Larsen and Syrdalen <sup>5</sup>	2-mm band	+0.98	
Kiernan et al. <sup>7</sup>	Half of a 7.5-mm sponge	No net change	No net change
Smiddy et al. <sup>20</sup>	Band ± tire	+0.99	-2.75

**Change in Refractive Error Over Time**

The change in refractive error induced by the scleral buckle also tends to normalize after several months due to two main factors. (1) In eyes with silicone bands such as #40 and #240-style, there is a stress relaxation of the band over time.<sup>22</sup> This can be understood by taking a rubber band and stretching it to near breaking. The amount of force needed to stretch the rubber band to the same length decreases with successive stretching cycles. This explains why the buckling effect from an encircling band tends to decrease over time. (2) In eyes with silicone sponges or tires held in place by sutures, the scleral invagination caused by the suture also decreases over time as the suture erodes the sclera where the suture enters and exits the scleral tunnel. This also decreases the buckling effect and refractive changes months to years following surgery.

**Scleral Chord Versus Scleral Arc Length**

The curvature of the spherical globe must be considered when distances on the surface of the globe are measured. Calipers are commonly used to measure distances for placement of scleral sutures and to measure the shortest line between two points on the

spherical globe, which is called the scleral chord length (Fig. 103.3). The distance measured along the curved surface of the globe between two points is the scleral arc length. The scleral chord length measured by the calipers is always shorter than the scleral arc length.<sup>23</sup> The scleral arc length can be calculated from the scleral chord length, and vice versa, using the formula in Fig. 103.4. Scleral arc length and scleral chord length are similar when the chord length is a small percentage of the radius of the globe. A caliper setting (chord length) of 8 mm corresponds to a scleral arc length of 8.16 mm, a 2% error; a caliper setting of 13 mm corresponds to a scleral arc length of 13.74 mm, a 5.7% error. The discrepancy between scleral chord length and scleral arc length increases nonlinearly whenever calipers are used to measure large distances on the globe.

**FIG. 103.3** Calipers are used to measure distances for placement of sutures around scleral buckles and to measure the shortest distance between two points on the sclera (scleral chord length). The distance between two points on the surface of the sclera (scleral arc length) is always longer than the scleral chord length.

$$S = R \left( \frac{\pi}{90} \sin^{-1} \left( \frac{C}{2R} \right) \right)$$

**FIG. 103.4** The scleral arc length (*S*) can be calculated from the scleral chord length (*C*) and vice versa. The inverse sin in the formula must be calculated in degrees to obtain the scleral arc length. The difference between the scleral arc length and the scleral chord length increases nonlinearly with larger distances measured by the calipers. *R*, radius of eye.

## Effects on the Internal Geometry of the Eye

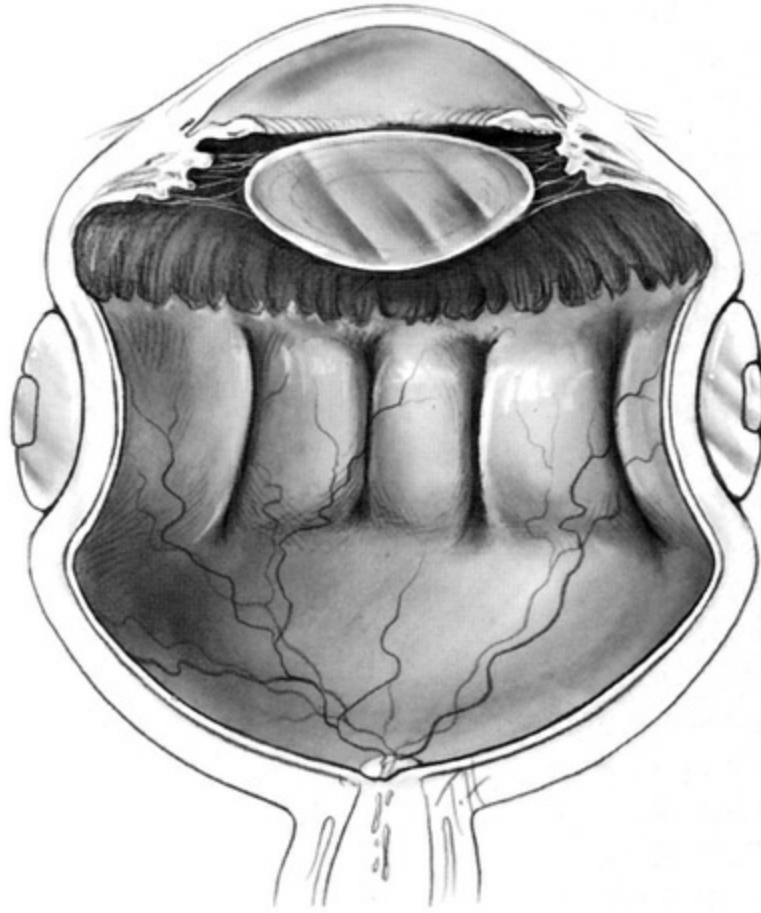

It is the buckling effect created by an episcleral buckle that is desirable in closing retinal breaks and relieving vitreoretinal traction. Intrascleral buckles were used in the early days of retinal detachment repair but are not currently used due to the difficulty in creating large, partial-thickness scleral flaps. The geometry of the episcleral scleral buckle and the technique of scleral buckle and suture placement determine the shape and height of the indentation. It may be desirable to create a high buckling effect in the treatment of certain retinal detachments, and suture placement is important in these eyes. Deep suture bites of at least 4–5 mm long are needed to allow maximum tension to be placed on the suture and transmitted to the scleral buckle. Superficial or short scleral suture bites tend to tear through the sclera and decrease the

effective buckle height. The tearing strength of 4-0 silk sutures through the sclera measured by a tensile strength tester is significantly greater for deep suture bites (50–90% depth) than for superficial suture bites (20–30% depth) (Thompson, unpublished data).

The major variables that determine the internal geometry of indentation induced by the scleral buckle explant include (1) shape of the buckle; (2) composition of the buckle (silicone sponge versus hard silicone); (3) suture placement with respect to the dimensions of the buckle; (4) suture tension; (5) distribution of tension from the suture to the buckle; and (6) intraocular pressure. An analysis of scleral indentation from a 5-mm radial silicone sponge showed that the following factors decreased indentation: (1) placement of the suture bites too close or too far apart; (2) high intraocular pressure; (3) short suture bites in the sclera; (4) loose sutures; and (5) use of a half-thickness sponge compared with a full-thickness sponge. Factors that increased scleral indentation included (1) low intraocular pressure and (2) tight sutures.<sup>24,25</sup>

The orientation of the scleral buckle also helps to determine the topography of the indentation in the sclera. Radial buckles appear to offer advantages in the support of a solitary horseshoe-shaped retinal tear.<sup>26–28</sup> Moderate to high circumferential encircling scleral buckles cause radial folding of the retina. This radial folding occurs because the encircling buckle forces a reduction in the normal circumference of the eye in the equatorial meridian. The sclera and retina are unable to shrink to the new, smaller circumference, so the “excess” retina, choroid, and sclera are thrown into radial folds to conform to the smaller circumference of the eye induced by the encircling buckle (Fig. 103.5). The circumferential shortening of the eye beneath an encircling buckle is the basis of the fishmouth phenomenon (Fig. 103.6).<sup>29,30</sup> Wedge-shaped buckles and radial scleral buckles minimize the risk of the fishmouth phenomenon because they cause less circumferential shortening over the retinal tear than do encircling scleral buckles.

**FIG. 103.5** Radial retinal folds on a broad encircling buckle induced by shortening the circumference of the eye. The sclera, choroid, and retina are unable to shrink to the smaller globe circumference beneath the scleral buckle indentation, so the “excess” retina on the buckle is thrown into folds.

**FIG. 103.6** The fishmouth phenomenon results when a radial fold bisects a retinal tear. The radial fold tends to keep the tear from settling on the buckle and may lead to persisting retinal detachment. The fishmouth phenomenon is most commonly produced by circumferential shortening of the globe from an encircling buckle, causing a radial fold to pass through a horseshoe-shaped retinal tear. Minimizing the circumferential shortening of the eye with a radial or wedge-shaped buckle decreases the likelihood of the fishmouth phenomenon.

Circumferential encircling buckles are necessary in some eyes because of multiple retinal breaks, circumferential vitreoretinal traction, or circumferential shortening of the retina caused by epiretinal membranes. Anterior circumferential vitreoretinal traction caused by cell-mediated contraction of the vitreous base or peripheral epiretinal membranes associated with funnel-shaped retinal detachments in eyes with proliferative vitreoretinopathy decrease the effective circumference of the peripheral retina. A broad circumferential encircling buckle is preferable in this

situation because it reduces the circumference of the eye wall, allowing reapposition of the retina against the retinal pigment epithelium (RPE). This can allow the surgeon to avoid having to perform circumferential retinectomy to remove the foreshortened retina. The risks and benefits of radial or encircling circumferential buckles must be evaluated in each circumstance so as to choose the optimal geometry of the scleral buckle for the particular retinal tear and retinal detachment configuration.

## Volume Changes in the Eye After Scleral Buckles

Indentation of the eye wall by a scleral buckle displaces fluid from the vitreous cavity, causing a reduction in the volume of the vitreous cavity. This occurs because a sphere contains the largest volume of fluid with the least surface area. The amount of fluid displaced depends on the buckle type and configuration. The amount of volume displacement is small for most buckles but can be substantial for broader encircling buckles. Estimation of the intraocular volume of an eye with a scleral buckle is important in several circumstances: (1) estimation of how much fluid must be withdrawn from the vitreous cavity or drained from the subretinal space to permit placement of a specific scleral buckle; (2) injection of pharmacologic agents such as antibiotics or antimetabolites into the vitreous, when therapeutic and toxic concentrations must be considered; and (3) injection of expansile gases into the vitreous. The volume displacement of a scleral buckle can be predicted as a function of the following variables: (1) the axial length of the eye =  $2 \times$  internal radius; (2) the buckle width measured anterior and/or posterior to the equator; (3) the buckle circumference; and (4) the buckle height. The formula for determining volume displacement by a scleral buckle is given in [Fig. 103.7](#). A 5-mm radial silicone sponge displaces only about 0.2 mL, or 5%, of the vitreous cavity volume.<sup>31</sup> This is why placement of a radial sponge in a nondrainage procedure only occasionally elevates the intraocular pressure substantially. A 2.5-mm-wide silicone encircling band (#240 style) displaces about 0.5 mL, or 12%, of the vitreous cavity volume.<sup>31</sup> A 7-mm-wide hard silicone encircling buckle (#287 style)

displaces from 1.3 mL (33%) to 1.7 mL (43%) of the vitreous cavity volume of a phakic eye, depending on the buckle geometry and height.<sup>31</sup> The decrease in vitreous cavity volume increases with increasing buckle width and height for circumferential buckles, as shown in Table 103.2. Magnetic resonance imaging has been used to confirm the decreased volume of the eye induced by scleral buckles. An encircling band in this study reduced the vitreous cavity volume by an average of 1.7 mL.<sup>32</sup>

$$V = c \frac{\pi}{360} (2 rh - h^2) (w1 + w2)$$

- V - Volume displaced (mm<sup>3</sup>)
- c - Circumference of buckle (degrees)
- r - Internal radius of eye (mm)
- h - Height of buckle (mm)
- w1 - Width of buckle anterior to equator (mm)
- w2 - Width of buckle posterior to equator (mm)

**FIG. 103.7** Indentation of the sclera by a scleral buckle displaces fluid from the vitreous cavity. The ocular volume displacement from a scleral buckle is a function of the circumference of the buckle, the radius of the eye, the height of the buckle, and the width of the buckle (1 mL = 1000 mm<sup>3</sup>).

**TABLE 103.2**

**Estimated Vitreous Cavity Volume Displacement of Scleral Buckles**

Scleral Buckle	Vitreous Cavity Volume Displacement (mL)
Half of 5-mm sponge	0.09–0.15
3×5 mm sponge	0.11–0.20
5-mm round sponge	0.14–0.22
#240 style (circumferential)	0.47–0.48
#276 style (circumferential)	1.08–1.13
#287 style (circumferential)	1.32–1.57
#280 style (circumferential)	1.82–1.88

Data from Thompson JT, Michels RG. Volume displacement of scleral buckle. Arch Ophthalmol 1985;103:1822–4.

**Scleral Buckles, Ocular Rigidity, and Corneal**

## Hysteresis

Placement of a scleral buckle changes the normal ocular rigidity. Ocular rigidity is the change in intraocular pressure for a given change in intraocular volume and is a measure of the elasticity of the eye. Intraocular pressure normally increases rapidly as microliter volumes are injected into the eye. The increase in intraocular pressure (ocular rigidity) is decreased in eyes with an encircling scleral buckle because the volume of the vitreous cavity was decreased with placement of a scleral buckle.<sup>33,34</sup> This decrease in volume is related to changes in the shape of the eye caused by the scleral buckle.<sup>31</sup> As the intraocular pressure is increased by injection of saline solution or gas into the eye, the eye becomes less elliptical and more spherical as the sutures holding the buckle are stressed or the encircling band is stretched. The net effect is to decrease the buckling effect and to increase the intraocular volume such that the intraocular pressure does not rise as rapidly as in the normal eye. This effect can be better understood by considering an eye with an encircling buckle and no invagination by scleral sutures. If water is injected into the eye, the encircling buckle will stretch as the eye assumes a more spherical shape. Once the buckle has stretched so that the eye returns to its original spherical shape (before placement of the buckle), the intraocular pressure will increase rapidly. The changes in ocular rigidity have several important clinical ramifications. First, methods of measuring intraocular pressure that depend on a standard ocular rigidity, such as the indentation tonometry (Schiotz), electronic indentation tonometry (Tonopen®), pneumotonometer, and ocular response analyzer (ORA), are less accurate in eyes with scleral buckles. The ORA tends to underestimate true IOP.<sup>35</sup> Second, an injection of fluid or gas into an eye with a scleral buckle will cause less elevation of intraocular pressure than injection of the same volume into a normal eye, if all other factors are equal. Placement of an intraocular gas bubble into the vitreous also itself reduces ocular rigidity because the gas in the vitreous cavity is more compressible than the vitreous fluid it replaces. This has been confirmed in a study showing that eyes with scleral buckles and small intraocular gas bubbles have less increase in intraocular pressure with air travel than eyes without scleral buckles.<sup>36</sup> Eyes with reduced ocular

rigidity from an intraocular gas bubble and an encircling scleral buckle require even larger volumes of fluid aspiration to reduce the intraocular pressure than normal eyes with elevated intraocular pressure.<sup>37</sup>

Corneal hysteresis is a property that measures the elasticity of the cornea by comparing the difference in pressure at which the cornea is depressed by an air jet compared to the pressure at which it bends back to its normal shape. The presence of a scleral buckle in eyes with vitrectomy increases corneal hysteresis compared to eyes without a scleral buckle, and this had secondary effects on intraocular pressure measurements.<sup>35</sup>

## **Scleral Buckles and Ocular Blood Flow**

Encircling scleral buckles also change ocular blood flow.<sup>38</sup> This does not create clinically recognizable problems in most patients undergoing scleral buckle for retinal reattachment but can create ocular ischemia or peripheral visual field defects.<sup>39</sup> As a result, a few surgeons advocate cutting the circumferential band routinely after the retina has reattached to improve ocular blood flow.<sup>40</sup>

## **Effects of Scleral Buckles on the Rpe and Retina**

A number of forces are associated with the production of retinal tears and detachments, and there are also forces that promote attachment of the retina. Scleral buckles act to alter the former and enhance the latter.

## **An Overview of Forces Acting on the Retina**

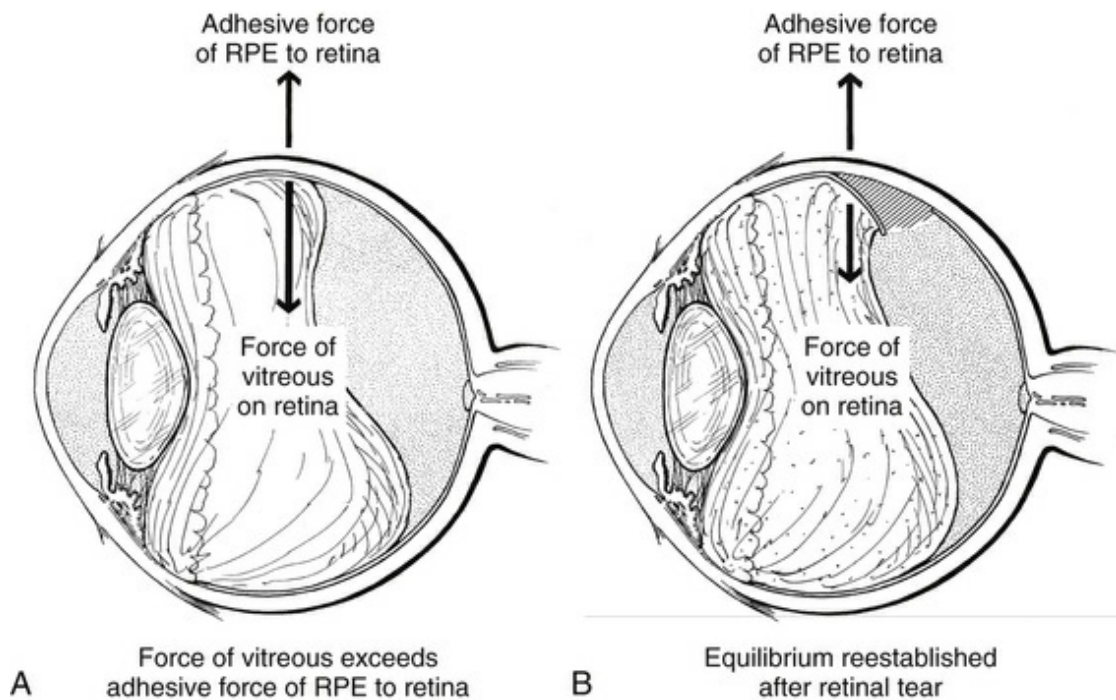

Vitreoretinal traction forces play an important role in the pathogenesis of retinal tears, rhegmatogenous retinal detachments, and traction retinal detachments. Forces that act on the retina have both magnitude and direction and are best represented by vectors. A force vector is represented graphically by an arrow with a length and a direction. The length of the vector is proportional to the magnitude of the force, and the direction indicates the direction

along which the force acts (Fig. 103.8). Simple arithmetical operations can be performed on vectors to determine the net force produced by two forces acting on the same point. The simplest way to add vectors is to draw the vectors so that the arrowhead of the first vector connects to the tail of the second vector. A new vector, which is the sum of the two vectors, is drawn from the tail of the first vector to the head of the second vector (Fig. 103.8).

**FIG. 103.8** Vitreoretinal traction forces have both magnitude and direction. These forces can be represented by vectors. Simple arithmetical operations, such as addition of vectors  $A$  and  $B$ , can be performed by drawing the resultant vector  $A + B$  from the tail of  $A$  to the arrowhead of  $B$ .

A second important concept is the equilibrium of vector forces. If two vector forces of equal magnitude simultaneously act in opposite directions on the same point, there is no displacement of the object at that point. A simple example of equilibrium involving opposing vector forces is found in localized vitreous traction on the retina at the edge of a posterior vitreous detachment (PVD). If the force of vitreous traction on the retina at the edge of a PVD is counterbalanced by retinal adherence to the eye wall, no tear will develop. If vitreous traction on the retina exceeds photoreceptor adherence to the RPE and retinal tensile strength, a retinal tear will develop to reestablish equilibrium (Fig. 103.9). Vector algebra can be used to understand how various forces acting on the retina lead to retinal tears, traction retinal detachments, and rhegmatogenous retinal detachments. Scleral buckles help to alter the magnitude and direction of these vectors, thus promoting closure of retinal breaks and retinal reattachment.

**A** Force of vitreous exceeds adhesive force of RPE to retina  
**B** Equilibrium reestablished after retinal tear  
**FIG. 103.9** (A) A retinal tear will result if the force of a posterior vitreous detachment exceeds the adhesive force of the retinal pigment epithelium (RPE) to the retina and the tensile strength of the retina. (B) The retinal tear reestablishes equilibrium between the traction of the posterior hyaloid on the retina and the adhesive force of the RPE.

## Forces That Lead to Retinal Tears and Detachments

Most retinal breaks are caused by a combination of forces, including vitreous traction and fluid movement during rotary ocular movements, and sometimes traction associated with epiretinal membranes.

### Vitreous Traction

Vitreous traction may be exerted in many different directions (i.e., perpendicular, tangential, or oblique) with respect to the curved surface of the retina. An example of relatively pure perpendicular (or radial) vitreous traction occurs with a superior horseshoe-shaped tear resulting from posterior vitreous detachment (Fig. 103.10). As the posterior hyaloid detaches, gravity causes the

vitreous gel to pull away from the superior retina. A focal adhesion of the vitreous to the retina may cause a tear to develop if the force exerted by the vitreous on the retina exceeds the adherence of the photoreceptors to the RPE and the tensile strength of the retina. The force exerted by the vitreous is primarily perpendicular or oblique to the surface of the retina. The importance of gravitational forces on the vitreous in the genesis of retinal tears is emphasized by the observation that most horseshoe-shaped tears occur in the superior retina. An example of relatively pure tangential traction on the surface of the retina occurs with a localized epiretinal membrane causing distortion of the macula (Fig. 103.11). Most of the traction from an epiretinal membrane occurs tangentially on the surface of the retina, although there is a small inward radial component to this traction because of the concave shape of the eye wall.<sup>41</sup>

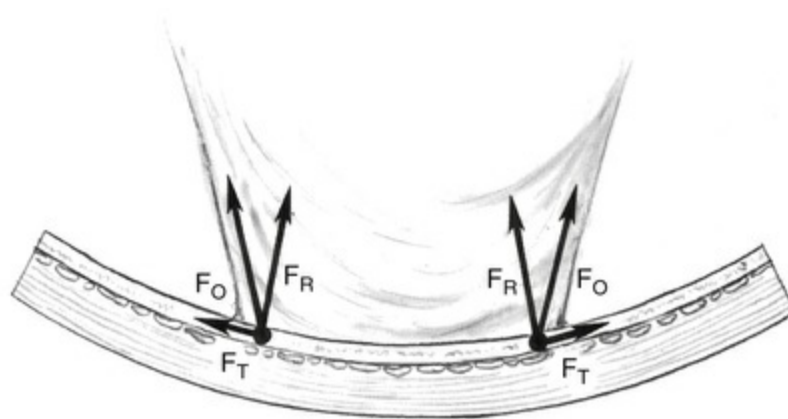

Vitreous traction directed toward center of eye

**FIG. 103.10** Radial retinal traction. The force of gravity on the vitreous in vitreoretinal attachment to the superior retina causes traction on the retina directed radially toward the center of the eye. Radial retinal traction is more likely to lead to a retinal tear than is tangential retinal traction. Gravitational forces of the vitreous on the retina can explain the greater incidence of superior horseshoe-shaped retinal tears.

**FIG. 103.11** Tangential retinal traction. The elastic force of an epiretinal membrane adherent to the surface of the retina causes relatively pure tangential retinal traction ( $T_1$ ). The traction is parallel to the curved surface of the retina at each point on the retina. There is also a small inward radial component to the traction ( $F_R$ ), caused by the epiretinal membrane because of the curved surface of the eye.

It appears that radial traction on the retina is more likely to produce retinal breaks than is tangential traction. Most vitreoretinal traction causing a retinal tear, traction retinal detachment, or rhegmatogenous retinal detachment is oblique to the surface of the retina. Oblique vitreoretinal traction can be separated into orthogonal vectors (oriented at  $90^\circ$ ) composed of varying mixtures of radial and tangential traction (Fig. 103.12). Some of the forces that can cause traction on the retina include (1) gravitational forces on the vitreous gel attached to the retina, particularly when the vitreous is adherent to a localized area in the superior retina and surrounded by an area of vitreous detachment; (2) inertial forces transmitted from the vitreous to the retina during ocular movements or blunt trauma; (3) contraction of the vitreous gel at sites of vitreoretinal attachment caused by cellular proliferation; and (4) contractile fibrocellular membranes on the surface of the retina posterior to a PVD. Myopic eyes with long axial lengths have higher shearing forces on the retina with saccadic eye movements than emmetropic eyes, which may predispose them to develop retinal tears.<sup>42</sup>

**FIG. 103.12** Vitreoretinal traction oblique to the surface of the retina is composed of different mixtures of radial and tangential traction. An oblique vector ( $F_O$ ) resulting from vitreoretinal traction can be divided into orthogonal vectors consisting of a radial vector ( $F_R$ ) directed toward the center of the eye and a vector tangent to the surface of the retina ( $F_T$ ).

## Fluid Movement and Retinal Breaks

Retinal traction can be created by saccadic eye movements in eyes with posterior vitreous detachment, and this traction may lead to retinal tears.<sup>43</sup> Fluid currents in eyes with retinal tears may allow fluid to move from the vitreous cavity into the subretinal space, creating a rhegmatogenous retinal detachment. Rotational eye movements appear to be especially important in forcing fluid through a retinal tear, leading to retinal detachment.<sup>44,45</sup> Fluid movement associated with rotational eye movements appears more likely to cause a retinal detachment when vitreous traction elevates the flap of a retinal tear than when a retinal hole is present without vitreous traction. The elevated retinal flap with vitreous traction may trap vitreous fluid and funnel it into the tear. The vitreous fluid can then act as a wedge, interposing itself between the retina and the RPE as the eye rotates (Fig. 103.13).<sup>46</sup> Once the normal adhesion of the retina to the RPE is disrupted, rotational eye movements can force additional fluid into the subretinal space, thereby extending the retinal detachment. A retinal hole in the absence of vitreous traction does not catch the vitreous fluid from rotational eye movements as easily and thus is less likely to lead to retinal detachment. If retinal detachment occurs, continued fluid

flux through the retinal tear is important in maintaining and enlarging the retinal detachment.<sup>47-49</sup>

**FIG. 103.13** Rotation of the eye causes traction on the retina at the insertion of the vitreous gel to the retina at the vitreous base. The inertia of the vitreous fluid may dissect under the flap of a horseshoe-shaped tear, resulting in retinal detachment. Additional fluid may be forced under the retina with rotational eye movements.

## **Epiretinal Membranes, Cellular Proliferation, and Retinal Breaks**

Epiretinal membranes with cellular proliferation on the surface of the retina may also cause retinal breaks and retinal detachment. As the epiretinal membranes contract, they seek the shortest distance between areas of attachment to the concave inner surface of the retina. The shortest distance between two points on the curved retinal surface is a straight line, or chord; the shortest distance between three points on the curved retinal surface is a series of lines

within a single plane. The epiretinal membrane that initially conforms to the concave inner surface of the retina can cause a traction detachment of the retina in the configuration of a plane. The planar configuration occurs because this will minimize the tangential tension within the epiretinal membrane (Fig. 103.14). In most instances the vitreous gel also contributes to the traction retinal detachment. Attachment of the vitreous gel to fibrocellular epiretinal membranes may produce additional radial or oblique traction on the retina, leading to more complicated configurations of retinal detachments such as the table-top traction retinal detachment sometimes seen in eyes with severe proliferative diabetic retinopathy (Fig. 103.15). These radial, tangential, and oblique forces on the retina may also cause retinal breaks, creating a traction–rhegmatogenous retinal detachment. The biomechanics of these detachments are much more complicated because their configuration is determined by an equilibrium of vitreoretinal traction, retinal elasticity, and fluid flux through retinal breaks and absorption of subretinal fluid. The detached retina will assume the configuration that balances all of these synergistic and opposing forces.

**FIG. 103.14** Tangential tension in an epiretinal membrane ( $T_1$ ) with its associated radial retinal traction ( $F_R$ ) may exceed the adhesive force of the retina to the retinal pigment epithelium (RPE). A localized traction retinal detachment will occur if the radial retinal traction ( $F_R$ ) exceeds the adhesive force of the RPE to the retina ( $F_R > F_A$ ). The traction detachment eliminates the radial force pulling the retina away from the eye wall ( $F_R$ ) and also minimizes the tension in the epiretinal membrane ( $T_2 < T_1$ ).

**FIG. 103.15** The configuration of a table-top traction retinal detachment in equilibrium is determined by a combination of tangential ( $F_T$ ) and oblique ( $F_O$ ) vitreoretinal traction forces. This is opposed by forces that promote retinal reattachment, such as the absorption of subretinal fluid ( $F_P$ ).

## Forces That Promote Attachment of the Retina

A number of physiologic forces maintain or attempt to restore attachment of the neurosensory retina to the RPE (see [Chapter 31](#), Cellular effects of detachment and reattachment on the neural retina and retinal pigment epithelium). Adhesions between the neurosensory retina and RPE/choroid also assist in maintaining reattachment. Scleral buckles alter the effects of vitreous traction, epiretinal membranes, and fluid movement.

## Physiologic Adhesion Between Retina and RPE

Several factors promote adhesion between the retina and the RPE. First, adhesion of the RPE and photoreceptors is assisted by a viscous mucopolysaccharide substance between the villous processes of the RPE interdigitating with the photoreceptors.<sup>50</sup> This appears to account for only a small component of the adhesion between the retina and the RPE. Second, an oncotic pressure difference between the choroid and subretinal space makes another small contribution to promoting adhesion of the retina to the RPE.<sup>51,52</sup> The oncotic pressure difference arises because proteins in the choroid cannot easily pass through the RPE and Bruch's membrane into the subretinal space.<sup>53</sup> Third, hydraulic forces on the retina promote adhesion of the retina to the RPE. The hydraulic forces are a result of intravitreal fluid pushing against the retina at a physiologic intraocular pressure. The hydraulic forces are produced by more rapid passage of fluid from the subretinal space through the sclera than from the vitreous through the retina.<sup>54</sup> The hydraulic forces have been compared to an inner tube (the retina) forced against the inner wall of a tire (the sclera). Hydraulic forces are independent of the RPE pump and explain why the retina can remain attached after removal of the choroid and RPE in an eye wall resection, such as is sometimes used for removal of a choroidal melanoma.<sup>55</sup> Hydraulic forces would be expected to produce a lower pressure in the subretinal space than in the intravitreal space. However, attempts to measure this small pressure difference directly have not been successful.<sup>56</sup> Finally, the most important factor maintaining retinal attachment is the RPE pump, which actively removes fluid from the subretinal space, promoting adhesion of the RPE to the photoreceptors.<sup>27</sup> These four types of force maintain apposition of the retina and the RPE.

Several properties of the RPE–photoreceptor adhesion are important in determining the types of retinal tears and retinal detachments that can occur with vitreoretinal traction. The adhesive force between the RPE and photoreceptors paradoxically appears to be weaker with small tractional forces than larger tractional forces *in vitro*.<sup>57</sup> The variability of the strength of adhesion between the retina and the RPE as a function of the tractional force on the retina is a result of the viscoelastic properties of the mucopolysaccharide

holding the retina and the RPE together. These viscoelastic properties can be understood by considering the force required to pull adhesive tape off a surface. The adhesion of the adhesive tape to a surface is lower at lower rates of traction than at higher rates of traction. Hence, the adhesion of the retina to the RPE would be expected to be lower at lower rates of traction than at a higher rate of traction.<sup>57</sup>

The retina itself also behaves like a viscoelastic substance when tractional forces cause elongation of the retina. The retina has greater elongation at lower peeling rates than at higher peeling rates.<sup>57,58</sup> Smaller tractional forces on the retina exerted over a longer period of time tend to produce larger traction retinal detachments than do larger tractional forces over a short period.<sup>59</sup> This can explain why relatively minimal chronic vitreous traction can produce an extensive traction retinal detachment, whereas larger forces from short-lived vitreous traction associated with ocular trauma may produce no retinal tears or detachment. The forces required to produce retinal tears and detachments are greater in vivo than in vitro because of active metabolic processes, such as the RPE pump, that favor retinal adhesion.<sup>60</sup> The presence of vitreous traction, retinal breaks, and fluid currents in the eye may overcome these adhesive forces, leading to retinal detachment. The scleral buckle and chorioretinal adhesion counteract the forces that detach the retina and help reestablish an adhesion between the retina and the RPE.

## **Thermal Chorioretinal Adhesions**

Three different thermal modalities can be used to create a chorioretinal adhesion around retinal breaks associated with a retinal detachment. The first is diathermy, whereby an electric current is applied to the external sclera. The current passes through the sclera, creating a burn that includes sclera, RPE, and retina. A chorioretinal adhesion or scar is created when the RPE undergoes proliferation at the site of the burn. The second type of thermal adhesion is cryopexy, whereby a freeze is applied to the external sclera or occasionally internally on the retinal surface. The freeze passes through sclera, RPE, and retina to create a thermal-induced scar. Cryopexy causes minimal change to the sclera compared with

diathermy, which causes some scleral necrosis. The third type of thermal adhesion is created by the laser. This type of adhesion is placed internally by focusing the laser on the retina. The laser energy is absorbed primarily by the pigmented RPE and choroid, leading to a chorioretinal scar. Laser photocoagulation causes no change to the underlying sclera.

The final chorioretinal adhesions formed by diathermy, cryopexy, and laser have similar strengths and are certainly adequate to maintain apposition of the retina and the RPE if there is no substantial traction on the retina. The rapidity of onset of the chorioretinal adhesion is not the same for these three methods, however. Laser photocoagulation appears to induce a more rapid chorioretinal adhesion than cryopexy or diathermy.<sup>61,62</sup> The chorioretinal adhesion induced by laser photocoagulation starts within 24 hours of treatment and increases rapidly within 3 days, whereas the adhesion formed by cryopexy or diathermy takes at least several days to start to form and does not reach maximum strength until about 2 weeks.<sup>61,62</sup> Cryopexy given at the time of scleral buckle for retinal reattachment and laser photocoagulation 1 month later have similar efficacy in maintaining retinal reattachment in one randomized trial.<sup>63</sup>

## **Scleral Buckles and Vitreous Traction**

Scleral buckles help in several ways to counteract the forces that tend to detach the retina. Indentation of the eye wall produced by the scleral buckle can decrease vitreous traction on the retinal tear in rhegmatogenous retinal detachment. Scleral buckles may also decrease vitreous traction in traction retinal detachments, causing the detachment to decrease in size or to resolve completely. Vitreous traction causing elevation of the retinal break in a traction-rhegmatogenous retinal detachment may perpetuate the retinal detachment by allowing fluid from the vitreous cavity to pass through the retinal break into the subretinal space. The scleral buckle relieves this vitreoretinal traction by decreasing the magnitude and possibly changing the direction of the vitreous traction on the retinal tear. Circumferential scleral buckles help to decrease transretinal traction by decreasing the diameter and circumference of the vitreous base. This effect can be understood by

comparing the vitreous to a spring and applying Hook's law. The force exerted by a stretched spring is greater than a spring with minimal stretch (Fig. 103.16). The force of stretch is directly proportional to the distance the spring is stretched. Reducing the diameter of the vitreous cavity in the vitreous base with a circumferential buckle decreases the transvitreal traction, shifting the equilibrium back toward retinal reattachment. Optical coherence tomography has been used to image the retina overlying scleral buckles and has confirmed that residual vitreous traction and unsupported retinal breaks are important causes of persisting retinal detachment.<sup>64</sup> The capability of the scleral buckle to relieve traction and promote retinal adhesion has been confirmed when scleral buckles are used to treat retinal detachments without the use of any chorioretinal adhesions. Two randomized trials found no difference in retinal reattachment rates with the use of scleral buckles, whether or not any retinopexy was used.<sup>65,66</sup>

**FIG. 103.16** The transvitreal contractile force is the product of a constant ( $K$ ) and the transvitreal distance ( $x_1$  or  $x_2$ ). The transvitreal force with a low circumferential buckle ( $F_1$ ) is greater than the transvitreal force with a high circumferential buckle ( $F_2$ ) since the transvitreal distance with the low circumferential buckle ( $x_1$ ) is greater than the transvitreal distance with the high circumferential buckle ( $x_2$ ). ## Scleral Buckles and Traction on the Retinal Surface

Cellular epiretinal proliferation adherent to the surface of the retina may also promote traction retinal detachment by exerting traction on the retina or may precipitate a rhegmatogenous detachment if the force is strong enough to tear the retina. An epiretinal membrane on the surface of the retina produces retinal traction along the concave eye wall. This traction is composed of two vectors. The first is tangential to the retina and is caused by tension in the contractile epiretinal membrane. The second is directed radially inward, toward the center of the eye, and is a result of tangential traction on a curved surface (Fig. 103.17). At each point along the epiretinal membrane is a small force tangential to the retina and a small force directed inward toward the center of the eye. The force directed radially inward tends to pull the epiretinal membrane and retina away from the RPE. This radial force is normally counterbalanced by adhesion of the retina to the RPE. If the tension on the epiretinal membrane becomes great enough, the radial inward force may exceed the RPE adhesive capacity, causing a traction retinal detachment or retinal tear (see Fig. 103.14).

**FIG. 103.17** Tension from an epiretinal membrane adherent to the concave surface of the retina produces a tangential force ( $T_1$ ) and a radial force ( $F_R$ ) at each point on the epiretinal membrane. The radial force tends to pull the retina off the retinal pigment epithelium (RPE). This inward radial force is normally counterbalanced by the adhesive force of the RPE to retina ( $F_A$ ), such that  $F_R < F_A$ .

The radial force from tangential traction on the retina can be

approximated by the formula in [Fig. 103.18](#).<sup>41</sup> The radial inward force on the retina per unit length is proportional to the tension of the epiretinal membrane. The greater the tension within the epiretinal membrane, the greater the radial inward force tending to detach the retina. The radial inward force from the epiretinal membrane is inversely proportional to the radius of curvature of the eye wall. Hence, an epiretinal membrane on an eye with a small radius of curvature exerts more radial inward force on the retina than does the same epiretinal membrane on an eye with a large radius of curvature, if all other variables are equal.

**FIG. 103.18** The magnitude of the inward radial force from an epiretinal membrane on the concave surface of the retina ( $F_T$ ) can be calculated from the tension on the retina ( $T$ ) and the radius of curvature of the eye ( $r$ ).

The radial force per unit length of the epiretinal membrane is proportional to the tension in the epiretinal membrane and inversely proportional to the radius of curvature of the eye wall.

The formula in [Fig. 103.18](#) also explains how scleral buckles help to promote retinal reattachment in eyes with breaks adjacent to

epiretinal membranes and in eyes with traction retinal detachments secondary to epiretinal proliferation. The scleral buckle alters the shape of the eye wall from the normal concave contour to a convex contour over the scleral buckle. Without the scleral buckle, the radial force induced by the epiretinal membrane on the retina is directed inward toward the center of the eye. With the scleral buckle, the radial force is directed toward the convex center of curvature of the radial buckle (Fig. 103.19). The scleral buckle reverses the direction of the radial force induced by the epiretinal membrane from an inward force, tending to detach the retina, to an outward force, promoting retinal reattachment. Furthermore, because the convex radius of curvature of the retina on the scleral buckle is much smaller than the concave radius of curvature of the eye, the magnitude of the radial outward force promoting retinal reattachment with a scleral buckle is larger than the original radial inward force tending to detach the retina.

**FIG. 103.19** A scleral buckle reverses the direction of the radial inward force on the retina ( $F_1$ ) to an outward force ( $F_2$ ), thereby promoting retinal reattachment of an epiretinal membrane. *B* is the site of attachment of the epiretinal membrane. The magnitude of the force promoting retinal reattachment is greater than the original inward force that tended to detach the retina.

This occurs because the radius of curvature of the sclera over the scleral buckle ( $r_2$ ) is smaller than the radius of curvature of the normal concave eye wall ( $r_1$ ).

This analysis of vector forces induced by an epiretinal membrane can be understood by considering a tight surgical glove on a hand. When the hand is cupped, the glove will lift off the palm of the hand because the glove is like a tight trampoline bridging the edges of the concave surface of the palm of the hand. The glove on a cupped hand is analogous to an epiretinal membrane lifting the retina off the RPE. Traction retinal detachments would always occur with epiretinal proliferation on the surface of the retina if no adhesive forces were present to counterbalance the radial inward force on the retina from the epiretinal membrane. When the palm of the hand is flattened and hyperextended, the elastic surgical glove is pulled tightly against the palm of the hand. The force vector that pulled the surgical glove off the cupped hand reverses when the hand is hyperextended, pulling the glove against the convex surface of the palm of the hand. This is analogous to the effect of a scleral buckle changing the concave eye wall to a convex configuration, promoting retinal reattachment. Radial scleral buckles may also assist in closure of retinal breaks by stretching the retina slightly on the scleral buckle, since the retina must conform to the increased arc length of the scleral buckle (Fig. 103.20).<sup>26</sup>

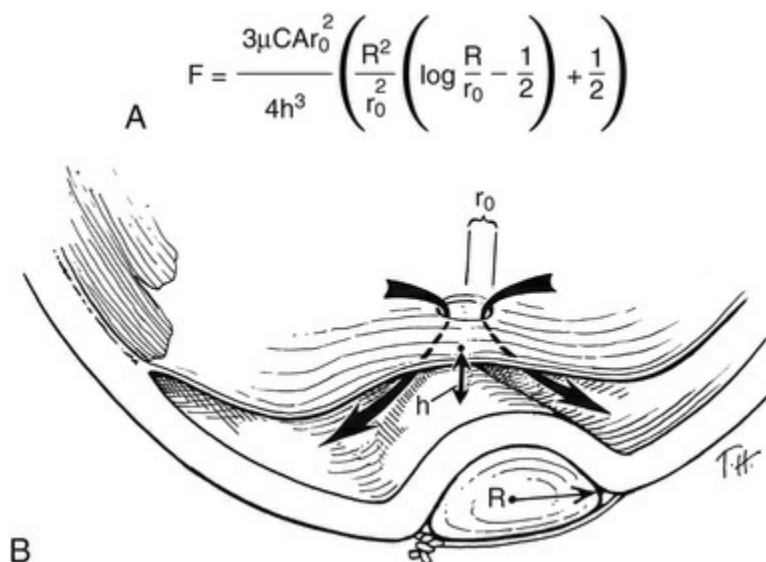

**FIG. 103.20** The retina is stretched when a scleral buckle is used to indent the eye wall. The distance from *A* to *B* on the upper diagram is less than the distance from *A'* to *B'* on the lower diagram since the retina must now conform to the longer outer circumference of the buckle and sclera rather than the shorter inner circumference of the nonbuckled sclera.

## Scleral Buckles and Fluid Movement

Fluid currents associated with rotational movements of the eye are important in creating and maintaining retinal detachments, as discussed previously.<sup>45</sup> Scleral buckles may alter the direction and magnitude of fluid currents in eyes with retinal detachment, decreasing the movement of vitreous fluid through tears into the subretinal space. Scleral buckles may change the fluid flux through retinal tears. The distance between the RPE and a retinal tear is reduced when the eye wall is indented by a scleral buckle. This displaces the preexisting subretinal fluid away from the tear and helps to bring the RPE and the retinal tear closer together. The distance from the retinal tear to the RPE is important in determining whether the retina will reattach or remain detached. The closer the retinal tear is to the RPE, the greater the force promoting retinal reattachment. A quantitative model of retinal

reattachment force was developed to try to predict the magnitude of retinal reattachment forces in eyes with rhegmatogenous retinal detachment treated with a radial buckle (Fig. 103.21).<sup>47</sup> The retinal reattachment force in this model results from the absorption of subretinal fluid by the RPE pump, which brings the retina and the RPE into closer apposition. This model predicts that the retinal reattachment force is inversely proportional to the cube of the distance from the retinal hole to the RPE on the buckle. Halving the distance from the retinal tear to the buckle causes an eightfold increase in the retinal reattachment force. This analysis would predict that most retinal tears within 3 mm of the RPE will spontaneously reattach without drainage of subretinal fluid, and this appears to be confirmed by clinical observations.<sup>47</sup> A subsequent finite element analysis using this model made the somewhat surprising prediction that rapid eye movements may actually help to reattach the retina better than relative ocular immobility, which has been advocated for years to help absorb persisting subretinal fluid.<sup>67</sup>

**FIG. 103.21** (A) Absorption of subretinal fluid by the retinal pigment epithelium (RPE) in an eye with a cylindrical radial buckle induces a flow of fluid from the subretinal space into the RPE and a secondary flow of fluid from the vitreous to the subretinal space. This creates a force that pushes the detached retina toward the RPE. The force of retinal reattachment ( $F$ ) is

proportional to the viscosity of vitreous cavity fluid ( $\mu$ ), the choroidal absorption rate ( $C$ ), the radius of the cylindrical buckle ( $R$ ), and the area of RPE exposed by the retinal detachment ( $A$ ). The force of retinal reattachment is inversely proportional to the height of detachment ( $h$ ) and the radius of the retinal break ( $r_0$ ) as long as the buckle is larger than the retinal hole. (B) Reduced flow of liquid vitreous through a retinal break (*arrows*) into the subretinal space compared with the rate of fluid absorption by the pigment epithelium induces a force that tends to flatten the retina against the pigment epithelium. This force depends on the radius of the retinal break ( $r$ ), the distance the break is separated from the scleral buckle ( $h$ ), and the radius of the scleral buckle ( $R$ ). (Panel B reproduced with permission from Wilkinson CP, Rice TA. Michels' retinal detachment. 2nd ed. St. Louis: Mosby; 1997.)

Scleral buckles can also displace vitreous fluid away from the tear, plugging the tear with solid vitreous gel. The movement of fluid from the vitreous cavity through the tear is impeded when the tear is occluded by solid vitreous gel.<sup>68</sup> Larger scleral buckles may displace more of the liquid vitreous, leaving solid vitreous gel in the vitreous cavity to plug retinal breaks. If additional tamponade of retinal breaks is needed, intraocular gas bubbles can eliminate or decrease the movement of vitreous fluid through the retinal break because of the high surface tension at the gas–water interface at the site of the retinal tear. It takes only approximately 0.625 mL of air injected into the vitreous cavity to cover 4 clock-hours of the peripheral retina, as shown in [Fig. 103.22](#).<sup>46</sup> The use of supplemental intravitreal air and appropriate positioning of the bubble to cover the retinal tear(s) is very helpful when there is substantial persisting subretinal fluid around the retinal break(s).

**FIG. 103.22** Relationship of meniscus height of the intraocular gas bubble, bubble volume, and arc of contact within the eye. A gas bubble with a meniscus height of 25% displaces 15.6% of the volume of the vitreous cavity with an arc of contact of 120° degrees or 4 clock-hours. A relatively small intraocular gas bubble volume can provide tamponade to retinal breaks between the 8:00 and 4:00 meridian with appropriate head positioning when there is persisting subretinal fluid around a retinal break. (Reproduced with permission from Wilkinson CP, Rice TA. *Michels' retinal detachment*. 2nd ed. St. Louis: Mosby; 1997.)

Scleral buckles help to reduce vitreous traction and diminish the flux of vitreous fluid through retinal tears, thus promoting reapposition of the retina to the RPE. The combination of relief of vitreoretinal traction by the scleral buckle and formation of a chorioretinal adhesion helps to maintain attachment of the retina postoperatively. It is the equilibrium between the forces promoting retinal attachment and the forces promoting retinal detachment that determines whether the retina remains attached or detached.

## Conclusion

Scleral buckles play an important role in the treatment of

rhegmatogenous retinal detachments by changing the geometry and physiology of the eye. Scleral buckles may cause secondary changes in axial length, corneal topography, and intraocular volume as a result of changes in the geometry of the eye. Forces that normally maintain retinal attachment include the mucopolysaccharide “glue” between the photoreceptors and the RPE, an oncotic pressure difference between the choroid and the subretinal space, hydraulic forces on the retina from vitreous fluid, and the RPE pump. Retinal detachment occurs when the forces promoting retinal attachment are overwhelmed by forces promoting retinal detachment. Forces that can lead to retinal detachment include vitreous traction, retinal tears, and cellular epiretinal proliferation. The normal ocular homeostasis may be disrupted by a retinal tear, and a new equilibrium is then established that can create a retinal detachment. The scleral buckle helps to alter this equilibrium favorably through changes in the vitreous fluid dynamics and geometry of the vitreoretinal interface. The use of a scleral buckle helps to overcome the forces tending to detach the retina in most eyes, allowing successful treatment of rhegmatogenous retinal detachments.

## **Introduction**

While almost any rhegmatogenous detachment can be managed with scleral buckling, there has been a trend towards increased use of pneumatic retinopexy and primary vitrectomy.<sup>1</sup> This chapter describes the techniques used in scleral buckling. The choice between buckling and other techniques is covered in [Chapter 109](#)

(Optimal procedures for retinal detachment repair).

The term “buckle” refers to deformation of a structure under stress. Sometimes the term “buckle” is used synonymously with some form of encircling explant, while others use the term to describe local explants.<sup>2</sup> In this chapter, the term is used in the more generic sense to imply any type of explant.

Different schools of buckling technique have arisen with divergent views in particular on the role of encirclement and subretinal fluid drainage.<sup>3</sup> This chapter has been written to reflect this diversity of practice.

Buckling of the sclera to close retinal breaks was initially achieved using combinations of lamellar scleral dissection with compression sutures until it was shown that it could be achieved more efficiently using scleral implants<sup>4</sup> and subsequently explants.<sup>5,6</sup> Scleral implants are now of purely historical interest. Likewise diathermy, which was used extensively in the past to achieve retinopexy,<sup>4</sup> has been supplanted by photocoagulation and cryotherapy. There have also been subsequent refinements of the basic technique of scleral buckling, including intraocular gas injection and subretinal fluid drainage. However, in contrast with other areas of vitreoretinal surgery, there have been no major innovations in the basic technique of scleral buckling in the past 20 years. (See Video 104.1 online for a demonstration of scleral buckling technique.)

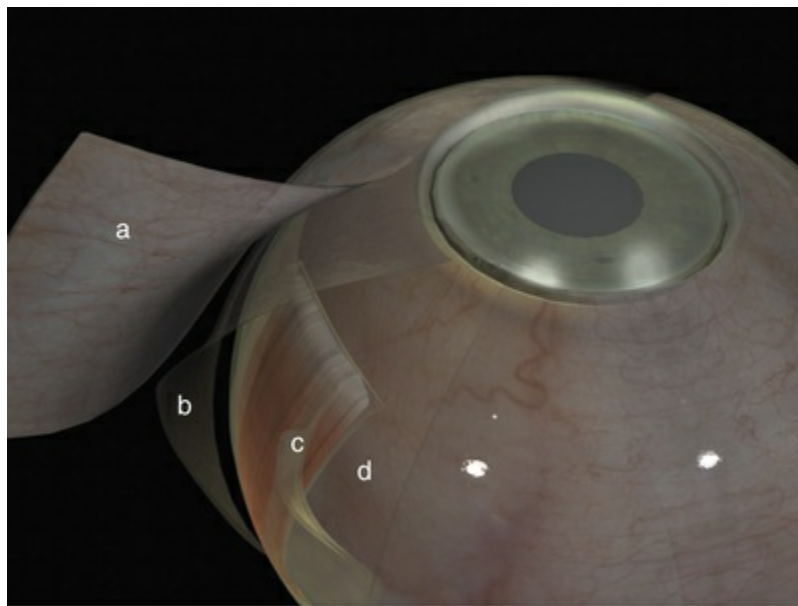

## Surgical Anatomy

### Coats of the Eye

The conjunctiva is adherent to the sclera at the limbus, so the radial incisions to enter the subconjunctival plane have to be made just behind the limbus. The conjunctiva becomes friable with age and care must be taken to avoid tearing and buttonholing. Nontoothed forceps (such as notched forceps) are used to grasp the conjunctiva.

The Tenon capsule is a layer of fascia that envelops the globe from the limbus to the optic nerve ([Fig. 104.1](#)). It is pierced by the extraocular muscles. A glove-like sleeve of fascia extends anteriorly (to the rectus insertions) and posteriorly (for several millimeters)

along the muscles from the points at which they pierce the Tenon capsule. Between the rectus muscles anteriorly these sleeves are joined by a layer of fascia: the intermuscular septum. The intermuscular septum and fascial sleeves of the recti are sometimes collectively referred to as the posterior Tenon capsule. The result of this complex arrangement is that several layers of tissue have to be incised to get access to the surface of the sclera (or sub-Tenon space). The anterior Tenon capsule may be dissected away from the sclera along with the conjunctiva (to which it is adherent by small fascial filaments). The intermuscular septum is then divided separately. Care must be taken when stripping fascia off the rectus muscles because ligaments from the recti to the wall of the orbit are functionally important in the actions of the muscle.<sup>7</sup>

**FIG. 104.1** Tenon's capsule. (a) Conjunctiva and (b) the anterior Tenon capsule have been dissected to reveal (c) the “posterior Tenon” glove-like extensions of the Tenon capsule along the recti and the associated intermuscular septum. Bare sclera (d) lies under this.

The thickness of the sclera varies. It is thickest around the optic nerve (1.2 mm) and thinnest under the recti behind their insertions, so attempts to pass scleral sutures under the muscles are particularly hazardous. Where scleral mattress sutures are more

typically passed, at the equator, it is approximately 1 mm thick. Passage of sutures is facilitated by the lamellar arrangement of collagen fibers, which allows spatulated (or “side cutting”) needles to follow a plane between lamellae.

## Extraocular Muscles

The recti are adherent to the sclera at the spiral of Tillaux. The location of this ring corresponds approximately to that of the ora serrata (Fig. 104.2).<sup>8</sup> Circumferential scleral tires are therefore often placed as anteriorly as the rectus muscle insertions will allow. In this position they support the retina as far anteriorly as the ora serrata (“break ora occlusive buckling”).

**FIG. 104.2** The ora serrata and the spiral of Tillaux (rectus insertions). The sclera has been rendered transparent to reveal the relationship between the ora serrata and the muscle insertions. Buckling anteriorly as far as the rectus insertions prevents anterior leakage.

The superior oblique muscle runs laterally from the trochlea to its insertion under the superior rectus. Passage of a superior rectus muscle hook from the temporal side of the muscle reduces the risk of inadvertently “hooking” the superior oblique, as well as does

keeping the sweep of the hook preequatorial. The superior oblique insertion is frequently encountered on the temporal side of the muscle where it can be an obstacle to scleral suturing. Division of a small ( $< \frac{1}{3}$ ) portion of the insertion to facilitate suturing seems to have little effect on ocular motility. Note that a vortex vein is usually present under the temporal edge of the superior oblique insertion.

The inferior oblique muscle passes under the lateral rectus muscle. The chance of inadvertently hooking it while passing a muscle hook under the lateral rectus is reduced by passing the hook from the superior side.

## Choroidal Vasculature

The long posterior arteries (as well as their corresponding nerves) run anteriorly from the equator at 3 and 9 o'clock and may be damaged by heavy photocoagulation or subretinal fluid drainage in these meridians (Fig. 104.3 online).

**FIG. 104.3** The choroidal vasculature. Surgical trauma should be minimized to all of these structures. *A*, anterior ciliary artery; *B*, long posterior ciliary artery; *C*, vortex ampulla; *D*, vortex vein; *E*, greater arterial circle of the iris.

The anatomy of the vortex veins is somewhat variable but one tends to leave the globe either side of the vertical recti just behind the equator. They may be inadvertently hooked along with a vertical rectus muscle if the muscle hook is passed behind the equator. Injury to the vortex veins may result in interruption to the venous drainage from the choroid and choroidal detachment. When operating near the vertical recti, the vortex veins should be identified to prevent injury.

The choriocapillaris itself is very vascular and prone to bleed when penetrated. Because the vortex veins tend to be located near the vertical recti, subretinal fluid drainage is carried out closer to the horizontal than to the vertical recti whenever possible.

The anterior ciliary arteries are useful indicators of the meridia of the rectus muscle insertions (Fig. 104.4). As they supply the arterial circles of the iris, surgical trauma (including diathermy) should be minimized.

**FIG. 104.4** The anterior ciliary arteries. A useful indicator of the location of the rectus positions especially in reoperations. Note that the lateral rectus only has one.

## Innervation

Sensory nerves from the globe and bulbar conjunctiva pass through the ciliary ganglion. Local anesthesia in this region, for example, sub-Tenon anesthesia, will therefore anesthetize the globe effectively. The innervation of the lids and palpebral conjunctiva is by the lacrimal, frontal, and infraorbital nerves, which do not pass through the muscle cone. Blockage of the ciliary ganglion alone does not therefore reliably provide adequate analgesia for buckling surgery.

## Preoperative Assessment

A careful preoperative assessment is required in every case. Having taken a careful history (and noted relevant systemic health problems and past ophthalmic history), the anterior and posterior segments of the eye are carefully examined using slit-lamp biomicroscopy and indirect ophthalmoscopy. A particular note is made of the following:

- Macular involvement
- Features suggesting that the retinal detachment is nonrhegmatogenous (see also [Chapter 99](#), Nonrhegmatogenous retinal detachment)
- The presence of vitreous detachment
- Significant ocular co-pathology, which may affect management (e.g., glaucomatous optic neuropathy, aphakia with vitreous in the anterior chamber, a history of strabismus surgery)
- The number and position of the retinal breaks.

## Finding the Retinal Break

Missed retinal breaks are an important cause of surgical failure, so the preoperative examination should be very thorough.<sup>9</sup> Even when a break has been found, it is essential to complete examination of the retina, as most retinal detachments have more than one break.<sup>10</sup> Their location is carefully documented on a chart that can be referred to subsequently during surgery ([Fig. 104.5](#)). These drawings should show the location of retinal breaks in relation to easily visible retinal landmarks such as small hemorrhages,

vascular bifurcations, and areas of pigmentation.

**FIG. 104.5** A retinal drawing – note the emphasis on easily visible features that can act as guides to the location of breaks intraoperatively. The outer circle corresponds to the location of the junction between the pars plana and the pars plicata. The middle circle represents the location of the ora serrata. The inner circle represents the location of the equator of the globe.

This carefully documented preoperative assessment has many advantages. If in doubt, an area of retina can be reexamined alternately with indirect ophthalmoscopy and slit-lamp biomicroscopy to establish whether a break is truly present. The drawings made can be referred to if the retinal view becomes obscured during surgery. If the breaks are not easily seen, the other retinal features on the drawings provide useful reference points to their location.

In children and uncooperative patients, it may be impossible to establish the position of the retinal breaks preoperatively. One is then forced to rely on the intraoperative examination under anesthesia.

## **Lincoff's Rules**

Lincoff has shown how the location of retinal breaks determines the distribution of subretinal fluid (Fig. 104.6).<sup>11</sup> Review of the retinal

drawings will therefore determine whether the break location is consistent with the subretinal fluid distribution. When the distribution of fluid does not seem to obey Lincoff's rules, reexamine the retina to ensure that no breaks have been missed.

**FIG. 104.6** The location of retinal breaks can be deduced from careful analysis of the topography of the detachment as described by Harvey Lincoff. (A) An inferior detachment slightly higher on the temporal side pointing to a break on that side. (B) A subtotal retinal detachment – the break is usually close to the upper border of the fluid on the side it is highest. (C) The fluid crosses the midline superiorly implying a superior break near 12 o'clock. The fluid has tracked down further nasal implying the break is slightly to the nasal

side. (D) The presence of bullae implies a superior break. A shallow sinus of fluid leads to a small superonasal break.

## Scheduling Surgery

In “macular on” retinal detachment, urgent surgery should generally be scheduled to prevent detachment of the macula. Cases with tractional tears tend to progress very rapidly and should be treated urgently. Asymptomatic retinal detachments and detachments without tractional breaks (e.g., those due to retinal dialyses, atrophic retinal breaks in young myopes, and cases with “tide marks”) progress more slowly. Some delay, if it allows optimal conditions for surgery, may then be acceptable.

Reducing eye and head movements seems to reduce the rate at which subretinal fluid accumulates. Bed rest, eye patching, and rectus sutures have all been used to reduce the amount of subretinal fluid. This may prevent extension of subretinal fluid to the macula and make it easier to identify retinal breaks. It may also avoid the need for subretinal fluid drainage.<sup>12</sup> Such measures are rarely practical now, as most retinal detachment care takes place in an ambulatory or semiambulatory setting.<sup>13</sup>

## Preparation for Surgery

### Anesthesia

General anesthesia provides ideal operating conditions for younger patients, uncooperative patients, and for reoperations (when local anesthesia may be less effective).

Peribulbar administration of a 50 : 50 mix of lidocaine and bupivacaine, particularly when used with adjunctive Hyalase, provides excellent anesthesia and akinesia. Its action is not limited to the nerves that travel in the muscle cone or the sub-Tenon space.

In theory, sub-Tenon anesthesia alone should be insufficient (see above). In practice, sub-Tenon anesthesia gives anesthesia equivalent to other techniques,<sup>14</sup> presumably due to overspill of anesthetic agents to the peribulbar space. A particular advantage of

sub-Tenon anesthesia is the ease with which it can be “topped up” intraoperatively.<sup>15</sup> Sub-Tenon anesthesia may also be a useful adjunct to general anesthesia<sup>16</sup> both to block the vagus (preventing bradycardia or asystole from rectus muscle traction) and for analgesia in the immediate postoperative period. The presence of buckles and scarring may make this technique more difficult and less effective in reoperations.

## Positioning the Head for Surgery

Surgical access is best when the orbital rim is horizontal. This is achieved by extending the neck slightly and tilting the nose away from the operated eye (Fig. 104.7 online). Once in the correct position the head may be fixed with a loop of clinical adhesive tape.

**FIG. 104.7** Improving surgical access by flattening the orbital rim: (A) extension of the neck; (B) slightly tilting the head.

## Preparation and Draping

The skin and lashes are cleaned with a disinfecting solution such as povidone iodine. A diluted aqueous iodine solution can be instilled in the conjunctival sac (avoiding the use of undiluted or alcohol-based preparations for this). The skin should be thoroughly dried before application of a sterile self-adhesive drape. Providing these steps are taken, it should be possible to tuck the eyelashes under the lid when the lid speculum is introduced, and it is therefore

unnecessary to trim the lashes preoperatively.

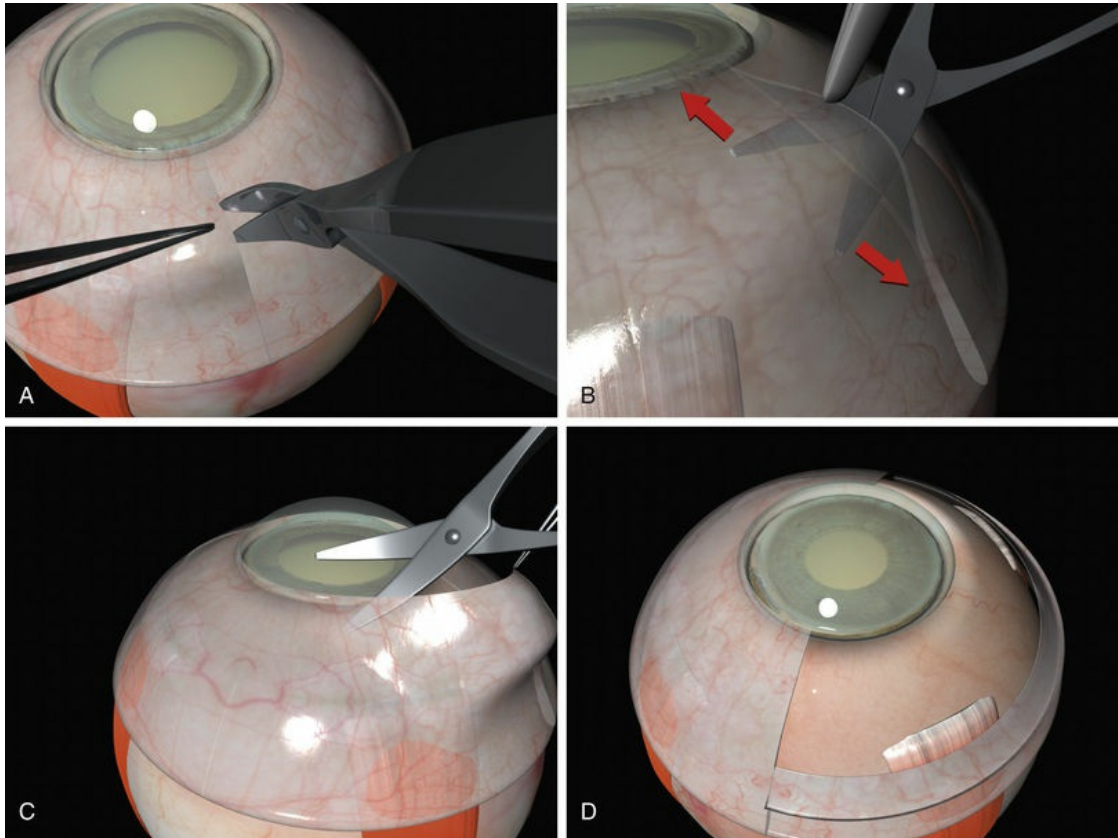

If the palpebral aperture is deemed too narrow, a lateral canthotomy may be performed.

## Surgical Steps

### Conjunctival Peritomy

Neat incisions with later anatomic reposition of the conjunctival edge prevents a number of unpleasant sequelae. Conjunctival misalignment with heaped scars may cause tear film dysfunction. Buttonholing the conjunctiva may lead to Tenon prolapse and delay healing. Recession of the peritomy edge leaves bare sclera and makes subsequent reoperation difficult.

A circumferential limbal peritomy with radial relieving incisions is made.<sup>17</sup> The conjunctiva 3–4 mm behind the limbus is grasped with forceps and gently lifted creating a radial pleat of conjunctiva (Fig. 104.8). A blunt-tipped spring scissors is used to make a vertical radial cut. A second cut is often needed to extend the incision through the Tenon capsule down to the sclera. Great care is taken not to tear the conjunctiva. The spring scissors can easily be used in either hand and the orientation varied as the incision progresses. A gentle spreading action of the scissors under the conjunctiva breaks the weak trabecular adhesions to the episcleral tissue.

**FIG. 104.8** Limbal peritomy. (A) The conjunctiva is grasped with a nontoothed forceps and elevated to create a pleat. Radial division of this with spring scissors initiates the peritomy. (B) Spreading action with blunt scissors to break the trabecular adhesions to the sclera. (C) Extension of incision around the limbus. (D) 180° peritomy for segmental buckle.

A slight modification of this technique with the circumferential incision 2 mm behind the limbus leaves a frill that may be useful during closure ([Fig. 104.9](#)).

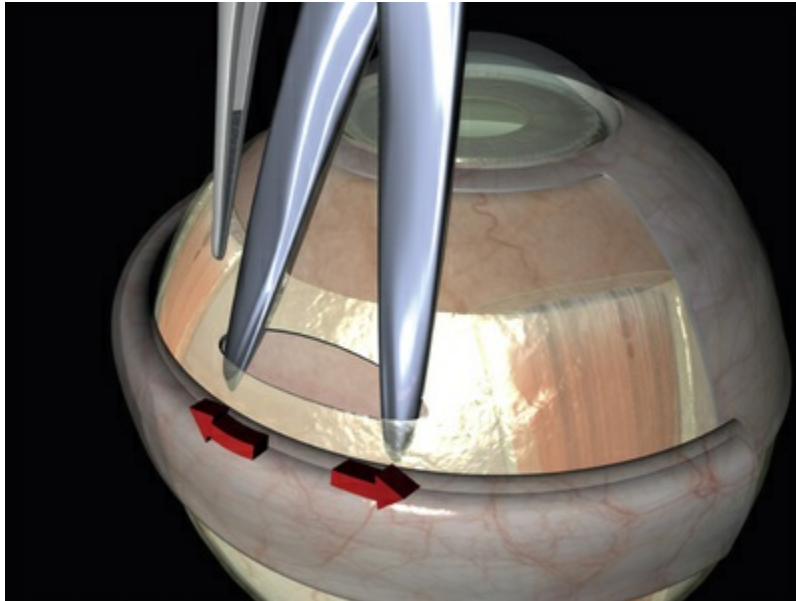

**FIG. 104.9** A 180° peritomy with a 2-mm limbal frill of conjunctiva to facilitate closure.

The extent of the peritomy depends on the size of the buckle planned. A 360° peritomy is not required if a local explant is planned. Note that it is not necessary to perform a 360° peritomy purely to sling all four muscles as rectus bridle sutures can be passed transconjunctivally.

## Slinging Rectus Muscles

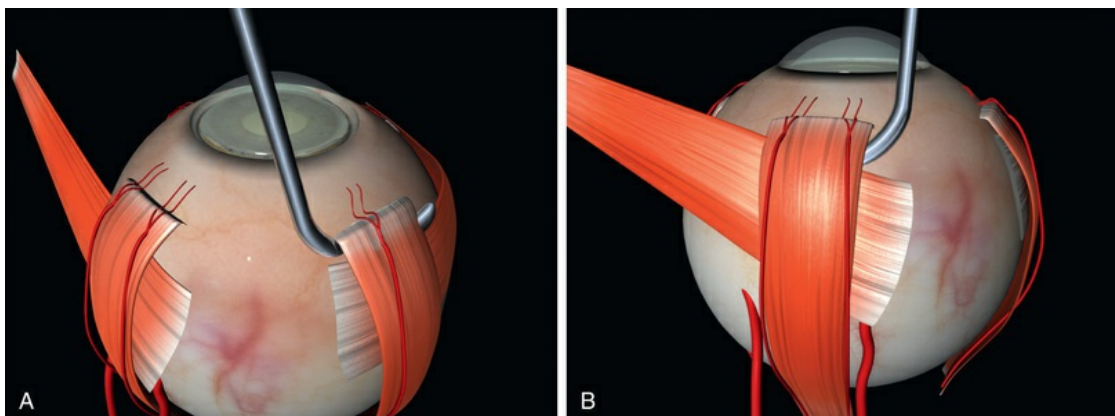

Between two and four rectus muscles are slung depending on the planned size of the buckle.

A closed pair of blunt scissors is pushed through the intermuscular septum between two recti. The opening created is enlarged by spreading the blades ([Fig. 104.10](#)). In this way, the sub-Tenon space is opened and bare posterior sclera is exposed.

**FIG. 104.10** Opening the intermuscular septum by spreading with blunt scissors. This opens the sub-Tenon space, exposing the posterior sclera.

The muscle is engaged with a sweeping posterior and circumferential movement around the globe employing a specialized muscle hook (Fig. 104.11 online). Very posterior “sweeps” risk damage to the vortex veins. Once a rectus has been successfully hooked, the globe moves with the hook. If the muscle is inadvertently split, a second hook can be passed from the opposite side of the muscle. The remaining anterior fibers of the intermuscular septum are now cut off or swept off. This dissection should be limited to the fascia required to visualize the sclera.

**FIG. 104.11** Passage of muscle hooks to avoid the obliques – the lateral rectus from above (A) and the

superior rectus from the temporal side (B).

A large braided (e.g., 2-0 silk) bridle suture is passed under the muscle. There are various ways of achieving this involving reverse passage of the suture under the muscle (to avoid engaging the tip in the sclera). Alternatively, a modified muscle hook with a threading eyelet at its tip can be used.<sup>18</sup> These bridle sutures can be clipped to the surgical drape to position and stabilize the globe thereafter (e.g., while suturing). When free movement of the globe is desirable (e.g., when searching for breaks), the clips are released.

The sclera is now inspected for dark ectatic areas (Fig. 104.12). Suturing and even cryotherapy or indentation at these sites can be perilous, so their early identification is essential.

**FIG. 104.12** Scleromalacia. The sclera is examined for any areas of thin sclera at the start of surgery. Surgical manipulation is avoided in these areas because of the risk of scleral perforation.

## Reoperations

Special precautions must be taken during revision surgery.

Adhesions are invariably present between the conjunctiva and sclera. A cutting action with the scissors is more effective than a

spreading action in breaking these. Care must be taken to avoid delaminating into the sclera or buttonholing conjunctiva.

A fibrous capsule forms around old explants. Incising this capsule exposes the surface of the explant. The plane thereby opened up is useful for slinging rectus muscles. The muscle hooks are placed around the muscles over the explants before these are removed. The rest of the periexplant capsule is then trimmed flush with the sclera. The sclera is often very thin in the bed of longstanding buckles, especially encircling elements. No attempt is made therefore to dissect capsule off the bed of the buckle. Particular care must be taken when dissecting the capsule from the very thin sclera under the rectus muscles. The scissors are gently lifted away from the globe while closing the blades.

## Examination Under Anesthesia and Break Localization

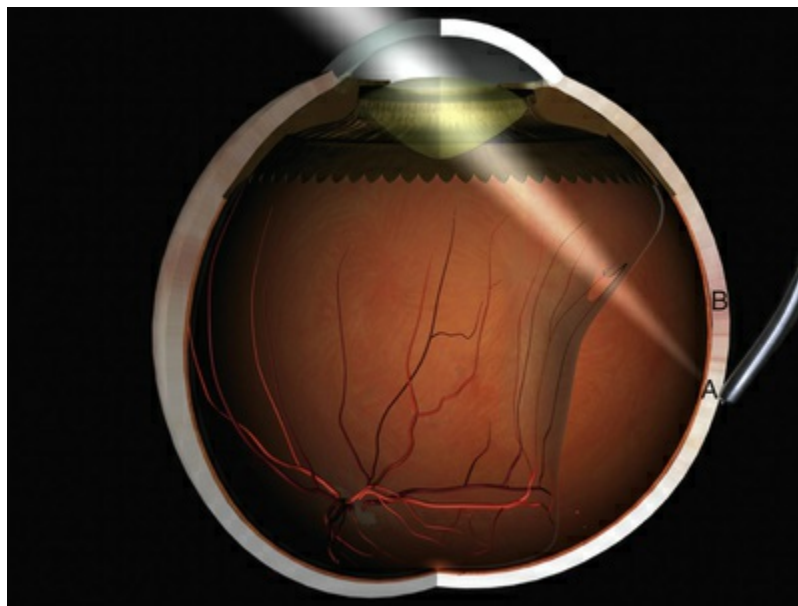

A careful indented examination under anesthesia of the whole peripheral retina is now carried out to confirm the location of the retinal breaks. The preoperative drawings provide a useful reference if they are difficult to locate.

Most surgeons employ indirect ophthalmoscopy using a sterile condensing lens. Some surgeons advocate microscopic visualization using endoillumination (such as a chandelier inserted through the pars plana) in combination with an indirect viewing system such as the Biom.<sup>19</sup>

The location of each break is marked on the sclera. This essential step is carried out while the cornea is clear and allows planning of the rest of the operation. The sclera is indented under indirect ophthalmoscopic indentation using a fine (but not sharp) tipped instrument such as a Gass scleral indenter.<sup>20</sup> Once the indent is seen to correspond to the position of a retinal break, sustained (for several seconds) indentation is applied. The resulting transient scleral thinning produces a focal area of scleral translucency, and the underlying choroid shows through. This point is then marked with very gentle diathermy or a surgical marker pen. If a marker pen is used, the sclera is dried both before and after the application to prevent the dye spreading. Several marks are made for larger

breaks.

Errors in break localization may lead to buckle malposition. Localization errors tend to be radial (i.e., determining how far back a break is) rather than circumferential (determining its clock hour). For example, if a retinal break is highly elevated (as in a bullous detachment), parallax errors may make the break seem more posterior than it truly is (Fig. 104.13).

**FIG. 104.13** Break localization error. When breaks are highly elevated, they appear more posterior than they really are due to parallax. *A*, apparent location; *B*, actual location.

Parallax errors may be avoided by draining subretinal fluid and then reforming the globe with air (the DACE – drain, air, cryotherapy, explant – operation) (Fig. 104.14).<sup>21,22</sup> The view of the retina through the gas bubble can be challenging for those not experienced with this technique.

**FIG. 104.14** Bullous retinal detachment: (A) managed with the DACE (drain, air, cryotherapy, explant) procedure. (B) The operation starts with subretinal fluid drainage and air injection. This aids subsequent break localization.

The development of corneal opacity greatly complicates surgery, particularly if it develops in the early stages of the procedure. This should be avoided by using preservative-free drops for preoperative pupil dilatation and avoiding the corneal epithelium desiccation by periodic irrigation with saline or use of a coating of dispersive viscoelastic. If corneal epithelial edema develops, the view may be transiently improved by rolling a damp cotton bud over the cornea accompanied by slight downward pressure on the globe. If this fails, corneal epithelial debridement may become necessary.

## Retinopexy

The indent from the explant closes retinal breaks, but retinopexy is required to produce an enduring bond between the retina and the retinal pigment epithelium that will persist even if the indent disappears.<sup>23</sup>

Retinopexy was initially achieved using diathermy in association with lamellar scleral dissection and scleral implants.<sup>4</sup> Cryotherapy has supplanted diathermy because it can be performed without scleral dissection and the treatment can be monitored ophthalmoscopically. More recently photocoagulation has also been used.

## Cryotherapy

The technique of cryotherapy is described in detail in [Chapter 110](#) (Prevention of retinal detachment). The aim is to produce freezing of healthy retina surrounding all the retinal breaks. The treatment is monitored using the indirect ophthalmoscope. When the indent from the tip of the cryoprobe is seen under a retinal break, the cryoprobe is activated. After a few seconds one observes whitening of the retina. Smaller breaks can be treated with a single application. The break is seen as a darker area within the freeze, and this is useful in confirming that the whole break has been treated. Larger breaks may need several applications. These are applied by working methodically around the edges of the break to ensure contiguous burns with minimal overlap ([Fig. 104.15](#)). Refreezing and freezing of the bare central RPE in large breaks are avoided to reduce the risk of RPE dispersion.<sup>24</sup>

**FIG. 104.15** Confluent cryotherapy burns with minimal overlap.

One can envisage the immediate tissue reaction as an ice ball expanding outwards progressively in every direction from the tip of the probe for as long as the cryoprobe is active. Some factors (the insulating effect of an intervening rectus muscle, the heat sink effect of the choroidal circulation) impede the development of a visible

reaction on the retina. Others (reduced choroidal blood flow in high myopia, the insulating effect of intraocular gas) hasten the development of retinal freezing. The effect of subretinal fluid is particularly important.

In the presence of shallow subretinal fluid, the indentation of the tip of the cryoprobe approximates the pigment epithelium to the retina and both freeze almost simultaneously. If the breaks are more elevated, the pigment epithelium cannot be opposed to the retina. Freezing of the pigment epithelium can then be clearly seen to precede freezing of the retina, sometimes by several seconds (Fig. 104.16). In this situation, what is the optimal end point of treatment: freezing of the pigment epithelium or the retina? This is a particularly important question given the concern about potential adverse effects of excessive cryotherapy on other tissues.<sup>25-27</sup> In an experimental model the adhesions produced by freezing of the retinal pigment epithelium alone lacked the microvillous interdigitations normally present between pigment epithelium and retina. The resulting chorioretinal adhesion was weaker than when the freeze was allowed to extend to the retina.<sup>28</sup> In practice, the chorioretinal adhesions that develop from freezing of the pigment epithelium alone seem to be sufficient. A further advantage of freezing the retina, however, is that the “lighting up” of the retinal breaks is a useful confirmation that all the edges of the break have been treated.

**FIG. 104.16** Cryotherapy in the presence of subretinal fluid. Freezing of the retinal pigment epithelium is seen to occur first (A). As the ice ball gets bigger, freezing of

the retina with lighting up of the breaks (B).

In the presence of bullous subretinal fluid, it may be impossible to approximate the retina to the retinal pigment epithelium. In this situation, subretinal fluid drainage is probably safer than very heavy cryotherapy, which may cause severe postoperative vitritis.

The tip of the cryoprobe must be allowed to thaw completely before attempted withdrawal, otherwise choroidal hemorrhage and even scleral avulsion may occur.

Cryotherapy to the disc or macula (Fig. 104.17) occurs when the indentation from the shaft of the probe is mistaken for its tip (“shaft indentation”) (Fig. 104.18). This cognitive problem can be avoided by encouraging trainees to intentionally indent posteriorly (without actually activating the cryoprobe!) (Fig. 104.19). They then become familiar with the distinctive appearance of shaft indentation.

**FIG. 104.17** Inadvertent cryotherapy to the posterior pole.

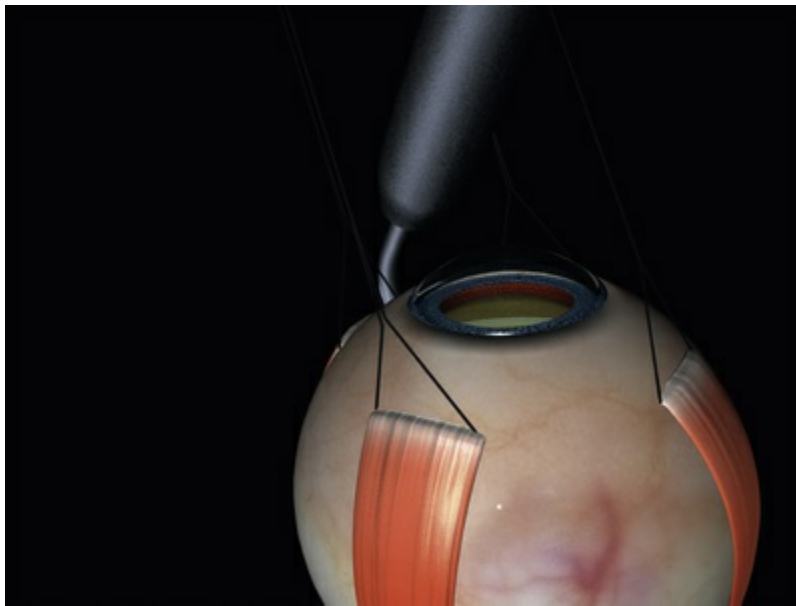

**FIG. 104.18** Shaft indentation – a cause of posterior cryotherapy.

**FIG. 104.19** The appearance of shaft indentation (right) compared with tip indentation (left).

Beginners find cryotherapy on anterior breaks challenging because the cryoprobe has a tendency to slip over the surface of the eye. This can be overcome with counter-traction from the bridge sutures on the opposite recti ([Fig. 104.20](#)). Alternatively, the cryoprobe is intentionally placed anterior to the break and the globe rotated using the tip of the probe. The pressure of the probe is then

slightly released while the indent from the probe is viewed using indirect ophthalmoscopy. As the globe returns slowly to the primary position, the tip indentation is seen to move. When the indentation of the tip is under the break, a very small increase in the pressure applied stabilizes the globe and the cryoprobe is activated.

**FIG. 104.20** Additional bridge sutures to stabilize the globe during treatment of large anterior breaks, e.g., a dialysis.

## Diode Laser

The delivery technique of transscleral diode laser uses a probe that indents the sclera under indirect ophthalmoscopic visualization. A diode laser aiming beam facilitates accurate placement of the tip. The endpoint of treatment can be difficult to titrate, particularly in blonde fundi, and overtreatment with choroidal hemorrhage and scleral thinning may occur during the learning curve.<sup>29</sup> The theoretical advantages of diode laser (less inflammation, blood–ocular barrier breakdown, and pigment dispersion) do not seem to translate into clinical practice as a large randomized trial failed to find any advantage over cryotherapy.<sup>30</sup>

## Photocoagulation

Photocoagulation may be applied several days to weeks postoperatively once the retina has reattached.<sup>31,32</sup> While visual recovery was faster in the postoperative laser retinopexy groups, the final anatomic and visual results are comparable to cryopexy. Photocoagulation on the buckle is uncomfortable and requires the use of regional anesthesia. The main disadvantage of this technique is the need for an additional procedure.

## Choice of Retinopexy Technique

Intraoperative cryopexy remains a quick and simple technique. The search for an alternative means of producing retinopexy is driven by the belief that cryotherapy is inherently dangerous. This view has been challenged.<sup>33</sup>

Manipulation of the globe after cryotherapy causes release of pigment into the vitreous cavity,<sup>24</sup> and some surgeons prefer to carry out cryotherapy at a later operative stage.

## Choice of Scleral Explant

Knowledge of the location of all the retinal breaks and their elevation allows planning of the rest of the operation, including the choice of scleral explant.

The aim of placing an explant is the creation of an indentation in the wall of the eye which provides adequate support to all the elevated retinal breaks. Areas of detachment where there are no breaks do not require support. Breaks in areas of attached retina can be treated with retinopexy alone.

Historically, a number of materials have been used in the manufacture of explants.<sup>34</sup> None of these seem to be as well tolerated as silicone rubber which is biologically inert and can be left in situ indefinitely.<sup>6,35</sup>

Two types of cylindrical silicone explant are currently in regular use: solid silicone tires and silicone sponges consisting of air-filled cells (Fig. 104.21). Early silicone sponges had communicating air cells and an increased risk of infection,<sup>36</sup> but this problem has been much reduced by the use of sponges with closed air cells.

**FIG. 104.21** Various types of explant may be used. Solid silicone tires of various sizes and profiles (A–C) are trimmed to the desired size (D–F). Silicone sponges also come in various sizes (G,H) and may have a circular or oval cross-section (I). Watzke sleeves (J) are used with bands (K) and silicone tires to create encirclements (L).

Solid silicone is, for practical purposes, noncompressible. Silicone sponges, because of their cellular composition, are easily deformable and compressible. When a sponge is initially sutured, the sponge is compressed and the intraocular pressure rises. As the intraocular pressure subsequently falls to physiologic levels, the sponge expands facilitating closure of elevated retinal breaks. (Details of the mechanism of action of scleral buckles are described in [Chapter 103](#), The effects and action of scleral buckles in the treatment of retinal detachment.)

The height of the indentation produced by an explant is a factor of the bite separation and the diameter of the explant. Silicone tires are generally thinner than sponges and therefore produce lower indents. When used to treat elevated breaks, an adjunctive measure such as subretinal fluid drainage or gas injection is more likely to be necessary if a circumferential tire is used.

The profile of the resulting indent also differs. Tires tend to produce broad indentation of uniform, albeit relatively low height. Sponges, particularly those with a circular cross-sectional profile,

are much higher centrally. Accurate localization in the transverse meridian is therefore critical when using a sponge with a circular cross-sectional profile.

The design of solid silicone tires reflects their original use as circumferential scleral implants. There is a groove on the upper surface with a rectangular profile to accommodate an overlying band. It was subsequently found that they can be used as explants.<sup>37</sup> Some surgeons dispense with the band and use them as purely local explants.

Silicone tires are usually oriented circumferentially. Sponges may be oriented either circumferentially or radially. The geometry of the indent favors radial orientation of sponges when treating retinal tears.<sup>2</sup> While the choice between tires and sponges is to some extent a matter of surgeon preference, their different physical properties favor their use in different situations depending on the number, size, and location of retinal breaks. This can be illustrated by some examples:

Example 1: A detachment with a single elevated equatorial tractional tear (Fig. 104.22). This may be closed successfully using a single radial sponge without drainage of subretinal fluid. If a silicone tire is used in the same situation, the indent may not be high enough to close retinal breaks without subretinal fluid drainage and/or gas injection.

**FIG. 104.22** (A) Elevated tear closed by (B) radial sponge (nondrainage).

Example 2: A detachment due to a series of round retinal holes (Fig. 104.23). The holes are anterior to the equator at various distances from the ora. They may be treated with a circumferential explant. A very high indent is not required because there is no traction on the breaks and the fluid is very shallow. As the distance from the ora varies the broader indentation from a tire can close all the breaks.

**FIG. 104.23** (A) Atrophic round holes (varying distances from the ora) closed with (B) a broad tire.

Example 3: A pseudophakic eye with a total retinal detachment. Good visualization of the peripheral retina is impeded by peripheral capsule opacification and limited pupil dilatation (Fig. 104.24). No tears are seen. An internal approach using pars plana vitrectomy has many advantages here.<sup>38</sup> If this is not possible, an encircling tire may be used. The buckle may be secured just behind the rectus muscle insertions to support the anterior retina where the breaks are likely to be located. The tire supports the whole area of subretinal fluid (“dry-to-dry” buckling). The placement of an encircling silicone band in the groove of the tire maintains the height of the indent so that undetected retinal breaks remain closed.

**FIG. 104.24** (A) Extensive detachment in a pseudophakic eye with poor peripheral fundal view. The breaks are likely to be quite anterior. (B) An encircling tire has been used to close them.

Example 4: Three tractional tears are present ([Fig. 104.25](#)). They can be treated with separate radial sponges or with a single circumferential buckle.

**FIG. 104.25** (A,B) Multiple tears closed with sponges.

Example 5: Three tractional tears are again present, but they are too close together to be easily closed with individual radial sponges ([Fig. 104.26](#)). A “raft” of radial sponges sewn side-to-side is possible, but a circumferential buckle is an easier option. A high circumferential sponge may be used, but it can be difficult to close all the breaks because of the variable distances from the limbus. Furthermore, high circumferential sponges are particularly likely to result in fishmouthing ([Fig. 104.27](#)). A

circumferential tire combined with subretinal fluid drainage and/or gas injection may be used.

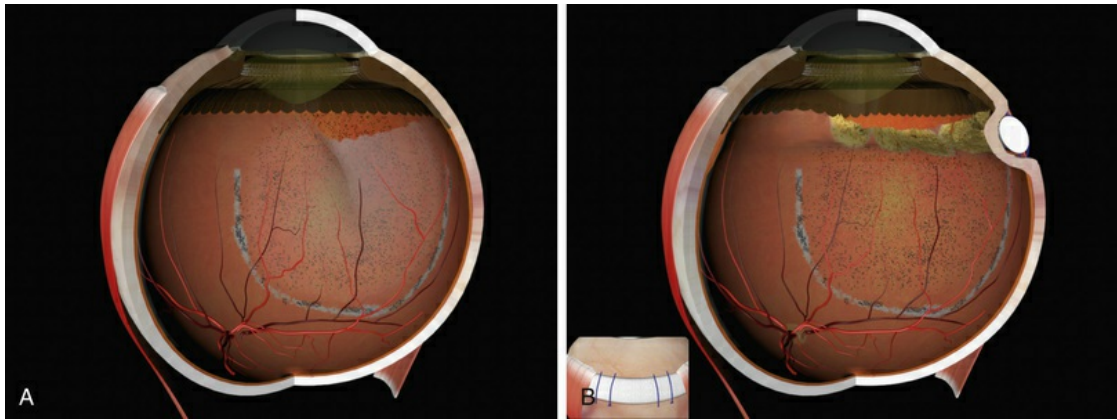

**FIG. 104.26** (A) Multiple tears closed with (B) a tire and gas bubble.

**FIG. 104.27** Fishmouthing. The high indentation causes radial redundancy folds which keep breaks open.

Example 6: A retinal dialysis. Provided the indent is high enough (a 3-mm circumferential sponge usually works well), it does not need to be very wide and subretinal fluid drainage is usually

unnecessary (Fig. 104.28).<sup>39</sup>

**FIG. 104.28** (A) Chronic dialysis closed by (B) an anterior circumferential 3-mm sponge.

## Scleral Sutures

Once the breaks have been marked, the size and position of the required buckle should be apparent so that partial-thickness scleral mattress sutures can be preplaced. Some surgeons prefer to carry out this step later in the operation following cryotherapy.

The desirable physical properties of scleral sutures are durability, biocompatibility, and ease of handling. Monofilament nylon and polyester both possess all these properties. A braided surface modified polyester is slightly easier to handle than a monofilament suture: the friction between throws of the knot makes it easier to tie the knot under tension. Nylon, however, has better “memory,” and several throws will keep the tension in the knot without resorting to slip knots or holding the knot between throws.

The suture bites are oriented parallel to the long axis of the explant (i.e., radial suture bites for a radial explant, circumferential bites for a circumferential explant).

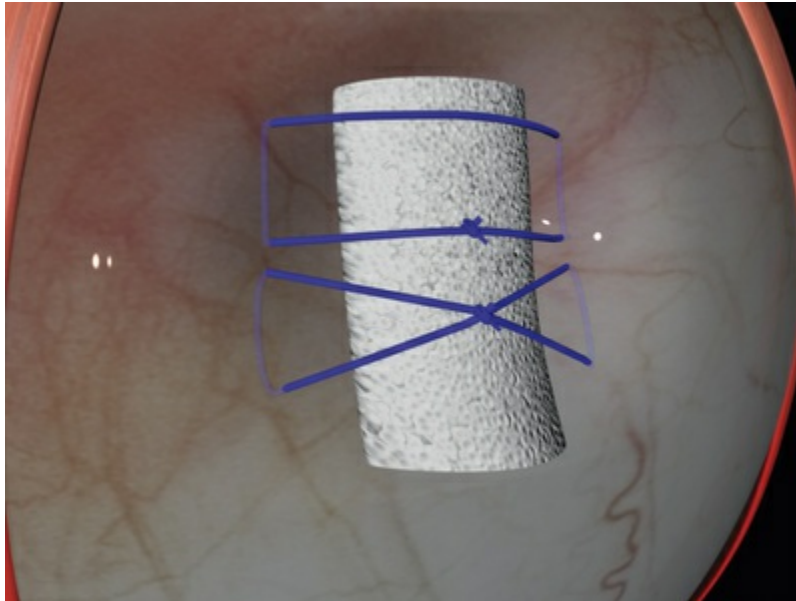

The distance between the bites is significantly greater than the width of the explant. This allows the sclera to partially envelop the explant, creating the indent. For example, when suturing a 5-mm sponge, the bites are placed 8 mm apart. Silicone tires generally need a bite separation 2 mm greater than their width. Failure to space the bites sufficiently reduces the height of the indent. Calipers

are used to ensure accurate bite separation (Fig. 104.29). The bites pass in opposite directions so that the mattress suture has a box configuration and the sutures do not cross over on the buckle. Crossing over of the sutures reduces the length of the indent (Fig. 104.30). A box suture may be difficult to achieve with posterior radial bites, as it is easier and safer to pass a bite anteroposteriorly than it is to pass it posteroanteriorly. Use of a double-armed suture allows two anteroposterior passes of the needle. Alternatively, a figure-of-eight suture may be converted to a box suture by dividing the suture between the bites (Fig. 104.31).

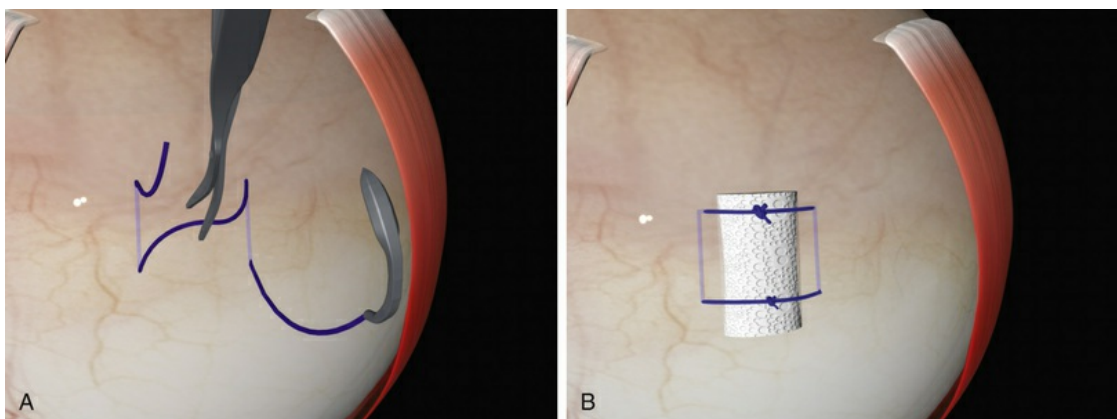

**FIG. 104.29** Calipers used to ensure the correct suture bite separation – in this case 8 mm for a 5-mm sponge.

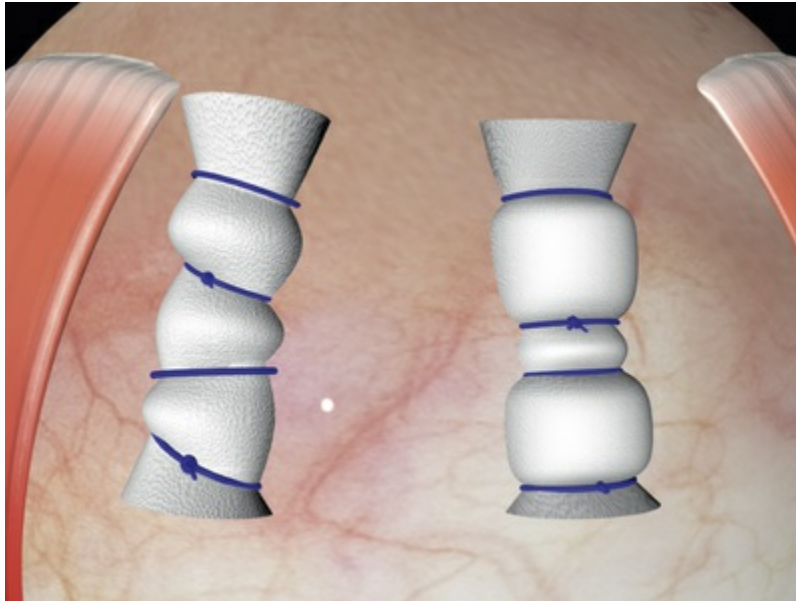

**FIG. 104.30** A crossed mattress suture (bottom) does not support the ends of the sponge as well as a box suture (top).

**FIG. 104.31** Conversion of (A) a crossed mattress suture to (B) a box mattress suture.

Mattress sutures should have a square configuration, with the bites parallel to each other and the long axis of the buckle. Irregular nonparallel sutures cause less-effective indentation ([Fig. 104.32](#)).

**FIG. 104.32** Irregular untidy sutures give uneven indents.

The sutures need to be placed partial thickness ( $\frac{1}{2}$ – $\frac{1}{3}$ ) through the sclera. As the sclera is only 1 mm thick, care needs to be taken to avoid scleral perforation. A spatulated needle rather than a cutting needle is used. The spatulated needle profile has a flat top and bottom and cutting lateral edges (Fig. 104.33). The sclera has a pseudolamellar structure.<sup>40</sup> When appropriately used, a spatulated needle tends to glide between the scleral lamellae.

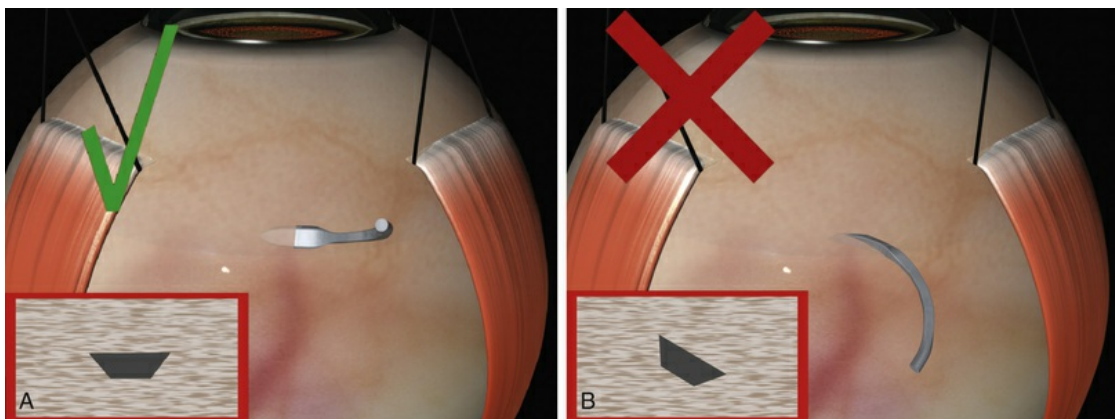

**FIG. 104.33** The structure of a spatulated needle. The

side cutting tip favors its passage at a constant depth between scleral lamellae. This is a  $\frac{3}{8}$  circle needle – a  $\frac{1}{2}$  circle may be needed when access is difficult (e.g., posterior scleral sutures).

When suturing (and whenever putting needles in the globe, e.g., during drainage) a forceps held in the nondominant hand is used to grasp a rectus insertion. This positions and fixates the globe for the suture and also allows the intraocular pressure to be adjusted if the eye is very soft. The spatulated needle is mounted  $\frac{2}{3}$  of the distance from its tip in a curved (e.g., Barraquer) needleholder.

The tip of the needle is placed on the sclera so that the tangent of the tip is parallel with the surface of the eye. It is important to ensure the needle does not bank, as this may cause the needle to cut out laterally (Fig. 104.34). When placing posterior sutures, this is easiest to achieve while sitting on the opposite side of the eye from the surgical area (Fig. 104.35). In fact it is a good principle to always operate “over the cornea,” as this gives better access to the recesses of the sub-Tenon space.

**FIG. 104.34** A spatulated flat should be laid flat on the sclera (A) – if it banks (B), it may cut out.

**FIG. 104.35** Operate from the other side (“over the cornea”) for access to the posterior sub-Tenon space.

Gentle downward pressure creates a small indent ([Fig. 104.36](#)). The needle is now advanced, keeping the tangent of its tip parallel to the surface of the eye. This causes it to advance progressively deeper into the sclera. Once it has reached the desired depth, no more downward pressure is applied. The spatulated design of the needle allows it to glide (or delaminate) between the scleral lamellae at a constant depth.

**FIG. 104.36** Safe passage of scleral sutures. The depth of the needle is gauged by its visibility throughout. At the correct depth the body of the needle is just visible as it passes through the sclera. If it is very clearly visible, the needle track may be too superficial and the suture may tear out when tied. If the body of the needle is not visible at all, it may have penetrated the sclera.

The depth of the needle passage is monitored continuously during its passage through the sclera. At a depth of 500  $\mu\text{m}$ , the needle is only just visible. The depth of the needle can be varied during the pass. Downward pressure while advancing the needle will take it deeper into the sclera and slight rotation (or lifting) of the needle can be used to reduce its depth. While care must be taken not to perforate the sclera, the entrance and exit from the sclera should not be too shallow (Fig. 104.37). If the start or end of the bite is very superficial, the sutures may partially tear out under tension. Once the bite is deemed of adequate length (usually 4–5 mm), the needle is rotated to bring the tip out of the sclera.

**FIG. 104.37** Suture track. If the entry or exit is too shallow, the suture may cut out.

Great care must be taken with the heel of the needle at this stage to prevent it penetrating the sclera. A good rule is to focus one's attention on the heel rather than the tip once the tip is clear of the sclera.

With experience, it is possible to modify this technique by initially engaging the scleral fibers more vertically with the tip before flattening the tip, indenting, and advancing the needle.

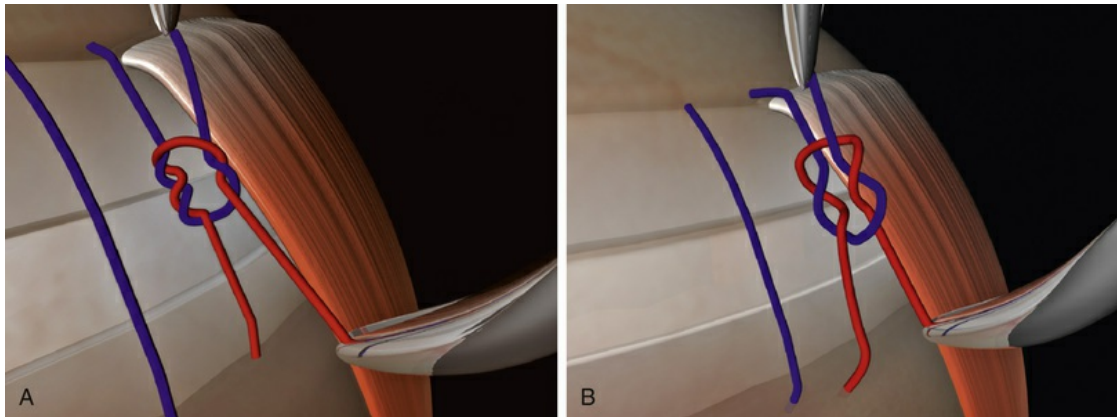

The consequences of deep sutures depend on the state of the underlying retina. If the perforation occurs at a site with deep subretinal fluid, the retina is generally unaffected, and unless there is significant hemorrhage, there are no adverse consequences. If a deep suture is passed in an area of attached retina, a retinotomy may be created which will require retinopexy. In any event, the suture can act as a conduit for microorganisms to enter the eye and should be replaced. Deep sutures anterior to the spiral of Tillaux (as used for circumferential explants) do not injure the retina.

## Tying the Sutures

The aspiring vitreoretinal surgeon should have a good understanding of basic surgical principles. The properties of surgeon's knots (Fig. 104.38A) and slip knots (Fig. 104.38B) are particularly important.<sup>41</sup> Scleral mattress sutures have to be tied under tension to create an indent. There are a number of ways of

doing this.

**FIG. 104.38** Surgical knots. The ends have been colored differently to highlight the knot architecture. A surgeon's knot (A) is a square (or reef) knot with an extra forward throw. It is secure and compact but will slacken between the forward and backward throws unless the tension in the forward throws is maintained by grasping them with a second instrument. Alternately, multiple forward throws will maintain their tension. The tension in the knot cannot be easily adjusted unlike a slip knot (B), which can be easily tightened if using a low friction material. Note that the knot is inherently less stable unless extra turns of the suture are then added.

A slip knot (1-1-1) can be tightened on the second throw. In this case, two single throws are made without the special care needed to produce a surgeon's knot. A slip knot generally occurs by default. One easy way of ensuring this is to do a single "forward throw" first and then a single "reverse" or "backward" throw but to pull the suture ends in the same direction on both throws (i.e., not to alternate the direction of pull as one would with a surgeon's knot). Knot slippage requires low suture friction and is easier to achieve with synthetic monofilament sutures such as nylon and virtually impossible with Ethibond. Slip knots require extra throws after the tension has been adjusted to prevent later slippage and loosening of the knot.

A "locking" knot, where the two ends of the sutures are pulled firmly to one end between throws, maintains its tension after the

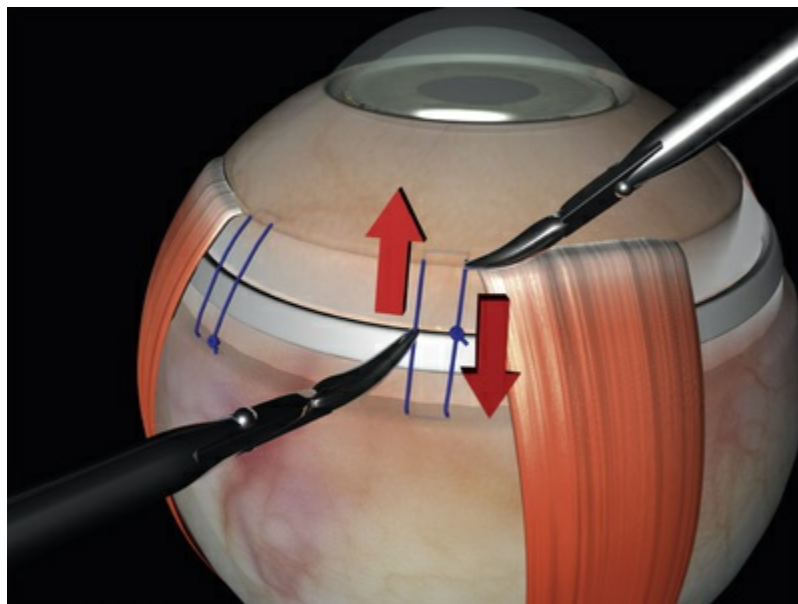

first throw (although a double or even treble first throw is required). This can be achieved using any suture material.

A surgeon's knot (similar to a reef knot but with a 2–1 structure) can be used if the assistant holds the knot with a pair of forceps between the first and second throws to maintain the tension of the first throw. The resulting knot is very compact.

Alternatively, one can rely on the friction and “memory” of a large number of throws to maintain the tension between the second and third throws. The resulting knot is bulkier than a surgeon's knot.

The use of releasable bow knots allows subsequent retying to adjust the height of the buckle. The bow can finally be converted to a surgeon's knot by cutting the loop and pulling on the shorter end of the cut suture through the knot.

Prominent suture ends may erode through the conjunctiva and ultimately lead to extrusion of the buckle. Once the knots have been tied securely, the sutures should therefore be rotated bimanually to leave the knot lying posteriorly (Fig. 104.39). If nylon is used, the ends should be trimmed close to the knot.

**FIG. 104.39** Bimanual suture rotation to leave knots lying posteriorly.

# Subretinal Fluid Drainage

## Indications for Drainage

There is no consensus on the role of subretinal fluid drainage. Approximation of retinal breaks alone is sufficient to cause retinal reattachment (see also [Chapter 103](#), The effects and action of scleral buckles in the treatment of retinal detachment).<sup>42</sup> Subretinal fluid drainage has been used to lower intraocular pressure, but this can be achieved in other ways, for example by paracentesis.<sup>43</sup> The anterior chamber depth is quickly restored particularly in myopic and pseudophakic eyes, allowing repeated paracentesis. A randomized controlled trial of medium complexity cases showed no advantage of subretinal fluid drainage.<sup>44</sup>

It is easier to state which eyes do not require subretinal fluid drainage. Scleral buckling is particularly effective in closing breaks without vitreous detachment. Detachments due to atrophic round holes and retinal dialysis can therefore usually be managed without subretinal fluid drainage. Conversely, most retinal surgeons will drain subretinal fluid in eyes with highly elevated tractional tears, very long-standing detachments or proliferative vitreoretinopathy (PVR). The decision whether to drain subretinal fluid is not made in isolation but is part of the overall planning of the surgery. For example, the choice of buckle or the need for intraocular air injection may influence the decision to drain. A case that could be managed with a nondrainage technique using a radial sponge may require subretinal fluid drainage if a circumferential solid silicone tire is used. While subretinal fluid drainage was previously in as many as 75% of cases, the trend towards increasing use of vitrectomy and pneumatic retinopexy in more bullous detachments has reduced the number of cases in which external subretinal fluid drainage is necessary in many surgeons' practices.<sup>45</sup>

## Technique of Drainage

### Timing.

Subretinal fluid drainage may be carried out at various stages in the operation. The DACE (drain, air, cryotherapy, explant) sequence was developed for bullous retinal detachments. Subretinal fluid

drainage followed by air injection to reform the globe prevents parallax errors during break localization. It has also been argued that cryotherapy may cause vascular congestion of the choriocapillaris and that subretinal fluid drainage should not therefore follow cryotherapy.<sup>46</sup> In practice, subretinal fluid drainage does not appear any more hazardous when performed after cryotherapy.<sup>47</sup> It can even be performed at the end of the operation.<sup>48</sup>

### **Location of Drain Sites.**

The long ciliary neurovascular complexes run at 3 and 9 o'clock, and these sites should be avoided, as should the area around the vortex veins. Sites adjacent to (but not under) the horizontal recti are optimal from the perspective of avoiding choroidal vasculature.<sup>46</sup>

Draining anteriorly may carry a lower rate of hemorrhage, but drainage may be less complete than if the drainage is carried out more posteriorly. Drainage near the equator is usually a reasonable compromise. One advantage of draining "in the bed of the buckle" is that any retinal incarceration or break will be supported once the buckle is tightened. The planned drain site should be examined by indirect ophthalmoscopy immediately before drainage is carried out to ensure that the subretinal fluid is deep enough. Drainage where the subretinal fluid is very shallow risks not just incomplete drainage but retinal injury.

### **Drainage Techniques.**

There are a number of different ways of draining subretinal fluid. Each relies on different strategies to avoid complications, such as choroidal hemorrhage and retinal incarceration. The techniques can be classified as either two-stage techniques in which a large (cut down) sclerostomy with separate choroidotomy is made or those in which a very small sclerostomy and choroidotomy are made together.

#### **Cut Down Techniques.**

A scleral incision 3 mm in length is made in the sclera, repeatedly spreading the edges, then incising the base of the resulting groove

(Fig. 104.40 online). The choroid becomes increasingly visible in the base of the incision. Finally, a small knuckle of bare choroid protrudes slightly.

**FIG. 104.40** Sclerostomy for a cut down drain. Note location in the posterior bed of the buckle.

The choroidotomy can be made with a needle. Transillumination may be used to visualize and avoid larger choroidal vessels, but there is still a risk of hemorrhage from the choriocapillaris.

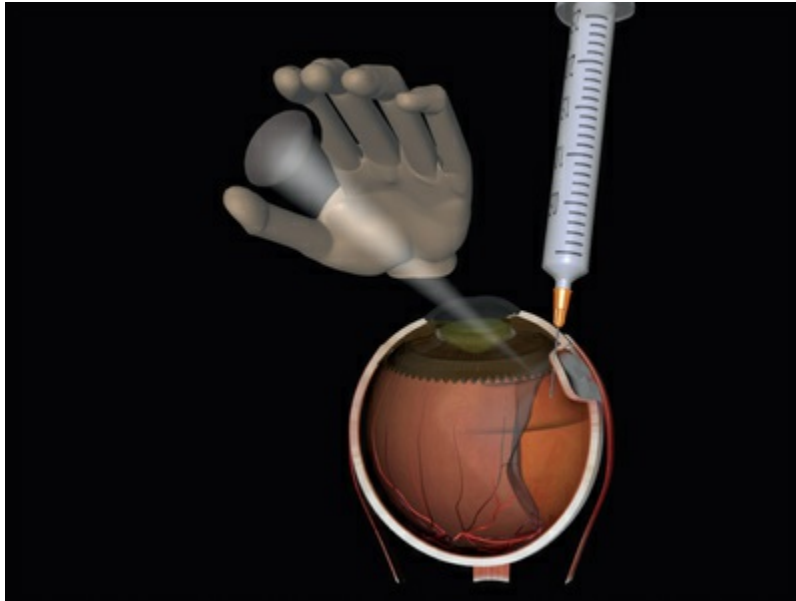

Thermal choroidotomy may be used to reduce the risk of bleeding with this technique. A diathermy needle may be used to coagulate the choroidal vessels<sup>49</sup> and a diathermy needle used to perforate the choroid.<sup>50</sup> Alternatively, photocoagulation may be used. The tip of a laser endoprobe is positioned very close to the knuckle of choroid (Fig. 104.41). The laser is activated for 1–2 seconds at very high power (600 mW) until subretinal fluid is seen welling forward. The high beam divergence makes unintentional retinotomy unlikely, and this technique has been used successfully in the presence of quite shallow subretinal fluid.<sup>51</sup> Use of an indirect laser for this step avoids the expense of an endolaser probe.<sup>52</sup>

**FIG. 104.41** Thermal choroidotomy using a laser endoprobe.

### Single-Stage Techniques.

Charles has described a technique using a 25-gauge hypodermic needle attached to an open syringe under ophthalmoscopic visualization (Fig. 104.42). The needle enters the globe anteriorly and is passed under the buckle and obliquely posteriorly in the subretinal space.<sup>53</sup> Retinal incarceration is extremely unlikely, and any retinal breaks created will be in the bed of the buckle and therefore supported. An increased risk of intraocular bleeding has been reported however.<sup>54</sup> This may be averted by increasing the intraocular pressure to close the choroidal vascular bed, for example, by tightening an encircling band prior to drainage.<sup>48</sup>

**FIG. 104.42** Hypodermic needle drain. Note the bevel faces away from the retina.

Suture needle drains use a spatulated needle held in a locking needleholder with 2.5 mm of the tip protruding (limiting the depth of penetration) (Fig. 104.43 online).<sup>55</sup> Very firm pressure on the globe with a forceps at a rectus insertion elevates the intraocular pressure, closing the choriocapillaris before and for 5 minutes after the drain. A single rapid and decisive stab is made into the sclera and the needle immediately withdrawn.

**FIG. 104.43** Suture needle drain. Note firm pressure on

the globe to close the choroidal vasculature.

It is also possible to penetrate the sclera and choroid together using a specially designed diathermy needle that cauterizes to reduce the risk of hemorrhage.<sup>56</sup>

### **Comparison of Techniques.**

While performing cut down drainage, intraocular pressure elevation is avoided to prevent retinal incarceration. In needle drainage on the other hand there is no risk of incarceration (because the choroidotomy is so small) and a high intraocular pressure is desirable to reduce the risk of bleeding. When operating on bullous detachments, very rapid release of fluid can make it difficult to maintain a sufficient intraocular pressure, and this may account for the increased risk of subretinal hemorrhage with this technique.<sup>57</sup>

### **After Drainage**

Whichever drainage technique is used, it is prudent to be prepared for postoperative hypotony. Prolonged hypotony is dangerous during buckling surgery. It may lead to suprachoroidal effusions and hemorrhage,<sup>58</sup> hyphema, and pupil constriction. The scleral sutures should therefore have been preplaced ready for tying and a syringe of air or saline with a small-bore needle at hand to reform the globe.

If subretinal fluid does not flow, or stops earlier than anticipated, the drain site is inspected to exclude a retinal incarceration and reassess the depth of subretinal fluid at the drain site. Star-shaped folds radiating from the drain site indicate a retinal incarceration (Fig. 104.44). It is not generally possible to re-posit the incarcerated retina in the eye and dangerous to try. The site of the incarceration is supported by an explant to relieve traction at this site, combined with retinopexy if there is also a retinal break.

**FIG. 104.44** Retinal incarceration.

If there is deep subretinal fluid at the drain site, gentle massage of the globe or distracting the sclerostomy edges may reestablish flow, otherwise a fresh choroidotomy may be needed.

The major complication of subretinal fluid drainage is choroidal hemorrhage. Subretinal blood tends to gravitate to the most dependent area of subretinal fluid – the macula if this is detached. The rate at which this occurs is probably contingent on the viscosity of the subretinal fluid (and therefore the chronicity of the detachment). It can have serious consequences for visual recovery, so steps should be taken first to limit bleeding and second, to displace the hemorrhage. First the intraocular pressure is elevated, either by tightening sutures or intravitreal injection (cut down drains should be closed with the prepared sutures if this is done). The patient's head may also be tilted towards the drain site. Subfoveal hemorrhage may be displaced pneumatically<sup>59</sup> or removed subsequently by vitrectomy.<sup>60</sup>

### **Air Injection**

When only small holes are present, a soft globe may be reformed with saline, but in the presence of large tears, the fluid quickly leaves the eye and the eye will re-soften. The surface tension of a gas bubble prevents its passage through breaks. An additional advantage of air and gas injections is their ability to supplement the

external buckling effect with internal tamponade of breaks. The major disadvantage of using air or gas is that they may make fundal view difficult particularly if the injection technique is poor. The gas injection technique is described in detail in [Chapter 107](#) (Pneumatic retinopexy), but there are some special considerations relating to the use of gases in buckling surgery.

Use of air or gas to reform a collapsed globe entails injecting into a soft eye. A number of modifications to the basic pneumatic retinopexy technique can make this easier. Use of an air pump can be particularly helpful for the less-experienced surgeon ([Fig. 104.45](#)). A 23-gauge needle is attached to the air line and the pump pressure set at a physiologic level (i.e., 20 mmHg) before being clamped. The needle is introduced into the eye taking the precautions described in [Chapter 107](#) (Pneumatic retinopexy). The clamp on the air line is released, and air rapidly enters the vitreous cavity until the preset pressure on the pump is reached. The rate of air flow is optimal and the final pressure physiologic. This technique is relatively forgiving of errors in placement of the needle (and fish eggs are virtually never encountered).

**FIG. 104.45** Air injection with an air pump. Note the single bubble despite suboptimal position.

Macular folds are a rare complication of the combination of

subretinal fluid, air injection, and buckling (Fig. 104.46).<sup>61,62</sup> There is some uncertainty about the best way to avoid this devastating complication. Face-down posturing immediately after surgery to displace subretinal fluid away from the macula may be helpful.

**FIG. 104.46** Compression fold following drain, air, and explant. This may be avoided by prone posturing.

Pneumatic retinopexy using expansile gas may be used to treat fishmouthing or to facilitate the closure of breaks that are significantly elevated after buckling.

If general anesthesia is used, nitrous oxide should be discontinued at least 15 minutes before the injection to prevent unpredictable expansion of the bubble.<sup>63</sup> Avoiding the use of nitrous oxide altogether removes this risk.

## **Encirclement**

Segmental buckles provide local support which often fades. This may lead to reopening of breaks if insufficient retinopexy has been applied.<sup>23</sup> Encirclement produces permanent support of the vitreous base retina. Indeed, encirclement has been used without any retinopexy:<sup>64</sup> as the breaks are permanently supported there is no need to seal them.

The indications and evidence for encirclement are reviewed more extensively in [Chapter 109](#) (Optimal procedures for retinal detachment repair). There is little evidence to support the routine use of encirclement in buckling surgery, and the procedure appears to have a significantly greater risk of complications than a segmental buckle. In practice, a case-by-case judgment has to be

made on whether the benefits (the increased chance of success is probably quite modest) justify the risks.

Encirclement has a particular role in certain situations:

- Early PVR
- Very extensive scleromalacia
- Extensive detachment in which breaks are difficult to detect (for example in some pseudophakic eyes with small anterior breaks and capsular phimosis)
- Multiple breaks in three or more quadrants.

Encirclement is produced with a combination of a local silicone tire (confined to the areas of visible the breaks) with a 2-mm band, which lies in the gutter of the tire and encircles the globe before being attached to itself (Fig. 104.47). The 2-mm band is often too narrow to support breaks, and its primary purpose is to maintain the height of the indent from the tire.

**FIG. 104.47** The basic elements of an encirclement: a tire, a band, and a silicone sleeve.

The steps are:

1. A 360° peritomy with slinging of all four rectus muscles.
2. Break localization, retinopexy, and preplacement of the mattress

sutures of the tire. Generally two sutures are required per quadrant.

3. Threading the tire and band together under the recti and mattress sutures. Ensure that both limbs of all the mattress sutures are above the buckle as it is not uncommon to leave one under the encirclement by mistake. Some thought needs to be given to where the ends of the band will be secured at this stage. It is also important to ensure that the band does not become twisted. An oblique trimming of the ends allows the orientation to be checked after the band has been passed around the globe (as a 180° twist will be immediately apparent).

4. Subretinal fluid drainage is required in the majority of cases. The exact stage at which it is performed is variable, but it may be done now to create space for the indent.

5. Tighten the mattress sutures over the tire to create a local indent.

6. Place a small holding stitch over the band in each quadrant where there is no tire to stop it bow stringing forward when tightened. These are placed at the equator (approximately 12 mm behind the limbus).

7. Fasten the ends of the band to each other. A Watzke sleeve is a small silastic tube designed to secure the ends and allow adjustment of the tension in the band. The steps for engaging the ends of the band in the sleeve with a specially designed cross acting (“Watzke”) forceps are illustrated in [Fig. 104.48](#).

**FIG. 104.48** Engaging (A–D) and (E) tightening the band, using a Watzke sleeve and forceps.

8. The ends of the band are pulled to create the encircling indent. A 6-mm shortening will produce approximately a 1-mm indent, irrespective of the size of the globe. The end point of this tightening is best judged ophthalmoscopically; a shallow indent should be just visible. The practice of tightening the band to reform the eye after drainage is dangerous as it may produce a grossly excessive indentation.

9. The optic nerve perfusion should be checked and, if necessary, steps taken to normalize it such as paracentesis, subretinal fluid drainage, or adjusting the buckle.

## Final Examination of the Retina

The retina is now examined to determine the adequacy of the buckle and the perfusion of the central retinal artery.

The buckle should be in the correct position and of sufficient height to support all the retinal breaks (Fig. 104.49). Unsupported breaks may be supported by moving existing explants or by placing additional explants as required (e.g., by the addition of more radial sponges under encircling circumferential explants).

**FIG. 104.49** Final check: all the retinal breaks (*arrows*) are supported on the buckle.

Judging the correct height of the buckle can be difficult, as even breaks that are not fully closed at the end of surgery may close postoperatively allowing the RPE to pump out the residual subretinal fluid. If the contour of the detached retina follows that of the buckle, the break is likely to close (Fig. 104.50). The height of the buckle may be adjusted by readjusting scleral sutures (if they have been tied on bows) or replacing scleral sutures (usually with wider

bites). Otherwise, the buckle may be replaced. The height of the buckle may also be adjusted by subretinal fluid drainage at this stage. A simpler alternative is adjunctive pneumatic retinopexy.<sup>65</sup>

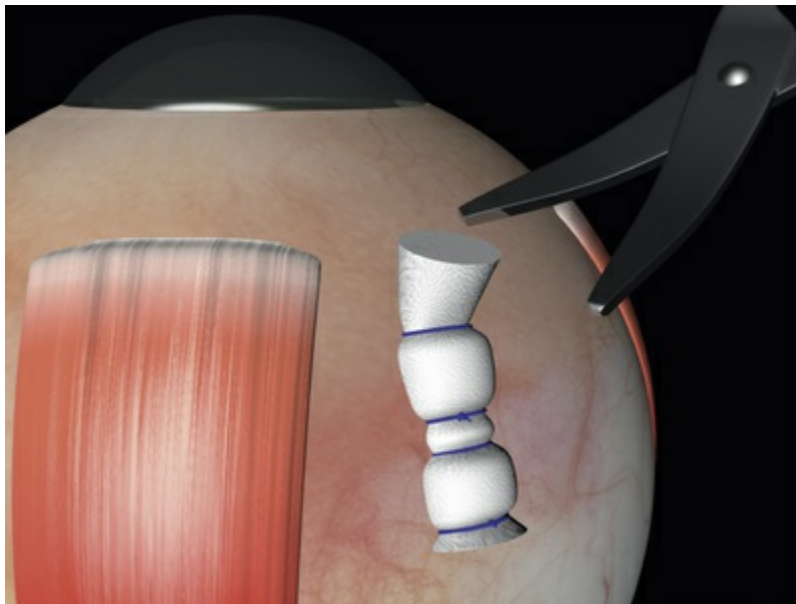

**FIG. 104.50** Final check of the retina. If the detachment follows the contour of the buckle: (A) the detachment is likely to settle postoperatively. If it does not, (B) further steps need to be taken – either adjustment of the buckle, drain, pneumatic, or a combination.

A pink disc with large-calibre retinal vessels indicates a pressure below the diastolic closing pressure of the retinal vessels. Spontaneous pulsation of the retinal arteries indicates an intraocular pressure between the systolic and diastolic closing pressure. Intraocular pressure greater than the systolic closing pressure of the retinal arteries causes a pale disc with thready vessels. Reducing the intraocular pressure, typically by paracentesis, is necessary to prevent permanent visual loss. The cornea is often hazy at this point in the operation, making it difficult to judge the patency of the central retinal artery. In this case, it is still usually possible to see vessel pulsation. If arterial pulsation can be induced with pressure on the globe, the intraocular pressure is acceptable (below the retinal artery diastolic pressure).

## Closure

The risk of buckle extrusion may be reduced by trimming any protruding edges of sponges (Fig. 104.51), rotating radial mattress

sutures so that the knots lie posteriorly, and ensuring that the buckles are covered by the Tenon capsule. This may entail closure of the Tenon capsule as a separate layer before closure of conjunctiva, particularly with radial sponges where the risk of exposure and extrusion is much greater.<sup>66,67</sup>

**FIG. 104.51** Trimming protruding pieces of explant does not compromise the indent and reduces the risk of extrusion.

An absorbable suture such as 7-0 Vicryl is used to close conjunctiva. The conjunctival edge is identified (taking care not to mistake the edge of the Tenon capsule or plica semilunaris). Accurate realignment is achieved using the “ship to shore” principle: sutures are passed from more mobile flaps of conjunctiva towards the incised edge.

A subconjunctival injection of broad-spectrum antibiotic and steroid may be given.

## Documentation

Clear documentation of the surgery, with diagrams to show the position and sutures of all explants (including Watzke sleeves), is very helpful if the eye has to undergo subsequent surgery.

## Outcomes

Reported outcomes for primary success with scleral buckling are generally high. In a series of 4325 patients, a success rate of 84% was achieved following a single operation.<sup>68</sup> There is some variation in reported success rates, and many failures are avoidable.<sup>69,70</sup> This underlines the importance of good surgical technique in achieving a satisfactory result.

Functional success with recovery of central vision is somewhat lower than anatomic success<sup>71</sup> and depends on the stage of presentation and the duration of macular detachment. It is important to remember that binocular visual function, ocular cosmesis, and ocular comfort are the most important outcomes for the patient. Measures taken to maximize the anatomic success rate (e.g., the routine use of large encirclements in simple cases) may not therefore be justified if they carry a greater morbidity.<sup>72</sup>

## Postoperative Complications

### Recurrent Retinal Detachment

Persistent subretinal fluid is often seen in the early postoperative period, particularly if a nondrainage operation has been performed. Resorption of fluid may take much longer (Fig. 104.52), particularly in chronic detachments with subretinal precipitates and demarcation lines.<sup>73</sup> Persistence of subretinal fluid alone is not an indication for revision surgery. Indications for early revision surgery are a visible open retinal break or increasing subretinal fluid.<sup>74</sup>

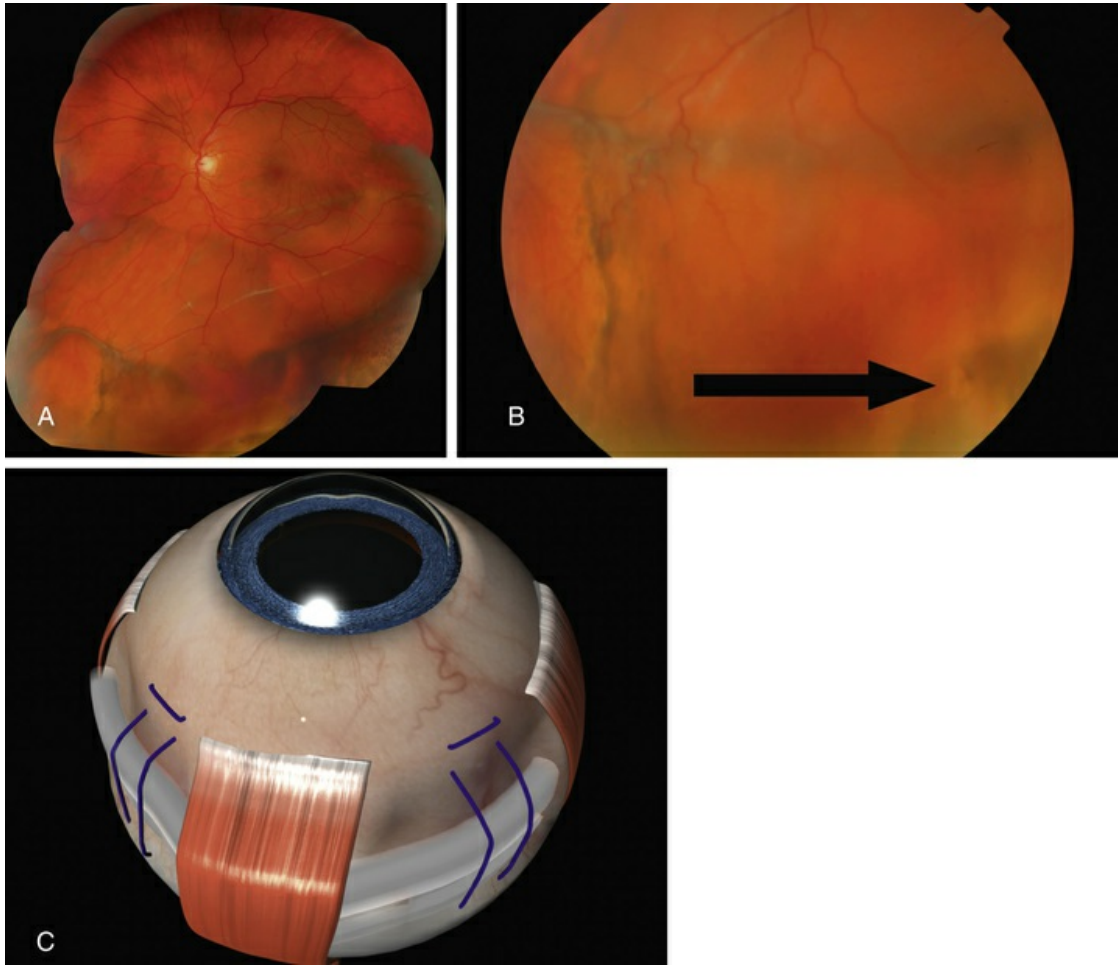

**FIG. 104.52** Rarely resorption of subretinal fluid (*arrow*) can take months.

Recurrent detachment is often due to errors in the initial surgery.<sup>9</sup> Successful revision surgery starts with an analysis of the cause of failure. Is there an open break? Are the indents in the right place? Are they high enough to close the breaks? These questions are answered by carefully observing the distribution of subretinal fluid, the presence of subretinal fluid on indents, and visibly open or unsupported breaks.<sup>9</sup>

Example 1: Inadequate buckle – A patient with a shallow inferior detachment due to several atrophic holes underwent a nondrainage procedure with a local circumferential tire. Postoperatively, the distribution of subretinal fluid was unchanged from before the operation, implying that one of the original breaks remained open (Fig. 104.53). There was subretinal fluid on the indent at 6 o'clock communicating with an open break. The height of the buckle was uneven, and at revision surgery no sutures were found near the site of the break. The addition of extra sutures to support this area successfully reattached the retina.

**FIG. 104.53** Failed buckle with subretinal fluid on the buckle inferiorly. (A) The indent is high in places but not over the break at 6 o'clock. Magnified view reveals open break (B, *arrow*). At reoperation (C) there is very little indentation inferiorly due to poor placement of the mattress sutures.

Example 2: Missed retinal break – A child presented with an extensive inferior detachment. The operation note stated that no definite breaks were found but cryotherapy and radial sponge were applied to a “thin area with probable hole” inferiorly. The amount and distribution of fluid was unchanged postoperatively. The fluid distribution did not obey Lincoff's laws. This suggested a break had been missed at the original surgery. At repeat surgery, a superonasal retinal dialysis was found ([Fig. 104.54](#)).

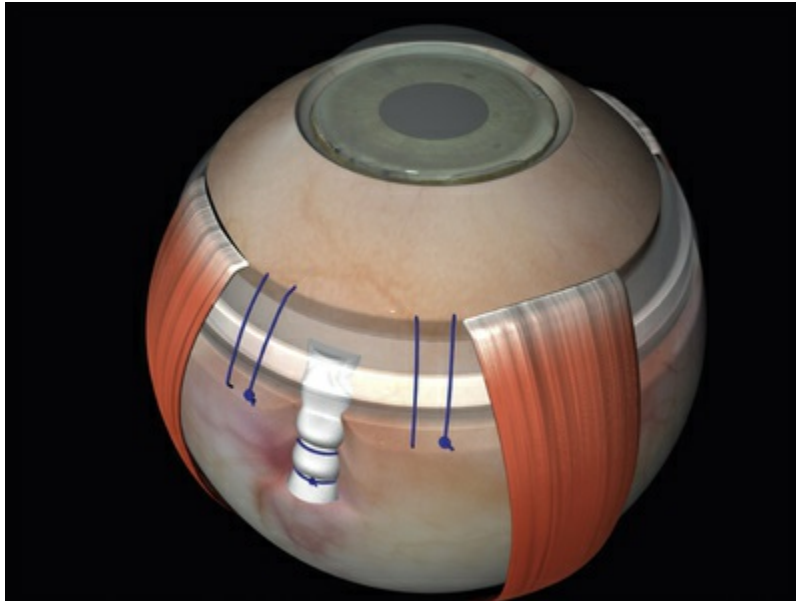

**FIG. 104.54** Failed retinal detachment due to a missed dialysis. Lincoff's rules indicate an undetected superonasal break.

Example 3: Misplaced buckle – A patient presented with recurrent retinal detachment following an encircling procedure. There was no subretinal fluid on the indent. Closer examination revealed a small tear behind the indentation ([Fig. 104.55](#)). This was managed by locally augmenting the encirclement with a radial explant ([Fig. 104.56](#)).

**FIG. 104.55** Recurrent retina detachment following encirclement (A). There is no fluid on the buckle. (B) Magnified view showing a break (*arrow*) posterior to the encirclement.

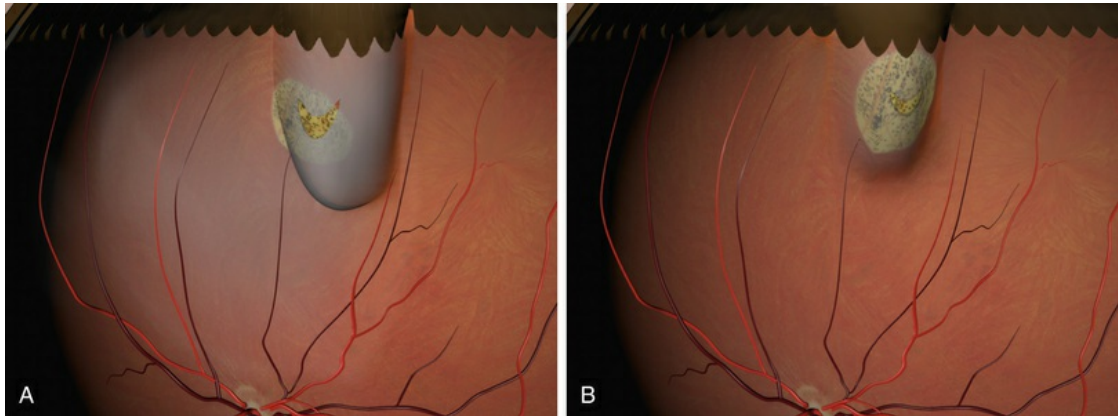

**FIG. 104.56** The case in [Fig. 104.55](#) managed by local augmentation of the buckle using a sponge.

Example 4: Fishmouthing – A patient underwent a local circumferential sponge nondrainage operation for a detachment due to several small tractional tears in one quadrant of the retina. Postoperatively, persistent subretinal fluid with folds of retina on the buckle were present ([Fig. 104.57](#)). One of these folds was in communication with a retinal tear. A diagnosis of fishmouthing was made.<sup>75</sup> Injection of 0.3 mL 100% SF<sub>6</sub> quickly resolved the problem.<sup>76</sup>

**FIG. 104.57** Fishmouthing. Folds on the tire (A) with fishmouthing of the break (*arrow*) apparent in magnified view (B). This was managed successfully by pneumatic retinopexy (C).

Example 5: Misplaced buckle: Radial sponge malposition in the radial meridian – A nondrainage operation with a radial sponge was used for a detachment due to a single tear. The amount and distribution of fluid were unchanged postoperatively (Fig. 104.58). The tear was on the edge of the indentation. Placement of a radial sponge in the correct meridian closed the break.

**FIG. 104.58** Misplaced sponge. The break is on the edge of the sponge (A), which has to be repositioned to close the break (B). Positioning of the apex of the indent under the tear is critical when using radial sponges.

Proliferative vitreoretinopathy, the most important cause of ultimate failure to reattach the retina, is discussed in [Chapter 111](#) (Proliferative vitreoretinopathy).

## Glaucoma

Retinal detachment is associated with glaucoma,<sup>77</sup> so in some cases postoperative glaucoma may have been present preoperatively.

A steroid response is the commonest cause of open angle glaucoma after buckling surgery. Most cases of buckle-related angle closure glaucoma occur without pupil block.<sup>78</sup> The central anterior chamber is shallow due to forward displacement of the ciliary body ([Fig. 104.59](#)). This may be due to the combined effects of interrupted choroidal venous drainage and the mass effect of a large explant. This condition does not respond to iridotomy or miosis (which tends to exacerbate it). Most cases resolve after 1 week with conservative measures including steroids, cycloplegia, and ocular hypotensive agents. In intractable cases, the Watzke sleeve may need to be loosened or the band divided.

**FIG. 104.59** Angle closure without pupil block after buckle. The high encirclement (A) causes choroidal venous congestion, which displaces the ciliary body, and thus the whole lens–iris diaphragm, forward. (B) A slit-lamp photograph shows central and peripheral anterior chamber shallowing (in pupil block the central anterior chamber is deeper).

## Epiretinal Membranes

Epiretinal membranes at the macula are the commonest cause of visual loss after successful scleral buckling.<sup>79–81</sup> Their management is discussed in [Chapter 120](#) (Epiretinal membranes, vitreoretinal traction, and cystoid macular edema).

## Extrusion/Infection

These typically present several weeks or months postoperatively as an inflamed eye with purulent discharge. Even if exposure of the buckle is not evident, it is often possible to express some pus through associated conjunctival dehiscence. As infection and extrusion are often associated, it can be difficult to establish which comes first. The risk seems to be heavily influenced by the surgical technique used, radial sponges having a greater risk than circumferential ones.<sup>67</sup> This fact, together with the delayed presentation, suggests that in most cases microorganisms gain access to the explants through conjunctival dehiscences over protruding segment of buckle or suture rather than being

introduced at the time of surgery. This highlights the importance of trimming the ends of sutures and explants and covering them well during closure. Closure of the Tenon capsule and conjunctiva in separate layers may be the best way of achieving this, especially if the conjunctiva is particularly thin.

Bacteria produce a biofilm coating on explants which makes it impossible to eradicate them medically.<sup>82</sup> The only definitive treatment is removal of the explant.<sup>83</sup> Provided adequate retinopexy has been performed recurrent retinal detachment is unusual.<sup>84,85</sup> If there is any doubt about this, supplementary retinopexy may be carried out around the breaks before removing the buckle.

Removal of extruding radial sponges is generally easy and can often be done on the slit lamp. Encircling elements are technically more challenging and may require general anesthesia. Occasionally exposed encircling elements with minimal symptoms can be managed conservatively, particularly if the patient is in poor general health or the initial surgery was complex or complicated.

Buckle exposure tends to follow a relatively chronic course, but occasionally patients develop acute sight-threatening complications such as endophthalmitis or scleritis<sup>86,87</sup> requiring urgent removal of all foreign material (explants and sutures) and local and systemic antibiotics.

## Band Migration

Encircling bands may intrude or migrate over the surface of the eye, usually anteriorly.

Intrusion is often an incidental finding but may cause vitreous hemorrhage or, less frequently, recurrent detachment many years after buckling surgery. It is usually managed conservatively. Vitreous hemorrhage and retinal detachment may both be managed by vitrectomy without disturbing the band.

Migration anteriorly may affect rectus muscle function and even cause the band to migrate anteriorly and extrude through the limbal conjunctiva.

## Diplopia

Diplopia is common after scleral buckling surgery.<sup>88</sup> It tends to

improve with time, and intervention is only indicated for persisting diplopia that does not respond to prisms. Removal of the explant alone may cure the problem.<sup>89</sup> Strabismus surgery can be challenging due to the presence of buckles and adhesions. In patients with very extensive buckles that cannot safely be removed, repeated injections of botulinum toxin may be useful.<sup>90</sup>

Metamorphopsia following detachment of the macula may lead to poor sensory fusion with diplopia. It is important to identify these cases as the diplopia does not respond well to surgical intervention.

## Anterior Segment Ischemia

Anterior segment ischemia is now rare, as very high encirclements and rectus disinsertion, both of which compromise the uveal circulation, are rarely used. Patients with sickle-cell disease are at particularly high risk<sup>91</sup> and may benefit from exchange transfusion particularly if an encircling buckle has to be used. Presenting features are corneal edema, pain, anterior chamber flare, and a deep anterior chamber. The intraocular pressure may be high initially but falls as the ciliary body fails. Mild cases may be managed with topical steroids, but severe cases carry a poor prognosis, and loosening or division of the band should be considered.

## **Introduction**

Vitreoretinal surgery is a complex blend of the most difficult high-technology microsurgery applied to complex pathobiologic systems. This rapidly growing field requires continued research and training and an honest assessment of one's surgical skills, knowledge, and experience. The surgical team must be well-trained, efficient, and technologically competent; the complex equipment must be constantly updated as the technology progresses.

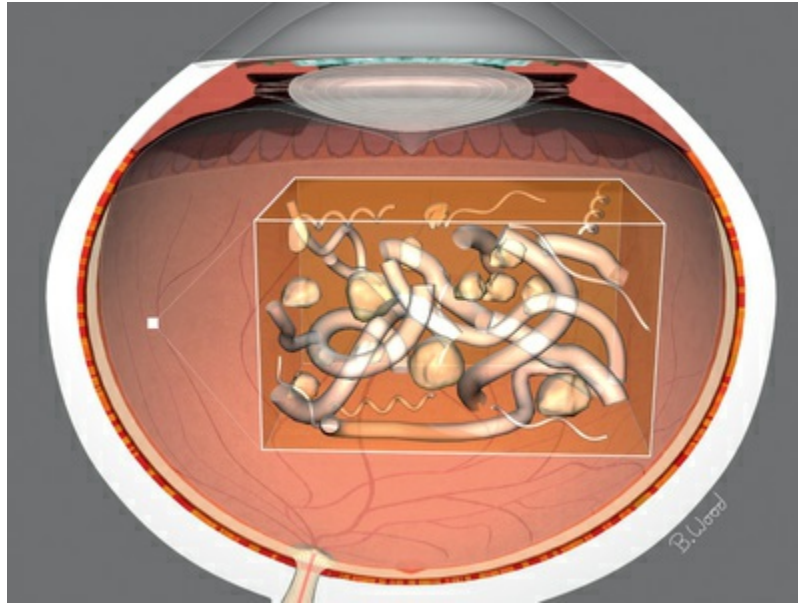

To help deal with the complexity of vitreoretinal surgery, the

author proposes an approach utilizing a surgical algorithm made up of scenarios. The surgical scenarios are similarly composed of smaller elements referred to as tasks, tools, associated analog parameters (pressure, power), and interconnects (fluid–gas exchange, air–silicone exchange). Tasks are common to the surgical approach to different disease states that share common pathoanatomic configurations. Each algorithm contains decision nodes with several alternative scenarios. The decision process requires outcome data, knowledge of physical principles, individual patient factors, and experiential information. This chapter will begin with a description of relevant general pathoanatomy, with specific information left to other chapters on specific disease states. Understanding the mechanics of the tools used will allow discussion of the details of how to perform each task. The chapter concludes with a suggested algorithm for each common disease state, with specific management details again left to other authors.

## Vitreoretinal Surgical Anatomy

The vitreous can be considered as a three-dimensional matrix of collagen fibers and hyaluronan gel (Fig. 105.1). In the normal state, the outer surface of the vitreous is in contact with the retina, pars plana, and ciliary body in a roughly spherical shape with an anterior facet abutting the lens. Disease-induced retinal pigment epithelium (RPE) and glial cell migration, attachment of cells to the extracellular matrix, and hypocoelular contraction of the collagen matrix take place with the majority of the relevant changes occurring at the cortex surface. The anterior vitreous cortex (AVC) is contiguous with the posterior vitreous cortex (PVC) and, for the most part, is not fenestrated.

**FIG. 105.1** The vitreous is a three-dimensional matrix of collagen fibers and hyaluronan gel.

Activated retinal glial cells, RPE cells, and cells of hematogenous origin migrate along the front and back surfaces of the retina and vitreous. These cells have coated pits lined with fibronectin, allowing them to attach to and contract the collagen matrix.

A detailed understanding of the abnormal vitreoretinal interface and its derivative geometry is requisite to undertaking vitreoretinal surgery. The task involves visualization of vitreous structures and a systematic search for membranes based on observed retinal topology. In general, membranes are white and matte-finish, whereas the retina has a reflective surface luster and appears pale yellow. If a complete posterior vitreous separation has not occurred, there is usually continuity between areas of epiretinal membrane (ERM) and adjacent detached PVC. Because the retina itself does not contract or develop substantial intraretinal proliferation, changes in contour occur because of perpendicular or oblique vitreoretinal traction (funnel, plateau, or ridge-like elevations) or tangential ERM-related traction (star folds, epimacular membranes).

Retinal breaks result in loss of the normal transretinal pressure gradient. Trans-hole flow is related to intraocular pressure, capability of the RPE pump, viscosity of the fluid, and the area and dimensions of the retinal break.

# Mechanics of Vitreoretinal Surgery

An understanding of the physical principles of surgical tools enhances the capabilities of the vitreoretinal surgeon. Discussion of the forces available for cutting and thermal effects follows. Cutting may simply be defined as the separation of a tissue into two parts.

## Peeling

Force along the axis of a collagen fiber bundle causes nonelastic collagen fibers to slightly stretch and ultimately to fail. Damage to attached structures is a function of the number of fibers and the strength of the attachment and the substrate. Membrane peeling requires force preferably tangential to the retina, which causes failure of the attachment at the vitreoretinal interface by elongation. Because dense, highly adherent membranes such as those associated with diabetic traction retinal detachments are approximately 100 times stronger than the retina, retina surface defects or retinal breaks usually occur before removal of the membrane occurs (Fig. 105.2). For this reason, membrane peeling may be inappropriate in diabetic traction retinal detachment cases.

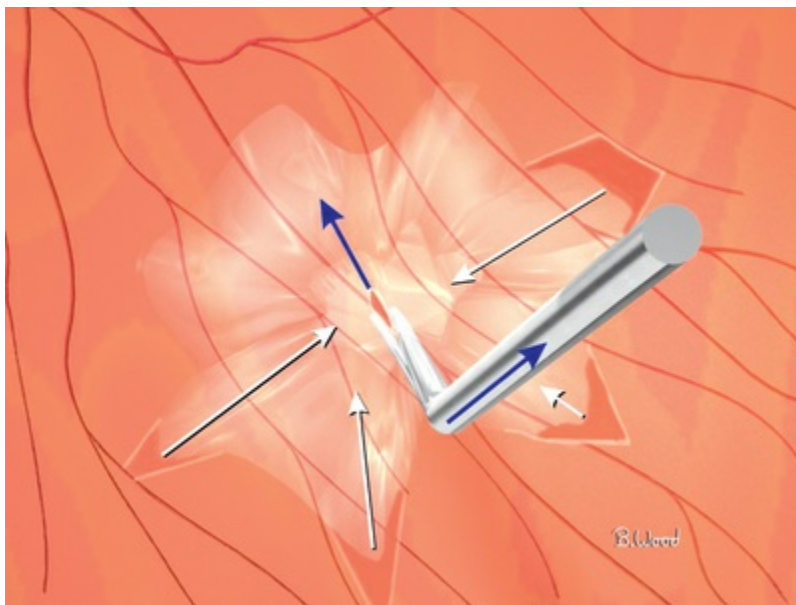

**FIG. 105.2** Forceps designed to place one blade under the epiretinal membrane (*ERM*) damage the retinal surface. Similarly, pincers and membrane scrapers

damage the retinal surface.

## Shear

Shear cutting occurs when force is applied along two opposing right-angle edges moving past each other and forced against each other. Vitreous cutters and scissors use shearing to cut tissue.

Inclusive shears such as a vitreous cutter prevent the push-out force that occurs as exclusive shears (scissors) close (Fig. 105.3), pushing the tissue away from the fulcrum, but require elastic deformation of tissue into the port caused by transport pressure gradient, which may cause fluid surge and iatrogenic retinal breaks (Fig. 105.4).

**FIG. 105.3** Scissors create a push-out force; if they are inserted open and then closed they tear the retina at the epiretinal membrane attachment points.

**FIG. 105.4** Inclusive shears (vitreous cutters) require elastic deformation of tissue into the port.

## Fatigue Failure

Fatigue failure occurs when repetitive motion, elongation, and compression weaken tissue structure and cause failure. Ultrasonic cavitation (fragmentation, phacoemulsification) is an example of this mode of cutting.

## Infusion System Management

Vitrectomy surgeons have occasionally experienced excessively low intraocular pressure (IOP) during vitreoretinal surgery throughout the history of vitreoretinal surgery. Gravity-fed infusion systems were simplistic and could only cause low intraocular pressure if the bottle was too low or the infusion fluid was depleted. Sutured 20-gauge (G) vitrectomy resulted in low intraoperative IOP if the cannula was initially positioned into the suprachoroidal space without surgeon recognition or displaced intraoperatively thereby causing suprachoroidal infusion. Digital display of infusion driven by an air pressure source in the machine created the false impression that IOP was controlled when in fact as much as 25 mmHg of difference existed between infusion pressure and IOP with typical flow rates during core vitrectomy and especially

fragmenter use. The fragmenter lumen, unlike the vitreous cutter, is not obstructed by an inner needle or port opening and closing. Low intraoperative IOP is prevented by using a sufficient infusion pressure to compensate for infusion line and cannula resistance-based losses. Ohm's law of fluidic resistance,  $\text{pressure} = \text{flow} \times \text{resistance}$ , explains pressure drop in the infusion system during flow. There are many causes of excessively low intraocular pressure during vitrectomy, each of which will be discussed. Inadvertent suprachoroidal infusion is a relatively common cause of low pressure as well as other more serious complications during vitrectomy with 23–25–27-gauge surgery as well as the 20G sutured systems used for over three decades. Sutureless 25G vitrectomy initially utilized straight-in trocar cannula trajectories to produce sclerotomies perpendicular to the sclera. When 23G, sutureless surgery was introduced subsequently, oblique trocar-cannula entry was utilized in order to construct a scleral tunnel to reduce wound leakage. Initially, surgeons used a two-plane approach; the initial trocar-cannula insertion segment was approximately  $30^\circ$  relative to the sclera and the second segment trajectory perpendicular to the sclera. Some surgeons even believed that a biplanar incision was constructed, although this is not true because the scleral tunnel was created before changing the trajectory. More recently, surgeons using both 23G and 25G systems have switched to oblique entry in order to create a long scleral tunnel;<sup>1–3</sup> unfortunately some surgeons use excessively steep angles ( $\sim 10^\circ$ ). Although near tangential entry creates a long scleral tunnel; it increases the chances of infusing into the suprachoroidal or subretinal space (Fig. 105.5). If the cannula is in the suprachoroidal space, the peripheral choroid, which is not observed by the surgeon, expands early in the case, allowing infusion without hypotony, later the choroid can no longer expand and infusion becomes limited, alerting the surgeon to the problem (Fig. 105.6). Thinking that hypotony caused a choroidal effusion leads to incorrect management. A single plane,  $30^\circ$  trajectory is better compromise between the benefits of a long scleral tunnel and the catastrophe of suprachoroidal infusion. Inspecting the infusion cannula with the operating microscope after insertion and before initiating infusion was standard practice with sutured 20G vitrectomy. Many surgeons have discontinued this practice since

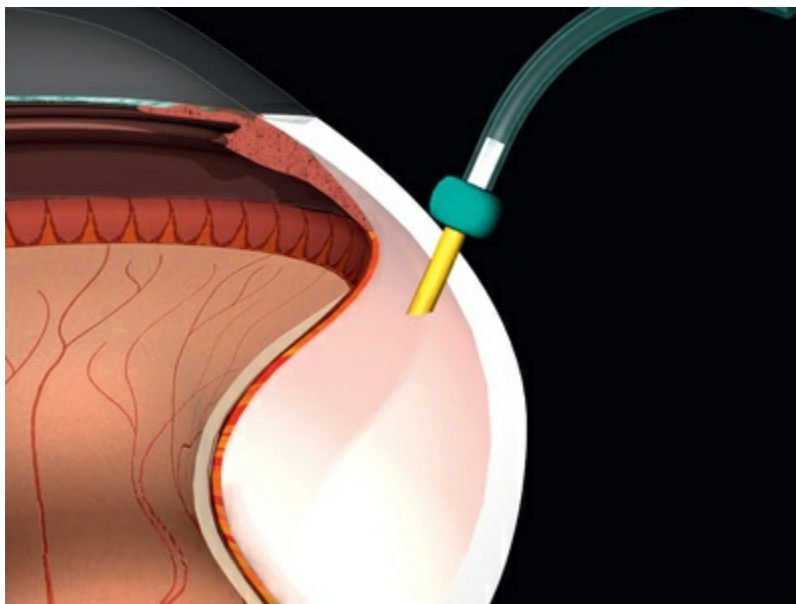

23/25G sutureless vitrectomy began; clearly the crucial step of observing the tip of the infusion cannula should not be omitted. It is best practice to insert the infusion port in the cannula with the infusion running to prevent bubbles followed by immediate inspection of the tip of the infusion cannula. The naked eye and endoilluminator provide insufficient magnification to make the determination that the cannula has penetrated the choroid and nonpigmented pars plana epithelium; microscope visualization is essential. Adhesively fastening the infusion cannula tubing and associated stopcock(s) and connectors to the drape is imperative to prevent traction on the infusion cannula and the eye. Unrecognized pulling on the tubing by the assistant or surgeon can easily cause the cannula to partially pull out causing a suprachoroidal infusion. Adhesively fastening the infusion cannula tubing to the drape with eye in the primary position with a short tubing loop can result in a suprachoroidal infusion when the eye is rotated to view the periphery creating tension on the cannula. Scleral depression is another cause of inadvertent suprachoroidal infusion by causing torque on the cannula as the eye is rotated by the depressor. In addition, scleral depression can force blood clots, dense scar tissue, peripheral vitreous, or silicone oil into the infusion cannula and tubing, effectively plugging it, giving the false impression of infusion system failure. Placing the infusion cannula too close to the lower lid rather than just inferior to the horizontal meridian is a common cause of suprachoroidal infusion created when the eye is rotated down to visualize the inferior periphery and the cannula is rotated into the suprachoroidal space. Kinking of the more flexible silicone tubing terminal segment of the infusion cannula can be caused by the surgeon or assistant accidentally pulling on the tubing. This problem is exacerbated by using excessively low infusion pressure settings (10–25 mmHg) insufficient to straighten out the tubing kink. The author has always used 45 mmHg except when operating on children or patients with very low systemic blood pressure, typically under general anesthesia. Some surgeons have recently advocated using infusion settings of 10–20 mmHg because of a completely unfounded belief that occult ischemia is common during vitrectomy. Using infusion settings of 10–20 mmHg causes miosis, bleeding, and corneal astigmatism from

contact lens pressure on the cornea and instrument forces on the sclerotomies as well as scleral infolding often mistakenly thought to be choroidals. Kinking as well as multiple bubbles in the infusion line increase resistance to flow and cause pressure drop, ultimately resulting in excessively low IOP. Surgeon remediation of intraoperative low IOP should be systematic; the first step is to inspect the cannula with the microscope to make sure it extends all the way through the choroid and nonpigmented ciliary epithelium. If not, a 25G MVR blade can be used to incise the tissue covering the cannula while pressing the cannula into the eye with smooth forceps (Fig. 105.7). Another option is to move the infusion system port to the supranasal cannula. The infusion tubing should be examined for kinking or inadvertent disconnection. Kinking is most common when excessively low infusion pressure settings are used and the tubing bends at the fluid–air stopcock/valve. If a suprachoroidal infusion occurs, infusion through a cannula with a 25G needle (if 25G surgery or 27G needle if 27G surgery) into the middle of the eye will compress the choroid against the sclera and cause the suprachoroidal fluid to disappear often via egress around the cannulas (Fig. 105.8). Cut down drainage is almost never necessary. If choroidals are present at the inception of surgery, a 6-mm instead of 4-mm cannula can be used and/or infusion initiated with a 25G needle as described above.

**FIG. 105.5** An excessively almost tangential entry angle creates a long scleral tunnel but increases the risk of infusing into the suprachoroidal or subretinal space.

**FIG. 105.6** Infusion into the suprachoroidal space causes expansion of the peripheral choroid.

**FIG. 105.7** If the infusion cannula does not extend into the vitreous cavity, a 25G MVR blade can be used to incise the tissue covering the tip.

**FIG. 105.8** Infusion through a 25G needle will compress the choroid and cause egress of the suprachoroidal fluid around the cannula.

## Vitreous Cutter Considerations

All current vitreous cutters utilize suction and inclusive shearing. Ideal tissue cutting is defined as that producing zero displacement of the tissue to be removed and no vitreoretinal traction. It is safest to use the lowest suction force sufficient to imbricate tissue or vitreous into the cutter port. High cutting rates (7500-10,000 cuts/minute) decrease pulsatile fluid flow and pulsatile vitreoretinal traction (Fig. 105.9). Port-based flow limiting via high cutting rates and smaller gauge cutters limits fluid surge after sudden elastic deformation of dense ERM, scar tissue, or lens material through the port, thereby reducing iatrogenic retinal breaks. Dual actuation eliminates the spring, which enables higher cutting rates while maintaining effective duty cycle control (Fig. 105.10). In summary, using the highest available cutting rate is usually the best approach for all tasks and all cases unless all the vitreous has been removed first.

**FIG. 105.9** High cutting rates reduce pulsatile vitreoretinal traction.

**FIG. 105.10** Dual actuated cutters eliminate the return spring and enable higher cutting rates.

## Fluidics

Venturi-based, vacuum-controlled aspiration systems are preferred over flow control using peristaltic pumps or piston pumps for all vitreoretinal tasks. Peristaltic pumps produce high transorifice pressure when dense vitreous or ERM transiently occludes the port leading to surge and iatrogenic retinal breaks when the material suddenly deforms through the port. In addition, peristaltic and piston pumps cannot function in an air-filled environment, thereby preventing use of the valuable technique of interface vitrectomy under air.<sup>4,5</sup>

## Control Systems

Analog parameters using surgical force such as suction levels, power scissors and forceps, and power injector rate are best controlled by proportional depression of the surgeon's foot (linear control). Switching of valves, pumps, electronic devices, and lasers are ideally controlled by a single integrated system, with functions controlled by the surgeon rather than the circulating nurse or even scrub tech.

## Microscope Requirements

A stereo operating microscope with magnification up to  $\times 30$  with coaxial illumination is required. The microscope should have a beam splitter to enable stereo-optical viewing by the assistant and television viewing for the operating room team. Illumination on–off should be controllable by the surgeon's foot. So-called heads-up surgery, viewing surgery with a television-based system and flat panel display, significantly reduces resolution and dynamic range and offers no advantage.

Microscope XY positioning must be controlled via surgeon footswitch. Power zoom and focus positioning are required. Physical stability of the microscope and patient's head is required to preserve the dimensional stability of the surgical view for microsurgery. Ceiling-mounted microscopes are less mechanically stable than floor-mounted microscopes because of longer moment arms and inherent lack of ceiling rigidity. The surgeon's hands should be in contact with the patient's head so hand motion can be coordinated with head motion. The goal is to provide a stable mechanical relationship between the microscope, the patient's head, the surgeon's hands, and the OR table resting on the floor.

All power and control sources for surgical tools should be integrated into a single system for greater efficiency. Advanced vitreoretinal surgery systems have a unified human–machine interface combining all surgical functions into an integrated system (Fig. 105.11). Illumination, diathermy, and infusion are referred to as global functions and are always available. Infusion is best controlled by digital, sensor-based, pressurized infusion systems.

**FIG. 105.11** Advanced vitreoretinal surgical systems utilize an intuitive human–machine interface and combine all surgical functions into an integrated system.

## Tool Ergonomics

All surgical tools should be as light as possible and held in the surgeon's fingertips. They should be contoured rather than cylindrical to reduce the force required to prevent dropping and constrain grip at a consistent position. They should be no longer than the distance from the fingertips to the point of contact with the hand. Shorter handles reduce the torque produced by the weight and reduce friction as the cables, fibers, and tubing used to connect surgical tools slide on the drape. Minimizing forces required to hold tools increase the surgeon's proprioceptive sense (Weber–Fechner law) and decrease fatigue and tremor. Standardization of tip-to-grip across all tools facilitates so-called muscle memory; the surgeon's cerebellum, motor strip, and frontal lobe trajectory generator knows where the tip is located if view is suddenly lost.

## Surgical Steps

## Transconjunctival, Small-Gauge Vitrectomy

Transconjunctival, sutureless 23/25/27G vitrectomy systems have improved to the point that there is no longer a need for 20G vitrectomy; referring to 20G vitrectomy as the “gold standard” is arcane. The advantages of 23/25/27G are improved safety because of fewer iatrogenic retinal breaks, reduced operating times, less patient discomfort, and faster visual improvement.<sup>6-8</sup> A single 20G sclerotomy is required to remove intraocular foreign bodies and for a fragmenter to remove dense lens material (Fig. 105.12).

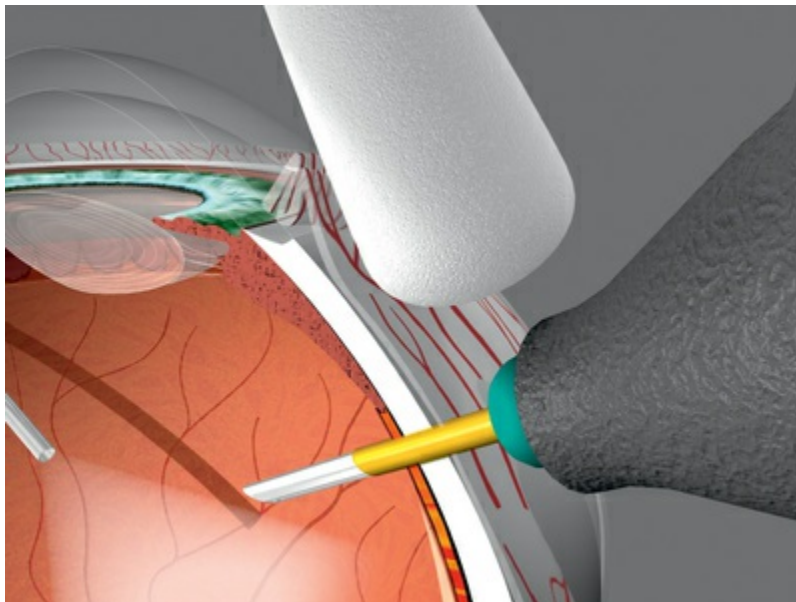

**FIG. 105.12** A single 20G sclerotomy can be used to allow fragmenter access or foreign body removal in microincision vitrectomy when using a 25G surgical approach.

There is no solid evidence that combining a scleral buckle with vitrectomy improves retinal detachment outcomes, especially in the absence of severe proliferative vitreoretinopathy (PVR). Elimination of the scleral buckle supports many of the advantages of sutureless, transconjunctival vitrectomy, i.e., no refractive error changes and no strabismus. Elimination of the scleral buckle eliminates the need for conjunctival incisions. Similarly, sutured-on contact lens rings make no sense in the context of transconjunctival, sutureless

vitrectomy.

## Sclerotomies

Conjunctival displacement ensures that the conjunctival trocar-cannula wound is not overlying the scleral trocar-cannula wound (Fig. 105.13). Conjunctival displacement is essential for the transconjunctival sutureless technique, to provide containment of vitreous wick as well as prevent access of tear film to the sclerotomies, thereby reducing endophthalmitis risk.

**FIG. 105.13** The 25G vitrectomy systems utilize transconjunctival trocars, which eliminate suturing, reduce surgery times, and increase patient comfort.

Conjunctival displacement ensures that the conjunctival wound does not overlay the scleral wound.

There is no rule that sclerotomies should be placed at certain hours of the clock or at the borders of the rectus muscles; they should be located to avoid conjunctival scars, filtering blebs, and regions of abnormal pars plana, as well as facilitate the greatest possible solid angle intraocular access (Fig. 105.14). The inferotemporal sclerotomy should be located just below the horizontal meridian to reduce the risk of bumping the lower lid when rotating the eye to view the inferior retina. The superonasal

sclerotomy should be located on a virtual line from the lowest point of the bridge of the nose to the pupillary axis. The superotemporal sclerotomy should be located on a virtual line from the lowest point of the supraorbital rim to the pupillary axis; the cannula hub will then be immediately adjacent to the inferotemporal cannula hub. More anterior or nonstandard locations are required in cases of congenital or pathologic abnormalities of the pars plana.

**FIG. 105.14** Sclerotomies should be located to avoid conjunctival scars, filtering blebs, regions of abnormal pars plana, and allow the greatest degree of intraocular access.

## Vitreous Removal

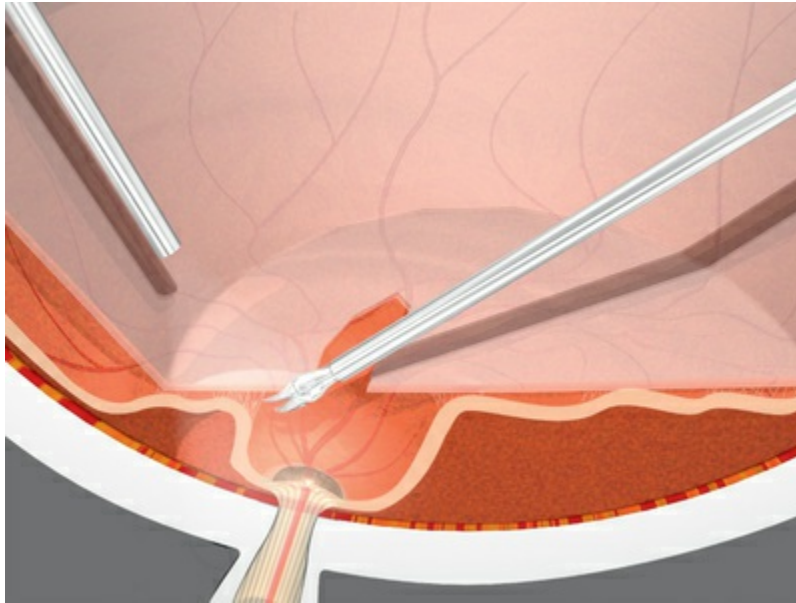

Conventional algorithms have stressed the sequence: core vitrectomy followed by posterior vitreous detachment (PVD) creation if PVD is not present, then so-called peripheral vitreous shaving and finally management of epiretinal membranes. Cutting technology, surgical techniques, and understanding of pathoanatomy have improved to the point that a linear algorithm no longer suffices; therefore, each algorithm should be selected according to case-specific pathoanatomy. If the AVC is semiopaque, opaque, or taut, it should usually be removed first. If it is clear and

the lens is to be left in place, it should be retained unless there is an element of anterior loop traction (anterior PVR) or compartmentalization requiring removal (see [Lens management](#), below). In the majority of cases, the “core” vitreous requires no specific attention, and the algorithm should proceed to the decision about whether to truncate the PVC or to delaminate ERM first. If the PVC is opaque or semiopaque, it usually requires truncation before the ERM can be peeled or delaminated ([Fig. 105.15](#)). When there is a partial PVD and the ERM is continuous with sections of the PVC, delamination should usually precede PVC truncation ([Fig. 105.16](#)).

**FIG. 105.15** Opaque posterior vitreous cortex should be entered away from the macula and periphery in an area known to be attached or away from the retina. This incision should be extended circumferentially to accomplish truncation.

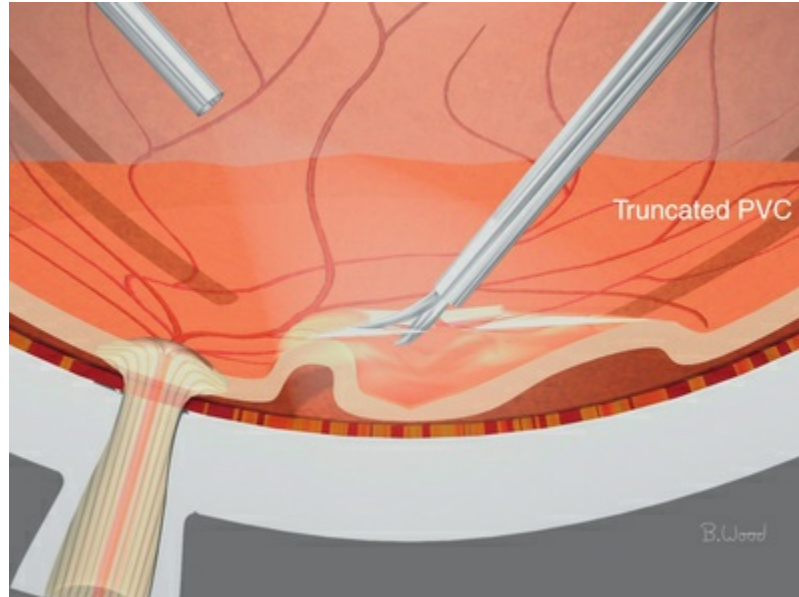

**FIG. 105.16** Access segmentation exposes the delamination plane to enable inside-out delamination.

If sub-PVC blood products are encountered while PVC truncation is under way, a soft-tip cannula or vitreous cutter with cutting deactivated should be used to remove blood; this is referred to as extrusion ([Fig. 105.17](#)). If, in the process of PVC truncation, regions of PVC are stretched between areas of ERM, they can be sectioned with the cutter only if it can be done without undue traction on the retina. Curved scissors are preferred over vertical scissors for segmentation of these sections of the PVC if there is concern about iatrogenic retinal breaks in atrophic, elevated retina ([Fig. 105.18](#)).

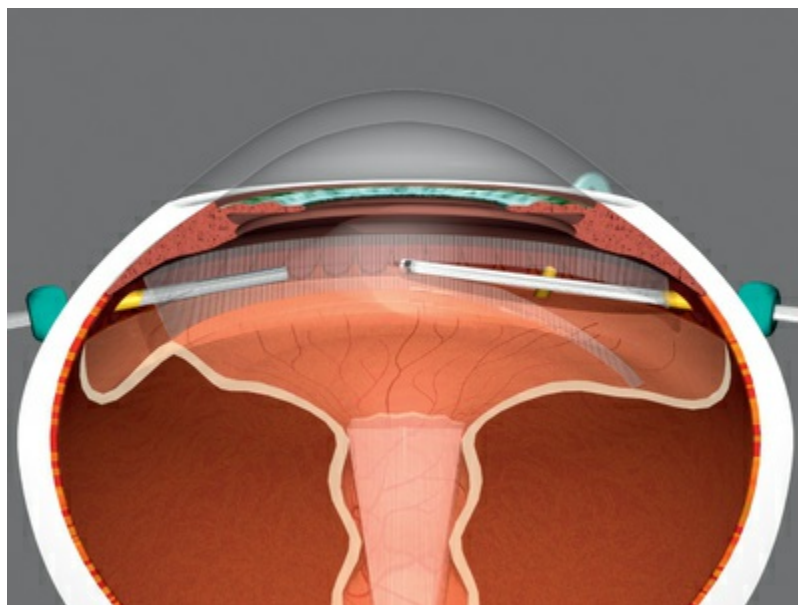

**FIG. 105.17** Proportionally controlled suction, rather than a flute needle or cutter, permits safe, nonpulsatile removal of subposterior vitreous detachment blood products.

**FIG. 105.18** Posterior vitreous cortex (PVC) truncation. Inside-out segmentation and delamination are required for much less common, dense, highly adherent membranes. Curved scissors should be used to segment these sections of the PVC if there is concern about iatrogenic retinal breaks in atrophic, elevated retina.

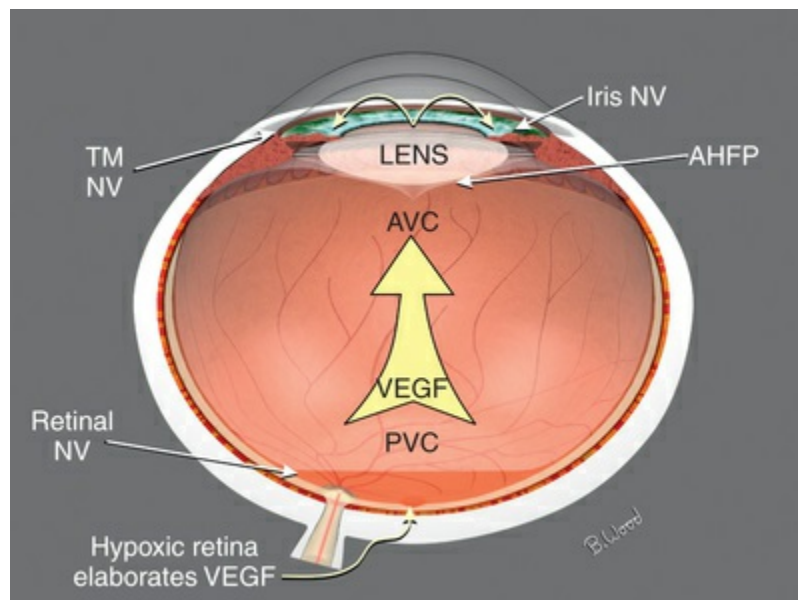

Anterior loop traction (radial fibers) is a significant feature of anterior proliferative PVR, some trauma cases, and anterior hyaloidal fibrovascular proliferation (retrolenticular neovascularization) in severe proliferative diabetic retinopathy (PDR) cases. Anterior cortical fibers are made taut by hypocellular vitreous contraction extending in the anteroposterior direction from the vitreous base to the pars plana, ciliary body, and even to the posterior iris surface. They can be present typically inferiorly in PVR cases, or in severe cases, this pathoanatomy can extend for 360°. Anterior loop traction is to be differentiated from the “skirt” that is left after core vitrectomy. Anterior loop traction can be visualized with contact-based wide-angle viewing, scleral depression by the surgeon using chandelier illumination, or scleral depression by the assistant. Wide-angle viewing systems are essential for viewing the periphery; contact-based wide-angle viewing provides 10° greater field of view than non-contact systems, eliminates all corneal asphericity, and requires less ocular rotation. Scleral depression is very effective but requires a skilled assistant or chandelier illumination, which reduces the ability to visualize clear vitreous. Anterior loop traction can usually be resected with a 23/25/27G vitreous cutter ([Fig. 105.19](#)).

**FIG. 105.19** Anterior loop traction can usually be resected with 23G or 25G vitreous cutters.

## Lens Management

In addition to its normal optical function for the patient, the lens affects the vitrectomy-based management of retinal detachment. Cells, as well as cytokines, proteins, and inflammatory components, are retained in the vitreous cavity and thus are exposed to the retina longer in the phakic and pseudophakic eye. In cases of severe inflammatory PVR, severe uveitis, and severe trauma, it may be advantageous to remove the lens to accomplish decompartmentalization of the eye (Fig. 105.20). Aphakia also permits better dissection of the anterior vitreous, eliminates concern about subsequent cataract surgery, improves visualization, and facilitates exchanges. In PDR, there is a trade-off in that the presence of the lens reduces neovascular glaucoma now manageable with anti-VEGF agents, but facilitates anterior fibrovascular proliferation (retrolenticular neovascularization) and greatly prolongs the retention time of postoperative hemorrhage. Lens removal in conjunction with vitrectomy is usually best managed with phacovitrectomy and introduction of an acrylic posterior chamber lens.

**FIG. 105.20** Decompartmentalization of the eye facilitates vascular endothelial growth factor (VEGF) access to the trabecular meshwork (TM) and iris but reduces retinal levels. NV, neovascularization; AVC,

anterior vitreous cortex; *AHFP*, anterior hyaloidal fibrovascular proliferation; *PVC*, posterior vitreous cortex.

Endocapsular lensectomy is an efficient and safe method of lens removal if intraocular lens (IOL) implantation is not planned. The first step is placement and verification of the infusion cannula insertion through the choroid and nonpigmented pars plana epithelium using the operating microscope, not the naked eye. Anterior vitrectomy should be performed before lensectomy to prevent traction on the retina from the fragmenter. The cutter should then be used to make a circular rhexis in the posterior capsule. Hydrodissection and delineation should be performed with a 27–30G blunt cannula. A fluid wave should be seen under the anterior lens capsule (Fig. 105.21). An assistant-held syringe or preferably a machine-controlled fluid injector connected to a short length of tubing facilitates this step. Sculpting of the epinucleus, nucleus, and inner cortex with the fragmenter at moderate power levels is the next step (Fig. 105.22). Simultaneous sonification and aspiration using a 20G fragmenter is better than intermittent suction followed by sonification without aspiration, because it is less likely to cause scleral burns. Constant fluid flow is required to dissipate frictional heat. The cortex should then be aspirated with the vitreous cutter in suction-only mode (Fig. 105.23). The cutter can then be used in cutting mode after the cortex has been displaced from the capsular bag. If severe miosis occurs, scleral depression or injection of 1 : 10,000 epinephrine (adrenaline) without preservative will facilitate the required removal of all peripheral cortex. Proportional (linear) suction should be used with typical suction levels of 100–150 mmHg while in the capsular bag. A capsulotomy to facilitate forceps removal of the capsule should be made with the MVR blade or cutter after all cortex is removed if lens implantation is not planned. The entire capsule should then be removed with textured end-grasping forceps using a circular, zonular rhexis motion (Fig. 105.24). Removal of the complete capsule prevents the inflammation and peripheral proliferation associated with the retention of lens material as well as fibrosis-based closure of peripheral iridectomies.

**FIG. 105.21** A fluid wave should be seen under the anterior capsule during hydrodissection and delineation.

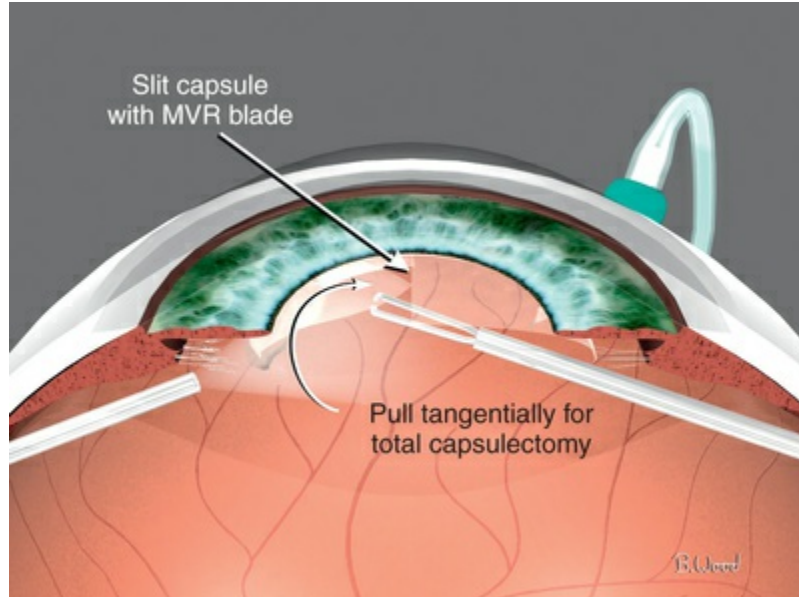

**FIG. 105.22** Simultaneous sonification and aspiration with the 20G fragmenter at moderate power is used to sculpt the epinucleus, nucleus, and inner cortex.

**FIG. 105.23** Use the vitreous cutter in suction-only mode to aspirate the cortex, then switch to cutting mode after the cortex has been displaced from the capsule.

**FIG. 105.24** End-grasping or ILM forceps should be used to remove the entire capsule using a circular, zonular rhexis technique.

Combining phacoemulsification with vitrectomy is now common practice; phacovitrectomy is ideal for rhegmatogenous retinal detachment, traction retinal detachment, and PVR cases with

significant cataract. Many surgeons incorrectly believe that vitrectomy always causes cataract; this is simply not literally true. Vitrectomy virtually always causes progression of preexisting nuclear sclerosis but not de novo cataract. Removal of clear lenses because of the false assumption that cataract is inevitable is overdone. Patients expect emmetropia after cataract surgery, and this is very difficult to achieve with phacovitrectomy because of axial length measurement error and surgeon variables. A better practice is to have a cataract surgeon perform phaco several weeks before vitreomacular surgery if preoperative examination indicates that the cataract will interfere with optimal visualization during vitrectomy. If moderate nuclear sclerosis is present, phaco and intraocular (IOL) implantation can be delayed for a month after vitreomacular surgery when the cataract progresses; this approach produces better refractive outcomes.

IOLs should be removed for most severe uveitis, AVC fibrovascular proliferation, and fibrin syndrome cases. Removal should be accomplished by making a cataract surgery-type incision and using specialized scissors to cut the implant into smaller segments, thereby reducing wound size. The wound should be closed with multiple X-type 10–0 monofilament sutures to prevent wound leaks and intraoperative iris prolapse. Residual capsule, cortex, and associated fibrous proliferation should be completely removed to reduce inflammation and peripheral proliferation.

## **Epiretinal Membrane Management**

The decision node in ERM management has three branches. ERM can be managed by peeling, segmentation, or delamination. If the membrane is segmented to release tangential force, the epicenters are retained. Choices are disease-dependent, in that diabetic traction retinal detachments usually require delamination often preceded by access segmentation. PVR requires peeling in most early, less adherent cases, with segmentation or delamination used in a small number of late-stage, dense, highly adherent membrane situations.

Disposable, 25G or 27G, end-grasping ILM forceps are the author's preferred instruments for peeling PVR membranes, as well

as epimacular membranes and internal limiting membrane (ILM) peeling (Fig. 105.25). End-grasping forceps membrane peeling eliminates the need for pics, membrane scrapers, and MVR blades, all of which can damage the retinal surface.

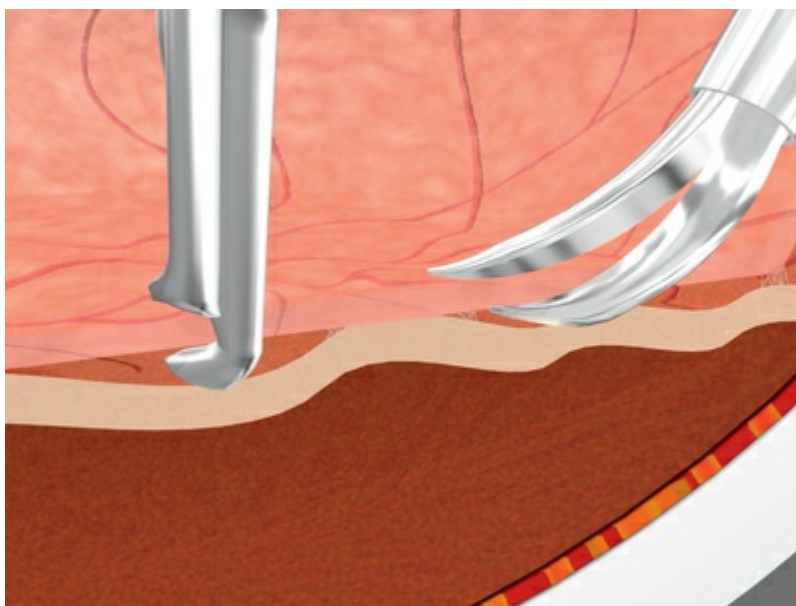

**FIG. 105.25** Internal limiting membrane (ILM) forceps are ideal for both epimacular membrane and internal limiting membrane peeling.

The preferred tool for delamination and access segmentation is 25G or 27G curved scissors (Fig. 105.26). Because the radius of curvature is similar to the retinal contour, the chance of making iatrogenic retinal breaks is reduced compared with the 135° (“right-angle”) scissors. Curved scissors are also preferred over vertical scissors for segmentation because blade thickness is much less than blade width (Fig. 105.27); iatrogenic retinal breaks are less likely when the bottom blade is inserted in the potential space between ERM and retina. In addition, transition from access segmentation to delamination does not require tool exchange, only small-angle tool rotation to place both blades under the ERM and begin delamination.

**FIG. 105.26** The 25G curved scissors have a radius similar to retinal curvature, reducing the chance of making iatrogenic retinal breaks.

**FIG. 105.27** Blade thickness of curved scissors is much less than blade width of vertical scissors facilitating access to the space between the epiretinal membrane and retina while decreasing the likelihood of retinal breaks.

The goal from a biologic perspective is to minimize trauma to the retina, eliminate all tangential force from the retina, and reduce

reproliferation due to bleeding resulting in fibrin bridges between epicenters of retained ERM.

When peeling the ILM, both indocyanine green (ICG) and triamcinolone should be employed with caution. In many reports, ICG has been shown to be toxic to the retina and RPE, and triamcinolone particles may get trapped within a macular hole or in the subretinal space. The author uses only end-grasping ILM forceps with or without the use of brilliant blue staining for all cases that require ILM peeling. In macular hole cases requiring surgery, ILM peeling removes tangential traction on the surface of the macula, guarantees that ERMs are successfully removed, and increases retinal elasticity, all of which increase the likelihood of successful hole closure. While never used as a primary approach, performing an arcuate retinotomy has shown some success in achieving closure of large, otherwise inoperable macular holes.<sup>9</sup>

## Management of Subretinal Proliferation

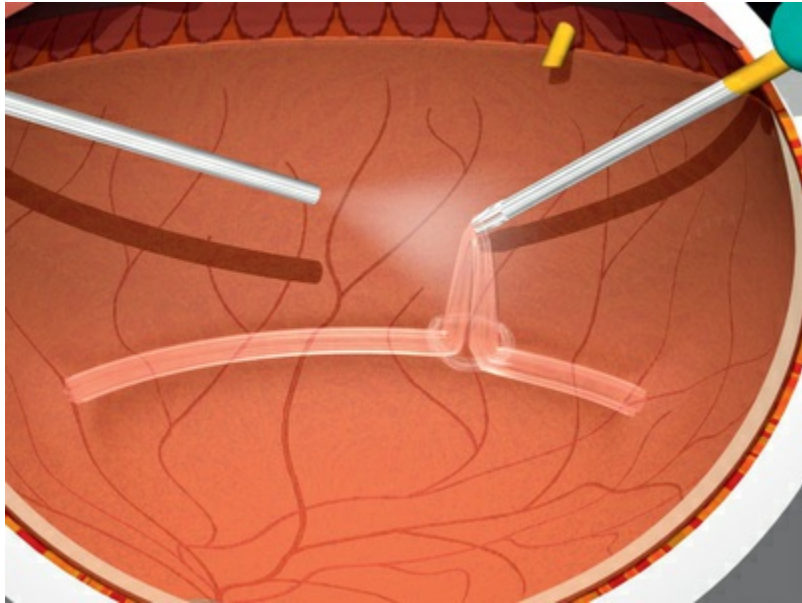

Subretinal proliferation can be placoid, band-like, or annular in configuration (Fig. 105.28). Because the biologic behavior seems to be less likely to result in reproliferation, subretinal membrane removal is dictated by geometric considerations. If the retina cannot be reattached with an undistorted macula due to subretinal proliferation, subretinal surgery is indicated.

**FIG. 105.28** Subretinal proliferation can be placoid, band-like, or annular in configuration.

Subretinal surgery can be categorized as peeling or scissors segmentation. If a retinal break is appropriately positioned, forceps can be passed through the break and used to grasp and remove long dendrites with a sequential regrasping technique (Fig. 105.29). If a convenient break is not present, punch-through retinotomy with the closed forceps tip is the preferred technique (Fig. 105.30). If the membrane is placoid, forceps removal should be used. Occasionally, subretinal bands are fibrovascular and require scissors segmentation rather than forceps removal.

**FIG. 105.29** Subretinal bands can be removed utilizing a sequential regrasping technique.

**FIG. 105.30** End-grasping forceps can be passed through an existing break or punch-through retinotomy to remove subretinal proliferation.

## Extrusion Techniques

Soft-tip cannulas ([Fig. 105.31](#)) can be used to remove material from

the eye using footpedal-controlled machine-driven aspiration; this is called extrusion. Soft-tip 25–27G cannulas with low suction levels are ideal for removing free blood products, PFO (perfluoro-n-octane), oil droplets, or small pieces of lens material from the retinal surface or vitreous cavity after the vitreous is removed with the cutter. Extrusion is preferable to using the flute cannula because inadvertent tip movement due to covering the egress hole on the handle, and extrusion provides more precise aspiration control as well as footpedal-controlled precision reflux.

**FIG. 105.31** Soft-tip cannulas are preferred for internal drainage of subretinal fluid, PFO (perfluoro-n-octane) removal, fluid–air exchange, and air–gas exchange.

Flexible cannulas are preferred for internal drainage of subretinal fluid (SRF) because they can be angulated into the subretinal space (Fig. 105.32) and are less likely to damage the choroid and cause bleeding with patient movement or suboptimal positioning due to poor visualization. The algorithm for internal drainage of SRF begins with drainage, then fluid–air exchange with continued or repetitive internal drainage of SRF. If fluid–air exchange is performed before internal drainage of subretinal fluid, the SRF is forced posteriorly, creating the need for drainage retinotomy,

potentially detaching an attached macula, and causing postoperative macular folds.

**FIG. 105.32** A soft-tip cannula held near the retinal pigment epithelium and controlled by proportional aspiration allows safe internal drainage of subretinal fluid.

## Interfacial Surface Tension Management

Air (gas) interface with aqueous ( $72 \text{ dyne/cm}^2$ ) provides greater interfacial surface tension than the silicone–aqueous interface ( $40 \text{ dyne/cm}^2$ ) (Fig. 105.33). Viscoelastics and lipoproteins from blood or inflammation lower the interfacial tension of the silicone–aqueous interface causing emulsification.

**FIG. 105.33** The interfacial surface tension between air/gas and aqueous is greater than that of the silicone/aqueous or PFO (perfluoro-n-octane)/aqueous interface.

Force due to interfacial surface tension is far more significant than buoyancy effects provided by air, gas, or silicone. The purpose of these agents is to eliminate trans-hole fluid flow, thus restoring a transretinal pressure gradient. This effect is termed rhegmatogenous confinement when using long-term silicone oil; it addresses missed breaks, breaks from subsequent surface proliferation, and the opportunity for retinopexy avoidance in inflamed eyes. Silicone oil is also useful for retinopexy avoidance to reduce the re proliferation that is associated with excessive retinopexy to large area breaks or retinectomies. Retinopexy can be performed weeks or months later when retinal edema, subretinal fluid, and inflammation have subsided.

Silicones and gases may contribute to re proliferation by sequestering cytokines, proteins, and cells at the retinal surface (Fig. 105.34). The best silicone oils are those with the highest electrical resistance, lowest vapor pressure, and 1000 cSt (centi-Stokes) viscosity. There is little scientific evidence that 5000 cSt oil has lower emulsification rates than 1000 cSt and 5000 cSt oil takes five times as long to inject and remove as 1000 cSt.

**FIG. 105.34** Silicone and gases may increase re proliferation by sequestering cells and factors at the retinal surface, and decrease access of therapeutic agents to the retina.

An inferior peripheral iridectomy in aphakic eyes or eyes with decentered intraocular lenses and capsular defects allows aqueous to enter the anterior chamber from below and reduces the chance of silicone oil contact with the cornea. Fewer than 5% of long-term silicone cases develop corneal problems because of the iridectomy and higher-quality silicone oil available today. Emulsification glaucoma is relatively uncommon if proper precautions are taken. With the improvements in silicone oil, the incidence of emulsification glaucoma is now less than 20%, as previously reported.<sup>10</sup> Nevertheless, silicone oil should be removed after the retina has been attached in most cases, especially if the patient is young because of initially subclinical emulsification in the trabecular meshwork and macular edema that often occurs with silicone oil.

Eyes filled with silicone oil requiring additional surgery (for epimacular membrane, proliferative vitreoretinopathy, recurrent retinal detachment, etc.) can safely be operated on “under” oil.<sup>11,12</sup> Utilizing a two-port approach, silicone oil is intermittently infused after subretinal fluid is aspirated to maintain a stable intraocular pressure. This technique avoids the excessive manipulation, complexity, operating time, and cost that are associated with

complete silicone oil removal then replacement.

## Fluid–Air Exchange

Air, for surface tension management, should be injected through the infusion cannula while simultaneously removing infusion fluid and SRF (Fig. 105.35), as described earlier (proportional suction, extrusion). Constant-pressure air pumps control intraocular pressure, are nonpulsatile, and can provide large flow rates to compensate for wound leaks. Incremental retinectomy and further vitreoretinal traction removal, forceps membrane peeling, segmentation, or delamination can be performed under air if persistent traction is identified.<sup>13–15</sup>

**FIG. 105.35** An air pump infuses air through the infusion cannula and maintains intraocular pressure while intraocular and subretinal fluid is removed with a proportionally controlled soft-tip cannula.

## Air–Gas Exchange

If a long-acting gas is chosen to maintain surface tension until retinopexy “seals” retinal defects, it should be injected in an isoexpansive concentration (25% SF<sub>6</sub> or 18% C<sub>3</sub>F<sub>8</sub>) through the

infusion cannula after fluid–air exchange and endolaser retinopexy has been completed (Fig. 105.36).<sup>16–23</sup> The air is aspirated with constant low suction near the optic nerve to ensure complete exchange and accurate gas concentration. Injecting aliquots of gas into an air-filled eye provides poor control of gas concentration and subsequent bubble size because of unknown ocular volume. This technique increases the likelihood of excessive intraocular pressure, potentially resulting in central artery occlusion or insufficient gas fills.

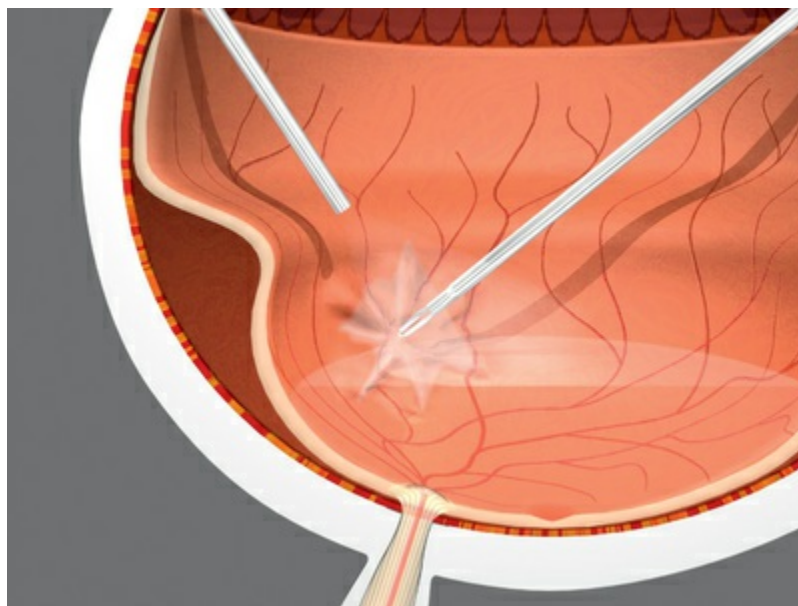

**FIG. 105.36** Air–gas exchange using an isoexpansive gas concentration produces predictable postoperative bubbles without causing increased intraocular pressure.

## Liquid Perfluorocarbon

Liquid perfluorocarbon such as perfluoro-n-octane (PFO) is essential for repositioning giant retinal breaks and can be used for

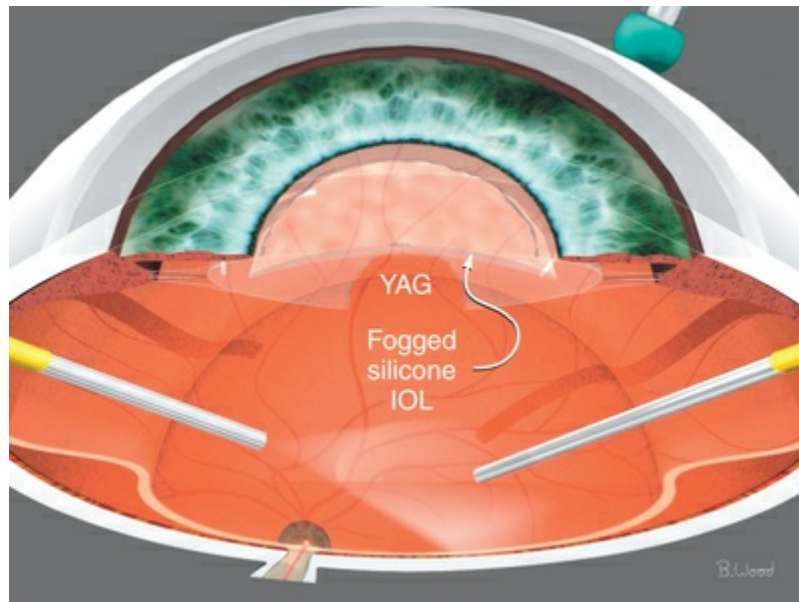

removal of subretinal fluid as well as stabilization of the retina to offset membrane peeling forces (Fig. 105.37).<sup>24-27</sup> Additionally, the use of medium-term PFO in cases of inferior retinal detachments can allow for upright positioning after surgery.<sup>28-30</sup> A foreign body response has been noted to occur in approximately 30% of eyes with PFO after 7–10 days.<sup>31</sup> This response is associated with longer duration of PFO, but was not associated with age, ethnicity, visual outcome, or persistent IOP elevation.

**FIG. 105.37** PFO (perfluoro-n-octane) can be used to stabilize the retina and offset membrane peeling forces.

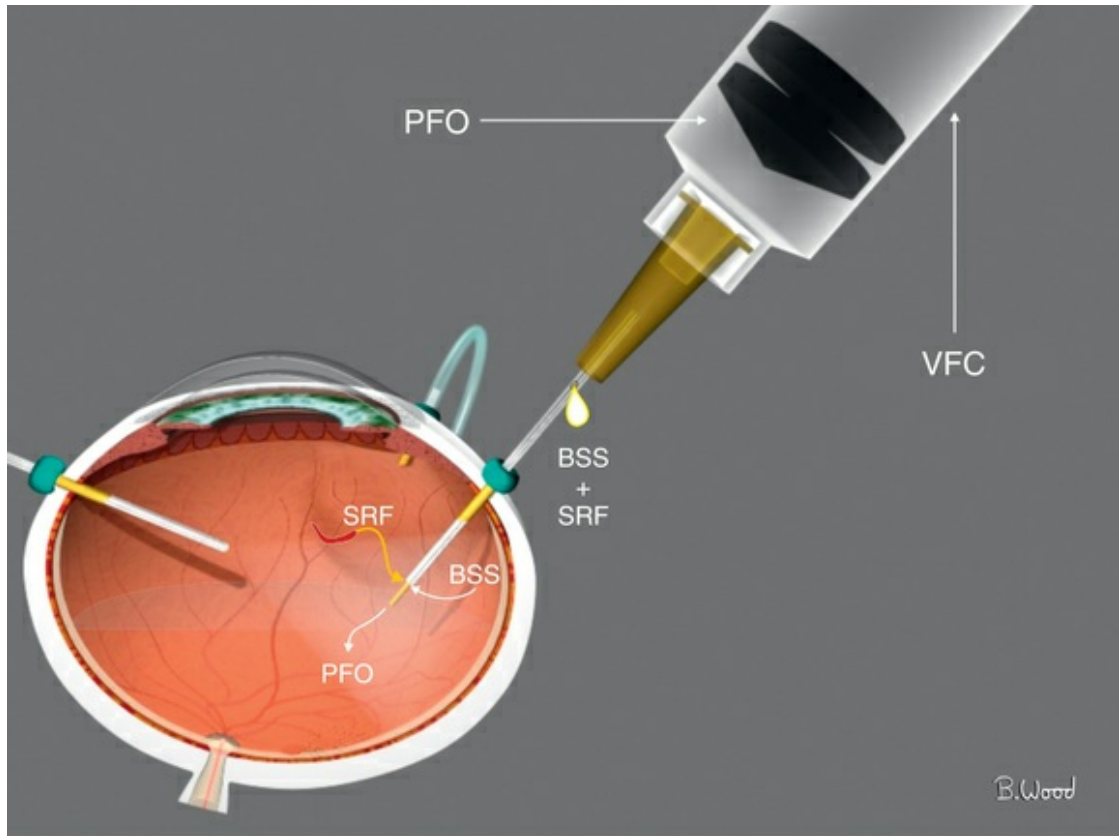

Fogging of the posterior surface of IOLs occurs because the room temperature infusion fluid cools the IOL and the infused air is saturated with water vapor (Fig. 105.38). A capsule defect as well as discontinuity in anterior vitreous cortex is necessary for fogging to occur. Fogging can occur with polymethylmethacrylate (PMMA) and acrylic IOLs, although it is more common with silicone IOLs because of higher posterior capsule opacification (PCO) rates and greater thermal mass. If fogging occurs, the best practice is to return to balanced salt solution infusion, remove the air, reattach the retina with PFO, and treat all retinal breaks with endolaser before performing PFO–gas exchange with isoexpansive SF<sub>6</sub> or C<sub>3</sub>F<sub>8</sub>. PFO can be used in all retinal detachment cases, but fluid–air exchange

and internal drainage of subretinal fluid is effective and does not add cost. PFO should be used with caution in PVR cases because of the not uncommon occurrence of subfoveal PFO due to retinal breaks combined with rigid retina.<sup>32</sup>

**FIG. 105.38** Fogging can occur when humid air contacts an intraocular lens (*IOL*) that has been cooled by infusion fluid. Fogging only occurs if there is not an intact posterior capsule and anterior vitreous cortex.

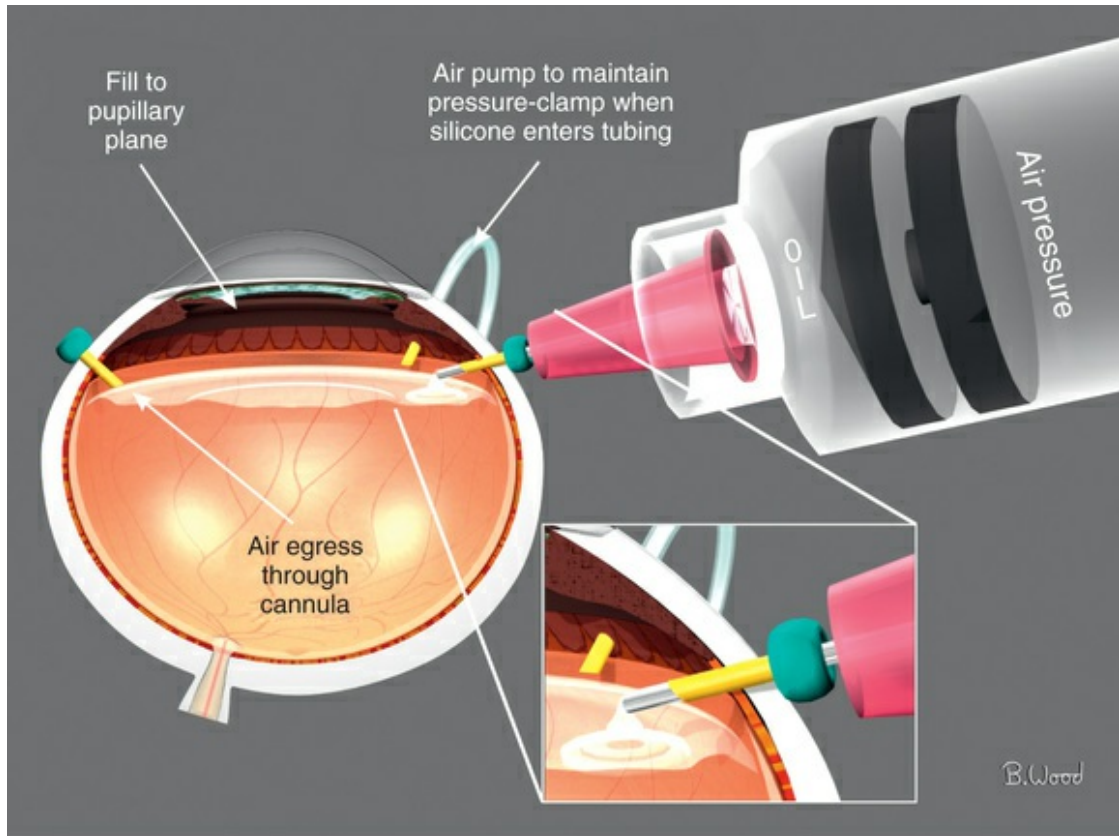

PFO should be injected under direct visualization by first injecting a small bubble at the optic nerve head with a 25G dual-bore cannula. This bubble is enlarged by injecting, using a power injector with 10 psi proportional injection pressure withdrawing the dual-bore cannula during the injection maintaining contact between the tip and the top of the PFO bubble. The proximal fluid egress port always stays above the PFO to avoid loss of PFO but allows fluid egress and a normotensive process (Fig. 105.39). PFO–air exchange in non-giant break cases is the inverse; the soft-tip cannula is always positioned at the periphery of the fluid–PFO interface and advanced posteriorly so all the fluid is removed and replaced with air before PFO is removed.

**FIG. 105.39** PFO (perfluoro-n-octane) is injected with a power injector at 10 psi, and a dual-bore cannula allows simultaneous fluid egress. *VFC*, viscous fluid control (Alcon Laboratories, Inc.); *BSS*, balanced salt solution; *SRF*, subretinal fluid.

## Air–Silicone Exchange

Because air has a higher interfacial tension than silicone oil, fluid–air exchange with internal drainage of SRF to reattach the retina should precede silicone infusion. Silicone should be injected with a pressure-controlled power injector through a short 23/25G straight cannula through the superotemporal cannula; not through the infusion cannula (Fig. 105.40). The air will egress through the open superonasal cannula until the silicone oil reaches the pupillary plane. Devices are required to hold valved cannulas open. Viscoelastics should be used to reform the anterior chamber if it becomes flat or if oil enters the anterior chamber.

**FIG. 105.40** Inject silicone through a short, thin wall, 23/25G cannula; air flows out through the superonasal cannula to enable normotensive air–silicone exchange.

## Perfluorocarbon–Silicone Oil Exchange

Direct perfluorocarbon–silicone exchange can be used instead of an intermediate step of fluid–air exchange followed by air–perfluorocarbon exchange in giant retinal break cases. The rationale for this approach is reduced chance of posterior slippage of the giant break. The goal is a full PFO fill and elimination of all subretinal fluid, infusion fluid, and liquid vitreous. The soft-tip cannula is used to remove PFO as the power injector is used to inject oil through a special infusion cannula (Fig. 105.41). If a standard cannula is used for oil injection, each of the surgeon's hands are in use therefore requiring a chandelier for illumination.

**FIG. 105.41** Simultaneous PFO(perfluoro-n-octane)–silicone exchange reduces the incidence of posterior slippage of giant breaks.

## Retinectomy

Retinectomy is preferred over relaxing retinotomy because removal of all tissue anterior to the cut reduces hypotony and recurrent PVR. Retinectomy should be performed in conjunction with fluid–air exchange and internal drainage of SRF ([Fig. 105.42](#)) (see also [Chapter 112, Retinotomies and retinectomies](#)). If subretinal air appears as internal drainage of SRF is slowly proceeding, the subretinal air location indicates residual retinal traction. Further vitrectomy, forceps membrane peeling, scissors segmentation/delamination, subretinal surgery, or retinectomy is required to achieve reattachment. Retinectomy should proceed incrementally with the vitreous cutter until the retina is reattached. Retinectomy performed under fluid is more difficult and may result in excessive or insufficient retinectomy. Large vessels should be precoagulated with bipolar diathermy.

**FIG. 105.42** Incremental retinectomy to manage retinal foreshortening or residual traction should be performed under air after fluid–air exchange and initial drainage of subretinal fluid.

## Hemostasis

Transient (approximately 5 minutes) elevation of intraocular pressure, preferably with a footpedal-controlled system, is the initial means of controlling intraoperative bleeding. Rapid elevation of intraocular pressure when bleeding is first noted will prevent the formation of extensive, tenacious preretinal blood clots. Holding the intraocular pressure between capillary and diastolic arterial pressure can be used while dissecting vascular ERM attachment points. The intraocular pressure should be normalized in a few minutes after clotting occurs. Any vessels that are still bleeding should be treated with endophotocoagulation, which is preferable to bipolar endodiathermy. Diathermy causes a larger area of retinal necrosis than laser, which can result in late, so-called, atrophic holes. Extensive pretreatment of vascular areas with diathermy or laser results in retinal necrosis and unnecessary coagulation of the tissue to be removed. Systemic blood pressure elevation should be very closely monitored in cases with a high potential for bleeding.

## Retinopexy

All forms of retinopexy create tissue destruction and re proliferation and therefore should be used as little as possible. Continuous (painting) laser endophotocoagulation surrounding retinal breaks and retinectomies is preferable to rows of spots because it results in more uniform tissue destruction and greater tensile strength (Fig. 105.43). Panretinal photocoagulation should be used only for neovascular retinopathies, never for PVR. Cryopexy causes more proliferation than laser or diathermy, and in my opinion, it should be avoided in vitrectomy surgery.

**FIG. 105.43** Confluent laser endophotocoagulation (painting) results in less tissue destruction, more uniform retinopexy, and stronger tensile strength of retinal–retinal pigment epithelium adherence than multiple rows of individual spots.

## Panretinal Photocoagulation

Panretinal photocoagulation reduces VEGF (vascular endothelial growth factor) production, causes the RPE to release an antiangiogenesis cytokine, RPE-derived growth factor, and increases choroidal oxygen transport to the retina. Diode-pumped,

frequency-doubled YAG (532 nm) lasers are preferable to near-IR diode lasers because they cause less damage to the choroid and are effective for hemostasis.

## **Subconjunctival Pharmacotherapeutics**

Subconjunctival antimicrobials for gram-negative and gram-positive bacteria and penicillinase-producing *Staphylococcus* can be considered after vitrectomy. Topical antibiotics do not reach a level above the minimal inhibitory concentration (MIC) in the vitreous cavity of phakic or pseudophakic eyes. A subconjunctival steroid injection such as dexamethasone should be considered unless the patient is known to have corticosteroid-induced glaucoma or has an immune deficiency.

## **Surgical Algorithms**

Earlier sections of this chapter provided an intellectual framework of physical, biologic, and surgical principles. Each of the surgical scenarios has been illustrated graphically and described. The combination of these scenarios into a surgical algorithm depends on the disease state, and indications and specific management of disease states are discussed in other chapters.

## **Conclusion**

Conservative indications, aggressive use of the best techniques and technologies, and careful follow-up are required for optimal results in vitreoretinal surgery. Continued improvements in instrumentation and biotherapeutics are needed for vitreoretinal surgeons to achieve better results in managing the diseases that potentially have high recurrence rates and occasionally poor outcomes.

## Introduction

Currently, rhegmatogenous retinal detachment (RRD) continues to be an important cause of visual loss. The fundamental principles involved in reattachment of a retina include identification of all retinal breaks and relief of the vitreous traction. Traditionally, scleral buckling (SB) was viewed as the gold standard treatment for uncomplicated RRD. Pars plana vitrectomy (PPV) was traditionally reserved for treatment of eyes with complications, such as those showing giant retinal tears or exhibiting significant proliferative vitreoretinopathy (PVR). In the 1980s, the indications for PPV in RRD patients were broadened to include less complicated instances and the term “primary vitrectomy” was introduced by Klöti<sup>1</sup> (Videos 106.1 and 106.2 online).

As the necessary instrumentation for, and safety of, PPV continue to improve with developments in microscope technology, intensified endoillumination, and wide-angle viewing systems, the indications for vitrectomy in RRD have been further expanded to include most patients with RRD. Indeed, PPV is more useful than SB in eyes requiring simultaneous cataract extraction or those of pseudophakic status.<sup>2-6</sup>

Compared to SB, PPV offers several advantages. The view of the retinal periphery is enhanced, identification of retinal breaks is rendered easier, achievement of complete intraoperative retinal

attachment is possible, the risks of hemorrhage or retinal incarceration inherent to the external drainage procedure applied during SB is eliminated, and the technique is less likely to cause a refractive change. In addition, the introduction of small-gauge vitrectomy has shifted the paradigm of standard vitreous surgery to microincision vitrectomy surgery (MIVS) that is less invasive, affords fast recovery, and is sutureless. As a result of these advances, vitreoretinal surgeons now have more procedural choices when treating RRD patients. Further, recently trained vitreoretinal surgeons may be more familiar with application of PPV (compared to SB) in challenging situations.

In this chapter, the use of primary vitrectomy for treatment of RRD, and the advantages and disadvantages of employing different gauges of vitrectomy system, will be explained and evaluated.

## **Pathogenesis of Rhegmatogenous Retinal Detachment**

The vitreous is firmly attached to the vitreous base, an area 3–6 mm in diameter that straddles the ora serrata surrounding the retina. The posterior border of the vitreous base is located farther posteriorly in older individuals and temporally. Therefore, retinal tears may occur at a higher frequency at the temporal periphery in such patients, following posterior vitreous detachment (PVD).

Three factors predispose to development of RRD: (1) the existence of a liquefied vitreous gel; (2) tractional forces that precipitate a retinal break; and (3) the presence of a retinal break through which fluid may access the subretinal space.

Liquefaction of the vitreous occurs naturally upon aging, developing more rapidly in eyes with significant myopia, surgical or nonsurgical trauma, and/or intraocular inflammation. Apart from liquefaction, alterations in the extracellular matrix of the vitreous facilitate detachment of the posterior vitreous from the underlying retina. PVD usually presents as an acute event, and is more prevalent in patients older than 50 years, with frequencies as high as 53%.<sup>7</sup> PVD often precipitates RRD, and the reported incidence of retinal tears in patients with acute symptomatic PVD

varies from 8% to 46%.<sup>8</sup> Risk factors for progression included fresh, symptomatic, horseshoe-shaped tears; breaks suggestive of the presence of subclinical retinal detachment (RD); and pseudophakia/aphakia.

## Categories of Rhegmatogenous Retinal Detachment

Retinal breaks are traditionally classified as round holes, tears, or resulting from retinal dialysis. Accordingly, RRD can be categorized as (1) round hole retinal detachment; (2) retinal detachment occurring secondary to retinal tears; and (3) retinal detachment attributable to retinal dialysis. This categorization, and the status of the vitreous, are important when exploring management options, in particular whether SB or vitrectomy should be employed.

Retinal holes are full-thickness retinal defects that usually occur as a result of localized atrophic intraretinal abnormalities or lattice degeneration, and are not associated with vitreoretinal traction. Typical RD patients with round holes show one or more areas of limited retinal detachment and may thus be optimally treated with either laser demarcation or segmental SB, rather than vitrectomy.

Retinal tears are usually produced by PVD and subsequent vitreoretinal traction. As persistent vitreous traction at an edge usually causes detachment to progress, the vast majority of RD patients in this category require surgical treatment. Among the various methods available, release of traction via PPV is preferred by many vitreoretinal surgeons.

Retinal dialysis is most often associated with blunt ocular trauma and rarely occurs spontaneously. Dialyses are most common in the inferotemporal quadrant. The vitreous remains firmly attached to the entire peripheral retina, and vitreoretinal traction caused by gravity results in slow retinal detachment. Vitrectomy in an eye with an attached vitreous gel can be technically difficult and may introduce unnecessary surgical complexity. Therefore, vitrectomy is less desirable than are other treatment options, e.g., a circumferential buckle.

The number of aphakic/pseudophakic patients with RRD has increased significantly over the past decades. After cataract surgery, vitreous liquefaction accelerates, causing premature PVD and subsequent RD. Aphakic/pseudophakic eyes tend to have small (and sometimes multiple) anterior breaks. The status of the posterior capsule also influences the speed of vitreous liquefaction. One study found that Nd : YAG laser posterior capsulotomy increased the risk of RD after cataract extraction up to 4.9-fold.<sup>9</sup> Because of the characteristics of the breaks and the status of the vitreous in aphakic/pseudophakic eyes, vitrectomy is preferred by many surgeons and has a good success rate.<sup>10</sup>

## Patient Selection for Primary Vitrectomy

SB and/or pneumatic retinopexy serve as the first treatment option(s) in patients with localized detachment in one quadrant together with single neighboring breaks. Young age and anteriorly located small holes in phakic patients encourage the use of SB. The success rates of final reattachment are 90–95%.<sup>11</sup>

PPV is indicated for patients with wide and bullous RD, and for older patients with a liquefied vitreous. The presence of RD with marked traction with different anterior posterior depth of breaks, the presence of breaks in multiple quadrants, or the absence of an apparent retinal break in a pseudophakic patient are all good candidates for the use of PPV. RD of preoperative PVR grade C, giant tear-induced RD, and macular hole RD are all commonly treated using PPV.

Recent developments in vitrectomy instruments, including small-gauge systems, wide-angle viewing systems, and endoilluminators, as well as adjuvants including triamcinolone acetonide suspension, perfluorocarbon liquids, and intraocular tamponades, led the choice of surgical technique for the treatment of RRD with medium complexity to shift more and more towards PPV.<sup>12,13</sup> Several trials comparing PPV to SB in patients undergoing RRD surgery have been reported.<sup>14–18</sup> In general, PPV was favored for treatment of pseudophakic eyes with unseen breaks, eyes featuring ocular

hypotony, or eyes showing prolonged macular detachment. The results to date suggest that SB or PPV is a good treatment option for primary phakic RRD, whereas PPV may be preferable to SB when pseudophakic RRD is to be treated.<sup>14</sup> It is important to consider individual patient factors, surgeon preference, and availability of equipment to make an optimal treatment decision.

## Principles of Vitrectomy

Abnormal vitreoretinal traction (either perpendicular or tangential) increases vitreous mobility caused by PVD, and atypical posterior extension of the anterior vitreous base predisposes to formation of retinal tears. Therefore, removal of the vitreous gel and any abnormal preretinal structure releases the tractional force causing retinal breaks and detachment.

After release of abnormal vitreoretinal traction, the detached retina must be reattached. To stabilize and flatten the detached retina, a heavy liquid is initially applied; this is subsequently replaced by sterile air. If the retina is mobile and becomes flattened in air, a nonexpansive gas–air mixture is used to achieve a postoperative gas tamponade. Although silicone oil is not routinely used in instances of uncomplicated RRD, use of silicone oil should be considered if eyes have multiple inferior breaks, if PVR is present, or if the eye is an only seeing eye. Retinopexy has been used to create permanent retinal–RPE adherence. Both forms of retinopexy (cryopexy and the laser photocoagulation) cause tissue destruction and cellular proliferation and should be used as little as possible.

## Surgical Techniques

Primary vitrectomy is commonly performed using a wide-angle viewing system attached to an operating microscope. The surgical steps of primary vitrectomy using sutureless MIVS are described below ([Figs. 106.1–106.4](#)).

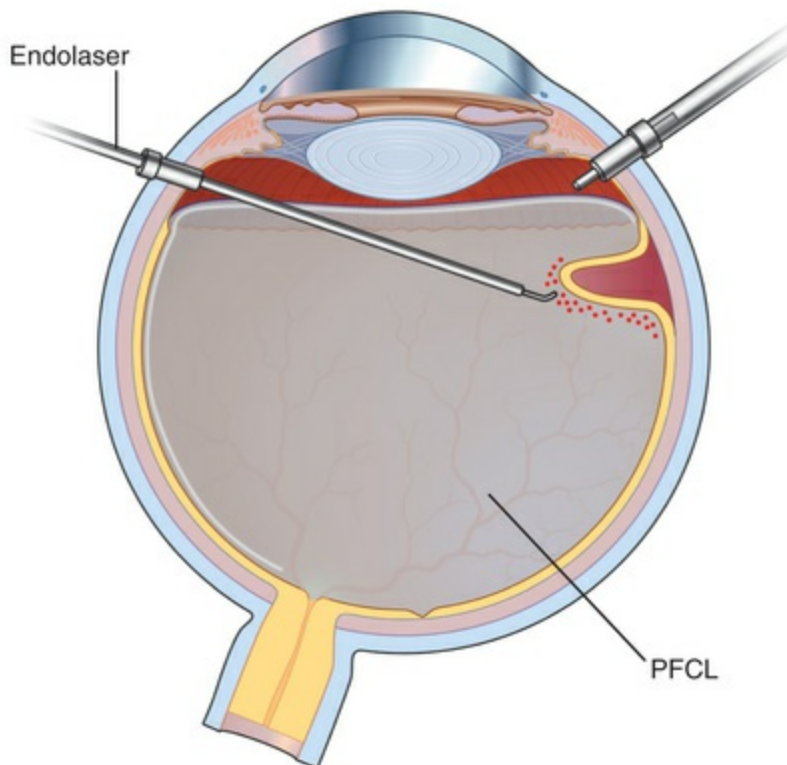

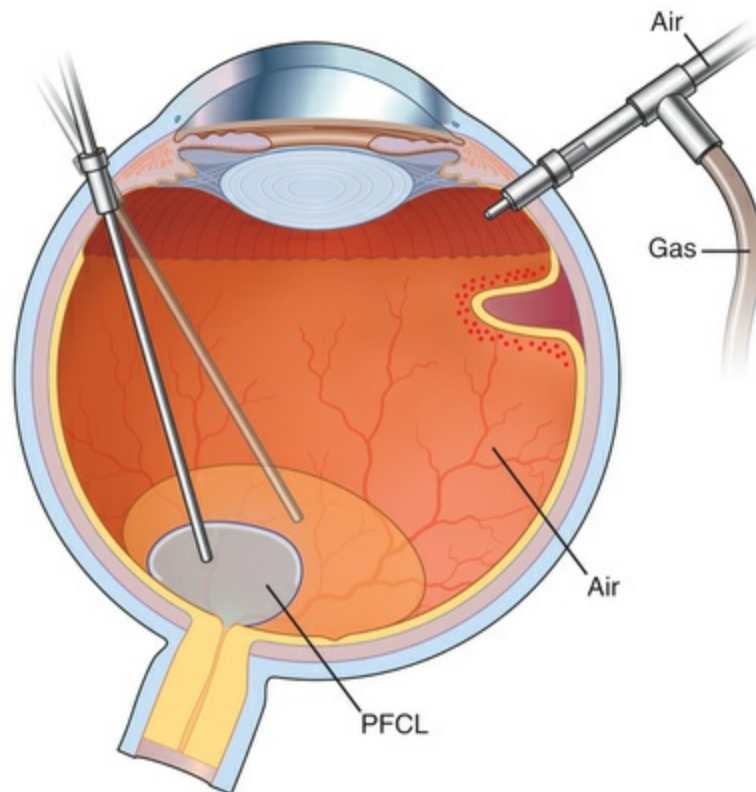

**FIG. 106.1** Detached retina with posterior vitreous detachment is shown. Core vitrectomy is performed.

**FIG. 106.2** A bubble of perfluorocarbon liquid (PFCL) has been injected to displace posterior subretinal fluid. While holding down the detached posterior retina, peripheral vitreous base is safely shaved and the flap of the retinal break is cut to release the vitreoretinal traction.

**FIG. 106.3** Endolaser retinopexy is applied around the retinal break under the perfluorocarbon liquid (PFCL) bubble.

**FIG. 106.4** Air–perfluorocarbon liquid (PFCL) exchange is performed, and air is replaced with SF<sub>6</sub>, C<sub>2</sub>F<sub>6</sub> gas.

## Anesthesia

The choice between general anesthesia and local anesthesia for primary vitrectomy depends on several factors, including patient age, surgeon preference, and the anticipated difficulty and duration of operation. Although general anesthesia is still preferred for complex surgery or young patients, local anesthesia for vitrectomy surgery has steadily increased because of several advantages: presumed reduced cardiopulmonary risk to patients, shorter turnover time, and cost-effectiveness.<sup>19</sup>

## Create Three Ports Through the Pars Plana

Firmly insert the infusion cannula. Irrigation pressure is set around 20–35 mmHg, depending on the choice of operating system gauge. Confirm that the infusion cannula is in the vitreous cavity by examining its position using an exterior light pipe.

## Core Vitrectomy

First, the central vitreous is removed (Fig. 106.1). When PVD is absent, or even when PVD has occurred, triamcinolone acetonide can be injected to afford better visualization of the vitreous gel, to facilitate PVD, and to completely remove the residual vitreous. The posterior vitreous membrane can be removed using a diamond-dusted scraper; this prevents secondary macular pucker (Fig. 106.5).

**FIG. 106.5** Core vitrectomy has been performed, and a small bubble of PFCL was injected to hold down the posterior retina.

## Peripheral Vitrectomy

After core vitrectomy, PVD is further extended using a wide-angle viewing system. Usually PVD is already present, up to the positions of the retinal breaks. However, abnormal attachment may be noted in other locations. If retinal breaks are located posterior to the equatorial zone, the vitreous bridge between the tears and the ora serrata must be separated and removed. If the breaks are peripheral to the equatorial zone, the vitreous on the flap should be shaved away, with scleral indentation. In case of bullous RD, perfluorocarbon liquid (PFCL) may be injected to flatten the detached retina so that the peripheral vitreous can be safely shaved

without creating an iatrogenic tear (Fig. 106.2).

## Fluid–Air Exchange

Subretinal fluid is removed through the original breaks using a backflush needle in the presence of air irrigation. PFCL may be injected, up to the level of the posterior edge of the break; the PFCL bubble displaces posterior subretinal fluid through the break. Next, air–fluid exchange at the top of the PFCL bubble may displace peripheral subretinal fluid through the break. PFCL is not indicated for all eyes. The preferable indications are bullous RD or RD that is associated with retinal breaks anterior to the equatorial zone; the subretinal fluid can thus be removed without creating a drainage retinotomy (Fig. 106.4).

## Photocoagulation/Cryopexy of the Retinal Tear

Whenever retinal breaks are found, endodiathermy may be used to mark the breaks. Once retinal reattachment is complete, endophotocoagulation is performed under air or a PFCL bubble. Two-to-three rows of laser burns can be applied around each break and site of lattice degeneration (Fig. 106.3). Strong photocoagulation should be avoided on the thin retina detached by the residual subretinal fluid. Alternatively, cryopexy may be utilized if a break is located at the far periphery of phakic RD eyes.

## Tamponade

If the retina is flattened under air, nonexpandable gas–air exchange is performed in order to achieve postoperative gas tamponade. The maximum concentrations to be used are 20% for SF<sub>6</sub>, 14% for C<sub>3</sub>F<sub>8</sub>, and 17% for C<sub>2</sub>F<sub>6</sub>; these levels ensure that eye pressure is not increased. RD in the inferior quadrant alone, or associated multiple breaks in various quadrants, is an indication for use of a long-acting gas such as C<sub>3</sub>F<sub>8</sub>. In a few exceptional instances, such as the occurrence of RD in the only seeing eye, the use of silicone oil should be considered.

## Positioning After Surgery

Face-down positioning should be commenced as early as possible after surgery to ensure that the macula is attached first and to prevent any shift of the reattached retina. Adjustable head positioning depending on the location of retinal breaks can be an effective and safe option after gas tamponade.<sup>20</sup>

In some cases, primary vitrectomy may be combined with additional surgical procedures such as encircling buckling or phacoemulsification.

## Vitrectomy With Encircling Buckling

The placement of an encircling band depends on the preference of the individual surgeon. A circumferential band can be placed in the preequatorial region to support the residual vitreous base, preventing recurrent detachment if peripheral breaks develop postoperatively. However, such bands are being placed less frequently because recent technologic advances, including high-speed cutters, intraoperative use of triamcinolone, wide-angle viewing systems, and chandelier illumination, allow surgeons to completely relieve vitreous base traction.

## Vitrectomy With Phacoemulsification and Intraocular Lens Implantation

A small incision (2–2.75 mm) is made in the peripheral corneal region or the limbus, and standard phacoemulsification is performed. An intraocular lens (IOL) may be inserted before or after vitrectomy, depending on the surgeon's preference. Currently, acrylic foldable IOLs with relatively hard haptics are preferred. As silicone oil adheres to a silicone IOL, such implants are not recommended.

## Sutureless Microincision Vitrectomy Surgery

Transconjunctival sutureless MIVS using 25-gauge (25G) instrumentation provides several advantages over conventional 20G surgery, including a shorter surgical time, less surgically

induced inflammation, and a reduced risk of postoperative corneal astigmatism. These factors ultimately lead to improved patient comfort and faster visual recovery. The 2009 Preferences and Trends (PAT) surveys conducted by the American Society of Retinal Specialists reported that nearly 80% of respondents commonly employ small-gauge MIVS systems.<sup>21</sup>

The original MIVS procedure, introduced in 2002,<sup>22</sup> had some limitations. The excessive flexibility of the first 25G instruments rendered it difficult for surgeons to adequately dissect the peripheral vitreous, to shave the vitreous base, and to rotate the eye. These limitations were particularly troublesome when operating on eyes with RRD. In addition, postoperative leakage of gas or silicone oil from the sclerotomies in the subconjunctival space was a further concern.

The introduction of 23G instruments solved several of these problems. The greater rigidity of such instruments, better illumination, and improved fluidics have facilitated manipulation of the peripheral retina, which is important when RRD is to be treated. MIVS technology continues to develop. Newly introduced 25G instruments, the 25G+ system, are substantially more rigid than their earlier counterparts. Further, an increase in instrument inner diameter has improved both infusion flow rates and illumination. In addition, a new trocar entry system and continued development of instrumentation have enhanced the performance of both 23G and 25G systems. Most recently a 27G vitrectomy system was shown to be a feasible option for repair of primary RRD.<sup>23</sup> [Figs. 106.6–106.8](#) show a surgical view of transscleral sutureless vitrectomy using the 25G+ system and a wide-angle viewing system.

**FIG. 106.6** After peripheral vitreous base dissection, more perfluorocarbon liquid (PFCL) has been injected to the level of the peripheral tear. Subretinal fluid was first displaced anteriorly by PFCL and then aspirated through the peripheral retinal break.

**FIG. 106.7** Endolaser retinopexy was applied around the retinal breaks under the perfluorocarbon liquid (PFCL) bubble.

**FIG. 106.8** Air–perfluorocarbon liquid (PFCL) exchange was performed while draining subretinal fluid through the peripheral retinal break.

The most recent vitrectomy system features a pneumatic dual-drive cutter with an ultrahigh cut rate of 7,500 cpm (cuts per minute) that effectively reduces vitreoretinal traction.<sup>23–25</sup> In this instrument, the port is also 50% closer to the tip than is the case with conventional cutters and the inner lumen diameter is enlarged. Therefore, surgeons may work remarkably close to a detached retina, with minimal movement of mobile tissue. Other features include IOP compensation via direct control of infusion pressure, and direct control of the duty cycle (this controls the proportion of time during which the port is open, in terms of the total time of the cutting cycle). These features afford excellent control of flow rate with a constant cut rate, thus increasing precision without sacrificing speed.

A new scleral entry system uses an MVR-style blade that features a trailing edge so that the cannula can be inserted via a linear incision. Such incisions are associated with a need for less force during trocar insertion, and retain shape well, resulting in less postoperative leakage than is the case when chevron incisions are made.<sup>23–25</sup>

Another advance in the field has been the wide-angle viewing systems that provide a better field of view compared to that afforded by contact lenses, improving surgeon recognition of peripheral fundus pathology and allowing lesions to be treated

safely and efficiently. A wide view of the fundus has become increasingly important during treatment of eyes with RRD employing 23G to 25G MIVS, because it is difficult to rotate the globe and indent the peripheral sclera during vitrectomy. Additionally, wide-angle viewing systems afford a relatively good view of the fundus in eyes with small pupils or mild corneal opacity. Further, surgeons do not need to change the contact lens during fluid–air exchange at the end of vitrectomy.

Several groups have reported good surgical outcomes when RRD was treated with transconjunctival MIVS, either the 25G or 23G systems (Table 106.1).<sup>5,6,12,26–30</sup> Although a few reports found that such MIVS afforded a lower single-operation success rate (SOSR) than did 20G vitrectomy,<sup>5,27</sup> most authors attained success rates (91.7–97.4%) similar to that of 20G surgery.<sup>6,26,28,29</sup> The major reported advantages of MIVS include no or mild pain on the first postoperative day in the majority of patients,<sup>27</sup> a shorter operation time,<sup>6</sup> and faster postoperative visual recovery.<sup>31</sup> Although some instances of transient hypotony have been reported following MIVS, no patient experienced significant postoperative leakage or endophthalmitis.<sup>5,6,12,27–31</sup>

## Surgical Outcomes

After the occurrence of any type of RD, approximately 40% of patients will not achieve reading ability, 10–40% will need more than one surgical procedure, and approximately 5% will suffer permanent anatomic and functional failure. The reported primary success rates for RRD repair by PPV range from 64% to 96%.<sup>2,3,14,17</sup>

In the time since the first report of the use of PPV without concomitant SB to treat retinal detachment in 1985,<sup>32</sup> numerous case series have been reported (Table 106.2). Although primary vitrectomy had historically been indicated principally for treatment of pseudophakic RD with superior retinal breaks, several studies found that the technique was also useful in phakic RD patients and in those with inferior breaks.<sup>17,33</sup> In general, the SOSR and the improvement in visual acuity appear to be comparable to those achieved using SB. Exploiting the recent advances in surgical technology including MIVS, several recent case series reported that the SOSR improved to over 90% and that the final average visual acuity was 20/40 or better.

**TABLE 106.2**

### Selected Case Series Using Pars Plana Vitrectomy to Treat RRD

Author	Year	Patients (n)	SOSR	VA Outcome	Comments
Escoffery et al. <sup>32</sup>	1985	29	79%	>20/50 in 81%	Phakic RD and PsRD
Sharma et al. <sup>17</sup>	2004	48	81%	Mean 20/66	Inferior breaks

Martinez-Castillo et al. <sup>33</sup>	2005	15	93%	Mean 20/30	PsRD, inferior breaks, air tamponade
Heimann et al. <sup>14</sup>	2006	512	70%	>20/50 in 48%	Some PPV/SB
Johansson et al. <sup>34</sup>	2006	131	87%	Mean 20/80	Phakic RD and PsRD
Mendrinós et al. <sup>4</sup>	2008	100	92%	Mean 20/50	Lens opacity 68% of phakic eyes

PPV/SB, combined pars plana vitrectomy/scleral buckling; PsRD, pseudophakic RD; RRD, rhegmatogenous retinal detachment; SOSR, single-operation success rate; VA, visual acuity.

Several retrospective series and prospective clinical trials comparing SB, PPV, and/or combined SB/PPV found no statistically significant difference in SOSR among the various procedures (Table 106.3).<sup>3,14,15,17,18,37-43</sup> However, a few studies reported that PPV was superior in terms of either anatomic or visual outcome in comparison with SB alone.<sup>14,15,17,40,44</sup> In addition, several reports comparing PPV and combined PPV/SB also found that the use of a combined procedure did not significantly influence anatomical or visual outcomes.<sup>38,39,41</sup>

**TABLE 106.3**

**Selected Comparative Trials: Scleral Buckling Versus Primary Vitrectomy in RRD**

Study	Year	Patients (n)			SOSR
		SB	PPV	PPV/SB	
Tewari et al. <sup>18</sup>	2003	20	0	20	Equivalent SOSR (70% SB, 80% SB/PPV), equivalent VA (median 20/120 SB, 20/200 SB/PPV)
Afrashi et al. <sup>37</sup>	2004	30	0	22	Higher SOSR (80% SB, 90% SB/PPV)
Stangos et al. <sup>38</sup>	2004	0	45	26	Equivalent SOSR (98% PPV, 92% SB/PPV), equivalent VA (improve ≥3 lines in 60% PPV, 69% SB/PPV)
Sharma et al. <sup>17</sup>	2005	25	25	0	All PsRD, equivalent SOSR (76% SB, 84% PPV), better VA with PPV (20/105 SB, 20/71 PPV)
Brazitikos et al. <sup>15</sup>	2005	75	75	0	All PsRD, higher SOSR for PPV (83% SB, 94% PPV), equivalent vision (20/50 SB, 20/43 PPV)
Halberstadt et al. <sup>39</sup>	2005	190	0	53	Phakic RD 88.9% SB, 82.1% SB/PPV
					PsRD 87.7% SB, 77.6% SB/PPV
Heimann et al. <sup>14</sup>	2007	342	339	0	Phakic RD 63.6% SB, 63.8% PPV
					PsRD 53.4% SB, 72% PPV
					No difference in VA
Azad et al. <sup>40</sup>	2007	31	30	0	80.6% SB, 80% PPV
Pastor et al. <sup>3</sup>	2008	108	278	160	Global SOSR 94.7%, equivalent (phakic RD/PsRD)
Orlin et al. <sup>41</sup>	2014	0	52	22	83% PPV, 86% PPV/SB

Wong et al. <sup>42</sup>	2014	308	415		84.6% SB, 84.6% PPV or PPV/SB
Falkner-Radler et al. <sup>43</sup>	2015	0	30	30	93.3% PPV, 93.3% PPV/SB

PPV, pars plana vitrectomy; PPV/SB, combined pars plana vitrectomy/scleral buckling; PsRD, pseudophakic RD; RRD, rhegmatogenous retinal detachment; SB, scleral buckling; SOSR, single-operation success rate; VA, visual acuity.

A meta-analysis of 29 studies on patients with pseudophakic RD found that both PPV and combined PPV/SB were associated with a higher SOSR and better visual acuity outcomes than was SB alone;<sup>45</sup> another review of nine reports comparing PPV to SB found no statistically significant difference with respect to SOSR or visual outcomes.<sup>46</sup>

Although the data are not entirely consistent, most surgeons agree that PPV without buckling effectively treats pseudophakic RD and results in better long-term outcomes than does conventional SB.<sup>4</sup> The rationale for use of primary PPV alone to treat pseudophakic RD patients is that visualization of the peripheral retina is good, the causative retinal breaks can be properly identified and treated, buckling-related complications are absent, and the risk of PPV-induced cataracts is absent. When it is considered that the need for reoperation is a (negative) indicator of the quality and efficacy of surgical techniques, the SPR study showed that the risk of such surgery was significantly reduced when PPV was used, compared to SB, in pseudophakic eyes, but not in phakic eyes. The results also showed that the prognostic factors differed between the pseudophakic and phakic subgroups.<sup>47,48</sup>

## Prognostic Factors

Identification of patients at high risk of failure at the time of initial presentation would allow surgeons to individually tailor patient management. Reported risk factors for surgical failure after PPV in the repair of RRD include duration of symptoms, older age, the extent of RD, macular detachment, involvement of inferior quadrants, absence of detectable retinal breaks, high myopia, hypotony, and PVR-related risk factors such as pseudophakia/aphakia, uveitis, vitreous hemorrhage, and preoperative PVR.<sup>4,17,45–52</sup> A recent study highlighted the role of

genetic factors as a useful tool for the identification of patients at high risk of suffering PVR and indicated that reduced apoptosis could be implicated as a possible new target in PVR prophylaxis after RD.<sup>53</sup>

The extent of RD can be considered to serve as a surrogate marker of RD duration, although the location of retinal breaks may affect the speed of detachment after onset. Nevertheless, such patients may have a higher level of retinal glial upregulation and RPE cell dispersion and may also develop PVR, which is an important risk factor in terms of surgical failure.<sup>54</sup>

A number of studies have found that previous lens extraction was a risk factor for development of PVR and was associated with worse outcomes.<sup>55</sup> The association between pseudophakia/aphakia and surgical failure may be related to the observations that (1) pseudophakic/aphakic patients often have small, sometimes multiple anterior breaks, which may be missed at the time of surgery; or (2) such patients tend to develop new retinal breaks after vitrectomy, caused by residual vitreous base traction. Many features of pseudophakic eyes, including anterior or posterior capsular fibrosis, the presence of cortical remnants, poor pupillary dilation, vitreous opacity, and optic aberrations secondary to IOL placement, *per se* may seriously compromise the surgical view, resulting in poor outcomes.

Macular detachment and subsequent structural change detected by OCT appear to cumulatively reduce final visual acuity.<sup>50,51</sup> An experimental study showed that rapid retinal reattachment reversed the retinal degeneration associated with detachment.<sup>56</sup> As complete intraoperative attachment of the macula is achieved in most patients during vitrectomy, visual recovery after surgery is faster. The recent development of intraoperative OCT allows the surgeon to detect any preretinal membranes at the macular area that may not have been visible preoperatively and to achieve good postoperative morphologic recovery of macular retina (Figs. 106.9 and 106.10). Delayed or incomplete visual recovery after SB for macula-off RD may be associated with macular subretinal fluid persistence, which can also be assessed using OCT.<sup>57</sup>

**FIG. 106.9** Preoperative wide-angle fundus photograph showing a bullous retinal detachment involving the macula. Optical coherence tomography imagery could not be obtained.

**FIG. 106.10** Intraoperative optical coherence tomography with a bubble of perfluorocarbon liquid (PFCL) revealed a fine epiretinal membrane on the macula, which was removed with a diamond-dusted eraser.

Inferior breaks have also been reported to be associated with

surgical failure following PPV for RRD.<sup>2,17,30,58</sup> The functional study of the SPR group showed that inferior detachment with breaks below the 4 and 8 o'clock positions was a significant risk factor in a pseudophakic/aphakic subtrial.<sup>49</sup> However, other studies have failed to show any advantage of combined PPV with SB, compared with PPV alone, in treatment of inferior retinal breaks.<sup>50</sup>

## Complications

The most frequent intraoperative complications are relatively high rates of iatrogenic retinal breakage (0.78–24%)<sup>4,15,17,18,37,38,40,59</sup> and crystalline lens damage (0.03–9%).<sup>16,37,59,60</sup> Several less serious complications include retinal incarceration at retinotomy sites (0.6–2.9%), corneal abrasion (0.6%), and choroidal effusion (0.5%), as reported in one national audit.<sup>61</sup>

Transient or persistent intraocular pressure increases have been reported in 15–24% of patients.<sup>4,36–38,40,59–61</sup> Phakic patients are at significant risk of developing nuclear cataracts; this is especially true of patients older than 50 years (21–86%).<sup>14,37,40,60,61</sup> Other anterior segment problems, occurring less frequently, include hemorrhage, subluxation or capture of intraocular lenses, posterior capsular opacification, and synechia.<sup>2,4,14,29,36–38,40,59–61</sup>

Major postoperative complications include retinal redetachment, with or without PVR, usually by new or missed breaks, or reopening of former breaks. In selected cases of redetachment, pneumatic retinopexy can be utilized as a rescue procedure.<sup>62</sup> As discussed above in terms of surgical outcomes, recent advances in surgical technology, including the development of MIVS and wide-angle viewing systems, have reduced the frequency of anatomic failures. Apart from recurrent detachment, several posterior segment complications may occur; these include cystoid macular edema and macular pucker.<sup>2,4,37,60,61</sup> Although very rare, endophthalmitis has been reported,<sup>61</sup> as has sympathetic ophthalmia. The incubation period for the latter condition after vitrectomy varies from 4 weeks to 2 years.<sup>63,64</sup>

Recently, as MIVS has become more popular, the risks of postoperative hypotony and endophthalmitis have become of concern. However, recent case series have found that

endophthalmitis did not occur more frequently than after conventional vitrectomy, and postoperative hypotony following MIVS was transient and resolved spontaneously in most patients.<sup>5,6,17,18,26,28–30</sup>

## Perspectives

Future studies should evaluate surgical interventions from multiple perspectives, not only clinical but also socioeconomic. In addition to final anatomic and functional outcomes, the rate of recovery and the need for secondary procedures should be considered. As the paradigm of vitrectomy has shifted from conventional 20G PPV to sutureless MIVS using either 25G or 23G, it is now imperative to assess patient outcomes including postoperative pain and discomfort, time away from work, and quality of life. Relevant societal outcomes include procedural cost and cost-effectiveness; these issues cannot be ignored as technology advances rapidly.

## **Introduction**

For more than a half century, the operation most favored for primary retinal detachment had been scleral buckling (SB). Between 75% and 88% of cases attain permanent reattachment with one operation with this procedure.<sup>1-3</sup> However, it frequently results in

tissue trauma, complications,<sup>4</sup> relatively high expense, and use of a hospital or surgicenter operating room.

In recent decades, pars plana vitrectomy has become the most frequently used procedure in industrialized countries for primary retinal detachments, as well as for complex and secondary retinal detachments, particularly in pseudophakic eyes. This technique also presents potential complications and requires an operating room with similar high expense.

Pneumatic retinopexy (PR) was developed in an attempt to minimize these problems in selected patients. This outpatient procedure for retinal reattachment consists of an intravitreal gas injection with transconjunctival cryopexy or laser photocoagulation, followed by a period of appropriate head positioning.<sup>5</sup> No incisions are required. PR is substantially less expensive than scleral buckling or vitrectomy and has become widely accepted as the treatment of choice for selected retinal detachments, with the vast majority of vitreoretinal surgeons employing this procedure.<sup>6,7</sup>

A multicenter, randomized controlled clinical trial has demonstrated that in selected cases the anatomic success rate of PR is comparable to SB, with less morbidity and with significantly better visual results than with SB.<sup>8</sup> Cataract surgery is required more often following SB than following PR<sup>9</sup> and is required substantially more frequently following vitrectomy. PR should be considered in patients who do not have detached inferior breaks, extensive retinal breaks, or significant proliferative vitreoretinopathy.

## History

Ohm<sup>10</sup> performed the first intravitreal air injection for retinal detachment in 1911. In 1938 Rosengren<sup>11</sup> reported the use of intravitreal air with drainage of subretinal fluid in a series of 256 retinal detachments. In 1973 Norton<sup>12</sup> reported intravitreal sulfur hexafluoride (SF<sub>6</sub>) injection used with SB or vitrectomy for various surgical problems, such as giant breaks, large posterior breaks, and fishmouthing. Blodi and Folk<sup>13</sup> treated detachments due to a macular hole using intravitreal gas. Retinal detachments treated with “repeated insufflations of expansive gas” were described by

Dominguez et al.<sup>14,15</sup> In 1985 Hilton and Grizzard<sup>5</sup> introduced the term “pneumatic retinopexy,” a procedure using only transconjunctival cryotherapy and gas injection without conjunctival incision.

Unlike SB or vitrectomy, PR affords no permanent relief of vitreoretinal traction. The fact that detachments can be cured without permanently relieving traction, demonstrated decades before by Ohm<sup>10</sup> and by Rosengren,<sup>11</sup> was reconfirmed in 1979 by Lincoff et al.,<sup>16</sup> who introduced the use of a balloon to achieve temporary scleral buckling. The efficacy of this procedure was demonstrated, but it never caught on, and the orbital balloon is not commercially available. However, retinal detachment repair without permanently relieving vitreoretinal traction, well proven by Lincoff's technique, combined with the demonstrated safety of intravitreal gas, formed the basis for PR.

In 1989 Tornambe and Hilton<sup>8</sup> co-directed a multicenter, randomized controlled clinical trial comparing PR with SB. Tornambe<sup>17</sup> reviewed over 200 studies on PR, including statistical reports on over 1300 cases. The single-operation success rate in these combined series was 80%, increasing to 98% after reoperations<sup>18</sup> – results that have been subsequently replicated.<sup>19</sup> Chan et al.<sup>20</sup> reviewed all published reports on PR cases from 1986 to 2007, totaling 4138 eyes. Single-operation success was 74.4%, and success with one or more operations was 96.1%.

## Basic Principles

### Intraocular Gases

Sulfur hexafluoride ( $\text{SF}_6$ ) and perfluoropropane ( $\text{C}_3\text{F}_8$ ) are the gases most frequently used with PR. Success has also been reported with sterile room air.<sup>21</sup> In 1993 the United States Food and Drug Administration approved certain  $\text{SF}_6$  and  $\text{C}_3\text{F}_8$  products for use in PR.

The value of the intraocular bubble is based on three features: buoyancy, surface tension, and isolation of retinal tears from intraocular currents.<sup>22,23</sup> Buoyancy applies upward pressure on the detached retina. The surface tension of the bubble closes the retinal

break and prevents the bubble from passing into the subretinal space. With the break closed, the retinal pigment epithelial pump removes the subretinal fluid.

Because of their low solubility in water, SF<sub>6</sub> and especially C<sub>3</sub>F<sub>8</sub> tend to diffuse from the eye very slowly. However, the nitrogen and oxygen that are in solution in the surrounding tissues of the eye are much more soluble and pass relatively quickly into the gas bubble, following the law of partial pressures. The net result is the initial expansion of a bubble of pure SF<sub>6</sub> or C<sub>3</sub>F<sub>8</sub> within the vitreous, followed by gradual resorption. Characteristics of gas expansion and resorption for SF<sub>6</sub>, C<sub>3</sub>F<sub>8</sub>, and air are listed in [Table 107.1](#).

**TABLE 107.1**  
**Intravitreal Gas Duration and Expansion**

Gas	Typical Dose	Average Duration	Largest Size	Average Expansion
Air	0.8 mL	4 days	Immediate	No expansion
SF <sub>6</sub>	0.5 mL	12 days	36 hours	Doubles
C <sub>3</sub> F <sub>8</sub>	0.3 mL	38 days	3 days	Quadruples

C<sub>3</sub>F<sub>8</sub>, perfluoropropane; SF<sub>6</sub>, sulfur hexafluoride.

SF<sub>6</sub> and C<sub>3</sub>F<sub>8</sub> are chemically inert, colorless, odorless, and nontoxic.<sup>24</sup> SF<sub>6</sub> has been studied extensively in experimental animals and has been found to be nontoxic as judged by electrophysiologic testing and electron microscopy.<sup>25</sup> One study of rabbits concluded that “eyes only partially filled with C<sub>3</sub>F<sub>8</sub> showed no permanent damage, with a total recovery of the cortical matrix, gel, and liquid vitreous.”<sup>26</sup> Early concerns<sup>27</sup> regarding PVR from intravitreal gas injection have not been substantiated. A 0.22-μm Millipore™ filter is sufficient to render gas sterile.<sup>25</sup>

Lincoff et al.<sup>28</sup> noted that gas bubble contact with the crystalline lens can produce cataract after several days, but this is avoidable by appropriate positioning. Mougharbel et al.<sup>29</sup> have demonstrated with Scheimpflug photography that PR does not cause cataract.

## Retina–Gas Interface

Larger areas of tamponade require disproportionate increases in

bubble volume. A 0.3 mL gas bubble in humans covers more than a 45° arc of the retina, but it takes approximately a 1.2 mL bubble to cover 80–90°. <sup>5</sup> Because surface tension causes the gas to take on a relatively spherical contour, particularly with smaller bubbles, the extent of retina–gas contact is significantly less than that published from studies of model eyes. <sup>30</sup> To cover the same arc of the retina, a highly myopic eye requires a larger volume of gas than an emmetropic eye. These factors are considered in deciding how much gas to inject.

## Case Selection

The multicenter clinical trial excluded cases with the following characteristics: <sup>8</sup>

1. Detached breaks larger than 1 clock-hour or multiple breaks extending over more than 1 clock-hour of the retina.
2. Detached breaks in the inferior 4 clock-hours of the retina.
3. Presence of PVR grade C or D (Retina Society Terminology Committee, 1983). <sup>31</sup>
4. Physical disability or mental incompetence precluding maintenance of the required positioning.
5. Severe or uncontrolled glaucoma.
6. Cloudy media precluding full assessment of the retina.

A review of 1000 consecutive detachments <sup>5</sup> revealed that 41% qualified for PR under these limiting criteria. Subsequent experience has demonstrated that selected cases that do not strictly meet these criteria can also be successfully treated with PR. <sup>32,33</sup> In our hands, about half of all primary retinal detachments are treated with PR using expanded criteria as described below.

## Extent of Breaks

Detached breaks spanning more than 1 clock-hour can be treated

with PR. Single or multiple detached tears spanning 2 or even 3 clock-hours pose no particular problem. Detached tears 6 clock-hours apart are difficult to fix with PR, although alternating positioning has been used successfully. Even detachments with giant retinal tears have been cured with PR.<sup>34</sup> However, scleral buckling or vitrectomy is usually preferred for detachments with widely separated or giant tears. Attached breaks can generally be ignored in deciding whether a case is amenable to PR, and postoperative positioning does not need to be planned to close them with the gas bubble. Attached break(s) should generally be treated with laser before the gas injection. Care should then be taken, such as by using the steamroller technique, if necessary, to prevent the bubble from pushing the subretinal fluid into the attached break and causing it to detach. By following these two steps, multiple attached breaks may be ignored in the calculation of bubble size and in positioning.

### **Inferior Breaks**

Most cases involving detached breaks in the inferior 4 clock-hours of the eye (from 4:00 to 8:00) have been difficult to treat with PR, despite various attempts.<sup>33</sup> Even for flexible patients, it can be difficult to tilt the head below the horizontal plane for extended periods, although this worked well in two series,<sup>35,36</sup> and another showed success positioning for only 8 hours.<sup>37</sup> Hilton et al.<sup>38</sup> treated retinal detachment with inferior breaks by augmenting PR with in-office partial vitrectomy, allowing injection of a large enough gas bubble to close the breaks with side positioning. We believe a detached break in the inferior 4 clock-hours represents a contraindication to PR in most cases, although breaks from 4:00 to 4:30 or from 7:30 to 8:00 may be attempted in a motivated patient using sideways positioning with an additional downward head tilt. Attached inferior breaks do not necessarily contraindicate PR if treated as described above, taking care to avoid iatrogenic detachment of an attached break caused by the gas bubble.

### **Proliferative Vitreoretinopathy**

Because PR does not relieve traction like vitrectomy or SB, significant preoperative tangential traction on a retinal tear (as in

periretinal proliferation) is a contraindication to the pneumatic procedure. When a tear is adjacent to a star fold, PR is not generally the procedure of choice. Mild to moderate proliferative vitreoretinopathy (PVR) (such as a star fold) that is distant from any retinal break generally does not contraindicate PR. More severe PVR requires vitrectomy or possibly SB, or both.

### **Inability to Maintain Positioning**

Failure to maintain the appropriate position faithfully is an important cause of failure of PR. It is important to ask patients about back or neck problems and to assess mental competence before deciding on PR. Some positions are quite easy to maintain, whereas others are more difficult. Positioning is easiest with tears between 11 and 1 o'clock. Positioning is probably easier for horizontally oriented tears (between 2 and 4 or between 8 and 10 o'clock) than it is for obliquely oriented tears (between 1 and 2 or between 10 and 11 o'clock).

### **Glaucoma**

The majority of patients with primary open angle glaucoma can be treated with PR without a problem. Performing paracentesis prior to gas injection may be prudent in patients with severe glaucoma (e.g., splitting of the macular field as a result of glaucoma) since they might suffer noticeable damage even from brief elevations in intraocular pressure. In glaucomatous eyes that have had trabeculectomy or may need it in the future, PR has advantages over SB in that it minimizes scarring of the conjunctiva. Except in cases of severely impaired trabecular outflow facility, serial measurements of intraocular pressure after gas injection are not necessary.

### **Cloudy Media**

For PR to be successful, all detached retinal breaks need to be identified and treated. Opacities that preclude an adequate view of the peripheral retina, such as peripheral vitreous hemorrhage or pseudophakic lens capsular opacification, represent relative contraindications to PR. However, there is no contraindication if the

extent of detached peripheral retina can be identified, treated with cryopexy, and then covered by gas. Because evidence suggests that PR does not jeopardize an eye for future vitrectomy or SB if needed,<sup>8,17</sup> we will frequently use the pneumatic procedure even when opacities obscure parts of the detached retina that cannot be covered by gas, but the chance of success may be lower.

## **Lattice Degeneration**

Many studies have shown no detrimental effect on single-operation success from lattice degeneration,<sup>17,39</sup> particularly if under 3 clock-hours in extent. Extensive lattice may indicate increased risk for vitreoretinal traction, and these cases may benefit from vitrectomy or SB.

## **Aphakia and Pseudophakia**

Retinal detachments in aphakic or pseudophakic eyes have a poorer prognosis than phakic eyes, no matter what surgery is performed.<sup>9</sup> In some series, aphakic eyes did poorly with PR,<sup>40</sup> especially if the posterior capsule was open,<sup>41</sup> but in other reports this was not the case.<sup>8,9</sup> Aphakic and pseudophakic eyes are prone to multiple, tiny, far-peripheral breaks and require an especially careful preoperative examination. In pseudophakic eyes, the view of the peripheral retina can be quite limited if much peripheral capsular opacity is present. PR should probably not be performed in these cases unless retinal detachment is rather limited. In our opinion, if the peripheral retina can be adequately examined, aphakia or pseudophakia is not a contraindication to PR.

## **Posterior Vitreous Detachment**

Phakic eyes with complete posterior vitreous detachment tend to have a higher success rate with PR than those with partial vitreous detachment.<sup>42</sup>

## **Cases Where PR Presents a Particular Advantage**

Compared with vitrectomy, PR is especially advantageous in the

management of the following three situations:

1. Phakic eyes. PR avoids the induced cataract to which vitrectomy is prone.
2. Impending macular detachment. Because PR can be performed promptly in the office without the delays required to prepare a patient for the operating room, a macula at imminent risk of detachment may be best served by PR, using the steamroller maneuver (see below) to move subretinal fluid away from the macula.
3. Limited operating room access. Financial and logistical difficulties may preclude use of the operating room and favor a procedure that can be done in the office.

Compared with SB, PR is especially advantageous in the management of the following five situations:

1. Macular breaks and other posterior retinal breaks. Posterior retinal breaks are difficult to treat with SB, so PR is the procedure of choice in many of these cases, especially in phakic eyes. It also has been reported as an effective option in the treatment of optic pits with macular detachment.<sup>43,44</sup>
2. Redetachment or persistent detachment after scleral buckling. When subretinal fluid accumulates or persists because of a superior break after SB, PR may be much easier to perform than buckle revision.<sup>45</sup> This is especially effective if the break is located on or anterior to the buckle.<sup>46</sup>
3. Isolated tears under the superior rectus. Placing a segmental buckle under a vertically acting muscle runs the risk of iatrogenic diplopia; this is eliminated with PR.
4. Filtering blebs. If a functioning filtering bleb is present, or if a filtering procedure may be necessary in the future, PR or vitrectomy should be considered instead of SB.
5. Bullous detachment. When retinal detachment is highly bullous,

retinal tears can be difficult to localize and treat with SB, a problem that is avoided by two-session PR.

## Preoperative Counseling

The details of the procedure should be explained to the patient and the potential risks and complications reviewed. Required postoperative positioning is described, and the patient's ability to comply is evaluated. The possibility of recurrence or persistence of detachment, with potential need for additional surgery, is explained. The patient is informed that infection inside the eye is a very rare but potentially devastating complication. Restrictions on air travel and travel to significantly higher altitudes while gas is in the eye is explained.

## Surgical Technique

### Anesthesia

Topical anesthesia, usually with subconjunctival anesthesia or application of lidocaine-soaked pledgets, may be adequate, but in sensitive patients or if extensive cryopexy is planned, retrobulbar anesthesia is often helpful.

If subsequent general anesthesia is used in a patient who has an intraocular gas bubble, nitrous oxide should not be administered. When gas is to be introduced into an eye during surgery, nitrous oxide should be turned off at least 15 minutes before gas injection.

### One-Session vs. Two-Session Procedure

See [Box 107.1](#) for indications for the one-session and two-session [Box 107.1](#).

### Indications for One-Session Versus Two-Session Procedure

#### Indications for a One-Session Procedure With Cryopexy

- Issues of convenience or logistics

- Small or hard-to-find breaks
- Media opacities preventing laser
- Pigment atrophy preventing adequate laser burns
- Appropriate laser not available

### **Indications for a Two-Session Procedure With Laser**

- Use of the “steamroller” procedure
- Large or extensive breaks (to minimize retinal pigment epithelial dispersion)
- Bullous detachment precluding accurate cryopexy
- Tear overlying a scleral buckle
- Recently operated eye (incision not healed)
- Very posterior breaks

### **Indications for a Two-Session Procedure With Cryopexy**

- Initially bullous detachment but cryopexy preferred
- New media opacities preventing intended laser treatment
- Persistent subretinal fluid precluding adequate laser burns

PR can be done in one session, with cryopexy applied to the retinal breaks just before gas injection, or as a two-session procedure, with initial gas injection followed by laser photocoagulation 1 or 2 days later, when the retina is reattached. One-session procedures always involve cryopexy since the laser cannot be applied to detached retina. Two-session procedures are usually, but not always, done with the laser.

The chance of dispersing retinal pigment epithelial (RPE) cells into the vitreous may be minimized by a two-session procedure,

flattening the retina with gas before later applying retinopexy, particularly if large retinal breaks are present or if the “steamroller” technique is used (see [page 1950](#)). Also, if a tear is so bullously detached that a cryopexy ice ball will not reach the retina, it may be difficult to place the cryopexy spots with sufficient accuracy, so a two-session procedure may be preferable. Small or hard-to-find breaks may become impossible to locate once the retina is reattached, so cryopexy treatment before gas injection in a one-session procedure maximizes the chance of all tears being treated. Whenever a two-session procedure is selected, it is important to make a careful preoperative drawing of the location of the breaks relative to vascular and other landmarks. For these reasons, pneumatic retinopexy is most commonly performed in a single session.

## Cryopexy vs. Laser

Cryopexy may be necessary if vitreous hemorrhage or other media opacities make laser treatment difficult. Laser application may be ineffective for tears that develop in areas of pigmentary atrophy. Cryopexy may be easier to apply than laser in some patients who have difficulty keeping their eyes still. In some cases, even after a few days of positioning, enough subretinal fluid remains that laser cannot be applied, and cryopexy may be necessary.

If a laser indirect ophthalmoscope (LIO) is not available, tears in the far periphery may not be treatable with laser delivered by slit lamp, necessitating cryopexy. The LIO is ideal for PR because it allows treatment of the far periphery and facilitates maneuvering of the gas bubble out of the way.<sup>35</sup> Although most tears can be treated with laser through a slit-lamp delivery system by tilting the patient's head as necessary to move the bubble away from the tear, this is difficult with tears from 11 to 1 o'clock. Although it is often possible to apply laser treatment through a large gas bubble as can be achieved with vitrectomy, it can be very difficult with the smaller bubble utilized with PR because of optical factors. Application of laser through gas causes concentration of heat due to the insulating effect of gas, and excessively hot burns may result.

Certain circumstances might indicate use of laser instead of

cryopexy. Laser is required if a tear develops overlying a previously placed scleral buckle, since cryopexy cannot penetrate the silicone. In eyes with a recent surgical incision (within the past 4–6 weeks), laser may be safer than cryopexy because the scleral depression of the cryoprobe elevates the intraocular pressure. Very posterior breaks are easier to treat with laser than with cryopexy, although a small conjunctival incision in the cul-de-sac allows passing of the cryoprobe posteriorly.

Chorioretinal adhesion may be quicker and firmer using laser rather than cryopexy.<sup>47,48</sup> In addition, some authors believe that cryopexy is associated with a higher incidence of proliferative vitreoretinopathy and other complications,<sup>49,50</sup> although others could find no such association.<sup>51</sup> Laser also has the advantage of less morbidity compared with cryopexy, especially if multiple or large breaks are present.

Although laser generally cannot be applied to detached retina, if the detachment is very shallow, it may be possible to apply laser using firm scleral depression to flatten the retina combined with increased laser power. However, this technique may cause retinal breaks as a result of excessive laser intensity, and it must be used with caution.

## **Applying Retinopexy**

Transconjunctival cryopexy consists of multiple contiguous applications that entirely surround the retinal tear and is monitored with binocular indirect ophthalmoscopy. Cryopexy to bare RPE in the middle of the hole should be avoided if possible. The RPE is pushed into apposition with the overlying retina, if possible, causing a visible white reaction in the retina. In very bullous detachments when the RPE cannot be brought into contact with the detached retina, the endpoint for cryopexy is the appearance of a dull, orange glow at the level of the pigment epithelium. Following treatment, do not attempt to move the cryoprobe until the freeze at the tip has thawed.

Laser application begins at a low intensity and is gradually increased until a dull, gray-white burn is achieved. If a red or infrared wavelength is used, an even less-intense burn is desired. Multiple rows of almost contiguous burns are applied to surround

all tears completely, with generous treatment along the anterior aspect of a horseshoe-shaped tear where it is most likely to extend.

## Amount and Type of Gas to Inject

PR usually requires a gas bubble large enough to cover all detached breaks simultaneously for about 5 days. The size of the gas bubble should reflect the extent of the break(s). Generally, the injected gas bubble before expansion must be moderately larger than the largest retinal break to prevent subretinal gas. In most cases, we prefer to have a bubble volume of 1.0 mL or more, which requires an injection of at least 0.5 mL of pure SF<sub>6</sub>.

If filtered room air is injected, we recommend at least 0.8 mL. If it is desired to inject more than 0.6 mL, multiple paracenteses (one before and one or more after the gas injection) or multiple gas injections may be needed.

We believe that it is optimal for the gas bubble to cover the break(s) for 5 days and then disappear as soon as possible. However, successful reattachment has been reported after as little as 6–8 hours of tamponade, as with inverted positioning for inferior tears.<sup>37</sup>

The longevity of an air bubble is probably sufficient for most cases, but occasionally the chorioretinal adhesion may not be sufficiently mature when the air has resorbed. The use of air also forfeits the advantage of postinjection bubble expansion within the eye, necessitating injection of a larger volume, but it offers the advantages of decreased expense and universal availability.

In most cases the prolonged longevity of a perfluoropropane (C<sub>3</sub>F<sub>8</sub>) bubble is a disadvantage. Air travel is contraindicated for a much longer period of time with C<sub>3</sub>F<sub>8</sub>, and patients are instructed not to sleep on their back until the bubble disappears to prevent prolonged contact between the gas bubble and the lens. However, the use of C<sub>3</sub>F<sub>8</sub> may eliminate the need to reinject gas if a new break develops, and C<sub>3</sub>F<sub>8</sub> allows the injection of a smaller amount of gas initially, thereby reducing the need for paracentesis. We recommend C<sub>3</sub>F<sub>8</sub> only when an unusually large gas bubble is needed.

Our usual procedure is to perform a preinjection paracentesis, followed by injection of 0.5–0.6 mL of pure SF<sub>6</sub>. The amount of fluid removed by paracentesis helps determine how much gas to inject. One can usually inject that amount of gas plus 0.15–0.2 mL without needing a second paracentesis, particularly if the eye was initially softened by cryopexy. Note that it takes more than 0.05 mL to fill the hub of the needle before fluid comes into the measuring chamber of the syringe. For example, if the paracentesis syringe fills to 0.40 mL, >0.45 mL has been removed from the eye. In that instance, 0.55 mL of gas can probably be injected into the eye without closing the central retinal artery. It may be possible to inject up to 0.60 mL, especially if the eye was substantially softened by firm depression during cryopexy.

## Sterilizing Ocular Surface

Meticulous attention to sterile technique is mandatory. Sterilization of the ocular surface requires topical antiseptics; antibiotics are inadequate. We recommend povidone–iodine solution,<sup>52</sup> and we do not recommend other preparations that contain detergent or alcohol.

A sterile lid speculum is utilized. Several drops of povidone–iodine solution are instilled directly onto the conjunctiva and left in contact with the eye while the gas is prepared. The injection site is then dried with a sterile cotton-tipped applicator, and the eye is ready for paracentesis and injection of gas. With these precautions, the occurrence of endophthalmitis after PR is extremely uncommon, with very few reported cases in the literature.<sup>53,54</sup>

## Preparing the Gas

A pressure-reducing system is attached to the gas cylinder to allow drawing of the gas from a low-pressure system. High pressure can blow out the Millipore filter and render it useless in sterilizing the gas.<sup>55</sup> A condom catheter can be attached to the cylinder, as shown in Fig. 107.1, or a step-down valve system can be used.

Alternatively, the gas can be drawn into a large syringe and then transferred to a small syringe.

**FIG. 107.1** The gas is transferred from the high-pressure tank into a low-pressure balloon made from an external urinary catheter. Gas is then easily withdrawn. Pressure in the balloon pushes gas through the Millipore filter into the syringe. To avoid dilution with air, gas in the syringe is expelled and refilled twice. (Reprinted from Hilton GF, Grizzard WS. Pneumatic retinopexy. A two-step outpatient operation without conjunctival incision. *Ophthalmology* 1986;93:626–41. ©1986, with permission from the American Academy of Ophthalmology.)

The selected gas passes through a Millipore filter into a 3-mL syringe in sterile fashion. The tube connecting the gas cylinder with the syringe, including the filter, is flushed through with gas to ensure no dilution with room air. The syringe is filled with a few milliliters of gas, and the gas is discarded. The syringe is then refilled. Passive filling of the syringe ensures that room air is not drawn in. A disposable 30-gauge (12-mm, half-inch) needle is then placed tightly on the syringe, and excess gas is expelled to leave the exact amount intended for injection. The gas should not be stored in the syringe for more than a few minutes before injection because room air infiltrates the syringe and dilutes the gas sample.<sup>56</sup>

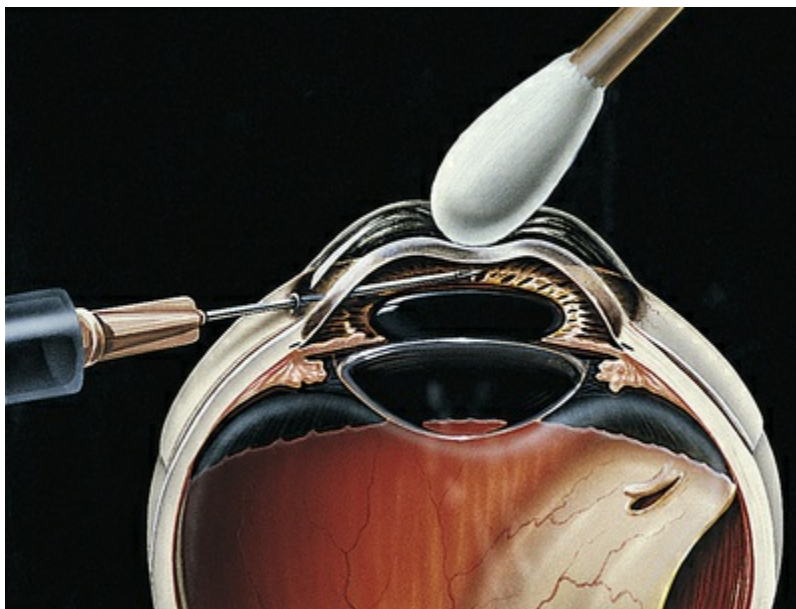

## Performing a Paracentesis

Although gas can be injected before paracentesis, we generally recommend a paracentesis first. Paracentesis performed after gas

injection can result in gas in the anterior chamber. Preinjection paracentesis helps determine how much gas to inject and avoids marked intraocular pressure elevations. Dehiscence of a recent clear corneal cataract incision has been reported following PR when preinjection paracentesis was not performed.<sup>57</sup>

For a paracentesis, we use a 30-gauge needle mounted on a 1-mL syringe without a plunger. After sterilization of the ocular surface, the needle is passed obliquely through the limbus into the anterior chamber, with the needle tip kept over the peripheral iris to avoid touching the lens.

The intraocular pressure quickly drops, so pressure must be applied externally to the eye in order for fluid to continue to pass into the syringe. Gentle pressure can be applied to the center of the cornea with a sterile cotton-tipped applicator, thereby forcing aqueous into the angle (Fig. 107.2). However, care must be taken to avoid contact between the cornea and the lens. Instead we prefer applying pressure with the cotton-tipped applicator at the equator of the eye, facilitating passage of fluid into the anterior chamber and allowing more firm and prolonged pressure on the eye.

**FIG. 107.2** Paracentesis of the anterior chamber with a 30-gauge disposable needle on a 1-mL syringe without a plunger. The lumen is open toward the cornea and positioned over the peripheral iris. Gentle pressure on the cornea with a cotton-tipped applicator forces

aqueous into the periphery of the anterior chamber near the needle tip, thereby facilitating more complete drainage. (Reproduced with permission from Hilton GF, Tornambe PE, and the Retinal Detachment Study Group. Pneumatic retinopexy: an analysis of intraoperative and postoperative complications. *Retina* 1991;11:285–94.)

Patience is called for when performing the paracentesis. Fluid will initially flow freely into the syringe, but will then slow. By continuing to press on the eye and very gradually withdrawing the needle over several minutes, one can usually remove another 0.05–0.2 mL from the eye, which will often be necessary in order to inject a 0.5–0.6-mL bubble. Highly myopic eyes tend to have more ample anterior chambers, but they also call for a larger intraocular gas bubble.

Paracentesis through the limbus may be done in phakic eyes and in pseudophakic eyes if the posterior capsule is intact or if a small capsulotomy is firmly closed against the intraocular lens (IOL); otherwise, paracentesis should usually be performed through the pars plana to prevent vitreous strands from incarcerating in the limbus. When performing paracentesis through the pars plana in a pseudophakic eye, the plunger is left in the syringe to prevent occlusion of the needle with vitreous. The needle is directed anteriorly into the anterior chamber through the pupil adjacent to the IOL. Paracentesis of the anterior chamber is contraindicated in the presence of an iris-supported anterior chamber IOL because of the possibility of the implant touching the endothelium.

## Injecting Gas

With the needle attached, gas is expelled from the syringe down to the amount it is intended to inject into the eye. With the ocular surface still sterile and the patient supine, the head and the eye are turned a total of approximately 45° to one side to place the pars plana injection site uppermost. The gas usually is injected temporally unless the pars plana epithelium is detached or large retinal breaks are present in that area, in which case another site is selected. The injection is made 3–4 mm posterior to the limbus with a 30-gauge needle. The needle is directed toward the center of the vitreous and inserted to a depth of 7 or 8 mm to ensure penetration

of the pars plana epithelium and the anterior hyaloid face. It is then partially withdrawn so that approximately 9 mm of the needle shaft is seen outside the eye, leaving only 3 mm of the needle tip inside the globe. With the injection site uppermost and the needle vertical, the gas is injected evenly and moderately briskly, but not too forcefully. We estimate that the injection should take place over 0.5–1.0 seconds. This technique creates one single bubble at the needle tip (Fig. 107.3C) rather than multiple small bubbles, often referred to as “fish eggs” (see below).

**FIG. 107.3** Summary of pneumatic retinopexy procedure. (A) The volume of the subretinal fluid is determined by the inflow of fluid vitreous (*green arrow*) and the outflow through the retinal pigment epithelial pump into the choroid (*red arrow*). (B) The area of the retinal break is treated with multiple contiguous applications of transconjunctival cryotherapy. (C) With the pars plana injection site uppermost, the needle vertical, and the needle tip placed shallowly within the vitreous, the gas is injected moderately briskly through a 30-gauge needle. For purposes of illustration, the artist has drawn the injection in the same meridian as the retinal break, but usually this meridian is avoided.

(D) The head is positioned so that the intravitreal gas bubble closes the retinal break. (E) With the break closed, the retina usually is reattached by the first postoperative day. (F) The gas bubble is spontaneously absorbed. (Reprinted from Hilton GF, Kelly NE, Salzano TC, et al. Pneumatic retinopexy. A collaborative report of the first 100 cases. *Ophthalmology* 1987;94:307–14. ©1987, with permission from the American Academy of Ophthalmology.)

It is not necessary to visualize the needle tip within the vitreous with the ophthalmoscope. As the needle is withdrawn from the eye, the needle tract is immediately covered with a sterile cotton-tipped applicator by rolling it onto the needle shaft simultaneously as the needle is withdrawn to prevent the loss of gas. The head is then rotated to the opposite side, moving the gas bubble away from the injection site, and the cotton-tipped applicator is then removed. Alternatively, the head can be rotated prior to removing the needle. Within seconds the needle tract swells closed, preventing further leakage.

## Assessing Intraocular Pressure

Despite preinjection paracentesis, the central retinal artery sometimes closes after gas injection. Several studies suggest that the retina can tolerate 60 minutes without blood flow as a result of elevated pressure.<sup>26,58–62</sup> If the artery does not reopen within about 10 minutes, intraocular pressure should be lowered by repeat paracentesis.

While waiting for the central retinal artery to reopen, intermittent ocular compression can hasten the return to normal intraocular pressure. A scleral depressor is pressed against the lateral aspect of the eye so that the eye is compressed against the medial orbital wall. This raises the intraocular pressure, augmenting fluid egress and stretching the scleral wall.<sup>63</sup> This is not recommended in eyes that have had recent surgery or penetrating trauma, or in eyes with severe glaucoma.

The patency of the central retinal artery is evaluated with ophthalmoscopy. If it is difficult to tell whether the artery is patent, the eye is compressed with gradually increasing force while

monitoring with an indirect ophthalmoscope. If pulsation of the central retinal artery cannot be induced in this manner, it is probably closed. In addition to ensuring patency of the central retinal artery, the ophthalmoscope is used to rule out the possible complications of anterior gas entrapment or fish egg bubbles.

Once patency of the central retinal artery has been reestablished, the outflow of aqueous is more than adequate to compensate for the expansion of the gas bubble in nonglaucomatous eyes. Accordingly, we no longer check postoperative pressures unless severe glaucoma is present.

## Instructing the Patient

The eye is irrigated to rinse out the povidone-iodine, an antibiotic-steroid ointment is instilled, and the eye is patched. Most patients require no pain medication. The axis of the retinal break is marked with an arrow on the bandage, and the head is tilted so that the arrow points toward the ceiling. Alternatively, a commercially produced “pneumo-level” disc can be attached to the forehead to indicate the required head tilt. Using a mirror to demonstrate, the patient is carefully instructed to position the head so that the break is uppermost. The patient is instructed not to lie on their back facing upward for three reasons: first, the gas will likely not be in position against the retinal breaks; second, prolonged gas contact with the lens may cause a cataract in a phakic patient; and third, egress of fluid from the eye may be blocked, resulting in a rise in intraocular pressure. The appropriate position, with the retinal break uppermost, should be maintained (at least during waking hours) for 5 days. If possible, maintaining the position during sleep is helpful, especially until the retina is reattached. Successful retinal reattachment has been described with positioning for shorter than 5 days, and positioning for 3 days or fewer may often be adequate.<sup>37</sup>

## Special Procedures

### Fish Eggs

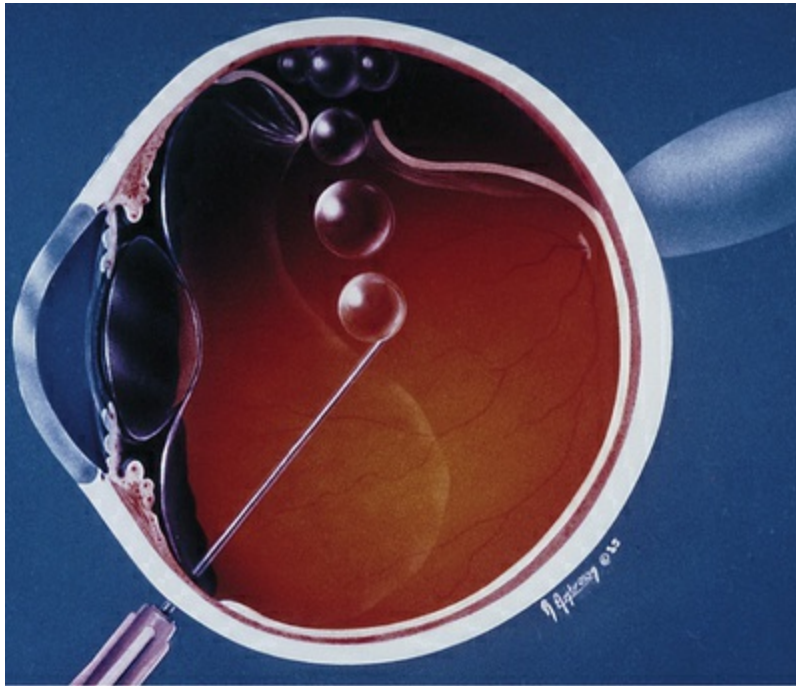

Multiple small intravitreal gas bubbles, or “fish eggs”<sup>18</sup> (Fig. 107.4),

can result in gas getting under the retina, particularly in the presence of large retinal breaks. This occurrence is generally preventable by performing the following steps (Fig. 107.5):

**FIG. 107.4** Fish eggs – multiple, small intravitreal gas bubbles, generally caused by faulty injection technique – can result in gas getting under the retina. (Reproduced with permission from Hilton GF, Tornambe PE, and the Retinal Detachment Study Group. Pneumatic retinopexy: an analysis of intraoperative and postoperative complications. *Retina* 1991;11:285–94.)

**FIG. 107.5** How not to inject gas in the presence of detached retinal breaks. (Reproduced with permission from Hilton GF, Tornambe PE, and the Retinal Detachment Study Group. Pneumatic retinopexy: an analysis of intraoperative and postoperative complications. *Retina* 1991;11:285–94.)

1. Make sure that the needle tip is placed shallowly within the vitreous at the time of injection.
2. Make sure that the injection site is uppermost.
3. Inject moderately briskly (0.5–1.0 seconds).
4. Inject with the needle vertical.

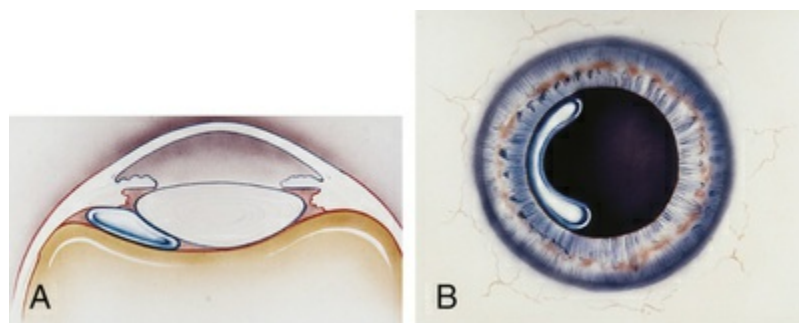

If fish eggs do occur, the patient is strictly positioned to keep the bubbles away from retinal breaks. If all retinal breaks are small, this may not be necessary, but keep in mind that breaks can stretch a little. The bubbles usually coalesce spontaneously within 24 hours, and then the patient can adopt a position with the retinal break(s) uppermost.

Alternatively, the bubbles usually can be caused to coalesce by flicking the eye with a sterile cotton-tipped applicator or gloved finger. The eye is turned so that sclera without underlying retinal

breaks is uppermost, and then this site is flicked moderately firmly. Since it may not be possible to keep fish eggs away from superior breaks, this maneuver is especially important if large breaks are present in the superior several clock-hours. Impending macular detachment might also indicate this procedure or indicate a face-down position until the bubbles coalesce.

## Gas Entrapment at the Injection Site

After gas injection, the head is turned to the opposite side and mobility of the gas is confirmed ophthalmoscopically. If the gas bubble remains trapped at the injection site, it is probably trapped in the canal of Petit (between the anterior hyaloid, the lens and zonules, and the pars plana epithelium). Typically, the gas trapped in this canal is visible peripherally behind the lens, forming a partial ring, variously described as the “bagel,” “donut,” or “sausage” sign (Fig. 107.6).

**FIG. 107.6** Gas entrapment at the injection site. (A) Gas trapped in the canal of Petit (between the anterior hyaloid, the lens and zonules, and the pars plana epithelium). (B) Gas is visible peripherally behind the lens, forming a partial ring (the “sausage sign”).

(Reproduced with permission from Hilton GF, Tornambe PE, and the Retinal Detachment Study Group. Pneumatic retinopexy: an analysis of intraoperative and postoperative complications. *Retina* 1991;11:285–94.)

If only a small amount of gas is trapped, no treatment is necessary. If most of the gas is trapped, the patient is advised to follow face-down positioning for 1 day. As the gas subsequently expands, it will generally break through and float up to the macula. Thereafter, the patient assumes the desired position with the retinal

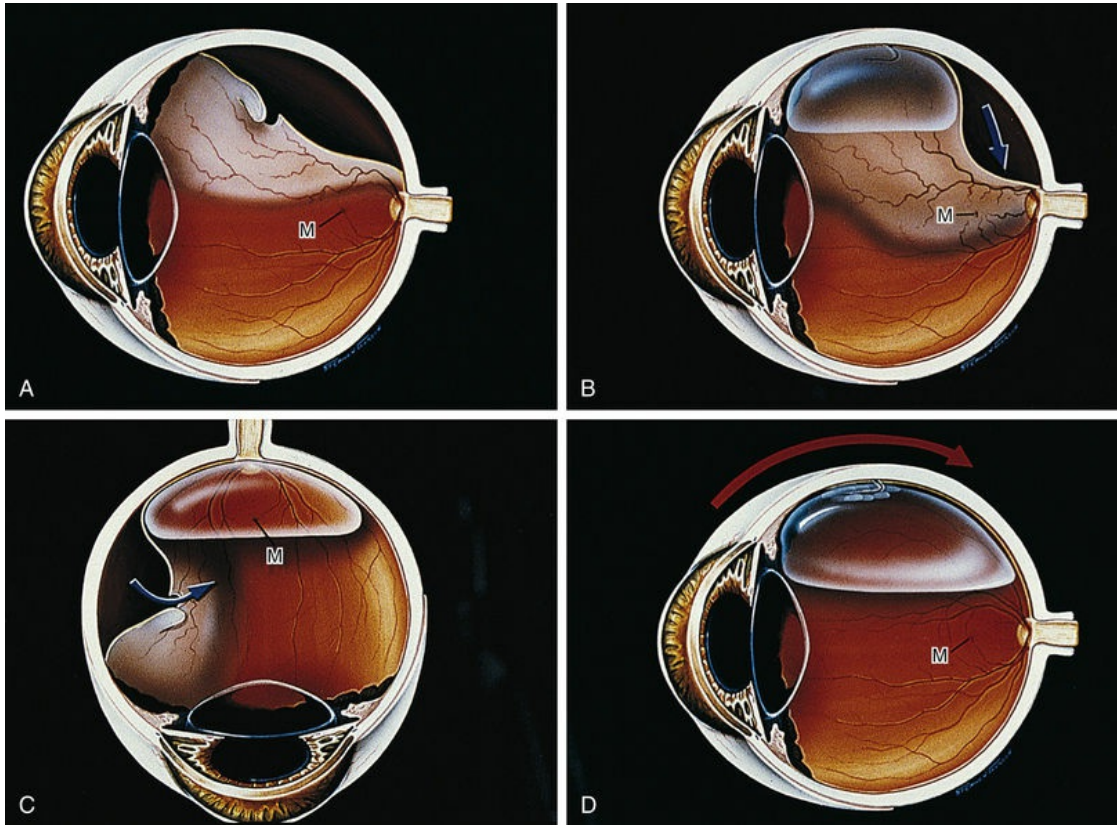

break uppermost.

Waiting for trapped gas to break free may jeopardize an attached macula imminently threatened by detachment. A trapped bubble can be removed by passing a 27-gauge needle back through the injection site. This needle is mounted on a syringe without the plunger, containing a small amount of sterile saline solution. The entry site is positioned uppermost, and the needle passed vertically into the bubble. Sometimes it takes a little manipulation to break the surface tension of the bubble and get it to pass into the needle. Most of the gas will escape, bubbling up through the fluid in the syringe. At another site, the gas is reinjected deeper into the vitreous, with 4–5 mm of the needle in the globe. This procedure also may be indicated if trapped gas does not become mobile after face-down positioning, which may constitute the rare and potentially painful occurrence of gas trapped beneath the pars plana epithelium or in the choroid.<sup>64,65</sup>

## Steamroller Technique

If bullous subretinal fluid extends almost to an attached macula, placement of a bubble against the bullous detachment peripherally may push fluid into the macula and cause it to detach.<sup>66</sup> This complication, as well as the impending threat of spontaneous macular detachment, usually can be avoided by the “steamroller” technique (Fig. 107.7).<sup>67</sup>

**FIG. 107.7** “Steamroller” maneuver: prevention of iatrogenic macular detachment. (A) Bullous retinal detachment near an attached macula (*M*), indicating the “steamroller” maneuver. (B) What to avoid – the gas bubble may force subretinal fluid posteriorly (*arrow*), causing iatrogenic detachment of the macula.

(C) Steamroller step 1 – iatrogenic macular detachment is prevented by placing the patient in a face-down position immediately following gas injection, making sure that the gas bubble traverses attached retina on its way to the macula. This frequently causes some subretinal fluid to pass through the break into the vitreous (*arrow*). (D) Steamroller step 2: over 1–10 minutes, the patient's head position is very gradually moved along the meridian between the macula and the retinal break (*arrow*) until the retinal break is uppermost. This causes the bubble to roll toward the retinal break, pushing the subretinal fluid away from the macula and back into the vitreous and flattening the retina. Cryopexy should generally not be performed before a steamroller maneuver. (Reprinted from Hilton GF, Kelly

NE, Salzano TC, et al. Pneumatic retinopexy. A collaborative report of the first 100 cases. *Ophthalmology* 1987;94:307–14. ©1987, with permission from the

American Academy of Ophthalmology.)

An injection site is selected in a meridian where the retina is attached. After injection of the gas bubble, the patient's head is placed face-down by turning the patient in a direction planned to ensure that the bubble traverses only attached retina en route to the macula. Over 1–10 minutes, the patient's head position is then gradually changed until the retinal break is uppermost, causing the bubble to roll from the macula toward the retinal break, pushing the subretinal fluid away from the macula and back into the vitreous, and flattening the retina. Because cryopexy causes liberation of pigment epithelial cells, which may cause PVR if they enter the vitreous cavity, cryopexy should generally not be performed before steamrolling.

Whether steamrolling is necessary to prevent macular detachment depends on several factors:

1. How close the detachment is to the macula (only detachments well within the arcades usually need steamrolling);
2. How bullous the detachment is; and
3. How large the gas bubble is.

Possible indications for steamrolling include the following:

1. Prevention of iatrogenic macular detachment.
2. Prevention of iatrogenic detachment of an attached retinal break.
3. Reduction of a bullous detachment overhanging the optic nerve, preventing visualization of the central retinal artery during the procedure.
4. Reduction of subretinal fluid to encourage more rapid resolution of retinal detachment (possibly of use in cases where all retinal breaks cannot be covered at one time by the gas bubble).
5. Avoidance of posterior gaping of the tear and subretinal gas in the presence of large retinal breaks (the extreme example of this being a somersault maneuver performed to unroll the inverted flap

of a giant retinal tear).

The movement of subretinal fluid into the vitreous has raised theoretical concerns about the production of PVR. However, two studies<sup>68,69</sup> showed no increase in PVR in steamrolled cases.

## Summary of Procedure

The following constitutes the sequence of a typical pneumatic retinopexy procedure (see [Fig. 107.3](#)):

1. Anesthetic: topical/subconjunctival or retrobulbar.
2. Cryopexy to retinal tears: if one-session procedure, in lieu of laser.
3. Sterilization of ocular surface: povidone–iodine solution.
4. Paracentesis: limbal, or via pars plana if capsule is open.
5. Intravitreal gas injection: 0.4–0.6 mL of SF<sub>6</sub>.
6. Second paracentesis and/or ocular compression: if needed to open central retinal artery.
7. Special procedures: e.g., steamroller if needed (cryopexy should not be performed before steamroller)Irrigate, apply antibiotic and patch: draw arrow.
8. Laser to retinal tears: next day or when retina is reattached (in lieu of cryopexy, as two-session procedure), with 360° peripheral laser if desired.

## Postoperative Management

The patient is usually examined in the office on the first or second postoperative day, at which time the retina is usually reattached ([Fig. 107.3E](#)), although an occasional case may take an extra day or two. If the fluid is not reabsorbing, there may be a new or missed

break, traction may be keeping the break open, the bubble may be too small, or the patient may not have maintained proper positioning. The importance of proper positioning should be reemphasized.

Inferior subretinal fluid or loculated pockets of subretinal fluid on rare occasion will persist for weeks or months. As long as the fluid is not increasing, there are no detached retinal breaks, and the macula is attached, reoperation is not necessary.

As a general guideline, the patient is examined on about postoperative days 1 or 2, 5–7, and 14–21 and periodically thereafter, looking especially for new retinal breaks. If close follow-up results in early detection and treatment, these breaks do not jeopardize the final outcome.<sup>8</sup> At least half of these can be cured with an office procedure without resorting to vitrectomy or SB.

The gas bubble will reabsorb spontaneously (Fig. 107.3F). Until it does, the patient is advised against air travel because the lower atmospheric pressure in flight can cause expansion of the gas bubble with a marked increase in intraocular pressure. We recommend that activity be limited until the gas bubble is small. For example, jarring activities (such as jogging) and rapid head tilting (as with somersaults) are best avoided.

## Results

In 1991 a compilation of 26 statistical series from seven countries including 1274 eyes treated with PR showed a single-operation success rate of 80%, with 98% cured with one or more operations.<sup>18</sup> More recently, Chan et al.<sup>20</sup> reviewed 81 published PR series from 1986 to 2007, totaling 4138 eyes. Single-operation success was 74.4%, and success with one or more operations was 96.1%. New retinal breaks occurred in 11.7% of eyes, and PVR occurred in 5.2% (Table 107.2).

---

### TABLE 107.2

#### Summary of 81 Published Statistical Reports on Pneumatic Retinopexy, 1986–2007: Anatomic Results and Two Postoperative Complications

---

Reports (n)	Eyes (n)	Reattached		Complications	
		One Operation <sup>a</sup>	Reoperations	New Retinal Breaks	PVR
81	4138	74.4%	96.1%	11.7%	5.2%

<sup>a</sup>Some series included postoperative supplemental laser photocoagulation or cryotherapy.

PVR, postoperative proliferative vitreoretinopathy.

Reproduced with permission from Chan CK, Lin SG, Nuthi AS, et al. Pneumatic retinopexy for the repair of retinal detachments: a comprehensive review (1986–2007). *Surv Ophthalmol* 2008;53:443–78.

Tornambe<sup>17</sup> reviewed the causes of failure and concluded that pseudophakia/aphakia, detachment of >50% of the retina, and multiple retinal breaks adversely influence single-operation success. Several studies<sup>9,70</sup> have shown that initial failure with PR, subsequently requiring vitrectomy or SB, does not adversely affect the final visual outcome compared with vitrectomy or SB alone. Unsuccessful initial PR, SB, or vitrectomy can often be safely and effectively rescued with a subsequent PR procedure.<sup>71</sup>

## Comparison of PR With Scleral Buckle

The multicenter, randomized controlled clinical trial compared PR and SB in 198 eyes, establishing two statistically similar groups with similar preoperative visual acuity. The conclusions of the study include the following:<sup>8</sup>

1. Postoperative morbidity was less and had a shorter duration in the PR group.
2. Postoperative visual acuity was significantly better with PR than with SB for eyes in which the macula was detached for up to 2 weeks ( $p=.05$ ). In this group, 80% of the PR patients regained 20/50 or better vision, compared with only 56% of SB patients.
3. With one operation and with occasional postoperative cryotherapy or laser supplementation, retinal reattachment was 84% in the SB group and 81% in the PR group. This difference was not statistically significant. However, subsequent studies have confirmed a modestly higher single-operation success rate with SB.<sup>72</sup>

4. With reoperations, the final reattachment rate was 98% in the SB group and 99% in the PR group, also not a statistically significant difference. Subsequent studies have confirmed comparable final reattachment rates.<sup>72</sup>
5. Complications were similar, based on a score system that weighted heavily the need for postoperative laser or cryotherapy.
6. Cataract surgery was required four times more often after SB than after PR.
7. New and missed retinal breaks occurred more frequently after PR but did not usually produce an unfavorable outcome. New and missed retinal breaks after SB had the worst prognosis, requiring more extensive reoperation with decreased visual results.
8. An open or absent posterior capsule was associated with an equally lower single-operation success rate in both groups.
9. Postoperative proliferative vitreoretinopathy occurred in 5% in the SB group and 3% in the PR group (not a statistically significant difference).

## Comparison of PR With Vitrectomy

Unfortunately, similar prospective data for a direct comparison of PR to primary vitrectomy are unavailable. As SB has declined in favor among retinal surgeons, vitrectomy for primary rhegmatogenous retinal detachment has gained tremendous popularity in recent years,<sup>73,74</sup> driven by continual advances in vitreoretinal instrumentation, microincisional techniques, endoillumination, and wide-field viewing systems. Similar to PR, vitrectomy avoids some of the morbidity more frequently associated with SB, such as induced myopia. Unlike PR, it tends to induce cataract and demands the time and expense associated with an operating room procedure.

Vitrectomy presents advantages in some circumstances where PR is inadequate. It is the procedure of choice in dealing with significant PVR and vitreoretinal traction, and it may be ideal when

vitreous or capsular opacity causes poor visualization. By facilitating placement of a large gas bubble, vitrectomy shares with SB the ability to treat inferior and widely spread breaks.

Because vitrectomy tends to induce cataract, it is used most commonly in pseudophakic eyes. Tiny breaks, common in pseudophakic eyes, may be most readily identified by internal search during vitrectomy. In a multicenter clinical trial of SB versus primary vitrectomy for rhegmatogenous retinal detachment,<sup>75</sup> vitrectomy yielded significantly better single-operation success rates than SB in pseudophakic eyes, but no difference in final vision. In phakic eyes, vitrectomy yielded poorer visual results than SB with no benefit in single-operation success.

In the more simple cases appropriate for PR, especially in phakic patients, PR may be preferable to vitrectomy or SB.

## Complications

Fish eggs, gas entrapment, and iatrogenic macular detachment are discussed under “Special procedures” above. Other intraoperative complications of PR are minimal. A number of postoperative complications have been noted in the literature, but most of these occur with an incidence of less than 2% (Table 107.3). The two major concerns are PVR and new or missed retinal breaks. The management of subretinal gas also warrants discussion.

**TABLE 107.3**  
**Postoperative Complications<sup>a</sup> in 565 Eyes in 10 Series<sup>b</sup>**

	Eyes	
	n	(%)
<b>OPERATIVE</b>		
Incarceration of vitreous	8	1.4
Subconjunctival gas	6	1.1
<b>POSTOPERATIVE</b>		
New or missed breaks	75	13.3
PVR	26	4.6
Redetachment	17	3.0
Mild macular pucker	10	1.8
Persistent subretinal fluid	12	2.1
Minimal epiretinal membrane	8	1.4
Reopening of original break	6	1.1

<sup>a</sup>Complications of 0.3–1.0% omitted: choroidal detachment, anterior gas entrapment, vitreous hemorrhage, subretinal gas, shift of subretinal fluid, and macular hole. Complications, one case each (0.2%): peripheral subretinal hemorrhage, hyphema, pars plana detachment, cataract, malignant glaucoma, and endophthalmitis.

<sup>b</sup>See references 5, 8, 33, 35, 40, 41, 67, 76–78.

PVR, postoperative proliferative vitreoretinopathy.

## Proliferative Vitreoretinopathy

PVR is the major complication for all types of retinal reattachment surgery. A review of the PR literature revealed an incidence of 4% (Table 107.2). PVR developed in 3% of eyes managed with PR compared with 5% in the SB control group in the multicenter clinical trial.<sup>8</sup> Evidence does not support the concern that intravitreal gas might stimulate PVR.

## New or Missed Retinal Breaks

The incidence of new and missed retinal breaks in a compilation of 81 series including 4138 eyes treated with PR was 11.7% (Table 107.2). Remarkably, this is less than the 14% figure reported in a study of 171 eyes with retinal breaks without significant retinal detachment, treated with laser photocoagulation or cryopexy but without gas injection.<sup>79</sup> This and other evidence suggests that intravitreal gas plays little role in causing new retinal breaks and underscores that the natural history of the disease includes the rather frequent development of additional breaks. The most common cause of detachment requiring reoperation following pneumatic retinopexy appears to be development of a new retinal break with new rather than persistent retinal detachment.<sup>80</sup>

In long-term follow-up, the need for reoperation is evident within the first 3 months in 89% of cases.<sup>19</sup> With or without gas, the majority of new breaks appear within the first postoperative month, suggesting that incomplete posterior vitreous detachment may be responsible for some postoperative breaks.<sup>8,79</sup> In phakic eyes with complete rather than partial posterior vitreous detachment, as determined by B-scan ultrasonography, Rezende et al.<sup>42</sup> reported a higher rate of single-operation retinal reattachment, particularly in

eyes treated with PR.

Since PR failures are sometimes caused by new retinal breaks in untreated areas of the retina, Tornambe has recommended that 360° laser retinopexy be applied between the insertion of the vitreous base and the ora serrata.<sup>17</sup> He reported a significant improvement in single-operation success with this approach, but only about 1 in 12 PR surgeons employs this technique.<sup>81</sup>

New retinal breaks following pneumatic retinopexy do not portend a poor outcome. Some 96% of such eyes were successfully treated in the multicenter trial.<sup>9</sup> New retinal detachments following pneumatic retinopexy do not necessarily require vitrectomy or scleral buckling and can often be treated by a repeat pneumatic procedure alone.

## Subretinal Gas

Subretinal gas is usually a preventable complication, as described above (see under “[Fish eggs](#)”). However, if gas does get under the retina, the bubble can generally be teased back through the break if the break is larger than the gas bubble or if the diagnosis is made promptly before gas expansion. Under indirect ophthalmoscopic visualization, scleral depression is used to maneuver the bubble to the break and force it through.

If this fails but the amount of subretinal gas is small relative to the intravitreal gas, it may not be necessary to remove the subretinal gas. In this instance, strict prolonged positioning may still resolve the detachment since the intravitreal gas will outlast the subretinal gas. Larger amounts of subretinal gas can be removed with a needle passed through the sclera and into the subretinal space, similar to the technique described above in the section “[Gas entrapment at the injection site](#).” Rarely, vitrectomy may be indicated to remove the gas.

## Utilization of Pneumatic Retinopexy

In a 2002 survey of the American Society of Retinal Specialists (then called the “Vitreous Society”), 72% of respondents selected PR for a phakic macula-on detachment with a 12 : 00 tear, and PR was also

the most commonly selected option if the eye was pseudophakic (45% for PR versus 13% for primary vitrectomy).<sup>81</sup> However, acceptance of PR in Europe has lagged far behind that in the United States.<sup>82,83</sup> Gains in popularity of vitrectomy have been mostly at the expense of scleral buckling. A 2010 analysis of Medicare claims showed that vitrectomies for primary retinal detachment increased 72% from 1997 to 2007, while SB decreased 69% and PR remained relatively unchanged.<sup>73</sup> According to a 2015 survey, microincisional vitrectomy is now performed more frequently than PR or SB in pseudophakic eyes.<sup>84</sup>

While treatment of retinal detachment is extremely cost-effective regardless of treatment modality,<sup>85</sup> significant cost savings could be achieved while maintaining anatomic and visual outcomes by increasing utilization of PR.<sup>86</sup>

## Algorithm for Choosing PR Versus Other Procedures for Retinal Detachments

In *Retinal Detachment: Principles and Practice*, Brinton and Wilkinson<sup>1</sup> presented an algorithm (Fig. 107.8) intended to organize the decision of type of surgery to use for a given retinal detachment case. This algorithm does not reflect all factors that may influence a decision. The individual circumstances of each specific patient, as well as the experience of the surgeon and the availability of equipment, should also be taken into account. This algorithm provides guidelines reflecting the opinion of the authors and is not intended to establish the standard of care for a given case.

**FIG. 107.8** Algorithm demonstrating an approach to selection of an appropriate retinal reattachment procedure. *PVR*, proliferative vitreoretinopathy; *RD*, retinal detachment. (Reprinted from Brinton DA, Wilkinson CP. Retinal detachment: principles and practice. 3rd ed. New York: Oxford University Press/American Academy of Ophthalmology ©2009, with permission from Oxford

## Conclusion

Pneumatic retinopexy (PR) may be the procedure of choice for selected uncomplicated retinal detachments without inferior or extensive retinal breaks or significant proliferative vitreoretinopathy. New retinal breaks or detachments following PR can also frequently be managed just by laser or repeat pneumatic techniques. PR requires thorough preoperative evaluation, skillful case selection, diligent postoperative positioning, and close follow-up.

Evidence shows that in selected cases, PR gives better visual results and minimizes morbidity at considerably decreased expense compared with vitrectomy and/or scleral buckling. PR yields a modestly lower single-operation success rate than these procedures, but PR failure does not jeopardize success if subsequent procedures are needed.

**The Concept of Heavy Tamponade**

**Drugs for the Prevention of Proliferative Vitreoretinopathy**

## **Introduction**

The first use of intraocular gas in treating retinal detachment dates back a century.<sup>1</sup> At that time, the causal relationship between retinal break and detachment was not fully appreciated. It was only later, when the importance of localization and sealing of retinal breaks was recognized, that the concept of air injection was introduced.<sup>2</sup> Rosengren described his technique of internal tamponade with air after subretinal fluid (SRF) drainage, coupled with external diathermy to create adhesion, and demonstrated an increase in success rate in retina detachment repair.<sup>2</sup> The technique of scleral buckling was introduced in the 1950s and in the 1960s, complicated retinal detachments were treated with a combination of scleral

buckling and intraocular gas injection.<sup>3</sup> As air is absorbed quickly, other longer-lasting gases were sought.<sup>4</sup> Sulfur hexafluoride and the perfluorocarbons have proved themselves to be the most popular intraocular gases. In the 1980s, pneumatic retinopexy was first introduced by Lincoff, and later popularized by Hilton and Grizzard.<sup>5</sup> It was made possible with the use of expansile gases and this procedure obviated the need for scleral buckling for some patients. More significantly, pneumatic retinopexy transformed retinal detachment surgery from an inpatient operation to an office-based procedure that has a reasonably high reattachment rate in selected patients. With the advent of vitrectomy,<sup>6</sup> the use of intraocular gas became indispensable. The combination of closed three-port pars plana microsurgical approach with long-acting gases improved the success rates especially for the more complicated situations such as proliferating vitreoretinopathy and giant tears. Indication for intraocular gas extended to macular hole repair and pneumatic displacement of submacular hemorrhage. There are surgeons who would argue that vitrectomy and gas are used in cases that might equally be treated with scleral buckling. The findings of randomized trials do little to change this trend.<sup>7</sup>

## Physical Properties of Intraocular Gases

The properties of an ideal intraocular gas are listed in [Box 108.1](#). In reality, no single gaseous product has all the desired properties. A variety of gaseous products have been investigated for intraocular use.<sup>8-12</sup> It is good to understand the different characteristics of the available products so that we as surgeons can make rational choices. Of interest to the clinician are the longevity inside the eye, expansion ratio in pure form, and the nonexpansile concentration. Gases could be used in their pure forms, or as a mixture with air. The expansile property could be adjusted by mixing the pure form with air in different proportions ([Table 108.1](#)). In daily practice, air, sulfur hexafluoride ( $\text{SF}_6$ ), perfluoroethane ( $\text{C}_2\text{F}_6$ ), and perfluoropropane ( $\text{C}_3\text{F}_8$ ) are most commonly used. [Table 108.2](#) highlights the physical properties of these gases. Historically, xenon [Box 108.1](#) for its shortest intraocular longevity.

## Properties of an Ideal Intraocular Gas

### Availability

- Readily available
- Cheap/not expensive

### Biocompatibility and safety

- Nontoxic
- Odorless
- Colorless
- Inflammable
- Not cause lens opacity

### Variability in terms of longevity and expansile property

- Water soluble

Stable when mixed with air

**TABLE 108.1**  
**Gases Investigated for Intraocular Use**

Nonexpansile	Expansile
Air	Sulfur hexafluoride (SF <sub>6</sub> )
Xenon (Xe)	Perfluoromethane (CF <sub>4</sub> )
Nitrogen (N <sub>2</sub> )	Perfluoroethane (C <sub>2</sub> F <sub>6</sub> )
Helium (He)	Perfluoropropane (C <sub>3</sub> F <sub>8</sub> )
Oxygen (O <sub>2</sub> )	Perfluorobutane (C <sub>4</sub> F <sub>10</sub> )
Argon (Ar)	Perfluoropentane (C <sub>5</sub> F <sub>12</sub> )
Krypton (Kr)	Octafluorocyclobutane (C <sub>4</sub> F <sub>8</sub> )

**TABLE 108.2****Physical Properties of Commonly Used Intraocular Gases**

	Chemical Formula	Molecular Weight (g/mol)	Odorless	Colorless	Inflammable	Inert	Expansion (Times Original Size)
Air	–	29	Yes	Yes	Yes	Yes	–
Xenon	Xe	131	Yes	Yes	Yes	Yes	–
Sulfur hexafluoride	SF <sub>6</sub>	146	Yes	Yes	Yes	Yes	2.0
Perfluoroethane	C <sub>2</sub> F <sub>6</sub>	138	Yes	Yes	Yes	Yes	3.3
Perfluoropropane	C <sub>3</sub> F <sub>8</sub>	188	Yes	Yes	Yes	Yes	4.0

Air was the initial gas to be tried in retinal surgeries. If the vitreous cavity is entirely filled with air, then the bubble does not dissolve or disappear for 5–7 days. It is nonexpansile for all intent and purposes. This is not a drawback but rather an advantage. In Europe, air is often used in conventional scleral buckling surgery. SRF is drained first, followed by the injection of air. This effectively restores the anatomy, in that the retina becomes reapposed to the underlying retinal pigment epithelium and choroid. Cryotherapy can then be applied. The application can be precise and limited as there is no need for a large ice-ball or to freeze through a depth of SRF. Equally, localization of the retina break can be precise. The scleral buckle need only be as low profile as the retinal break/breaks, as the retina is already attached.<sup>13</sup> Air injection is useful in three specific ways. First, the intraocular pressure (IOP) is restored after air injection. Secondly, the surface tension of the air bubble enables the retina to be kept opposed and attached (had saline been injected instead, the liquid might go through the retinal breaks and the retina might redetach again). Thirdly, air is nonexpansile. This eliminates the concern about causing traction to the inferior retina and new break formation. This last point is not often appreciated. The use of air combined with scleral buckling is highly popular in Europe. There are many complications, including the break-up of the air bubble into “fish eggs” by poor injection techniques. Inferior breaks, however, is not one of the complications noted, despite a large number of publications on this

technique.<sup>14</sup> This is in contrast to pneumatic retinopexy. The fact that the bubble expands may cause further collapse of the gel with trans-gel traction. Because the gas bubble floats, this trans-gel traction is transmitted to the vitreous base inferiorly to give rise to inferior retinal breaks.<sup>15</sup> The fact that air does not expand makes it uniquely safe when combined with scleral buckling in nonvitrectomized eyes. Air has also enjoyed a resurgence of popularity when combined with vitrectomy. The success of retinal detachment relies on identification of all offending retinal breaks and sealing them. With the increasing use of endolaser, it is generally acknowledged that adhesion can develop much more quickly. Hence, there is therefore reduced need for prolonged tamponade. The duration of tamponade from a gaseous bubble only needs to be long enough for chorioretinal adhesion to develop. In the absence of any risk factors for developing proliferative vitreoretinopathy and when the causative retinal breaks are confined to 1 or 2 clock-hours, air is a perfectly acceptable tamponade.<sup>16</sup> The rapid absorption is an advantage. It simply means that the patients can be rehabilitated quicker and that they can travel by air sooner.

When the retinal breaks are multiple and their locations widely separated (in terms of clock-hours), then it would be desirable to have a large postoperative bubble. Long duration of tamponade is not particularly needed if proliferative vitreoretinopathy (PVR) is not anticipated. Sulphur hexafluoride ( $\text{SF}_6$ ) in these cases might be suitable. The nonexpansile concentration of  $\text{SF}_6$  is 20%. As a rule of thumb, if the vitreous cavity were totally filled, a bubble of 20%  $\text{SF}_6$ /air would last for about 2 weeks.<sup>17</sup> The bubble would be relatively large in the first few days to give a sufficiently large area of tamponade to widely separated retinal breaks.  $\text{SF}_6$  is seldom used neat. It is inert, nontoxic, colorless, and is five times heavier than air. Hydrolysis only occurs at high temperatures (>500 °C). We will discuss the choice of tamponade agents later in this chapter.

The perfluorocarbon gases have the generic chemical formula ( $\text{C}_x\text{F}_{2x+2}$ , where x can be 1 to 4). These are inert gases with no odor or color. Water solubility varies according to the carbon chain length. The longer the carbon chain, the lower the solubility in water, hence

the longer is the intraocular longevity. For instance as a rough guide, 1 mL of pure  $C_2F_6$  expands 3.3 times when injected into the eye, and stays in the eye for 4–5 weeks; but for 1 mL of  $C_3F_8$ , the same volume expands four times, and stays for 6–8 weeks.

When a gas bubble is injected into the eye, two forces act on the gas bubble. There is a downward force caused by gravity, and there is an upward force generated by buoyancy. Gravity equals the weight of the intraocular gas. Archimedes' Principle states that any floating object displaces its own weight of fluid. For instance, 1 mL of  $C_3F_8$  weighs 0.001 g. Hence 1 mL of  $C_3F_8$  displaces 1 mL of fluid, which weighs 1 g (specific gravity of water is 1.0). Therefore buoyancy is 1 g upwards (1 g equals 0.0098 Newton; gram is used here for ease of understanding). Net weight acting on the  $C_3F_8$  bubble is therefore 0.999 g (i.e., 1 g buoyancy minus 0.001 g gravity). This force is pushing the bubble upwards. In terms of magnitude, this upward force is large compared with that of a silicone oil (SO) bubble. This upward force is the same order of magnitude as the downward force associated with perfluorocarbon liquids, with a specific gravity close to 2 g/mL. The orthodoxy is that perfluorocarbon liquid (PFCL) is too heavy to be left in the eye, as this may cause retinal damage.<sup>18</sup> It is interesting that no one speaks of gas bubbles pressing too hard and causing toxic changes to the upper retina.<sup>19</sup>

The classical concept of tamponade is that the bubble makes contact with the retina and prevents water from gaining access to the subretinal space via the retinal breaks. The interfacial tension between water and gas is high. The bubble therefore wants to stay as one bubble, and it would not go through a small aperture such as a retinal break. To do so, it would need to deform. The bubble would need to assume a smaller radius, and this would require higher surface energy.

In practice, an air or gas bubble would seldom have a chance to go through retinal breaks, except when they were associated with fixed retinal folds. If a retinal detachment were mobile, as soon as a bubble was injected, the bubble would float to the uppermost position of the vitreous cavity. Any SRF would be displaced inferior to the bubble. The upper retina would be opposed to the underlying retinal pigment epithelium, including any retinal breaks

that might be situated in that upper part of the retina. Furthermore, there are those who believed that direct contact between the retina break or bubble might not be necessary. Clinical studies have shown that inferior retinal breaks can be successfully treated with vitrectomy, gas tamponade, and no scleral buckling.<sup>20</sup> One school of thought is that gas bubbles (for that matter oil bubbles) act inside the eye as splints, thereby reducing intraocular currents. In the absence of traction, the lack of intraocular currents would allow the retina to settle back. There may or may not be a need for direct contact between the bubble and the retinal breaks.<sup>20</sup>

If, however, contact were important, then the shape of the bubble would determine the effectiveness of tamponade. When buoyancy was large, the bubble would take on the shape of the vitreous cavity and assume a flat bottom. This way, most of the volume would contribute to making contact with the retina. Thinking about it in another way, very little volume would be wasted in forming the meniscus. If the buoyancy were small, as would be the case with SO, the shape of the bubble would be rounded. In other words, very little of the volume would contribute to making contact with the retina; much of the bubble would go to form the meniscus, which would make no contact with the retina. The extreme case would be a spherical bubble inside a spherical cavity. Unless the fill is 100%, the contact would go from nil to total. In practice, total tamponade is probably unachievable. Most surgeons use the so-called nonexpansile concentration of gases. By definition, the volume of the bubble decreases in the postoperative phase. Those who use "slightly expansile" concentration are risking high IOP. In a normal eye, any increase in IOP would result in an increase in outflow that in turn would lower the IOP pressure. If the vitreous cavity was totally filled with gas, the only aqueous available to increase the outflow would be that in the anterior chamber (AC). The AC would then be shallow. If the iris lens diaphragm was lax, then secondary angle closure might ensue. In practice, we could not know, for a given individual, precisely what the nonexpansile concentration of each gas might be. Using expansile concentration would therefore be unnecessarily risky.

## Functions of Gas

The main functions of a gas bubble inside the eye are to: (1) provide internal tamponade; (2) flatten folded retina; (3) enable visualization; (4) replace globe volume; (5) reduce intraocular currents.

## Internal Tamponade

Providing internal tamponade for retinal detachments has been the main indication of intraocular gas use.<sup>21</sup> The purpose is to oppose the break by utilizing the surface tension of the bubble. The surface tension of gas is high compared with liquid tamponade agents such as SO. The interaction between buoyancy, weight, shapes of intraocular gas bubbles and contact have been alluded to previously.

It is worthwhile mentioning that the shape of a gas bubble varies with its volume. When a small gas bubble is injected, it takes on a rounded shape. This is observed routinely when pneumatic retinopexy is performed. For example, where 0.3 mL of C<sub>3</sub>F<sub>8</sub> is injected the bubble stays relatively rounded until it expands in size over the next 24–48 hours. It then clearly adopts a flattened shape (this shape is referred to as a “spherical cap”). When a gas bubble is small, its shape is mainly determined by its surface tension. Because the surface tension is high, the bubble is rounded. When the bubble expands, buoyancy becomes important. Every molecule of the bubble wants to float upwards, which is why the bottom of the bubble has a flattened shape. Lincoff made this observation many years ago and went on to suggest a means of assessing the size of intraocular gas bubble by observing this flattened bottom surface of the gas bubble.<sup>22</sup> In terms of upward force, it is greatest at the apex of the bubble, whereas it is near zero at the bottom. [Table 108.3](#) gives an estimation of the volume of the gas injected and the effective arc of tamponade. It has been shown by using a model eye constructed of surface modified polymethylmethacrylate to mimic the hydrophilic retinal surface. The efficiency curve plots the arc of contact against the percentage fill. It was shown that the curve was sigmoidal. Initially, the plot was exponential. It showed that a relatively small bubble would provide a large arc of contact. The plot was linear; the fill and contact was proportional, and towards the end, the plot was exponential again. This time, a slight underfill

would leave a large arc of retina out of contact with the bubble.<sup>23</sup>

---

**TABLE 108.3**

**Changes in Arc of Contact With Gas Bubble Volume (Assume a Vitreous Cavity Diameter of 21 mm)**

---

Arc of Contact (°)	Gas Bubble Volume (mL)
90	0.28
120	0.75
150	1.49
180	2.40

The tamponade bubble also acts to seal off the break, such that cellular elements can no longer escape from the subretinal space into the vitreous cavity. This was considered important in preventing proliferative vitreoretinopathy (PVR). However, cellular elements that have already gone into the vitreous cavity tend to concentrate in the thin film of fluid just beneath the bubble. This accounts for why postoperative PVR is more commonly found inferiorly.<sup>24,25</sup>

### **Unfolding and Folding of the Retina**

The surface tension and buoyancy force of the bubble can help to unfold the retina. Circumferential folds sometimes occur with high radial buckles. If SRF was drained and air was injected, these folds would be less prominent. The so-called retinal redundancy would be minimized, as the retina would be made to follow closely the contour of the indent. Equally, if SRF drainage was incomplete and a large bubble was injected, retinal fold could occur. When these folds involve the macula, the patients would be very symptomatic, complaining of distortion and poor vision.<sup>26</sup> This complication could be prevented by achieving a more complete drainage of SRF before injection and judicious posturing of the patients immediately postoperatively. This posturing might involve “steam-rolling,” with the patient lying first with the retina break lowest most, then turning slowly to position the bubble to the posterior pole, followed by posturing on the correct side.<sup>27</sup> This type of maneuver aims to use the bubble to express the SRF out through the retinal break and to protect the macula from being affected by retinal folds.<sup>28,29</sup>

## Postoperative Visualization

In the postoperative period, after vitrectomy and gas tamponade, the view of the fundus may be obscured by vitreous hemorrhage. It is usually possible to have a glimpse of the upper fundus by looking through the gas bubble. The observer, however, needs to be positioned lower than the patient. Specifically, the aim is to look through the lower flat bottom surface of the gas bubble. Asking the patient to stand, while the physician remains seated, can work well. If other parts of the fundus are to be viewed, the patient can be asked to lie on their side. Again, if the vantage point is lower than the fluid level, the ophthalmologist can easily see the lower nasal or temporal half of the fundus. If the bubble is small, then fundoscopy is difficult. It would be better to rely on B-mode ultrasonography. One additional point should be made, i.e., looking through the bubble, the retina often appears to be attached, even in the presence of residual fluid. This may simply be due to the buoyancy of the bubble displacing SRF laterally and posteriorly.

## Replace Globe Volume

Air is used in conventional scleral buckling surgery after the drainage of SRF. The air prevents SRF being recruited again. The air also restores the IOP. At this stage, effectively a flat retinal tear would be treated. Without the presence of SRF, cryotherapy would be limited and break localization would be more accurate. The fact that the IOP is normal also means that suture can be applied to the sclera more safely. In this way, air serves a role as an intraoperative tool.

## Dynamics of the Gas Bubble Inside the Eye

### Different Phases of Gas Resorption

After injection, the gas bubble inside the eye undergoes three phases before complete resorption. The three phases are expansion, equilibration, and dissolution. This occurs when pure expansile gases (i.e.,  $\text{SF}_6$ ,  $\text{C}_2\text{F}_6$ , and  $\text{C}_3\text{F}_8$ ) are injected. Air does not expand, and this will be discussed later. Due to lower water-solubility than nitrogen, pure  $\text{SF}_6$ ,  $\text{C}_2\text{F}_6$ , and  $\text{C}_3\text{F}_8$  will expand when injected into

the eye. This is because nitrogen diffusion rate into the bubble is higher than the rate of gas dissolving into the surrounding tissue fluid compartment. Expansion is most rapid in the initial 6–8 hours, and is similar for all gases. This is because the rate is mostly affected by the convection currents in the surrounding vitreous fluid.<sup>30</sup> The bubble reaches its maximum size when the gaseous diffusion in and out of the bubble equilibrates. For SF<sub>6</sub>, this occurs around 1–2 days after injection; for C<sub>3</sub>F<sub>8</sub>, it takes 3–4 days to reach maximum expansion.<sup>31</sup> This has practical implications, as IOP may rise if the outflow facility cannot cope with the rapid increase in intraocular volume. It has been found that the eye can accommodate up to 1.2 mL of pure expansile gas injection without significant IOP change.<sup>12,31</sup> This equals 20–25% of the vitreous cavity volume. In eyes with occludable angles, pure expansile gas should therefore be avoided, or prophylactic IOP-lowering agents should be used.

The equilibration phase begins when the partial pressure of nitrogen in the bubble equals that in the surrounding fluid compartment. During this phase, there is a small net diffusion of expansile gas into the fluid compartment. This can be explained by the higher solubility of nitrogen, such that nitrogen equilibration is reached at a faster rate than other gases. Hence, the bubble diminishes slightly in volume during this phase. Duration of this phase differs for different expansile gases and is dependent on solubility. For C<sub>3</sub>F<sub>8</sub>, this phase lasts 2–3 days.<sup>31</sup>

When partial pressure of all gases within the bubble equals that in the fluid compartment, the dissolution phase begins. The gas compartment gradually decreases in size as gases dissolve into the fluid compartment. The decrease in volume follows first-order exponential decay.<sup>32</sup> This phase is the longest among all three phases. Despite the fact that it may take up to 6–8 weeks for a bubble to completely resorb, internal tamponade is often only effective during the initial 25% of the bubble's lifespan. This is because it requires at least 50% of the initial size to provide an effective tamponade. If the bubble is smaller than 50% or it breaks into a few smaller bubbles (i.e., fish eggs), internal tamponade is ineffective and no therapeutic effect can be achieved, even though it may still remain in the eye for a long time. [Fig. 108.1](#) illustrates

gaseous transfers in and out of the bubble during the three phases.

**FIG. 108.1** Preparation for gas injection. (A) Pure gas is stored in a cylinder with a regulatory valve. Two sterile filters should be connected between the cylinder and the syringe in use. (B) As physiologic dead space exists within the system, accuracy may be affected by the air contained within these spaces. Pure gas should then be drawn from the cylinder and the syringe flushed a few times to ensure complete evacuation of air from the dead space. The appropriate amount of pure gas is then drawn into the syringe. (C) The syringe with one filter is then disconnected. The three-way tap is then turned to the other unused filter, and air is drawn in to achieve the appropriate concentration of air–gas mixture.

Air, which is already a mixture of gases, does not expand and enters the dissolution phase immediately after injection. This is because the partial pressure of nitrogen, oxygen, and carbon dioxide roughly equal that in the blood. Since equilibrium has

already been reached during gaseous exchange in the lung, dissolution phase begins immediately after injection.

In clinical practice, expansile gas is often mixed with air to give a “nonexpansile” concentration. This can be interpreted as injecting two separate gas compartments into the eye, one being pure expansile gas, the other being pure air. The reduction in volume of the air compartment compensates for the increase in volume of the expansile gas compartment. When the appropriate ratio of these two compartments is met, the overall gas compartment volume remains constant. The percentages of gas/air mixtures to produce a nonexpansile volume are outlined in [Table 108.2](#).

The time taken for complete resorption of the bubble also depends on other factors such as lens status, aqueous turnover, presence of vitreous, presence of periretinal membranes, ocular blood flow, and ocular elasticity.<sup>32</sup> The lifespan of SF<sub>6</sub> and C<sub>3</sub>F<sub>8</sub> may be more than twice as long in phakic nonvitrectomized eyes than in aphakic vitrectomized eyes.<sup>33</sup>

## **Special Considerations When Under General Anesthesia**

During general anesthesia, the anesthetic gases inhaled may interfere with intraocular gas volume. Nitrous oxide (N<sub>2</sub>O) is, respectively, 34 times and 117 times more water-soluble than nitrogen and SF<sub>6</sub>.<sup>33</sup> Therefore, when there is a gas bubble in the eye, nitrous oxide quickly diffuses from the fluid compartment into the bubble and increases the bubble volume. If SF<sub>6</sub> is used, the bubble may increase up to three times its original size during anesthesia with nitrous oxide. Because of its high solubility, maximum IOP rise may occur after 15–20 minutes of nitrous oxide use; and IOP decreases once it is discontinued, as it diffuses out of the body through ventilation. It has been found that the concentration of nitrous oxide in the lung alveolars is reduced by 90% after it has been stopped for 10 minutes. Therefore, in practice, nitrous oxide should be discontinued for at least 15 minutes prior to intraocular gas injection to avoid interference in the desired bubble volume. If it has been continued during gas injection, the resultant bubble will be smaller than expected.

Special attention is required for patients undergoing general anesthesia for nonocular purposes while they still have an intraocular gas in situ. Severe visual loss resulting from central retinal artery occlusion and choroidal ischemia have been reported.<sup>34,35</sup> This was thought to be due to the uncompensated rapid rise in IOP during surgery as a result of nitrous oxide diffusion into the bubble. For this reason, every patient with an intraocular gas bubble should be given a wristband to wear, indicating clearly the type and time of intraocular gas injection. It should be worn throughout the lifespan of the bubble.

## **Response to Changes in Altitude**

Assuming most patients remain at a similar altitude after intraocular gas injection, the bubble size would not change significantly. However, when there is a change in altitude, significant changes in bubble size may occur. This is especially important for patients undertaking air travel shortly after surgery, because airplane cabin pressure is only equal to atmosphere pressure at an altitude of 8000 feet. Climb rate occurs at roughly 2000–3000 feet per minute during airplane ascent, and the rapid expansion in bubble size may be translated into IOP rise.<sup>36</sup> Central retinal arterial occlusion may result. It has been reported in animal studies that a bubble equivalent to 10% of the vitreous cavity or 0.6 mL may be safe for air travel. Up to 1.0 mL of gas was reported to be tolerable without significant IOP change.<sup>36</sup> However, this is entirely dependent on outflow facility, and some surgeons feel that no volume is safe for air travel.<sup>17</sup>

For the same reason, air bubble size may change during scuba diving.<sup>37</sup> During scuba diving, gaseous equilibrium under atmospheric conditions may be affected by inhalation of oxygen from compressed air tanks. When the diver returns to the surface, the bubble expands inside the eye and gives rise to an increase in IOP.

## **Preparation for Injection**

Gases of highest purity from either a disposable or reusable cylinder should be used. Prior to obtaining gas from the cylinder,

gas pressure within the cylinder should be checked to ensure no gas leakage has occurred, which may affect the concentration of the gas inside. Silicone tubing is first connected to the cylinder at one end, and to two 0.22- $\mu\text{m}$  Millipore filters (Millex-GS) at the external end. A 50-mL syringe is then connected to the filters. The syringe is then flushed two to three times to remove air trapped within the tubing and filters. Pure gas is then drawn into the syringe to the desired volume. For pure gas injection, the syringe could then be connected to either a needle or the infusion for use. For air-gas mixtures, the syringe should be disconnected from the cylinder at the junction between the two filters, having one filter still connected on the syringe. Sterile air is then drawn into the syringe to achieve the desired concentration of air-gas mixture. The filter is disconnected and syringe connected to a needle of the infusion for use. The gas or gas mixture should be used immediately to avoid inaccuracy in the concentration as a result of air influx from the surroundings. [Fig. 108.2](#) illustrates how gas is prepared for injection.

**FIG. 108.2** The three phases of gas transfer after injection of pure expansile gas.

Human error can occur in the process of gas preparation. It is therefore imperative that all operating theater staff are acquainted with the techniques of gas preparation. It is also vital that they do not confuse the different gases for use, and proper labeling is done to ensure the correct gas is injected into the correct eye. When mixing pure gas with air, it is also especially important to ensure that the correct concentration is produced. This is because an expansile bubble in an eye intended for a nonexpansile bubble could have devastating consequences.

## Clinical Applications and Surgical Techniques

The most common indications for intraocular gas injection are to assist: (1) retinal detachment surgery with vitrectomy; (2) pneumatic retinopexy; (3) retinal detachment surgery with scleral buckle; (4) macular hole surgery; (5) displacement of subretinal hemorrhage; and (6) postvitrectomy gas exchange in vitrectomized eyes. The techniques discussed below are based on the authors' personal surgical experiences and preferences, and may not necessarily be applicable in all cases.

### In Vitrectomy for Retinal Detachments

This is the one of the most common indications for intraocular gas injection. After full vitrectomy and relieving of tractions, fluid–air exchange is used to flatten the retina. Residual traction is indicated by persistence of SRF and inability of retina to flatten out. Fluid has to be reinstalled, and all traction must be relieved prior to proceeding. When the retina is flat, and air is in situ, endolaser can be performed. The advantage of performing laser under air is that the peripheral retina is easier to visualize. In cases where PFCL is required to flatten the retina or to assist drainage of SRF, endolaser can be performed under PFCL, and PFCL–air exchange should be performed afterwards. Direct PFCL–gas exchange is generally not advised as (1) residual traction could be seen on extraction of PFCL,

fluid has to be reinstilled for further intervention, and gas injected would be wasted, and (2) closure of the wound after gas injection could potentially cause gas leakage and postoperative hypotony.

When the eye is filled with air, air–gas exchange can be performed. The infusion line should be kept in place, and IOP controlled by the air-insufflation pump of the vitrectomy machine. The other two sclerotomy wounds should then be closed. This should be done with suturing in a 20-gauge (G) system or the trocars be removed in a 23G system, and air-tightness ensured. The syringe holding the desired gas or gas/air mixture should then be connected to the infusion line, at a site as close to the eye as possible. This is to minimize dead space in the tubings that may interfere with the desired concentration of the gas. A 27G needle connected to an empty syringe, with plunger removed, is then inserted through the sclerotomies, or through the sclera at the same plane as the sclerotomies, to allow exit passage for the air inside. The gas or gas/air mixture is then flushed into the eye through the infusion line. Flushing the eye with a minimum of 25 mL of gas or gas/air mixture is required to achieve an identical concentration to that in the original syringe. The infusion line is then pulled and the last sclerotomy closed. Another method is to inject the gas or gas/air mixture directly into the eye through the sclera or sclerotomy and allow air inside to exit via the infusion line, which is opened to atmosphere on the other end. In both techniques, the needle tip, be it for exit passageway or for injection, has to be clearly visualized through the cornea before any air–gas exchange is performed. This is to avoid the inadvertent insertion of the needle in the suprachoroidal space. If gas has leaked during the sclerotomy closure, additional gas could be injected directly to maintain a normal IOP at the end of surgery. Conversely, if IOP is high, gas could be released by either depressing the sclerotomy wound or by inserting a syringe into the eye to relieve part of the gas. [Fig. 108.3](#) shows how this is performed.

A

B

**FIG. 108.3** Technique of air–gas exchange in a vitrectomized eye. (A) Injection of gas through a syringe connected to a needle. Air inside the eye is flushed out through infusion, which is disconnected externally. (B) Injection of gas is done through a syringe connected to the infusion, and gas is flushed into the eye. Air is allowed to exit the eye through the needle inserted with the plunger of the syringe removed.

The choice of gas is sometimes based on the availability of gases, and the surgeon's experience and preferences. In general, the choice of gas is dependent on the intended duration of tamponade. For simple cases where duration required is short, air could be used.<sup>16,38</sup> In more complicated cases where longer tamponade is desired, nonexpansile concentration of gas/air mixture (18% SF<sub>6</sub> or 14% C<sub>3</sub>F<sub>8</sub>) should be used.<sup>33,39</sup> When a larger bubble is needed, a gas/air mixture with an expansile concentration should be used. This is especially important for inferior breaks where a larger bubble could provide better tamponade. A larger bubble also has the advantage of being able to unroll folded retina. In the Silicone Study, C<sub>3</sub>F<sub>8</sub> has been found to be more effective than SF<sub>6</sub> in cases with PVR.<sup>14,40,41</sup>

## In Pneumatic Retinopexy

As mentioned earlier, careful patient selection is important, as failure of opposing the retina may subject the patient to further operations. Up to 63% success with this as the only procedure has been reported.<sup>42</sup> Before gas is injected, there are several prerequisites: (1) the retinal detachment has to be in the superior half of the retina; (2) the break or hole is ideally solitary or grouped within 1–2 clock-hours; (3) there are no inferior breaks or retinal thinning; and (4) preferably the presence of posterior vitreous detachment (PVD). This can be an office procedure, and local anesthesia is usually sufficient in experienced hands. In contrast to buckled cases, internal traction is not counteracted therefore opposition of the retina to choroid has to be provided by the bubble initially, and later by the chorioretinal adhesion induced by

cryotherapy.

Gas is injected only after adequate cryotherapy. Pure expansile gas should be used.<sup>43</sup> In practice, 0.3 mL of 100% C<sub>3</sub>F<sub>8</sub> is used most commonly. The same volume of SF<sub>6</sub> can also be used. First, the injection should be on the side of the break. If the break is located at 12 o'clock, then the injection is at the midline. Gas is then injected through a 27G needle, 3.5–4 mm behind the limbus. Normally 0.3 mL 100% C<sub>3</sub>F<sub>8</sub> is used. To avoid "fish-egg" formation (small bubbles instead of one large bubble), the injection site should be rotated such that it is in the uppermost part. The needle should be inserted just deep enough to penetrate all layers, and the injection force should be swift and constant, aiming at creating a single bubble. After injection, the injection site should be rotated laterally before pulling the needle out of the eye. This is to ensure the bubble moves away from the opening before the needle is retrieved, to prevent leakage. If fish-egg has formed, the sclera can be gently tapped a few times to promote fusion of the small bubbles. [Fig. 108.4](#) illustrates how this is performed. After injecting gas, AC paracentesis can be performed to counter the increase in intraocular volume. The patient's head is then rolled 180°, to the face-down position. This serves to unroll any folded retina associated with the break. The patient is then instructed to assume this position as much as possible, until complete dissolution of the bubble has occurred. Careful monitoring is required during the postoperative period for proper opposition of the retina, resolution of SRF, and any new break formation inferiorly. In cases where opposition is doubtful, SRF persists, or new breaks are found, a reoperation with either scleral buckling or a vitrectomy approach has to be performed.

**FIG. 108.4** Injecting gas in pneumatic retinopexy or postscleral buckle cases. (A) Detachment is located superiorly. Injection of gas is done via a needle, with the patient lying supine. (B) When the patient assumes an upright position, the bubble tamponades the break and displaces subretinal fluid (SRF). Detached retina is opposed to the original position.

## In Scleral Buckling for Retinal Detachments

Intraocular gas injection is generally not required, provided adequate drainage of SRF and relieving of traction with the buckle has been achieved. However, its use is still invaluable in certain cases, for example when fishmouthing of the break on a circumferential buckle is seen and is insufficiently opposed by the buckle, or as a “salvage” procedure to save the patient from a reoperation.

For intraoperative use, we prefer injecting the gas towards the end of operation. This is mainly because the view of the fundus will be obscured by the bubble after injection. The injection technique is identical to that in pneumatic retinopexy. It should be stressed that the major therapeutic component under these circumstances is still the sclera buckle, whereas gas bubbles only act as an adjunct, and should not be relied on totally to treat the detachment.

The “salvage” procedure for postscleral buckled cases is an invaluable tool to save the patient from a reoperation. When after

sclera buckling surgery a persistent layer of SRF remains underneath the break, or meridional folds are present, or there is fishmouthing of the break, injecting gas could be of help. The technique is identical to pneumatic retinopexy; 0.3 mL gas should be injected followed by AC paracentesis. Depending on the location of the break and likelihood of redetachment, different gases could be used. For instance, for superior breaks with minimal SRF, air could be used. For inferior breaks with fishmouthing breaks, an expansile bubble of 0.3 mL 100% C<sub>3</sub>F<sub>8</sub> would be desired, although a reoperation would likely be required.

### **In Macular Hole Surgery**

When first described, macular hole surgery was not complete without the injection of intraocular gas tamponade followed by face-down posture for 1 week. This provides a mechanical effect by the buoyancy force of the bubble, over the macular hole, in hope of assisting closure. The injecting technique is identical to that in retinal detachment surgery with vitrectomy approach. The duration of postoperative posturing has been a topic of debate in recent years. Similar closure rate was found between air and 20% SF<sub>6</sub>, and that between 20% SF<sub>6</sub> and 12% C<sub>3</sub>F<sub>8</sub>.<sup>44</sup> The choice of gas is generally based on the surgeon's preference and experience. The authors' choice of gas is 12% C<sub>3</sub>F<sub>8</sub> followed by face-down posturing until dissolution of the bubble.

### **In Displacement of Subretinal Blood**

Pneumatic displacement of subretinal blood clot has been found to be therapeutic in treating polypoidal choroidal vasculopathy, macroaneurysm, choroidal neovascularization, and trauma. It has been shown to allow speedier recovery of vision, and may potentially reduce the harmful effect of blood on the photoreceptors. The original procedure was to treat within 1 week from onset of hemorrhage, coupled with tissue plasminogen activator (TPA) injection. There are recent reports showing improvement in vision and reduction in scar area following the use of TPA.<sup>45,46</sup>

Prior to injection, careful patient selection should be done.

Distinction between subretinal blood and intraretinal blood should be made. Injecting gas for intraretinal blood will not displace the clot, but rather increases the chances of blood dispersing into the vitreous. When there is retinal thinning or lattice formation, particularly inferiorly, or when there is no PVD, the risk of inducing retinal breaks cannot be omitted, and close monitoring should be performed.

The injection technique is identical to that in pneumatic retinopexy, where 0.3 mL 100% C<sub>3</sub>F<sub>8</sub> should be used, with or without the injection of TPA. This is followed by a strict face-down posture for a few days.

### **In Postvitrectomy Gas Exchange**

This technique is invaluable for recurrent detachment, and can avoid the need for reoperation.<sup>47</sup> Success rate is highest when there is no evidence of PVR. If PVR has already set in, gas injection may be complicated by formation of new retinal breaks or extension of existing breaks, which usually occur at the edge of laser marks. A fluid–gas exchange could be performed at the slit lamp, via a 30G needle connected to a syringe filled with the desired gas of injection. The needle is inserted at 3.5–4 mm posterior to the limbus, at the inferotemporal quadrant, from a dependent angle, aiming towards the center of the globe. Fluid–gas exchange is then performed via a push–pull technique. When the plunger is pushed, gas is injected into the eye. This is followed by aspiration of intraocular fluid by pulling the plunger. This cycle is repeated until the bubble has reached the desired size. Special note has to be taken to visualize the needle tip prior to any movement of the plunger. This is to avoid any inadvertent entry of the needle into the suprachoroidal space. If the patient is aphakic, the procedure could be performed by inserting the needle into the AC through the cornea, instead of the pars plana approach. The choice of gas is dependent on the condition of the redetachment. If a larger bubble is desired, expansile gas should be injected; whereas if a smaller bubble is needed, air or nonexpansile concentration of gas/air mixture could be used. [Fig. 108.5](#) shows how this could be done at the slit lamp.

**FIG. 108.5** Technique of postoperative gas exchange at the slit lamp.

Gas–gas exchange is sometimes required. For instance, when a patient is required to undergo air travel before the expected dissolution of the bubble, another gas of shorter longevity (i.e., air or xenon) could be exchanged. This could be done using the same technique described above, with the needle connected to two syringes via a three-way stopper. The bubble in the eye is aspirated into one syringe, which is followed by injection of the desired gas into the eye from the second syringe. It should be noted that it is difficult to ascertain an accurate concentration of the second bubble with this method.

## Postoperative Care

### Head Posture After Intraocular Gas Injection

Proper opposition of the break is only ensured by proper posturing of the head. This is done such that the break is located at the uppermost part of the eye, and be in direct contact with the bubble. Face-down posturing with the use of expansile gas has another advantage of preventing pupil block glaucoma or optic capture. Another potential advantage is that in a phakic patient this reduces the contact between the posterior surface of the lens and the gas bubble, and reduces the risk of cataract development. This should be done by assuming a face-down or prone posture immediately after surgery. If face-down or prone posture is difficult, or the patient needs to take rest from prolonged face-down position, lying laterally on the opposite side of the break is also accepted (i.e., lying on the left for a right-side break). This could be facilitated with the use of pillows designed for posturing purposes. As chorioretinal adhesion from laser or cryotherapy takes 2–3 days to become effective, the initial tamponade by bubble is the main force to keeping the retina attached. This should be conveyed to the patient and compliance should be checked every visit or over the phone. If the patient has good compliance to face-down posturing, precipitates could be noted on the central corneal endothelium, which are sometimes referred as “positioning spots.” This is due to gravitational deposition of intraocular inflammatory elements, which is usually more obvious in combined phacovitrectomy cases. In nonvitrectomized cases, it is especially important for the patient to assume proper posturing. Movement of the bubble may cause traction in the vitreous gel and may induce new breaks. This is problematic if inferior breaks are induced, since the bubble cannot provide tamponade for these breaks and reoperation is likely. Posturing is needed until complete dissolution of the bubble has occurred. As the bubble gets smaller, patients with good visual prognosis may report seeing the bubble inferiorly. Fundal exam and sometimes history taking can tell when the bubble has completely dissolved. The wristband indicating an in situ bubble can only be removed at this time.

## **Fundal Exam in the Postoperative Period**

Examining the fundus with an in situ bubble can be difficult in inexperienced hands. When there is a near complete fill, examination through the bubble is relatively easy. As the bubble gets smaller, the retina is easier to see through the gas compartment. This is due to reflections from the gas–fluid interface. To visualize the whole fundus, the head has to be tilted sideways, to allow the bubble to cover different areas for inspection. When the gas compartment is smaller than the fluid compartment, examining the patient when lying supine helps to bring the bubble behind the pupil and reduces glare.

## **Intraocular Pressure Measurements**

Maximum expansion of the bubble occurs within the first postoperative day. During this period, monitoring of intraocular pressure (IOP) is important, as an overfilled expansile bubble may predispose to central retinal arterial occlusion. Measurement with applanation tonometry has been found to be more accurate than other measures, including dynamic contour tonometry.<sup>48,49</sup> Risk of having an IOP rise is lower with air injection or nonexpansile gases. For high-risk cases, prophylaxis with oral acetazolamide and topical timolol should be given, especially in cases having preexisting glaucoma.

## **Laser Photocoagulation**

When more photocoagulation is deemed necessary, it can be done through the bubble. Hypotony may cause corneal striae when contact lenses are applied on the eye for photocoagulation. This can be overcome by temporarily injecting air into the eye to increase the IOP, which could then be released afterwards with a needle and syringe. The peripheral fundus may not be easily visualized with a wide-angle contact lens, and photocoagulation via laser indirect ophthalmoscopy (LIO) may be necessary. In cases where LIO is not possible, cryotherapy should be used. It has been reported that up to 85.7% of redetachment can be flattened with the use of fluid–gas exchange coupled with supplementary photocoagulation.<sup>50</sup>

It should be emphasized preoperatively to the patient that vision

will drop after injecting gas. This is vital in cases of macular-on retinal detachments, where preoperative vision may be normal. Vision is usually poor during the lifespan of the bubble, mainly due to diffraction and glare. After dissolution of the bubble, vision may slowly return, provided the patient has good visual prognosis.

## **Changes in Altitude**

As mentioned above, the gas bubble changes in size at different altitudes. It is therefore important to advise the patient to refrain from changing altitudes. If the change in altitude is gradual and could be compensated for by outflow facility, IOP change may not be apparent and would not cause significant problems. However, rapid changes in altitude may cause a sudden expansion in bubble volume and IOP, which may not be compensated for in time, and central arterial occlusion may occur. The use of scleral buckles reduces the capacity of deformation of the sclera, hence may further predispose the patient to significant IOP changes during air travel.<sup>17</sup> Air travel should therefore only be permitted after complete dissolution of the bubble(s).<sup>51</sup>

## **Complications and Management**

### **Cataract Formation**

Gas-induced cataract is usually in the form of feathery posterior subcapsular cataracts. It can also appear as vacuoles at the superior portion of the lens. Incidence is higher if the eye is two-thirds or more filled with gas. It is also more likely to occur if the gas of choice is of higher purity and longer longevity.<sup>11,52</sup> Assuming a prone position, as well as leaving a thin layer of anterior hyaloid help prevent this from occurring. These help to isolate the bubble from the lens. If in mild form, gas-cataracts tend to resolve without treatment. For persistent opacities, which are more likely to occur with gases of longer longevity, surgical removal may sometimes be required, especially when view of the fundus is compromised. If cataract extraction has to be performed when the bubble is still in situ, aspirating the gas before cataract extraction is needed. Otherwise, the bubble will push the posterior capsule upwards and increase the risks of complications.

## **Raised Intraocular Pressure**

Expansile gases or gas/air mixtures of high purity tend to cause IOP rise more frequently. Various risk factors include the combined use of encircling band, the agent of tamponade, and the combination of cataract extraction. In a recent series, a risk of up to 37.9% for raised IOP was seen in cases with gas tamponade.<sup>53</sup> It is usually due to overfill or expansion of the bubble, which cannot be compensated for by the outflow facility. This is usually short-lived and can be managed without difficulty using antiglaucoma medications. Refractory cases may be due to outflow compromise. For cases with peripheral anterior synechiae (PAS), preexisting angle closure glaucoma, or neovascular glaucoma, care must be taken when choosing the gas for injection. In general, air or a nonexpansile gas/air mixture should be used in these cases, to reduce the risk of postoperative IOP rise. Other than medical treatment, excess gas could be partially aspirated to reduce the volume and hence IOP.

Secondary glaucoma with intraocular gas use is infrequently seen. It can occur with angle disruption from forwardly displaced lens–iris diaphragm, by a large bubble. This is more frequently seen in patients who cannot adopt a prone posture after surgery. Therefore in patients with cervical spine problems or who cannot assume a face-down posture, nonexpansile gas or air should be used, and a complete fill should be avoided.

## **Hypotony**

The bubble can leak from sclerotomies either at the end of operation during wound maneuvers, or postoperatively, through a leaky wound. This results in hypotony. This should not be overlooked, as choroidal effusion or hemorrhage may occur with prolonged hypotony. Observation is enough for mild cases, but when hypotony is prolonged or if the risk for choroidal hemorrhage is high, reinjecting the eye with more gas is indicated. This could be performed using the pars plana approach at the slit lamp.

## **Subretinal Gas**

Migration of gas into the subretinal space can occur both intraoperatively, or in the postoperative period. It can occur either

because the bubble is smaller than the tear, or when persistent traction elevates the retina and allows passage for gas into the subretinal space. If noted during surgery, the bubble can be displaced with the help of scleral depression externally. During the postoperative period, if the bubble has gone into the subretinal space, it can affect proper attachment of the break and may lead to redetachment. If away from the break and it does not affect break attachment, it can be left alone and will usually be absorbed within a few days. If break adherence is affected, reoperation may be required, and presence of residual traction should be inspected and released prior to reinjection of gas.

### **Gas in the Anterior Chamber and Corneal Decompensation**

This may occur in aphakic eyes or in pseudophakic eyes with a nonintact posterior capsule. View of the fundus is often compromised if this happens. If noted intraoperatively, AC could be filled with viscoelastics prior to proceeding. If found postoperatively, it can usually be left alone and will be absorbed within a few days. Reoperation is seldom required. However, prolonged contact of the bubble in aphakic eyes with the use of expansile gases may predispose the corneal endothelium to hypoxia and decompensation.<sup>54</sup> This is mainly due to the interruption of aqueous flow to the endothelium, which in turn reduces the oxygen supply. Avoiding lying supine may reduce bubble–endothelium contact and potentially reduce the risk of corneal decompensation in such cases. In patients with cervical spine problems that prevent them from posturing, a large bubble should be avoided.

### **Intraocular Lens Capture**

With combined phacovitrectomy and intraocular gas injection, the intraocular lens (IOL) may be pushed forward into the AC, causing optic capture. This could be prevented by limiting the anterior capsulorrhexis to a size smaller than the optic of the IOL. The patient should also be advised to avoid a faceup posture. The condition may be left alone if there is no tilting of the IOL and disturbance to vision is minimal. However, repositioning of the IOL

may be needed if dislocation has occurred or pigment dispersion is significant.

## Conclusion

Intraocular gas has grown into an indispensable part of vitreoretinal surgery. Its use has been extended to indications other than retinal detachment. The high surface tension and buoyant force is highest among the vitreous substitutes available. The versatility of types and concentration of gases available enables the surgeon to manipulate procedure according to clinical scenarios, and has hugely improved operative success rates. A clear understanding of the properties of available gases is essential to making the right choice for different circumstances.

# Perfluorocarbon Liquid in Vitreoretinal Surgery

## Introduction

Perfluorocarbon liquid (PFCL) was initially designed for use as a blood substitute.<sup>55</sup> Clark and Gollan first used it as an oxygen transporter in a mouse model.<sup>55</sup> In humans, its use was involved in coronary angioplasty to deliver oxygen to ischemic myocardial tissue. PFCL has a high oxygen-carrying capacity and is also chemically inert. In 1982, Haidt and associates first examined its use as a vitreous substitute.<sup>56</sup> Clark later examined its possibility as an intraoperative tool, as well as postoperative vitreous substitute.<sup>57</sup>

In 1987, Chang pioneered its use in humans.<sup>58</sup> He investigated the possibility of PFCL as an intraoperative tool to assist the manipulation of the retina in complicated retinal detachments (RD). This was acknowledged by many as a major advancement. The use of PFCL has greatly improved retinal attachment rates, especially in complicated RD. This chapter will cover the physical and chemical properties of PFCL, surgical techniques, and the potential complications that may arise with its use.

## Types and Properties of Perfluorocarbon Liquid

PFCL is a synthetic fluorinated hydrocarbon containing carbon–fluorine bonds. Some also contain other elements such as hydrogen, bromide, and nitrogen. Their chemical structures can be either straight chains or cyclical. Straight chain compounds contain carbon chains from  $C_5$  to  $C_9$ , whereas cyclic compounds are made up of carbon chains from  $C_5$  to  $C_{17}$ . For compounds with a carbon chain shorter than  $C_5$ , e.g., perfluoropropane ( $C_3F_8$ ) and perfluoroethane ( $C_2F_6$ ), they exist in gaseous form at room temperature. In general, all PFCLs are odorless, colorless, low viscosity, and have higher specific gravity and density than water. They are stable under high temperatures and do not absorb wavelengths of commonly used lasers. A few low-density PFCLs have been investigated for potential use in ophthalmology. This includes perfluoro-n-octane ( $C_8F_{18}$ ),<sup>59</sup> perfluoroethylcyclohexane ( $C_8F_{16}$ ),<sup>60</sup> perfluorodecalin ( $C_{10}F_{18}$ ),<sup>61</sup> perfluoro-octylbromide ( $C_8F_{17}Br$ ),<sup>62</sup> perfluorophenanthrene ( $C_{14}F_{24}$ ),<sup>18,62</sup> perfluorotributylamine ( $C_{12}F_{27}N$ ),<sup>63</sup> and perfluorotri-n-propylamine ( $C_9F_{21}N$ ).<sup>64</sup> Details are listed in Table 108.4. Chemical and physical properties vary according to chemical structures. Of these,  $C_8F_{18}$  was found to possess higher efficacy and was approved by the US Food and Drug Administration for intraocular use.

**TABLE 108.4**

### Characteristics of Perfluorocarbon Liquids Being Investigated for Intraocular Use

Chemical Formula	Molecular Weight (g/mol)	Specific Gravity	Surface Tension (dyn/cm at 25 °C)	Refractive Index	Vapor Pressure (mmHg at 37 °C)	Viscosity (cSt at 25 °C)
$C_8F_{18}$	438	1.76	14	1.27	50	0.8
$C_{10}F_{18}$	462	1.94	16	1.31	13.5	2.7
$C_{14}F_{24}$	624	2.03	16	1.33	<1	8.03
$C_2F_6$	138	1.83	n/a	1.29	55	0.94
$C_6F_{13}C_8H_{18}$	433	1.35	20	1.34	n/a	2.5
$C_{12}F_{27}N$	671	1.89	16	1.29	1.14	2.6
$C_8F_{17}Br$	499	1.93	18.2	1.30	1.1	2.3

cSt, centistokes.

There are several advantages that have made PFCL popular: (1) optical clarity allows manipulations under PFCL possible; (2) high density and specific gravity allows flattening of the retina and unrolling of folds, and also avoids the need for a posterior retinotomy to drain SRF; (3) different refractive indexes from saline allow a visible PFCL–fluid interface, which aids intraocular maneuvers, and ease of removal; (4) that it has a higher boiling point than water and no interference to laser wavelengths allows endophotocoagulation under PFCL;<sup>59</sup> (5) low surface tension and high interfacial tension tends to hold it in a big bubble, and reduce the risk of PFCL migration into subretinal space through the break; (6) low viscosity allows easy injection and aspiration even with small-gauge vitrectomies; (7) immiscibility with water resists incursion by saline and blood and allows a clear operating field despite intraoperative bleeding; (8) immiscibility with silicone oil allows PFCL–SO exchange, which is helpful when treating giant retinal tears by reducing risk of slippage.

## Technique of Perfluorocarbon Liquid Injection

Viscosity of commonly used PFCLs ranges from 0.8 to 2.7 milliPascal-seconds (mPa · s) at 25 °C ([Table 108.4](#)). When using a 20G vitrectomy system, a dual-bore cannula should be used to inject PFCL. Under standard three-port vitrectomy conditions, all the ports will be occupied by the infusion, the light-pipe, and the PFCL injection cannula. If a single-bore cannula is used, IOP will elevate during the process, and resistance to injection will increase. A dual-bore injection cannula provides an exit passageway for intraocular fluid and reduces resistance during injection. High resistance plus forceful injection may dislodge the cannula from the syringe, and serious complications if the cannula is impacted into the retina and choroid. Therefore, a syringe with a Luer-lock is preferred. When a chandelier endoillumination source is used, any vacant port should be plugged prior to injecting PFCL. Escape currents through the vacant port may cause mobile retina to incarcerate into it.

When using the 23- or 25G system, if there was a separate light-infusion, PFCL should be injected with a single-bore cannula, while fluid is aspirated using a cutter. This system gives more control over the exchange procedure. Another complication is that vitreous can be forced to incarcerate by this high injection pressure, either into the infusion port or at any one of the remaining sclerotomies. Blockage of the infusion port can give rise to hypotony and intraocular hemorrhage, if the surgeon is unaware of the condition.

The injection speed should be sustained and gradual. This allows time for SRF to be displaced, retina unfolded and flattened. If a dual-bore cannula was to be used, injection must be gradual and a Luer-lock-enabled syringe must be used. This will prevent dislodgement of the needle from the syringe due to the build-up of injection pressure inside the syringe. If traction has not been completely cleared and injection was too forceful, PFCL may go through breaks into the subretinal space. The interface with fluid should also be observed and injection stopped when it has reached the desired level. During the injection process, the tip of the cannula should always be submerged in the formed PFCL bubble. This prevents formation of small bubbles of PFCL, which can also migrate under the retina.

With a 20G system, especially when the ports are free flowing, removing instruments from one of the ports can cause a jet of infusion fluid into the vitreous. Such a jet of fluid can give rise to disruption of the PFCL into tiny droplets. With the modern 23- or 25G system, some of the cannulas are guarded to prevent free flow of infusion fluid out of the sclerotomies. Equally, some vitrectomy machines are designed to match the flow of intraocular pressure. Nonetheless, surgeons' awareness of this potential complication can prevent its occurrence. Ideally, PFCL should be injected once and then removed. However, with complex manipulations of the retina, sometimes it is necessary to remove the PFCL and reinject. This again is a major cause for dispersion into droplets.

## **Technique of Perfluorocarbon Liquid Removal**

After PFCL has served its function, it should be removed

completely from the vitreous cavity. Depending on the indication of PFCL use, PFCL–fluid, PFCL–air, or PFCL–SO exchange could be performed. A flute needle or a soft-tip needle should be used in this regard. Technique varies under different scenarios and will be discussed below.

An air-insufflation pump with IOP control should be used. As the level of PFCL lowers, the tip of the aspirating needle should be placed at the edge of the PFCL bubble. With the eye in the primary position, the PFCL bubble would have a dome upper surface. In order to aspirate all the vitreous fluid before removing the PFCL, a wide-angle optical viewing system is necessary to get access to the recess between the PFCL and the retina. Rotation of the eye should be avoided. Any vitreous fluid would be less accessible when the eye is rotated.

For PFCL–SO exchange there are two pathways where SO can be infused. The first option is to use a chandelier endoillumination and an automated SO injection through one of the sclerotomies. This frees a port for the passive extrusion of PFCL. The second option is to infuse SO through the infusion port. With both options, the SO injection cannula should first be inserted into the eye and positioned for injection. A flute needle is then inserted and placed within the PFCL bubble. Aspiration of PFCL is usually passive, and it starts once SO infusion begins. As SO is lighter than PFCL, it floats on top of PFCL, and fills the eye from anterior to posterior (Fig. 108.6).

**FIG. 108.6** Perfluorocarbon liquid (PFCL)–silicone oil (SO) exchange. SO is filled progressively superiorly, while PFCL is being extruded through the flute needle placed within the PFCL bubble. The giant retinal tear is kept constantly flat by the tamponade agents to avoid slippage.

To avoid slippage, the draining needle should be passed through the incoming SO bubble, into the PFCL bubble, several times. This has the effect of making the PFCL bubble join up with the SO bubble. As both bubbles are hydrophobic, they will preferentially stay in contact with each other and form a single bubble. Any aqueous would be excluded from the interface, and displaced either laterally or superiorly. This way, slippage is avoided. Slippage is the posterior displacement of vitreous fluid underneath the retina to the posterior pole, by the incoming SO bubble. By joining the SO bubble with the PFCL bubble, such posterior displacement is much less likely to occur.<sup>65</sup>

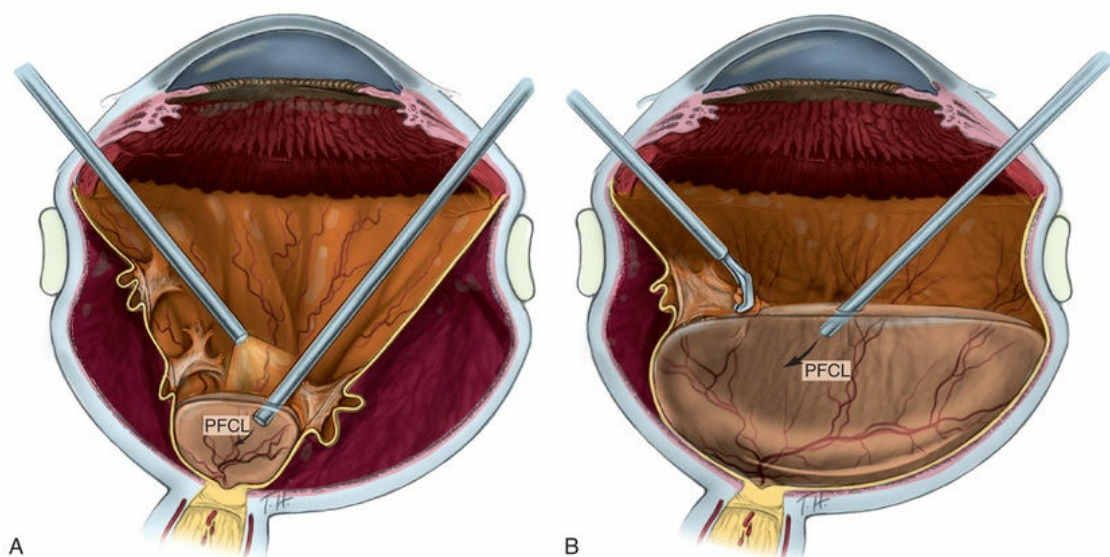

An additional maneuver to ensure that there is no aqueous in the

eye is to overfill the eye with PFCL all the way back to the three-way tap, before commencing the PFCL–SO exchange process. This method expels all aqueous from the eye, as well as the infusion tubings, and reduces the risk of slippage when SO is filled in progressively.<sup>66</sup>

## Indications for Use

### Proliferative Vitreoretinopathy

The use of PFCL has changed the management of proliferative vitreoretinopathy (PVR). Before the introduction of PFCL, PVR would be dealt with from anterior to posterior. After PFCL was introduced, dissection of membranes starting from the posterior pole was made possible (Fig. 108.7).<sup>67</sup> This is a safer approach as it reduces the risk of iatrogenic tears and the trauma to the retina. The success rate for severe PVR has been reported to range from 84% to 96%. Its use also shortens operative time, and allows more thorough removal of membranes.<sup>68</sup>

**FIG. 108.7** Use of perfluorocarbon liquid (PFCL) facilitating the removal of membranes.

For cases with PVR, some surgeons prefer to insert an encircling buckle prior to performing vitrectomy. This provides additional relief of traction anteriorly and maximizes anatomic success rate.

Following core vitrectomy and initial anterior dissection, PFCL is injected over the disc to open up the funnel-shaped detachment. Usually PVD has already occurred, but if not, this helps to dissect the posterior hyaloid from the disc and retina. By doing so, the peripapillary retina is flattened and provides an initial platform for later dissections. As dissection proceeds anteriorly, more PFCL is injected to aid visualization of residual membranes.<sup>67,69</sup> This delineates areas that require further peeling. As the peeling process progresses anteriorly, more PFCL is injected to stabilize the retina and aid visualization of the membranes. The procedure is complete only when the whole retina is flattened under PFCL and no residual traction is left up to the vitreous base anteriorly. Scleral depression with vitreous base shaving is advisable in severe PVR to reduce the risk of repletions.<sup>70</sup> A bimanual dissection technique using a lighted pic and membrane forceps has been reported to reduce the likelihood of creating iatrogenic breaks. In severe PVR, where fibrotic membranes cannot be completely removed, retinotomies are created to relieve traction.<sup>71</sup> PFCL should only be filled posterior to the retinotomies to avoid any subretinal migration. When all traction has been relieved, PFCL could be added to tamponade the retina over the retinotomy. Risk of subretinal migration is low if all traction has been relieved and PFCL remains in one single bubble. Endophotocoagulation could be performed under PFCL at this point.

Depending on the extent and duration of internal tamponade required, PFCL–air or PFCL–SO exchange can be performed at this time. For less severe cases and those not requiring retinotomies, a PFCL–air exchange followed by internal tamponade with an expansile gas/air mixture (e.g., perfluoropropane- $C_3F_8$ ), may be sufficient. This could be done with the technique described above. For more severe cases where extended tamponade is required, a PFCL–SO exchange needs to be done. This has the advantage of having tamponade over the entire retina throughout the process, keeping the retina stabilized and preventing slippage from occurring. Endophotocoagulation could also be performed after PFCL exchange, either under air or through SO.

In recent series, the possibility of using PFCL as a short- to mid-term tamponade agent, to keep the retina flat postoperatively in

complex retinal detachments, has been explored.<sup>72-74</sup> Successful reattachment of the retina has been reported in up to 80% to 92.4% of eyes. Main problems reported were cataract formation, transient IOP rise, and a foreign body response in the eye.<sup>73</sup>

In general, PFCL has improved the outcomes in terms of anatomic success rate and visual outcomes in PVR surgeries.<sup>72-76</sup> PFCL provides the best available internal tamponade during membrane dissection. It has proved to be an indispensable tool when dealing with PVR cases.

## **Vitreous Base Shaving**

The dissection of vitreous base is difficult even in the presence of PFCL. The reason is that the retina has already been stretched out to length. Additionally, the vitreous base cannot be separated from the retina. Most surgeons feel, in the case of PVR, meticulous dissection of the vitreous base is important as well as a close shaving of the vitreous base. The challenge of vitreous base shaving is to visualize the vitreous. The PFCL displaces the vitreous anteriorly, and the high refractive index shows a clear interface between PFCL and vitreous fluid. The contrast between vitreous fluid and gel, however, is poor because they have similar refractive indexes. It has been proposed that triamcinolone be used in combination with transscleral illumination to increase the light scatter. Particles of triamcinolone caught up in the peripheral gel can easily be seen especially when light is shone perpendicular to the line of sight. The technique of vitreous base shaving using PFCL and triamcinolone was described by Veckeneer and Wong.<sup>77</sup>

In all instances, vitreous base shaving should be a bimanual technique with the surgeon in control of the indentation. The use of an additional one or more fiberoptics inserted at the pars plana can make the procedure highly controllable. The availability of PFCL to stabilize the retina greatly reduces the risk of iatrogenic retinotomies. This is because the retina is less likely to engage the cutter accidentally when under the tamponade by PFCL.

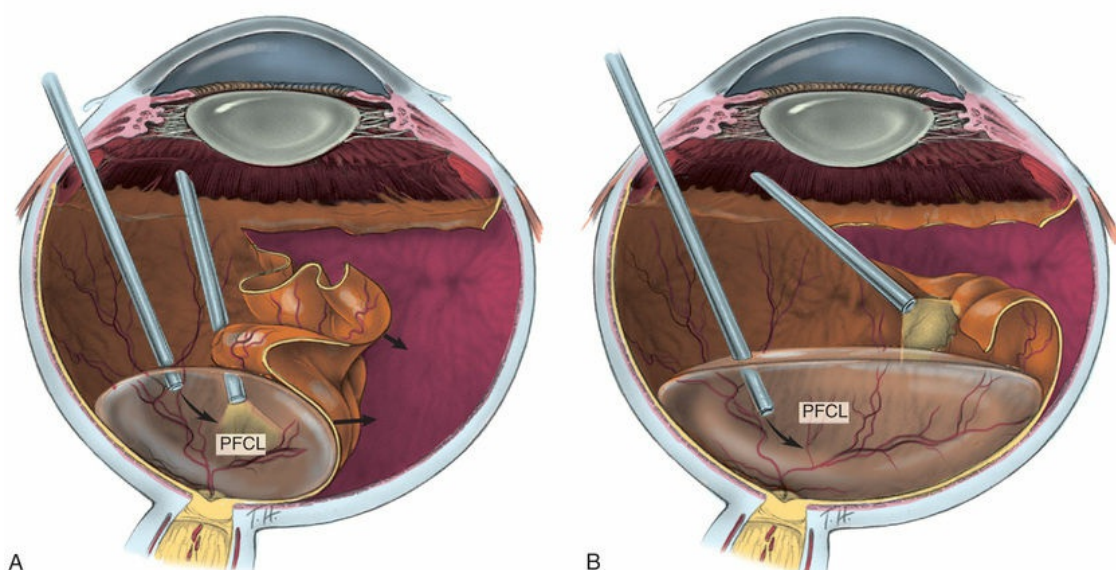

Vitreous base shaving is needed in PVR cases, not only for a more complete removal of anterior traction systems; it is also desirable to ensure a more complete removal of vitreous gel. This in turn would result in a more complete SO fill. Fawcett and associates have

shown in the past that a slight underfill with SO would give rise to large area of retina unsupported.<sup>23</sup> If there was substantial residual gel left after a vitrectomy, it would be compressed and dehydrated by the silicone bubble, thus increasing the capacity of the eye and resulting in an underfill. When injecting PFCL, care must be taken not to overfill the vitreous cavity before adequate relieve of traction. Otherwise, there would be a substantial risk of the PFCL migrating into the subretinal space.

## Giant Tears

In many parts of the world, before PFCL was available, giant tear repair involved using the Stryker table as described by Peyman.<sup>78</sup> This involved rolling the patient intraoperatively into a prone position and unfolding the retina with the help of an intraocular gas bubble. This proved to be difficult and yielded low success rates.<sup>79</sup> The introduction of PFCL allows the entire surgery to be performed with the patient lying supine. In eyes without PVR, the folded flap can be slowly repositioned by injecting PFCL slowly over the optic disc. This allows manipulation of the retina in a gentle manner and assures that endophotocoagulation is performed with the retina attached to the underlying retinal pigment epithelium (Fig. 108.8). This method hugely improved the anatomic success rate to over 88%, even without the use of a scleral buckle.<sup>80</sup>

**FIG. 108.8** Perfluorocarbon liquid (PFCL) could be used to unroll folded retina in cases of giant tears. (A) When the posterior flap of a giant retinal tear is inverted, the flap is elevated to allow delivery of PFCL into the preretinal space. (B) Additional PFCL is injected, and the retina is repositioned. (C) Endphotocoagulation can be applied through the PFCL bubble as the retina is stabilized by the posterior tamponade force of the heavy liquid.

For cases with immobile inverted flaps and PVR, thorough dissection of membranes is critical to reattaching the retina. Using PFCL, a high success rate of up to 90% can be expected.<sup>70</sup> Additional encircling buckle is favored by some. Endphotocoagulation is performed under PFCL, as the heavy tamponade opposes the retina to the underlying RPE, ensuring good uptake of laser energy. Two to three rows of confluent laser spots are created at the edge of the tear. Additional 360° endphotocoagulation can be done on the indentation created by the buckle. It is, however, controversial as to whether this should be done routinely. The majority of surgeons will do this, believing that it can reduce the risk of redetachment. Heavy 360° endphotocoagulation is associated with brisk uveitis

postoperatively. Similarly, heavy treatment at 3 and 9 o'clock might damage the anterior ciliary nerves and result in a permanently dilated pupil and reduced accommodative ability.

To prevent slippage of the retina during PFCL–SO exchange, a modified PFCL injection technique was recommended by Li and Wong.<sup>66</sup> First, the infusion is opened to the external atmosphere at the three-way tap, and the eye is filled with PFCL until it overflows into the infusion tubing. More PFCL is filled such that all aqueous is expelled from the three-way tap opening. This is done until PFCL is dripping out of the three-way tap. This ensures complete aqueous evacuation during PFCL injection. During subsequent PFCL–air or PFCL–SO exchange, risk of slippage is lower, as there is no residual fluid in the system (Fig. 108.9).

**FIG. 108.9** Complete perfluorocarbon liquid (PFCL) fill to prevent slippage. PFCL is filled progressively into the eye. The external end of the infusion is disconnected, and excess PFCL is allowed to drip out from the external end of the infusion. This ensures the whole system is filled with PFCL and prevents slippage due to residual aqueous in the system.

Previously, there have been reports of using PFCL for prolonged internal tamponade.<sup>69,81</sup> Different PFCL and duration have been tried. In a study using perfluoroperhydrophenanthrene, it was left in situ for a mean of 20.5 days.<sup>69</sup> In another study using perfluorophenanthrene (Vitreon), it was left in situ for up to 4 weeks.<sup>81</sup> However, due to potential intraocular toxicity and other complications such as cataract formation, extended tamponade with PFCL is seldom used nowadays. Surgeons in Australia, in particular, are choosing PFCL to treat giant retinal tear. The PFCL is usually left in situ for 1–2 weeks. A second operation is then carried out, during which the PFCL is removed and further assessment of the retina is made. If the retina was deemed to be stable, gas is then used, otherwise further manipulation including photocoagulation and epiretinal membrane dissection are carried out, followed by the use of SO as a prolonged tamponade.

The rationale for the use of PFCL was to avoid slippage during air–PFCL exchange or a SO–PFCL exchange. Using the technique described by Li and Wong, a low rate of slippage was reported.<sup>66</sup> If PFCL is to be used for giant retinal tear and prolonged tamponade, it might be advisable for the patient to remain relatively still during convalescence. The rationale is that less dispersion might occur. Correspondingly, less inflammation might ensue. Complications related to PFCL use will be discussed below.

## **Ocular Trauma**

Traumatic retinal detachments can be managed with the help of PFCL.<sup>82</sup> Coexisting intraocular hemorrhage is common and the hemorrhage may be situated in the suprachoroidal space, choroid, retina, and vitreous cavity. Most patients do not have established PVD. And in the case of laceration or rupture, vitreous incarceration is a feature. Management of these cases poses great

challenges. The use of PFCL has several advantages under these circumstances, it can: (1) stabilize the retina during vitrectomy; (2) assist separating the posterior hyaloid and retina; (3) displace preretinal, subretinal, or suprachoroidal blood; (4) assist removal of incarcerated vitreous or retina; (5) facilitate the removal of dislocated lens, intraocular lens implant (IOL), or intraocular foreign bodies (IOFB), and (6) maintain a clear media for visualization.

Traumatic incarceration of the retina through sclera can be repositioned with the help of PFCL.<sup>83</sup> Any incarcerated vitreous must first be completely removed. PFCL is then instilled in the vitreous cavity, to tamponade the posterior retina. This produces a tamponade effect on the posterior retina, to pull the incarcerated retina back into the eye. With this method, the incarcerated retina can sometimes be retrieved without damage. Where the retina cannot be freed, a limited retinotomy to circumscribe the incarcerated site is considered important to prevent subsequent entry-site proliferation, PVR, and recurrent detachment. The use of PFCL ensures a clear media through which such manipulation is made possible, while at the same time stabilizing the retina.

PFCL is also valuable in the removal of intraocular foreign body (IOFB). Organic or nonmetallic IOFBs can usually float on PFCL, and hence could be retrieved through the sclerotomy, or from an anterior approach. For metallic or sinking IOFBs, filling PFCL over it helps to stabilize and make grasping easier. If the foreign body is impacted in the retina, then the PFCL provides a counter pressure to any pulling force used to extract the foreign body. Large foreign bodies that float can be levitated by the PFCL to facilitate extraction through either the pars plana or a corneal wound. Extraction of impacted IOFB might lead to subretinal hemorrhage postoperatively. A small bubble of PFCL placed over the macula would ensure that this bleeding does not spread to the submacular region.

## **Dislocated Lens**

PFCL has helped in the management of dislocated crystalline lens, dropped cataract fragments,<sup>84</sup> and intraocular lens (IOL) implant.<sup>76</sup> It is generally advisable to carry out a thorough vitrectomy,

including the separation of posterior hyaloid face, before PFCL is injected.

Small fragments can be removed successfully without the use of the heavy liquid. The technique generally involves either using a vitreous cutter or an ultrasound fragmentation. Lens fragments should be purchased using aspiration, and then levitated to the midvitreous cavity before activation of pulsed ultrasound fragmentation. Some surgeons instill a small bubble of PFCL in the posterior pole as a “cushion” against transmitted ultrasound energy causing damage to the vital structures such as the macula, optic disc, and major vessels. Others feel that PFCL hinders fragment removal rather than helps it, as it tends to displace the fragments to the edge of the bubble where they are less easily accessible. For large fragments, including the whole crystalline lens, PFCL is used as a way of lifting the whole lens to the midvitreous cavity, where it could be safely broken up and removed either by a cutter or by ultrasound fragmentation. PFCL can also be used to float the whole lens to the anterior segment in an aphakic eye, where it can be delivered through a scleral or corneal wound. If such a maneuver is attempted, some PFCL could leak through the corneal or scleral wound, such that the lens seems to drop back further into the vitreous cavity. Practically for some surgeons, there is never “enough” PFCL to float the lens clean out of the eye. One way is to perform an “expression” of the lens, much like the technique used in the extracapsular cataract extraction. The lips of the wounds are held open, and indentation of the sclera would cause the lens to be “expressed” and delivered outside the eye. PFCL is particularly useful when the dropped lens is associated with retinal detachment, where subretinal migration of fragments is prevented.<sup>76,84</sup>

In the case of dropped IOLs, PFCL is used to float up the IOL. It can then be grasped from an anterior approach and delivered through the limbus, or repositioned in the sulcus if there is enough capsule remnant (Fig. 108.10). Whether it is IOL or crystalline lens, if PFCL is to be used, the lenses are often displaced laterally. The upper surface of a PFCL bubble inside the eye is convex. Therefore, the crystalline lens or IOL cannot be expected to stay in the middle where convexity is highest. Instead, the lens slides off to the periphery and often becomes engaged with any residual vitreous.

Therefore, a moderately thorough shaving of the vitreous base should be carried out prior to any attempts to float the lens.

**FIG. 108.10** Perfluorocarbon liquid could be used to float the nucleus fragment out through the pupil in cases of dropped nucleus after complicated cataract surgery. Perfluorocarbon liquid is used to float the nucleus fragment away from the surface of the retina. This allows easier manipulation of the lens fragment during phacofragmentation and reduces the risk of injuring the retina.

## Suprachoroidal Hemorrhage

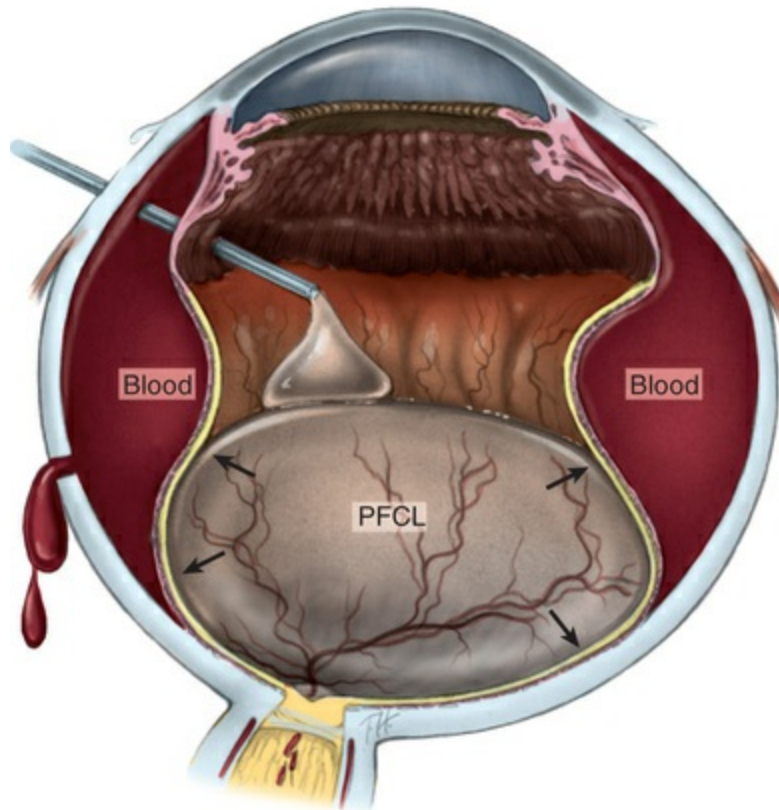

Suprachoroidal blood may not necessarily require drainage. This particularly applies to small suprachoroidal hemorrhages that do not involve the posterior pole or the macula. B-mode ultrasound is

used to assess the degree of liquefaction of the suprachoroidal hemorrhage before drainage is attempted. Such liquefaction is recognized by a “Brownian”-type movement of speckled ultrasound signals. The simple fashioning of the sclerotomy is sometimes associated with significant drainage of the altered dark-colored blood. Therefore, a scleral cut-down over the posterior choroid is unnecessary, except when there is a large posteriorly loculated hemorrhage, in which case, the injection of PFCL may be attempted. The liquefied blood would be lighter than PFCL, and as such, be displaced anteriorly towards the port. Otherwise, a sclerotomy, specially fashioned for drainage purposes, can be used. Complete drainage of suprachoroidal blood is seldom achievable. Partial drainage may be sufficient to relieve patients of pain associated with suprachoroidal hemorrhage or to prevent kissing choroidals, and the retina developing a fixed retinal fold.

However, PFCL can be of help in some cases. Following vitrectomy, 3-mm circumferential sclerotomies are created 4 mm posterior to the limbus, in the superior, nasal, and temporal quadrants. The eye is then filled with PFCL, which exerts an internal tamponade, to facilitate the evacuation of blood through the sclerotomies ([Fig. 108.11](#)).<sup>85</sup> Air or gas tamponade have also been tried but the evacuation with PFCL was found to be more complete.<sup>86</sup>

**FIG. 108.11** Displacement of suprachoroidal blood clot through an external sclerotomy, with the help of perfluorocarbon liquid (PFCL) internally.

## Other Indications

PFCL has also been reported to be useful in a certain number of conditions.<sup>87</sup> These include retinal detachment associated with diabetic retinopathy,<sup>68</sup> detachment associated with disc coloboma,<sup>88</sup> detachment from retinopathy of prematurity,<sup>89</sup> vitrectomy for endophthalmitis,<sup>90</sup> displacement of submacular hemorrhage during surgical drainage,<sup>91</sup> and the excision of subretinal membranes. Surgical principles are the same. It helps stabilize the retina, displaces subretinal blood, reveals preretinal membranes, and assists drainage of SRF. With these numerous advantages, PFCL has become an indispensable operative tool.

## Complications and Management

Although PFCL is primarily used as an intraoperative tool with good safety profile, toxicity from extended intraocular use has been

reported in animal as well as human reports.<sup>66,92</sup> Although toxicity has not been observed when PFCL is retained in rabbit eyes for up to 48 hours, white precipitates appear when it is left for longer periods. In humans, Elsing and associates reported the appearance of white flake-like deposits on intraocular structures and showed inflammatory response featuring macrophages.<sup>93</sup> Hence, complete removal of PFCL from the eye towards the end of surgery is therefore recommended. Complications related to the use of PFCL can be divided into those seen during surgery, or after surgery, due to the effect of retained PFCL.

### **Subretinal PFCL**

PFCL may go into the subretinal space during surgery or may be seen under the retina postoperatively. During surgery, predisposing factors for PFCL going under the retina include: (1) PFCL breaking into globules; (2) giant retinal tears; and (3) incomplete relief of tractional membranes on the retina.

PFCL bubbles have high interfacial tension against water, therefore tend to hold themselves together. If the injection process is too forceful or rapid, it may, however, break into smaller bubbles. These bubbles usually fuse together to form a large bubble fairly quickly. However, if the tear is too large, or the retina is elevated due to traction, small PFCL globules may go into the subretinal space. Therefore, injection speed should be gradual and monitored, with the injecting needle tip buried in the PFCL bubble already formed, to avoid small globule formation. A small bubble also invariably occurs if the PFCL has been injected, aspirated, and reinjected. Ideally, therefore, PFCL should be injected once and removed. However, with complicated surgical maneuvers, injection, aspiration, and reinjection repeatedly might be unavoidable. The use of dual-bore cannula for small-gauge vitrectomy is now the trend. A recently published new dual-bore cannula with four vent ports have been shown to be able to create a broad fan-like egress of fluid that is perpendicular to the axial direction of the needle.<sup>94</sup> This new cannula may avoid the risk of traumatizing the retina due to the jet of PFCL, and also the risk of PFCL going under the retina due to this. Some surgeons use PFCL to test the relief of traction. The understanding is that a detached

retina with no epiretinal membrane would be reattached readily with PFCL injection. This maneuver can be hazardous when injecting PFCL in the presence of one or more retinal breaks. The first sign that the traction relief was inadequate might be the migration of PFCL into the subretinal space. Small bubbles of PFCL in the subretinal space far away from the macula might be ignored. A large bubble, especially when situated above the macula, should be removed, as it could migrate and involve the fovea.

If PFCL has accidentally gone under the retina, it should be removed with every effort during the surgery, as it eventually migrates under the fovea with time even if it was located peripherally initially. It may reduce retinal function, and may cause central scotomas.<sup>95</sup> Retinal hole formation has also been reported in long-standing subretinal PFCL.<sup>96</sup> In recent reports damaged retinal function is partially recovered following removal of PFCL surgically.<sup>97</sup> This can either be done through a small drainage retinotomy adjacent to the PFCL bubble, or by creating a peripheral retinotomy and inserting a flute needle directly under the retina for drainage. The former technique used a small-gauge cannula (39–50G), inserted through the retina adjacent to the bubble for direct aspiration.<sup>98,99</sup> The latter method should be performed if a large amount of PFCL has gone under the retina. At least a 90° peripheral retinotomy has to be created to allow insertion of a flute needle under the retina for direct drainage, which is followed by gas or SO infusion. If subretinal PFCL is only noted postoperatively, drainage should be performed, as retinal sensitivity is regained after PFCL drainage.<sup>97</sup> A recent report utilizes intraoperative optical coherence tomography to aid visualization of the remaining PFCL during surgery, to ensure complete removal of the residual subretinal PFCL.<sup>100</sup>

The latter approach could be modified. Following partially detaching the retina, the PFCL bubble would then be surrounded by fluid and be round in shape. The bubble can then be removed via a retinotomy and a flute needle passed through the retinal opening to gain access to the subretinal PFCL. Equally, it is possible to displace the PFCL by simply injecting a gas bubble into the eye. This has the effect of displacing the PFCL bubble to the most dependent part of the limited retinal detachment. This is probably

the least traumatic procedure and may be suitable for bubbles of PFCL under the macula, or just above it. This strategy is essentially only displacing the bubble to an extramacular and inferior location, rather than removing the PFCL entirely.

## Intraocular Toxicity

Most toxicities are related to incomplete removal of PFCL at the end of surgery, which has a reported incidence of 0.9–11.1%.<sup>98,101</sup> Risk is higher when peripheral retinotomy is large, especially for those where a 360° retinotomy was performed.<sup>101</sup> Residual PFCL can either be seen during fundal examination, appearing as fluid level inferiorly, or when it permeates into the AC, appearing as fluid level inferiorly, or as small PFCL globules resting in the inferior angle (Fig. 108.12). The presence of PFCL in the AC does not necessarily mean that there is extensive PFCL in the vitreous cavity. This is because once it permeates into the AC, it is prevented from flowing back by the iris, as one assumes an upright posture most of the time.

**FIG. 108.12** Perfluorocarbon liquid (PFCL) globules in the anterior chamber. (A) Slit-lamp photos showing globules of PFCL in the anterior chamber. (B) Presence of keratic precipitates can be seen on the corneal endothelium. This signifies the presence of inflammation in the anterior chamber as a result of retained PFCL.

Toxicity to ocular tissues may be chemical or mechanical. Chemical toxicity is related to the both the high oxygen carrying capacity and the presence of polar impurities.<sup>102</sup> High oxygen

carrying capacity of PFCL might induce damage to the retina and blood vessels in two ways.<sup>102</sup> First, a high partial pressure of oxygen in the residual PFCL bubble causes vasoconstriction of the retinal blood vessel.<sup>102,103</sup> Second, direct oxygen toxicity is also capable of inducing damage to the retinal vessels, as shown in histologic reports.<sup>102,104</sup> The damage included loss of pericytes and endothelial cells of the retinal vessels.<sup>104</sup> Impurities may alter the PFCL interface, making it less resistant to absorbing lipoproteins, which is considered important in the formation of fibrotic membranes.<sup>105</sup> Of the various PFCLs, perfluoro-n-octane is preferred by some, as it is FDA-approved. It is also available in its purest form. It has been found to be free from toxicity when left in rabbit eyes for up to 1 week.<sup>64</sup>

Mechanical toxicity is due to the extended compression of inferior retina by retained PFCL, due to its higher specific gravity. Histologic changes in the retina as a result of prolonged compression include loss of the outer plexiform layer, displacement of photoreceptor nuclei into the outer segments, and atrophy of the retinal pigment epithelium.<sup>63</sup> We have also postulated that the trophic changes observed in the retina might be due to the exclusion of water from the surface of the retina, thus, disrupting the potassium siphoning mechanism of the Müller cells. This in turn may lead to excitotoxicity. The weight of the PFCL cannot account for similar histologic changes observed in the superior retina when SO is used. The buoyancy of a SO bubble and the force exerted on the superior retina is several folds smaller, but the changes to the retina are similar.<sup>106</sup>

## **PFCL in the Anterior Chamber**

If present in the AC, PFCL may cause visual disturbance, corneal endothelial loss, as well as rise in IOP.<sup>93</sup> If the level of PFCL is high enough, it may block visual axis and cause disturbance of vision.

PFCL has been found to cause secondary open angle glaucoma in rabbits by causing inflammation and trabecular damage.<sup>85,107</sup> Pupil block glaucoma has also been reported following the use of PFCL.<sup>107</sup> PFCL removal is indicated under these circumstances and can be done at the slit lamp. After sterilization, a fine needle connected to a syringe is inserted into the AC, through the limbus from inferiorly.

PFCL is slowly aspirated into the syringe (Fig. 108.13). This could be repeated several times as needed, over a few hours, giving sufficient time for the AC depth to replenish. Occasionally drainage with revision vitrectomy may be required.

**FIG. 108.13** Aspiration of perfluorocarbon liquid (PFCL) from the anterior chamber at the slit lamp. A 27-gauge needle connected to a syringe with plunger removed is inserted into the anterior chamber at near 6 o'clock position. PFCL will then be drained through the needle due to gravity.

A recent report has described a new technique using a Rycroft cannula mounted on the tip of a tuberculin syringe with continued irrigation by means of an anterior chamber maintainer.<sup>108</sup> This may represent a novel attempt to remove PFCL from the AC. However, this requires more intervention as an AC maintainer has to be used.

## Conclusion

The perfluorocarbon liquids have proved to be an invaluable tool for the retinal surgeon in tackling challenging cases. Its use has greatly improved the outcomes of retinal detachments associated with proliferative vitreoretinopathy and use of PFCL was also proved to be helpful in assisting removal of dislocated lens, giant tears, drainage of suprachoroidal blood, and trauma cases. We anticipate that the indication for PFCL may increase, as newer techniques are developed.

## Silicone Oil in Vitreoretinal Surgery

### Introduction

Silicone oil (SO) was first introduced as an internal tamponade agent in the early 1960s.<sup>109</sup> It has since grown into an invaluable tool to the retinal surgeon in managing complex rhegmatogenous retinal detachments, especially those with severe PVR. Indications of SO have been extended to include the treatment of giant retinal tears, viral retinitis, traumatic retinal detachments, proliferative diabetic retinopathy (PDR), complicated pediatric retinal detachments, macular hole surgeries, and endophthalmitis. (This list is not exhaustive.) The use of SO has its advocates and its doubters. Here, we review the physical and chemical properties of SO, current indications of use, the surgical techniques involved, as well as the potential complications and their management.

### Background

Clinical usage of SO in treating retinal detachment was first introduced by Paul Cibis in the 1960s,<sup>109</sup> before the introduction of pars plana vitrectomy. SO was initially injected into nonvitrectomized eyes as an aid to overcome tractional forces and the dissection of preretinal membranes.<sup>110</sup> This was met by initial enthusiasm, but its use later declined owing to the encountered complications and possible toxic effects reported from histologic studies.<sup>111</sup> As a result, many surgeons discontinued its use, especially in the United States. Despite that, some persisted in its

usage and, later, combined it with vitrectomy.<sup>112</sup> This achieved higher anatomic success, especially in cases of PVR that were previously thought untreatable. Through the perseverance of some surgeons, higher anatomic success rates were gradually achieved.

By the 1980s, SO had successfully re-established its role as an internal tamponade agent in many European countries. Long-acting intraocular gas was introduced and gained popularity in the United States. The divergence in the choice of tamponade agents led invariably to a head-to-head comparison: the Silicone Study. The Silicone Study was a series of randomized controlled trials comparing the efficacy and safety of SO against intraocular gases, sulfur hexafluoride (SF<sub>6</sub>), and perfluoropropane (C<sub>3</sub>F<sub>8</sub>), in the management of retinal detachments with PVR.<sup>21,113</sup> Results showed that the differences between SO and intraocular gases were not as significant as expected. There are observations to show that the agent of choice is different between those in Europe, and those in the United States,<sup>114</sup> both SO and long-acting gases have their own advantages and disadvantages. To this day, the indication for SO remains controversial.

## Chemical Properties of Silicone Oil

Silicone is made up of repeating units of siloxane. In fact, the term silicone is a generic term referring to all materials made up of siloxane, including silicone in its fluid form (e.g., SO), as well as silicone in its solid form (e.g., encircling band, gutters, and tires). Siloxane consists of a silicon and an oxygen molecule, with the chemical formula [-Si-O-]. Since silicone is capable of forming two additional bonds on its sides, different organic or inorganic side chains could be attached to the silicone molecule to form polymers with different properties.

Silicone oil is described as being either lighter, or heavier than water. Heavier-than-water SO is in fact a solution of a mixture of polymethylsiloxane and semifluorinated alkanes or alkenes. Lighter-than-water silicone oils (i.e., conventional SOs) vary with regards to their viscosities (Table 108.5). Heavier-than-water SOs are designed for inferior tamponade purposes. For instance, the most common SO consists of polydimethylsiloxane (siloxane with

two attached methyl side chains), also known as PDMS. PDMS has a specific gravity of 0.97, which is lighter-than-water. On the other hand, a methyl and a trifluoropropyl side chain could be added to the siloxane unit to form polytrifluoropropylmethylsiloxane, also known as fluorosilicone oils.<sup>115</sup> Fluorosilicone oils have a specific gravity of 1.25–1.3, hence its heavier-than-water properties.

**TABLE 108.5**

**Chemical Properties of Silicone Oil and Other Commonly Used Intraocular Tamponade Agents**

Tamponade Agent	Chemical Composition	Specific Gravity (g/cm <sup>3</sup> at 25 °C)	Viscosity (cSt at 25 °C)	Surface Tension (mN/m)
Silicone oil (1000 cSt)	PDMS – 100%	0.97	1000	21
Silicone oil (2000 cSt)	PDMS – 100%	0.97	2000	21
Silicone oil (5000 cSt)	PDMS – 100%	0.97	5000	21
C <sub>8</sub> F <sub>10</sub>	C <sub>8</sub> F <sub>10</sub> – 100%	1.94	0.69	14
C <sub>10</sub> F <sub>18</sub>	C <sub>10</sub> F <sub>18</sub> – 100%	1.76	2.7	16
F <sub>6</sub> H <sub>8</sub>	F <sub>6</sub> H <sub>8</sub> – 100%	1.35	3.44	19.7
Densiron 68	F <sub>6</sub> H <sub>8</sub> – 30.5% PDMS (5000 cSt) – 69.5%	1.06	1349	19.13
Oxane HD	RMN3 – 11.9% Oxane 5700 – 88.1%	1.02	3300	N/A
HWS 46–3000	F <sub>4</sub> H <sub>5</sub> – 55% PDMS (100, 000 cSt) – 45%	1.118	2903	18.8
Air	N/A	<0.0001	N/A	70
C <sub>3</sub> F <sub>8</sub>	N/A	<0.0001	N/A	70
SF <sub>6</sub>	N/A	<0.0001	N/A	70

cSt, centistokes; PDMS, polydimethylsiloxane; F<sub>4</sub>H<sub>5</sub>, perfluorobutylpentane; F<sub>6</sub>H<sub>8</sub>, perfluorohexyloctane; C<sub>8</sub>F<sub>18</sub>, perfluoro-n-octane; C<sub>10</sub>F<sub>18</sub>, perfluorodecalin.

Silicone oil is also described as being highly purified. This refers to the removal of impurities that are usually present, which can impact on the chemical properties of the end-product. For instance, unpolymerized residual monomers, low-molecular-weight oligomeric chains, high-molecular-weight polymeric chains, cyclic forms of siloxane, and siloxane chains with a methyl group at its end, are usually present.<sup>116</sup> Other than having polymer chains of undesired lengths, other impurities such as residual catalysts from

the manufacturing process may be present. Catalysts are involved in the ionic ring-opening polymerization of cyclic siloxane, to yield polysiloxane chains of different lengths. Catalysts, such as tetramethylammonium siloxanolate, are often highly toxic.<sup>117</sup> At the moment, albeit some SOs have obtained Food and Drug Administration approval for ophthalmic use, there is still no International Standard for the manufacturing process and the purity gradings of SO products available commercially.<sup>118</sup> Commercially sold SO is classified according to the average viscosities. The lower-molecular-weight SOs tend to promote emulsification. Highly purified SO refers to SO that has had impurities and the lower molecular weight components removed. Molecular weights of polymer chains are determinants of viscosity and are in proportional relationship. Hence, overall viscosity may be higher than expected if more high-molecular-weight polymers are produced and low if more low-molecular-weight polymers are produced. While the product is essentially a mixture of compounds, viscosity is judged by measuring the overall average value as a whole.<sup>119</sup> Therefore, commercially available SOs are sold and classified according to the average viscosities (which is a representation of the averaged molecular weights).

## Physical Properties of Silicone Oil

### Specific Gravity

Aqueous has specific gravity of around 1.01. Hence, we can assume it is about the same as water (1.00). Polydimethylsiloxanes (PDMS) all have a specific gravity of 0.97. It must be noted that for all PDMS, specific gravity remains the same regardless of its chain length or molecular weight. This is because the molecular density of the repeating unit of dimethylsiloxane is independent of the chain length. Hence, all PDMS have identical specific gravities of 0.97, and they all float in the presence of water or aqueous. Specific gravities of heavier-than-water SOs and heavy tamponades are discussed later in this chapter.

### Buoyancy

Details of the physics involved are discussed above. The area in

contact with the retina, and the bubble's size and shape determines the effectiveness of tamponade by a bubble. This is governed mainly by buoyancy. When buoyancy is large, as in gas bubbles, the bubble takes on the shape of a spherical cap. A spherical cap is a sphere with a flat bottom. Conversely, when buoyancy is small, the bubble assumes a relative spherical shape, as in the case of SO. For this reason, a gas bubble makes a larger area of contact against the retinal surface than an equivalent volume of SO bubble. It has been demonstrated that a SO bubble virtually makes no contact with the retina until the eye is near 50% filled. In contrast, a small gas bubble (as small as 0.28 mL) already tamponades up to 90° of arc on the retina (Fig. 108.14).<sup>120</sup> Scleral buckles cause an indent into an otherwise near-spherical vitreous cavity. SO has been shown not to make contact with the retina on either side of the indent. Hence, SO retains a spherical shape, and it does not fill the recesses created by the indent. Therefore, when SO use is intended, it is important to achieve a near 100% fill, in order to achieve a good tamponade effect.

**FIG. 108.14** Slight underfill predisposes to formation of a fluid film between silicone oil (SO) bubble and retina.

This reduces the tamponade effect because the buoyancy of SO is less than that of intraocular gas. (A) Due to the lower buoyancy, the SO globule assumes a

round shape when injected into the eye, leaving a film of fluid between it and the retina. This happens even with only a slight underfill. (B) When the eye is slightly underfilled with  $C_3F_8$ , the tamponade effect is relatively better with only a film of fluid underneath the bubble.

## Surface Tension and Interfacial Tension

Surface tension refers to the Van de Waal forces between molecules. In a drop of liquid in air, the molecules in the center are attracted equally to every other molecule. A molecule on the surface, however, is only attracted to its neighbors. As a result, the surface energy always acts to try to reduce the surface for a given volume. Interfacial tension is a more general term relating to the surface tension between two immiscible liquids. Surface tension specifically refers to the surface energy when one of the two liquids is air. The forces reach equilibrium when free energy at the interface is kept at a minimum. This is usually reached when all like-molecules reside on one side and unlike molecules settle on the other side. Hence an interface is formed, which acts like a taught membrane across two phases.

Here, interfacial tension refers to the force that tends to keep a bubble as a whole.<sup>121</sup> It has been found that an oil bubble remains intact as long as the interfacial tension is above 6 mN/m (milli-Newton/meter). This is important as a single bubble enhances effectiveness of the tamponade. When SO (1000 cSt) comes in contact with pure water, interfacial tension was found to be 40 mN/m. This value was reduced to 33 mN/m when it is physiologic fluid. Presence of impurities such as proteins and lipids, or simply blood, can also alter the interfacial tension. For example, it was found that in the presence of blood the interfacial tension can be further reduced to 14 mN/m.<sup>122</sup>

## Viscosity

Viscosity is a measure of the resistance of a fluid towards being deformed when under shear stress. Hence, it is also known as shear viscosity. It is caused by the attractive forces between molecules in close contact and the friction between molecular chains. Higher

energy is required to deform a highly viscous liquid, while lower energy is needed when deforming a less viscous fluid. Generally, SOs with longer chain lengths have higher viscosity. This has practical implications, as ease of injection and removal is directly proportional to viscosity.

Two kinds of viscosities are involved, namely “shear” and “extensional” viscosities. It has been shown that the lower the shear viscosity, the greater the propensity for dispersion; this has been demonstrated up to a viscosity of 12, 500 cSt. It has also been shown that the presence of low-molecular-weight components also increases the readiness of the oil to disperse. The second type of viscosity that is important refers to extensional viscosity. This is a measure of the resistance of the SO to break up when a globule is drawn into a strand. When the strand breaks, satellite droplets tend to form ([Fig. 108.15](#)). Williams and associates added these high-molecular-weight polymers to low-viscosity SO (1000 cSt) and successfully increased the extensional viscosity to a level equal to that of SO of 5000 cSt.<sup>123</sup> By adding 5% or 10% of 423 kD to 1000 cSt SO, the shear viscosity of the mixture can be increased to 2000 cSt and 5000 cSt, respectively. At the same time, the extensional viscosity can be increased, especially when the liquid is subjected to shear stress. Whether these silicone oils are more stable when used in the eye is yet to be proven in clinical trials.

**FIG. 108.15** Demonstration of how a thin strand of silicone oil breaks up when pulled apart.

“Dispersion” and “emulsification” are terms sometimes used interchangeably. Technically, dispersion refers to the break-up of a large bubble of oil into smaller droplets. These droplets naturally have higher surface energy and will tend to coalesce back into a single bubble. Emulsification only occurs when this surface energy is reduced by the presence of surfactants. The droplets are therefore stabilized and tend not to reform into a single bubble.

## Indications

Usage of SO as described by Cibis was without vitrectomy.<sup>109</sup> Reports of complications associated with its use have led to slow adoption by many surgeons.<sup>124,125</sup> It was only after the introduction of the vitrectomy system that usage of SO became more popular, especially after the Silicone Study.

## Retinal Detachments With Proliferative Vitreoretinopathy

The Silicone Study<sup>21,113</sup> defined the role of SO in the management of retinal detachments. It was a multicenter prospective randomized

clinical trial comparing the effect of SO with long-acting intraocular gases ( $\text{SF}_6$  and  $\text{C}_3\text{F}_8$ ) in the management of complex retinal detachments associated with PVR grade  $\text{C}_3$  or above (i.e., full retinal thickness retinal folds in three or more quadrants; Retinal Society Classification). In general, SO was found to be as effective as  $\text{C}_3\text{F}_8$  and better than  $\text{SF}_6$ , in reattaching the retina.<sup>21</sup> Both SO and  $\text{C}_3\text{F}_8$  were equivalent in terms of improving visual function and low complication rates.<sup>21</sup> Regarding postoperative complications, in particular hypotony and keratopathy, SO did better than  $\text{SF}_6$ .<sup>21</sup>

Despite having equivalent results, subgroup analyses revealed relative superiority in SO under certain circumstances. Subjects were divided into Group 1 (no history of previous vitreous surgery) and Group 2 (had at least one vitrectomy with gas use). Among Group 1 eyes that required retinotomy to flatten the retina, use of SO initially increased the likelihood of visual recovery and reduced risk of hypotony at 6 months. However, at 24 months, a deteriorating trend was observed among eyes that used SO; whereas an improving trend was seen in eyes that used intraocular gas. Risk of recurrent detachment after SO removal was also studied. In a matched-pair cohort comparing SO-removed eyes with SO-in-situ eyes, risk of recurrent detachment was increased if SO was removed. However, if the retina remained attached, despite SO removal, visual acuity tended to be better and complication rates were lower.

In a recent meta-analysis published by the Cochrane Collaboration,<sup>126</sup> the reviewers concluded that the Silicone Study remained the only well-conducted randomized controlled trial comparing the effect of SO in treating retinal detachments. The evidence from the Silicone Study did not reveal any significant differences between SO and  $\text{C}_3\text{F}_8$ . While  $\text{SF}_6$  was found to be inferior to both within the first year of the study, the differences diminished towards the end of the second year of follow-up. The reviewers pointed out that at the time of the Silicone Study, only SO of 1000 cSt was used, while currently, SO of other viscosities (i.e., 1300/5000/5500, etc.), is available. Perfluorocarbon liquids (PFCLs) were only introduced later during the Silicone Study, hence most subjects in the studies had surgery performed without the use of

PFCL.

Some relative indications for SO use in detachments with PVR remain controversial. In addition to the surgeon's preference, the patient's ability to comply with postoperative posturing, and the need for air travel shortly after surgery, are used as justifications for the use of SO. Relative contraindications for SO use include a deficient iris diaphragm (e.g., aniridia) that might predispose to keratopathy.

## **Giant Retinal Tears**

In giant retinal tears, the posterior flap of retina is independently mobile. It is because the edge of the posterior flap does not have any vitreous attaching to it. Therefore it has a tendency to slip posteriorly, especially when the extent of the tear is  $>90^\circ$ . Traditionally, the role of SO in managing giant retinal tears is twofold: (1) to unroll folded retina and (2) to act as an extended internal tamponade agent. With the introduction of PFCLs,<sup>58</sup> unfolding the retina is easier.

The principle of surgical repair is to reattach the retinal detachment without slippage or exposing a large area of RPE. With the help of PFCLs, folded retinal flaps are unrolled and repositioned. Endophotocoagulation is then performed along both edges of the tear. This is followed by either a PFCL–SO exchange,<sup>127</sup> or a PFCL–air exchange and air–SO exchange. It has been shown that PFCL–SO exchange reduces the risk of slippage during the exchange process.

The use of SO in giant tears without PVR remains controversial. In Europe, SO remains the agent of choice, while in the United States some still prefer intraocular gas. Good anatomic success with either SO or gas has been reported.<sup>128</sup> In particular, a 100% success rate with SO was reported by Leaver and Lean.<sup>129</sup> To date, there are still no randomized controlled trials to compare the outcomes between SO and gas. The authors prefer SO to gas when the patient cannot posture or when the tear is more than  $90^\circ$  in size, especially when it involves the inferior retina.

## **Severe Proliferative Diabetic Retinopathy**

In Europe, SO tamponade is frequently used at the primary

vitrectomy for traction retinal detachment associated with severe proliferative diabetic retinopathy (PDR).<sup>130</sup> However, there are still no randomized controlled trials in this regard to address its efficacy and outcomes. While the main drawback is the need for a second operation to remove it from the eye, SO has several theoretical advantages if used as a tamponade agent following vitrectomy. It enables rapid visual recovery; it reduces postoperative vitreous hemorrhage and allows clear visualization of the fundus during examination; it may provide better tamponade for those who cannot posture after operation.<sup>131</sup> Because SO occupies most of the vitreous cavity, it potentially confines all dissolved oxygen in the anterior segment. It also prevents vascular proliferative factors in the posterior segment from coming anteriorly. This can be beneficial in cases of severe PDR where anterior segment neovascularization is prominent, especially during the postoperative period.<sup>132,133</sup> In a series of 18 patients with anterior proliferation and anterior segment neovascularization, vitrectomy with SO infusion stabilized the neovascularization in 83% of eyes, and achieved retinal attachment in 56%.<sup>133</sup> As a general rule, injection of SO should only commence after hemostasis has been achieved and most, if not all, preretinal blood has been aspirated. This reduces the risk of proliferative changes after the surgery.

## **Macular Hole**

Traditionally, vitrectomy with or without internal limiting membrane (ILM) peeling, followed by internal tamponade with either gas or SO, combined with postoperative face-down posturing has been the treatment of choice for idiopathic macular holes. It was believed by some that mechanical force generated by the tamponade agent and posturing would be helpful in closing the hole. In an early study by Goldbaum and associates, an 80% closure rate on first operation was achieved with vitrectomy and SO tamponade. This figure went up to 92.5% with two operations.<sup>134</sup> However, a later trial by Lai comparing the efficacy in closure rate with either gas or SO as tamponade after vitrectomy revealed a lower closure rate with SO.<sup>135</sup> Due to the differences in results, gas has grown in popularity as the agent of choice.

The current focus has shifted to looking at the efficacy of ILM

peeling, choice and duration of gas tamponade, and need for postoperative posturing.<sup>136-139</sup> A recent study using spectral-domain optical coherence tomography (OCT) to capture hole closure showed that following vitrectomy with ILM peeling and gas tamponade, 77% closure rate was achieved as fast as on postoperative day 1.<sup>140</sup> Another similar study yielded a 90% closure rate on postoperative day 1.<sup>141</sup> This supports the idea of using a gas with shorter intraocular longevity such as air, and obviates the need for posturing. A recent meta-analysis failed to show any significant benefit for extended posturing after surgery, in terms of closure rates.<sup>142</sup> One of the determinants of success rate seems to be hole size. For holes smaller than 400  $\mu\text{m}$ , the lesser algorithm can be applied, namely shorter-acting gases, no posturing, and no need to peel the ILM. With the success of gas tamponade and posturing in the repair of idiopathic macular holes, the role of SO has diminished. Nevertheless, it could still be considered for those who need to travel by air shortly after surgery.

The situation regarding reoperation is less clear. Virtually all series report a reasonable success rate (range 70–80% closure rates) with gas. Some reported up to 100% with the use of heavy tamponade agents,<sup>143</sup> while others have shown less consistent results.<sup>144</sup> It has been shown in a large series that closure rate after reoperation for holes that never closed was far worse than for holes that reopened. It is recommended, for holes that are large and which failed to close with the first operation, that a thorough discussion with the patient is needed, regarding visual expectation and the likelihood of success with further operations.<sup>145</sup>

For retinal detachments associated with macular holes in pathologic myopia, the current trend is to perform vitrectomy with an intraocular gas tamponade. Satisfactory anatomic successes have been achieved with this approach.<sup>146</sup> We performed a prospective case–control study with a double-peel technique, employing triamcinolone (TA) and trypan blue (TB) to assist removal of the adherent cortical vitreous and ILM, respectively. Reattachment rate of 70% was achieved in the study eyes, compared with 44% in the controls, where no staining was used.<sup>147</sup> There has been more evidence to support the use of SO as a primary tamponade agent for macular hole detachments associated with high myopia. Chen

compared the results of 57 cases performed with either gas or SO as tamponade agent. The reattachment rate was in favor of using SO.<sup>148</sup> In another study by Nishimura and associates, 100% reattachment rate was achieved with SO, as primary tamponade following vitrectomy.<sup>149</sup> A prospective randomized controlled trial should be conducted to compare the efficacies of gas versus SO in these cases.

## **Viral Retinitis**

The nature of retinal detachment associated with viral retinitis tends to be diffuse, relentless, and have a high redetachment rate.<sup>150</sup> These are commonly due to cytomegalovirus (CMV) retinitis, as seen in immunocompromised patients, or due to acute retinal necrosis (ARN) associated with herpes simplex type 1.<sup>151</sup> Necrosis of the retina gives rise to large areas of retinal defects that lead to the detachments. Under these circumstances, SO offers long-term, sometimes permanent, internal tamponade, and reduces the risk of redetachment. Azen and associates conducted a prospective observational multicenter study to evaluate the first operational anatomic success rates of using vitrectomy and SO tamponade for CMV-related retinal detachments. At 6 months after surgery, 78% remained attached with this method.<sup>152</sup> In a series with detachment related to ARN, vitrectomy and SO tamponade yielded 100% anatomic success rates.<sup>153</sup> These are anecdotal cases. There are variations in individual presentations, and speed of progression. Response also depends on how promptly intervention is given.

Most patients with CMV retinitis are immunocompromised, usually associated with acquired immunodeficiency syndrome (AIDS). These patients tend to be relatively young and they usually have clear crystalline lens at the time of retinal detachments. Tanna conducted a retrospective cohort study to investigate the incidence of cataract among those that required vitrectomy and SO tamponade. Results showed an estimated median time to cataract formation of 1.8 months after retinal detachment repair with SO. Adjusted relative risk when compared with eyes that did not require retinal detachment repair was 6.74 (<.001). Following phacoemulsification for cataracts, subjects developed posterior capsular opacification at a median time of 7 days only.<sup>154</sup> Results

suggested that clear lens extraction in these patients at the time of retinal detachment repair with SO tamponade may be beneficial. This was later supported by a study by Engstrom et al., who carried out combined clear lens extraction and intraocular lens implantation with vitrectomy, and SO tamponade was performed on 12 patients with retinal detachment associated with CMV retinitis. Retinal attachment rate was 83% and median best corrected visual acuity raised from 20/75 before surgery to 20/50 after surgery.<sup>155</sup> Such a combined approach may be considered in cases of CMV retinitis.

When the eye is filled with SO after surgery, intravitreal injection of ganciclovir would be concentrated in the thin layer of fluid film between the SO and retina. Normal concentration of intravitreal injections would therefore be inappropriately increased. This would cause retinal toxicity and create undesirable effects.<sup>156</sup> An appropriate method is to insert a ganciclovir implant.<sup>157</sup> Ganciclovir implant has been proven to give comparable concentrations in both vitrectomized and nonvitrectomized eyes.<sup>158</sup> A recent study showed that by combining vitrectomy, SO tamponade, and ganciclovir implant insertion, 100% reattachment rate was achieved and 80% showed no CMV retinitis progression.<sup>159</sup> This would be a reasonable option in selected patients where retinitis is still active in the presence of retinal detachment. Otherwise, antiviral treatment would have to be given via the systemic route.

## **Complicated Pediatric Retinal Detachments**

Main indications of SO tamponade in the pediatric population are mainly retinal detachments associated with trauma, retinopathy of prematurity, congenital anomaly such as coloboma or optic disc pit, and myopia (see [Chapter 119](#), Surgery for Pediatric Vitreoretinal Disorders).

Wong and colleagues have published a method in which sequential use of conventional SO and Densiron, a heavier-than-water SO, has helped reduce the number of reoperations. Mean LogMAR visual acuity before surgery was 1.57 among 10 cases, and mean postoperative visual acuity was 0.82. In our series, visual outcomes were favorable despite the need to undergo multiple operations.<sup>160</sup>

## Retinal Detachments Associated With Choroidal Coloboma

Coloboma of the choroid is a congenital condition characterized by an area, usually inferonasal to the disc, devoid of retina, retinal pigment epithelium, and choroid. Retinal detachment in these eyes has a reported incidence of 23–42%.<sup>161,162</sup> As the area of detachment is adjacent to the disc, difficulties in exposure translates into poor surgical outcomes with scleral buckling approach.<sup>161,162</sup> In the past, radial explants to both the nasal and temporal edges have been applied. This sometimes resembles the Chinese character for “eight,” and has been referred to as such. Anatomic success rates of less than 60% only were reported.<sup>161,162</sup> With modern vitrectomy and SO tamponade, Pal and associates reported a long-term attachment rate of 88.1% at 6 months.<sup>163</sup> In their series, out of the 21 cases that underwent SO removals, only two experienced redetachment. This shows the effectiveness of vitrectomy and SO tamponade in managing these cases. The retinal breaks can overlie bare sclera, and achieving chorioretinal adhesion is not possible simply because there are no choroids for the retina to adhere to. Therefore the retinal breaks overlying the coloboma stay open. Some surgeons attempt to form a barrier by lasering the edge of the coloboma. This laser needs to be applied to the whole extent of the coloboma and may or may not be effective. For this reason, a number of children ended up with permanent SO. Lastly, with use of SO, hyperopic shift after surgery is very amblyogenic. Virtually all will need patching from the early postoperative period.

## Trauma

In severely traumatized eyes, internal tamponade with SO may help to flatten the retina and prevent hemorrhage, which is known to increase the risk of PVR formation.<sup>164</sup> In a series of 435 eyes with ocular injury, Spiegel and associates performed vitrectomy and SO tamponade as primary surgery within 24 hours in 13 eyes (3%).<sup>165</sup> These eyes had either retinal lacerations larger than 4 disc diameters, or persistent intraoperative bleeding, with or without retinal detachments. Mean follow-up was 28.7 months and 11 out of the 13 eyes achieved visual acuity 20/200 or better, with the highest

being 20/25. Removal of SO was performed in 11 of the 13 eyes at an average of 6 months and of those, two had recurrent PVRs. While standardization of trauma cases is difficult, the results of this study show that SO tamponade at primary repair of the injury is feasible and relatively reasonable visual outcome is achievable.

In a recent retrospective case series with 88 patients who suffered ocular injury with retinal detachment, Nashed and associates performed primary vitrectomy and SO tamponade within 8 hours of injury.<sup>166</sup> Proliferative vitreoretinopathy occurred in 44% of cases and redetachment was noted in 38% of all cases. Visual outcome was worst with globe rupture cases. Endophthalmitis occurred in 3.4% of cases. Nashed went on to conclude that frequency of endophthalmitis was relatively low and the development of postoperative PVR was avoided in most cases. This might have been the effect of SO in situ. In any case, the great variability in degree of injury makes it difficult to draw conclusions on the role and necessity of SO in these series.

## **Endophthalmitis**

Apart from acting as an internal tamponade agent, SO has been suggested to possess antimicrobial activity. Azad and associates performed a prospective randomized controlled trial, comparing the effect of vitrectomy with or without SO tamponade for posttraumatic endophthalmitis cases.<sup>167</sup> In cases where SO was used, vision achieved a level of 20/200 or better in 58% of cases (seven out of 12), versus only 8% (one out of 12) among those where SO was not used. In another study, Yan and associates performed vitrectomy and SO tamponade in 18 posttraumatic endophthalmitis eyes. Postoperative visual acuity increased in 83% of eyes.<sup>168</sup> In another recent case series, 108 consecutive eyes with bacterial endophthalmitis were randomly assigned to receive either vitrectomy and intravitreal antibiotic alone, or with silicone oil as tamponade. The overall success rate with silicone oil was significantly higher than those without (67.3% vs. 43.4%,  $p=.01$ ).<sup>169</sup>

In the presence of SO, it is difficult to be certain of the correct concentration of antibiotic used. Using magnetic resonance imaging, we have shown that an aqueous bolus of antibiotic gets outside the oil bubble relatively quickly and joins the retro-oil

aqueous film. This film of aqueous is usually very small. Hence the concentration of the antibiotic would be higher than expected. One way to ensure correct dosing is to carry out a fluid–air exchange at the end of vitrectomy. Antibiotics of the correct concentration are then used to fill the air-filled vitreous cavity, before SO is injected. This maneuver ensures that a toxic dose of drugs is not administered.

## **Surgical Techniques of Silicone Oil Infusion**

### **General Considerations**

Although surgical techniques involved in SO infusion varies considerably between surgeons, the principles behind how SO behaves as a tamponade agent remain constant. Physical properties of SO such as interfacial tension, specific gravity, and viscosity, which dictate how SO behaves, should be considered.

Commercially available SO has viscosities ranging from 1000 cSt to 5700 cSt. The lower viscosity SO (i.e., 1000 cSt) was used in the Silicone Study, while the 5000 cSt SO is the only SO approved by the Food and Drug Administration for intraocular use in the United States. Practical differences between SO of different viscosities are threefold: (1) difficulty in injection is higher as the viscosity goes up; (2) ease of removal is higher as the viscosity goes down; and (3) risk of emulsification. The tamponade effect appears to be similar among SO with different viscosities.<sup>170</sup>

It must be noted that the interfacial tension between SO and water is lower than that of gas to water. Hence, when the retina appears flat under air before SO infusion, the retina may still be elevated when SO is infused, and SO may migrate subretinally where traction is still present.<sup>171</sup>

Owing to the high viscosity of SO, high pressure is required to infuse it into the eye from its container (i.e., syringe). Generally, 5–10 mL of SO is sterilized and stored in a 20 mL syringe. The infusion could be made through either of the two open sclerotomies. The syringe is first connected to an injection cannula, which can be either metal or plastic. Syringes with a Luer-lock are preferred, as they are more secure under high injection pressures. Short metal injection cannulas can be used as they are, while

plastics ones should be cut short for use. As flow is inversely proportional to its length, injection can also be done via the infusion cannula. The cannula should also be short and rounded to avoid leakage or breakdown during injection.

Injection can be done either with an automated pneumatic pump or manually. Most surgeons now prefer using an automated infusion pump, connected to the SO-containing syringe. This has the advantage of being faster and allows more surgeon-control through a foot pedal-controlled system. The disadvantage of this system is that there is no pressure-feedback mechanism, hence a risk of over- or underfill exists and is dependent on the surgeon's experience. Surgeons are advised to monitor the intraocular pressure digitally during the process. An IOP of around 10 mmHg is desirable at the end of the surgery. Fluid is incompressible, and the sclera is relatively inelastic. A slight overfill can give rise to an exponential rise in IOP. Rupture of the globe, collapse of the AC in the presence of a phaco wound or prolapse of the iris can result from an accidental overfill.

## **Considerations of Lens Status**

In phakic eyes, practical concerns regarding the lens arise when SO tamponade is required. These include whether to remove the lens, and whether to implant an IOL. If the primary pathology is posterior, the lens can be left alone. Some believe that leaving the eye phakic would enhance the tamponade effect of the oil to the superior and inferior retina. Cataract invariably occurs following SO tamponade, even if SO is removed shortly after surgery (i.e., 6 weeks).<sup>172</sup> In this regard, many surgeons prefer removing the lens at the same sitting. Rendering the eye pseudophakic facilitates vitreous base dissection and shaving. Phacovitrectomy is commonly the standard approach by retinal surgeons in most countries except in the United States, where the referral pattern discourages retinal specialists from carrying out phacoemulsification themselves. A combined effort between cataract and retinal surgeons is sometimes practiced. Alternatively, some retinal surgeons still use lensectomy, perhaps preserving the anterior capsule for subsequent secondary lens implantation. Rendering the patient totally aphakic is unacceptable as it would

increase the risk of oil keratopathy even if an inferior peripheral iridectomy was performed. Retention of the anterior lens capsule has also been reported to reduce complications related to either gas or SO use, and can maintain a normal iris appearance.<sup>173</sup>

An IOL made up of polymethyl methacrylate (PMMA) or acrylic should be used to avoid the risk of undesirable adhesions of SO to the IOL. When this happens, the patient becomes very symptomatic. The adherent oil droplet gives rise to often high refractive error. High and irregular astigmatism cannot be fully corrected by spectacles. Monocular diplopia, polyopia, blurred and distorted vision will render the patient symptomatic.

## **Silicone Oil Infusion in Small-Gauge Vitrectomy Systems**

With the advent of sutureless small-gauge vitrectomy systems, such as the 23G or 25G systems, the possibility of SO tamponade in conjunction with these systems has been explored.<sup>174-178</sup> Kapran and associates reported the use of a 25G transconjunctival sutureless system in removing silicone oil. Mean removal time required was  $8.93 \pm 0.85$  minutes.<sup>175</sup> In another series by Lewis, no difference was noted when using 20G, 23G, and 25G systems.<sup>176</sup> For the 25G vitrectomy system, Riemann and associates reported their success in infusing both 1000 cSt and 5000 cSt SO in 35 patients who underwent 25G vitrectomy.<sup>177</sup> Due to the unavailability of a 25G cannula at the time of the study, SO infusion was done using a 24G angiocatheter. In their series, SO of both 1000 cSt and 5000 cSt were used and the authors trimmed the angiocatheter to 4 mm in cases where 5000 cSt SO was used, to speed up the injection process. No difficulties were encountered, and this was supported by a later study by Altan et al.<sup>178</sup> Altan and associates injected 1000 cSt in 14 patients undergoing 25G vitrectomy, using a 25G cannula designed for SO infusion (Polytip-VFI, MedOne, Sarasota, FL). No difficulties were encountered during the infusion process. With the increase in popularity of small-gauge vitrectomy systems, and the advent in instrumentation correspondingly, the future trend is to combine the use of SO with these systems. All these injection techniques involve using short cannulas. The time taken for injection would be longer because the flow is inversely proportional to the 4th power of the

radius of the cannula.

The newly introduced SO with high-molecular-weight additives (HMWA) have been shown to be easier to inject and remove. The reason is physical. For instance, Siluron 2000 is a mixture of 1000 cSt SO with 5% 423 kD PDMS. The HMWA increased the shear as well as extensional viscosities. The shear viscosity is around 2000 cSt, however, under extensional flow (i.e., when forced to flow through a narrow cannula), the PDMS macromolecule unfolds and lines up with the flow. In this state, the flow rate is increased. Effectively, when it comes to injection or removal, Siluron 2000 behaves much like SO with 1000 cSt.

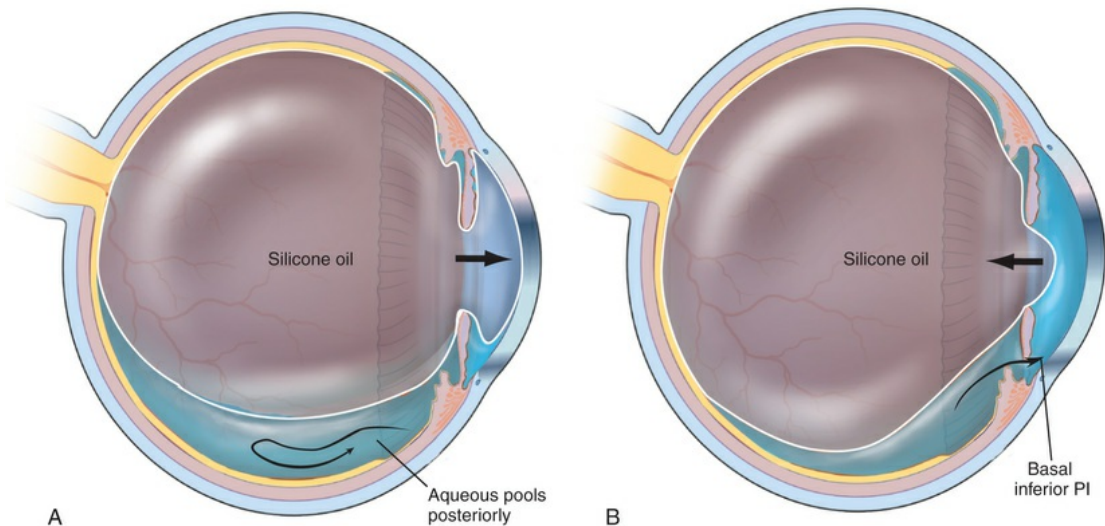

### **Air–Silicone Oil Exchange**

This is commonly done towards the end of surgery, when air–fluid exchange has been performed. At this point, the retina should be flat under air, with no or minimal SRF. The presence of fluid inside the vitreous cavity predisposes to underfilling of SO. Endolaser photocoagulation should have been performed to seal all retinal breaks. Injection of SO is then carried out, with the injection cannula inserted through either of the two open sclerotomies. The illumination should be withdrawn after the initial gush of SO has been infused. This allows air inside the eye to escape through the vacant sclerotomy, as SO is being filled progressively. To ensure a good fill of SO, the vacant sclerotomy should be maneuvered to the most independent position such that no bubbles will be trapped when SO fills up to the sclerotomy internally. The endpoint of SO infusion is either when it fills up to the vacant sclerotomy – SO is seen filling the infusion tube from internally – or when it reaches the iris plane in aphakic eyes. In pseudophakic eyes a sign that signifies near complete fill is when the enlarging SO bubble touches the undersurface of the posterior capsule, which can be seen easily under the microscope ([Fig. 108.16](#)). The IOP should be normal, or at around 10 mmHg at the end of surgery, otherwise overfill is likely. Overfill prevents the normal egress of aqueous from the posterior chamber anteriorly and predisposes to shallow AC and intractable IOP rise. Therefore, if IOP tends to be on the high side, some SO should be expressed through the sclerotomies passively until the pressure is normalized to around 10 mmHg.

**FIG. 108.16** Silicone oil (SO)–air exchange. This is the most commonly performed technique. Air–fluid exchange has to be performed prior to this procedure. Adequate drainage of subretinal fluid has to be ensured prior to instilling SO.

In pseudophakic eyes with a posterior capsulotomy or zonular dehiscence, migration of SO into the AC is frequent, and can sometimes be troublesome. Droplets of SO can be aspirated using an irrigation and aspiration cannula, and if this fails, viscoelastic materials can be injected into the AC to displace the SO posteriorly. In aphakic eyes, an inferior peripheral iridectomy (Ando's PI) needs to be done.<sup>179</sup> This prevents pupil block by the SO droplet and allows a passageway for aqueous to egress through the pupil plane (Fig. 108.17). This is easily performed by first placing the tip of the vitreous cutter under the iris at the desired position, followed by active suction. This creates a dimple on the iris. If positioning is correct, the cutter is activated to create an opening. If the position needs adjustments, suction is released and suction at another site is applied.

**FIG. 108.17** Mechanism by which an inferiorly placed peripheral iridectomy can prevent pupil block glaucoma and silicone oil migration into the anterior chamber. *PI*, peripheral iridectomy.

## Perfluorocarbon Liquid–Silicone Oil Exchange

This technique is useful in cases where there is significant risk of slippage.<sup>58,180</sup> Slippage occurs when aqueous is displaced posteriorly by an incoming air bubble. To prevent this, the objective is to get rid of any residual aqueous in the vitreous cavity. First, a PFCL–fluid exchange has to be done. PFCL is injected via one of the ports, while the other port is left vacant, until the eye is almost full. With the PFCL cannula still inside the eye, the infusion of balanced salt solution (BSS) is switched off. This is done by disconnecting the infusion at the three-way tap so that the infusion is now opened to the atmosphere. Then, more PFCL is injected to maintain a normal IOP. As the infusion is open to the atmosphere, any excessive PFCL would displace the aqueous in the infusion tubing between the eye and the three-way tap. Next, a flute needle is inserted via the open port to extract every last drop of aqueous. The whole eye, including the infusion line, is now free of aqueous, and filled with PFCL. The three-way tap can then be switched to continuous air infusion.<sup>66</sup> Following this, a leisurely direct PFCL–air exchange can now be carried out in full confidence that slippage cannot occur, as there simply is no aqueous in the whole system. This could be followed by SO infusion into the air-filled eye, with the technique mentioned

above.

Equally, a direct PFCL–SO exchange could be done. A flute needle is held in one hand, while the other takes the syringe containing the SO. An independent light source is required, because both sclerotomies will be occupied. This could be achieved using an illuminated infusion, or a separate chandelier illumination system.<sup>181–187</sup> Alternatively, SO could be infused through the infusion, such that both sclerotomies are occupied by the light-pipe and flute needle. When active infusion of SO begins, PFCL will be extruded passively through the flute needle (Fig. 108.18). The PFCL–SO interface could be visualized as the PFCL bubble shrinks in size. The tip of the flute needle has to be buried in the PFCL bubble during the whole process. As the PFCL bubble gets progressively smaller, it is often difficult to maintain the tip of the flute needle in the PFCL bubble. If this occurs, SO can block the flute needle. If SO is continuously being infused with the flute needle being blocked, IOP can rise quickly. Therefore it is vital to also monitor the perfusion of the central retinal artery during the process. When all PFCL has been aspirated from the eye, proper filling of the eye with SO should be judged, and the wound closed according to the principles described above.

**FIG. 108.18** Silicone oil (SO)–perfluorocarbon (PFCL) exchange. This method is particularly useful when the risk of slippage is high. Technique of “over-filling” of perfluorocarbon liquid during PFCL–SO exchange. This method effectively eliminates all aqueous from the system. The “sandwich” technique is used to squeeze subretinal fluid into the vitreous cavity for drainage. (A) Overfilling of the entire eye with PFCL ensures removal of all aqueous and prevents slippage. (B) After overfilling of PFCL has been achieved, the eye is filled with silicone oil from anteriorly. A flute needle aspirates PFCL as more SO is being injected. This prevents slippage of retina.

It has been shown that for giant retinal tear or 360° retinotomy, a direct SO–PFCL exchange is less likely to cause slippage.<sup>66</sup> Both SO and PFCL are hydrophobic and prefer to be in contact with one and other. Once joined, the two liquids form a single bubble and exclude aqueous from the interface. This bubble initially would have a specific gravity greater than water. For example, if 1 mL of SO was used to join with 4 mL of PFCL, the resultant bubble would have a specific gravity of  $(1 \times 0.97 + 4 \times 1.94)/5 = 1.75$  (assuming that the PFCL used has a specific gravity of 1.94). Importantly, the aqueous is displaced anteriorly and laterally towards the sclerotomies, where it might be expelled out of the vitreous cavity.

The important features of this technique are: (1) PFCL is filled as full as possible to expel as much aqueous before the exchange; (2) as oil is injected, an instrument should be passed from the SO into the PFCL to promote contact between the two liquids such that they join to form a single bubble. Slippage does not occur because during the initial stage of the exchange, the single bubble formed by the SO and PFCL is effectively a heavier-than-water bubble.

## Complications

### Silicone Oil in the Anterior Chamber

This occurs in cases where the barrier at the level of the lens–iris diaphragm is inadequate to stop SO from migrating into the AC.

This can be due to aphakia, loose zonular support, blockage of the inferior peripheral iridectomy, or a break in the posterior capsule. SO in the AC can occur either during surgery or in the postoperative period. When the AC is completely filled with SO, it can be undetected, because there is no fluid meniscus present. Confirmatory signs of an AC completely filled with SO include a slightly posterior bulging iris, shimmering reflex on the iris crypts, and absence of aqueous flare in the AC. The pupil can also appear mid-dilated with a raised IOP. The cornea is often perfectly clear, because the AC is totally filled with SO, and hydration of the cornea is not possible. Corneal edema may ensue if SO is later removed and significant damage to the corneal endothelium has occurred.

The SO can be displaced back into the vitreous cavity at the end of the surgery with air or viscoelastic agents. An inferior peripheral iridectomy needs to be done, and the patient should be postured upright or slightly face-down. Any small bubble of SO in the AC would empty itself into the large bubble behind in the vitreous cavity, if they were allowed to join. This is because Laplace's Law states that smaller bubbles have higher surface energy compared with larger bubbles. If a small bubble in the AC fails to reunite with the larger bubble behind and is not causing any complications, it can be left in situ.

SO can egress into the AC in a pseudophakic or phakic eye during surgery. This signifies the inadequacy in the barrier effect of the lens–iris diaphragm, zonular dehiscence, or a defect in the posterior capsule. This can sometimes occur as a result of overfilling of the eye with SO. It is therefore important to leave the eye normotensive to avoid overfilling. Attempts could be made to displace the SO droplets back into the vitreous cavity using viscoelastic agents. Routine inferior peripheral iridectomy in pseudophakic eyes is unnecessary.

During the postoperative period, SO migration into the AC sometimes occurs. This is due to either an inadequate lens–iris diaphragm, or a nonpatent inferior peripheral iridectomy. Blockage of the peripheral iridectomy frequently occurs if there was extensive surgery involving retinotomies, 360° photocoagulation, and extensive cryotherapy. If left alone, it can cause visual disturbance, induce corneal endothelial cell loss, and trabecular

damage. YAG laser is usually ineffective in reopening the iridectomy. Some surgical maneuver is usually needed. If the amount of SO is small, it could be displaced posteriorly through the pupil by injecting viscoelastic agents into the AC. Viscoelastic agents could also be injected through the iridectomy to keep it patent. Occasionally, the patient needs to be taken back to the theater for SO removal and reinjection.

Late migration of SO into the AC is commonly due to recurrent detachment or hypotony. Hypotony is usually caused by a combination of ciliary body shutdown and overdrainage by the uveal-scleral pathway (especially where large retinotomies have been done). Conservative management is appropriate. Heroic surgeries to dissect the vitreous base seldom yield satisfactory outcomes.

## **Glaucoma**

Rise in IOP after surgery with SO can be grossly divided into: (1) pupil block glaucoma; (2) overfill of SO; (3) secondary open angle glaucoma; (4) migration of SO into the AC; (5) secondary angle closure glaucoma.

Pupil block glaucoma occurs in an aphakic eye, usually during the early postoperative period, where the peripheral iridectomy is nonfunctioning. This could be due to closure of the peripheral iridectomy, which has a reported incidence of up to 33%,<sup>184</sup> or due to blockage by inflammatory products such as fibrin or blood. When the peripheral iridectomy is nonfunctioning, aqueous accumulates behind the iris and forces the SO bubble through the pupil. Pupil block results when this phenomenon progresses. Treatment involves reopening the peripheral iridectomy, either with a YAG laser or surgically.<sup>179,185</sup> If the cause is a blockage by fibrin or clot, injection of tissue plasminogen activator (tPA) into the AC has been reported with successes.<sup>186</sup>

If the cause of IOP rise is due to overfill of the eye with SO, the AC will appear shallow. In the aphakic eye, the AC can be so shallow that there could be secondary angle closure. In the pseudophakic or phakic eye, an overfill can result in oil coming in front of the crystalline or intraocular lens, and herniating through the pupil.<sup>187</sup> In the aphakic eye, overfill can be treated with removal

of oil via a corneal or pars plana incision. Care must be taken to ensure that the peripheral iridectomy is patent. In the pseudophakic or phakic eye, removal of the oil from the posterior segment may not be sufficient once the oil is trapped between the lens or intraocular lens and the iris. Its evacuation is difficult, and the patient may need to be taken back to theater for complete evacuation of the oil and reinjection. To avoid overfilling, pressure should be normal at the end of surgery. This applies especially if encircling or scleral buckling is applied after SO injection. The explant or the suture may store elastic energy, creating intractable glaucoma, unless the oil is removed. To avoid overfilling, pressure at the end of surgery should be at its most normal.

Secondary angle closure glaucoma is a diagnosis of exclusion. Care must be taken to ensure that the peripheral iridectomy is patent, and there is no oil in the AC, and no oil is trapped between the iris or crystalline lens and the iris. Some patients may have raised IOP in the fellow eye or a tendency to have glaucoma in the affected eye. They may present with normal IOP in the presence of a retinal detachment. However, when the retina is reattached, angle closure glaucoma may become apparent. The cause of secondary open angle glaucoma associated with SO could be due to mechanical blockage of the trabecular meshwork, or trabeculitis induced by emulsified SO (Fig. 108.19).<sup>188</sup> Medication comprises the initial treatment. If IOP continues to rise, glaucoma surgery in the form of drainage device is preferable over trabeculectomy. One of the reasons why trabeculectomy gives rise to failure is thought to be fibrosis; SO under the conjunctiva is known to cause periorbital fibrosis involving foreign body giant cell reaction (Fig. 108.20). A simple unguarded trabeculectomy or drainage device without a valve, or even an ill-fitted valvular implant, can easily overdrain in these cases, in the absence of vitreous, instead of showing simply a shallow AC. The absence of vitreous in the posterior segment means that the whole eye can collapse. Massive suprachoroidal hemorrhage is a devastating complication. In the Silicone Study, 8% of cases that underwent SO tamponade experienced glaucoma at the 36-month follow-up (2% for intraocular gas;  $p < .05$ ).<sup>189</sup> In a series by Al-Jazzaf and associates, the incidence of secondary glaucoma was 11% among 450 eyes that underwent vitrectomy and SO

tamponade. Among the 51 eyes that developed secondary glaucoma, 78% (40 eyes) were successfully treated with medication only, while 22% (11 eyes) required a glaucoma drainage device (Ahmed glaucoma valves were used).<sup>190</sup> Effectiveness of drainage devices in lowering IOP in this regard has been well documented,<sup>191</sup> although failure rates were found to be higher in these cases when compared with cases without history of vitrectomy and SO tamponade.<sup>192</sup>

**FIG. 108.19** Gonioscopic picture of emulsified silicone oil at the superior angle.

**FIG. 108.20** Silicone oil globules trapped under the

conjunctiva.

Some also suggested that simply removing the in situ SO would be beneficial in terms of IOP.<sup>193</sup> Budenz and associates compared the surgical outcomes among 51 cases of secondary glaucoma due to SO tamponade.<sup>194</sup> In their series, three options of surgical approaches were adopted: removal of SO alone, glaucoma drainage device alone, and combined glaucoma drainage device with SO removal. Results showed that all three approaches were effective in lowering IOP, but risk of reoperation due to uncontrolled IOP was more likely among those who had SO removal alone; and when combining SO removal and glaucoma drainage device, risk of postoperative hypotony was more likely. Jonas concluded that this type of secondary glaucoma is reversible upon removal of the in situ SO, based on results from their series.<sup>195</sup> Flaxel and associates, on the other hand, reported that IOP remains elevated in all eyes even with SO removal.<sup>196</sup> In our experience, IOP remains elevated in most patients, even with SO removal. This may be due to the problem of incomplete removal of SO from the eye, especially those trapped within the trabecular meshwork. If damage has already been made to the trabecular meshwork, and scarring has already set in, removal of SO at a later stage may not bring about an IOP-lowering effect.

In refractory cases, transscleral cyclodiode photocoagulation (TSCP) could be used to lower IOP. Ghazi-Nouri and associates achieved sustained IOP-lowering effects up to at least 1 year with this treatment.<sup>197</sup> This was in accordance with a similar study by Han.<sup>198</sup> Some advocate TSCP as a first-line treatment in all cases of open angle glaucoma associated with SO use.<sup>199</sup> Until recently, there have been reports suggesting that the IOP-lowering effect of TSCP may not be sustainable.<sup>200</sup> While the controversy goes on, TSCP remains a reasonable option in refractory cases, especially those that have low visual prognosis and have already tried other options.

## **Chronic Hypotony**

This complication usually occurs during the late postoperative period. It is defined as having IOP  $\leq 5$  mmHg in the Silicone

Study.<sup>189</sup> This cutoff level is arbitrary. There are patients with IOP of <5 mmHg, yet the eye is relatively normal and healthy. Equally, there are patients with IOP above this level in which the eye is complicated with swollen optic disc, macular edema, and epiretinal membrane formation. The different clinical picture may be due to different mechanisms giving rise to hypotony. It is assumed that a low IOP may be a combination of increased aqueous uveal–scleral outflow and reduced production.

Large retinectomies are thought to be the cause of increased aqueous uveal–scleral outflow. Ciliary body alterations are thought to be the cause of reduced aqueous production. Nehemy and associates imaged the ciliary body with ultrasound biomicroscopy (UBM), in 44 eyes with chronic hypotony following vitrectomy and SO tamponade.<sup>201</sup> A total of 20 eyes with normal IOP after vitrectomy were used as controls. Results showed that none of the control eyes had ciliary body pathologies, whereas 98% (43 out of 44 eyes) of the study eyes had UBM-detectable ciliary body abnormalities. These include traction ciliary body detachments ( $n=16$ ); exudative ciliary body detachments ( $n=11$ ); combined traction detachment and atrophy of the ciliary body ( $n=7$ ); hypotrophy of the ciliary body ( $n=5$ ); combined traction and exudative detachment of the ciliary body ( $n=3$ ); and ciliary body edema ( $n=1$ ).<sup>201</sup> In the Silicone Study, prevalence of chronic hypotony following vitrectomy with SO tamponade was 18% at 36 months.<sup>189</sup> Prognostic factors included presence of preoperative hypotony, diffuse contraction of retina anterior to the equator, presence of rubeosis, and large retinal breaks.

Treatment of this condition has been disappointing so far. As suggested by findings on ultrasound biomicroscopy, residual membranes on the ciliary processes and ciliary body may cause hyposecretion of aqueous, as a result of traction and fibrosis. Reoperation with further excision and dissection of membranes over the ciliary body has been suggested as a treatment option.<sup>202</sup> The results are usually disappointing. Removal of SO risks the progression to phthisis, hence hypotony with IOP <10 mmHg is a relatively contraindication to SO removal. Finally the measurement of IOP in patients with uveal–scleral outflow should be done with care. With applanation tonometry, the IOP can appear to be high

initially. The act of appplanation and indentation causes an increase in uveal outflow. With repeated measurements, the IOP can come down to zero. These eyes are in effect hypotonic. Removal of SO would further increase the access of aqueous to the uveal–scleral pathway and promote phthisis. Hence, in these cases, the SO is preferably left in situ.

## **Cataract Formation**

Formation of cataract in phakic eyes undergoing vitrectomy and SO tamponade is multifactorial. Apart from the SO, cataract can also form as a result of vitrectomy or surgical trauma. Many early studies have provided evidences to suggest an association between long-term SO tamponade and cataract formation. The exact mechanism remains uncertain, although the possibility of impaired metabolic exchange across the posterior capsule and direct toxicity has been speculated. As with the case of gas tamponade, posterior subcapsular feathery lens opacity can be seen in the early postoperative period. A more specific early feature of SO-induced cataract is formation of lens vacuoles in the posterior part of the lens. Early posterior lens opacities may resolve and give way to nucleus-sclerosis. As with cataract formation associated with vitrectomy, nucleus-sclerosis associated with SO can occur with little or no brunescence. Finally, rapid progression to hypermaturity can occur with white cataracts. The lens swells up quickly over a matter of days, with leakage of protein into the AC and brisk uveitis. However, this usually resolves spontaneously with time. If SO is kept in situ for long-term tamponade purposes, cataract inevitably forms, which could be in the form of posterior subcapsular cataract or nucleus sclerosis. Although early removal of SO has been suggested to be beneficial in minimizing the risk of cataract formation, there are reports of cataract formation even with SO removal as early as 6 weeks following the surgery.<sup>203</sup> A practical question presenting to the surgeon is whether to remove the cataract, and if so, when to do so.

Cataract formation is inevitable when SO is used. Leaver and associates showed that in relatively young patients, cataract occurs with a follow-up of 2 years, despite early removal of SO. Some surgeons therefore prefer routine combined phacovitrectomy when

SO use is intended. The advantage is that a more complete vitrectomy, and therefore a better fill with SO, can be achieved. In phakic SO-filled eyes, a combined phacoemulsification with planned continuous capsulorrhexis of the posterior capsule, with in-the-bag implantation of the intraocular lens, can be an elegant and satisfactory approach.

Intraocular lens power calculations can be difficult without prior planning. It is recommended that, routinely, all patients undergoing vitrectomy and SO infusion should have B-mode axial length measurements done prior to surgery. SO in contact with the posterior surface of the intraocular lens would greatly reduce the refractive power. Most intraocular lenses have biconvex configuration. There are intraocular lenses specifically designed for the use of SO, with a concave posterior surface, such that the intended final correction will be correct even with SO in situ.<sup>204</sup>

With the introduction of PMMA and acrylic IOLs, the use of silicone IOLs has become less popular. Risk associated with silicone IOLs in eyes that have SO in situ is the formation of intractable adhesion of SO onto the surface of IOLs.<sup>205</sup> SO adherent to intraocular lens implant can give rise to blurred vision, polyopia, and distortion. To understand this, surgeons need to appreciate that the refractive power can be as high as  $-60$  diopters in some cases. The astigmatism present is often irregular and cannot be corrected by glasses. This occurs where there is a breach in the posterior capsule, such that SO comes into direct contact with the IOL. Adherent SO droplets can cause visual disturbance to the patient.<sup>206</sup> Removing these droplets has proved to be difficult.<sup>207</sup> Various techniques and solvents have been described to aid removal of these SO droplets.<sup>207-211</sup> In a recent laboratory study by Stappler and colleagues,  $F_4H_5$ , a hydrophobic semifluorinated alkane, was used to dissolve adherent SO droplets on IOLs.<sup>209</sup> With a simple immersion, over 91.4% of SO droplets were successfully washed off the surface of IOLs. Removal rate surged to over 93.7% with immersion time of over 1 minute. Following treatment with  $F_4H_5$ , the IOLs remained optically clear. Currently,  $F_4H_5$  is not available on the market. So effective is it in removing SO, undoubtedly it may represent a new treatment method for SO-related glaucoma. Other options using PFCL, methylcellulose, and mechanical scrubbing

with sponges are all clumsy and traumatic compared with the use of an appropriate solvent. Furthermore, intraocular lens exchange seems unnecessary when the droplets can be washed away with  $F_4H_5$ . In a recent in vivo study of 72 patients undergoing vitrectomy for macular holes requiring the use of silicone oil, Stalmans and colleagues compared the outcome of removal of silicone oil from the eye either with or without the use of  $F_4H_5$ . There were no major complications encountered, and the group that used  $F_4H_5$  had marginally less silicon oil droplets left.<sup>212</sup>

With ultrasound biometry, measurements of axial lengths in SO-filled eyes may be affected by differences in the speed of sound wave in vitreous and SO. The speed of sound wave in SO is 986 meters per second (m/s), and that in vitreous fluid is 1552 m/s. Hence, if an eye is filled with SO, the time taken for the sound wave to return to the receiving sensor is longer than when the same eye is filled with vitreous. The resulting axial length may be falsely long, which would cause a hyperopic shift if the uncorrected measurement were used for IOL power calculation. Care must be taken, as specific SO-formulae are used when the eye is filled with SO. Furthermore, impurities within the SO bubble, and underfilling of SO may cause disturbances to the signal when using ultrasound biometry.<sup>213</sup> In a recent study, immersion B-scan guided ultrasound biometry has been found to perform better as compared to contact A-scan biometry in SO-filled eyes.<sup>214</sup> A “conversion factor” of 0.71 has been found to give good accuracy with a mean of only 0.74 diopters difference between the predicted and actual postoperative refraction.<sup>215</sup> While ultrasound biometry with special formulae are still the “gold standard” to measure axial lengths in SO-filled eyes, interests in using partial coherence laser interferometry (PCI) has grown.<sup>216–219</sup> A recent study by Parravano and associates showed that measurements of axial lengths were not significantly different before and after SO removal.<sup>219,220</sup> Unlike ultrasound, the speed of light is constant, and therefore unaffected by SO. Using infrared partial coherence interferometry, measurements in axial length could also be done. An additional consideration is that a myopic shift has been reported with the use of combined phacovitrectomy and intraocular lens implantation, with or without tamponade. The precise cause of this myopic shift is uncertain. Some feel that it is

important to slightly undercorrect the patient. However, its measurements are limited by the presence of corneal opacities or media opacities, such as band keratopathy and cataract, which are frequently present in SO-filled eyes. Further studies comparing the outcomes of measurements using ultrasound biometry and PCI need to be done.

## **Recurrent Retinal Detachment**

Silicone oil is not a panacea. Successful retinal detachment repairs rely on identification and closure of all causative retinal breaks. Missed retinal breaks give rise to recurrent retinal detachments, even in the absence of PVR, either with SO in situ or after SO removal. It is highly doubtful whether there is a state of total tamponade that can be achieved with SO fill; the evidence points to the contrary. A slight underfill with SO leaves a large area of the retina unsupported.<sup>23</sup>

Results from the Silicone Study showed that the rates of redetachment were not significantly different when comparing eyes randomized to SO or to gas use. Therefore, redetachment in this regard may not have a direct relationship with whether SO was used or not. Jonas and associates identified risk factors associated with redetachment after SO removal among 225 patients.<sup>221</sup> These include the number of previously unsuccessful retinal detachment surgeries, preoperative visual acuity, incomplete removal of the vitreous base, and absence of an encircling band. Method of SO removal and duration of SO endotamponade were independent of the rate of redetachment. In another study, Jonas found that the mean time taken from SO removal to occurrence of redetachment was 1.3 months.<sup>222</sup> If retina remains flat 3–5 months after SO removal, redetachment becomes unlikely. Preoperative examination to identify all breaks and meticulous removal of all tractional membranes and retinectomy if necessary, are the keys to ultimate anatomic success and the reduction of redetachment in this regard.

In a prospective randomized trial, Avitabile and associates examined the potential benefit of prophylactic 360° laser in cases where there is a need for SO tamponade. Prophylactic 360° laser was done in 151 study eyes, while no laser was done in 152 control eyes. Redetachment occurred in 8.63% among the study eyes, as

compared with 20.93% among the control eyes ( $p=.007$ ).<sup>223</sup> This was supported by a retrospective study by Falkner-Radler and associates, where a comparable redetachment rate of only 9% was seen when prophylactic 360° laser was done.<sup>224</sup> Another study by Laidlaw and colleagues showed that 360° laser can be performed before SO removal, which may probably reduce the risk of redetachment.<sup>225</sup> Hence, 360° laser as prophylaxis in high-risk patients could be considered, as an adjunct to enhance the chance of anatomic success after SO removal.

## **Emulsification**

Emulsification of SO is an inherent problem. Dispersion of SO is the breaking-up of large bubbles into smaller droplets. The surface energy of these smaller droplets is higher, and therefore they have a tendency to coalesce to form a larger bubble. Emulsification only occurs when surface energy of the droplets is reduced in the presence of surfactants. Surfactants may include phospholipid, protein, lipoprotein, or even solid cellular debris. Dispersion requires shear force between the oil and the retinal surface and is dependent on rate of eye movement. Normal saccadic velocity reaches 300–400/second. All intraocular fluid remains relatively stationary, while the eye moves. The peak shear velocity therefore approximates closely to the saccadic velocity of the eye. The shear force depends on this relative velocity, and also the thickness of the film of aqueous between the SO, and the surface of the retina. Although the thickness of this film of water has not been measured in vivo, when the SO fill of the eye is near complete, this film of fluid can be very thin. Correspondingly, the shear force to disperse SO would be very high.

It has been found that higher viscosity SOs tend to be more difficult to disperse. In vitro, the reason may be purely physical. The higher the shear viscosity, the higher the extensional viscosity (extensional viscosity is usually three times that of shear viscosity, depending on the shear strength). There is, however, little evidence that using oil beyond 5000 cSt, shear viscosity would be of any benefit. The reason is that there are many confounding factors, including the degree of blood–ocular barrier breakdown, the degree of inflammation, and the completeness of the oil fill. These factors

are individual to a particular patient, such that, occasionally, we see very early marked emulsification in an otherwise normal eye. There is, however, consensus that if SO is to be used as a permanent tamponade, SO of 5000 cSt should be used.

Emulsification can lead to glaucoma, inflammation, and PVR formation.<sup>152,226</sup> Emulsification can occur as quickly as 1 week after surgery, but the most common timeframe is a few months after surgery.<sup>227</sup> It was thought to be the combined result of friction between SO and other intraocular fluids, and a reduction in the interfacial tension as a result of absorption of active components from other intraocular fluid, that causes the emulsification process. Likelihood of emulsification of SO is inversely proportional to its viscosity.<sup>228</sup>

However, with the advent of small-gauge vitrectomy systems, the use of SO with lower viscosity has increased, mainly due to its ease in injection and removal through a smaller-gauge trocar. Williams and associates showed that by adding very-high-molecular-weight polymers to low-viscosity SO (1000 cSt), the rate of emulsification was successfully reduced.<sup>123</sup>

In a recent study on patients with macular holes requiring silicone oil tamponade, Siluron 2000 appeared to be equally effective and safe, when compared to the more stable alternative Siluron 5000. The result in terms of emulsification was rather similar but allowed for better handling with the potential for reducing procedure time.<sup>212</sup>

## **Keratopathy**

Prolonged use of SO is associated with keratopathy, either in the form of band keratopathy, which is more commonly seen in early stages, and bullous keratopathy in the late stages. Rate of keratopathy observed in the Silicone Study was 27% at the 24-month follow-up.<sup>229</sup> This was identical to the rate seen in eyes randomized to C<sub>3</sub>F<sub>8</sub>. Risk factors identified in the Silicone Study include: being pseudophakic or aphakic before surgery; the presence of iris neovascularization before surgery; postoperative aqueous flare, and the need for reoperation. Contact between SO and the corneal endothelium has been thought of as a major contributor to the development of keratopathy. Strategies in

minimizing the risk of keratopathy mainly involve reducing the chance of SO migration into the AC. This includes ensuring a patent peripheral iridectomy and removing the SO as soon as practical.

The increasing use of primary vitrectomy with intraocular lens implant ensures a more effective barrier to the egress of oil into the AC. Some surgeons feel that lensectomy and leaving the eye even temporarily aphakic is not such a good option. Efforts should be made to preserve an intact posterior capsule, until such time as when the oil is to be removed.

## **Unexplained Visual Loss Following Silicone Oil Tamponade**

The precise mechanism is unclear. The characteristic is that optical coherence tomography and angiography reveal no obvious explanation. Multifocal electroretinogram has showed only the foveal segment is involved. It can be speculated that it may be the sudden change in physiologic environment affecting ionic exchange. In a recent report, Scheerlinck investigated the contents in retro-oil fluid and paired serum from 16 patients undergoing oil removal. Results showed that the mean potassium levels in retro-oil fluid and vitreous humor were similar. However, the levels of magnesium and chloride were lower in retro-oil fluid compared with vitreous humour. Lactate dehydrogenase levels (LDL) were, on the other hand, higher in retro-oil fluid. This may make the potassium accumulation theory less likely. However, the differences in magnesium levels and LDL across the retro-oil fluid and vitreous humor may give hints to further research to find out the ultimate cause.<sup>230</sup> Moreover, during SO removal, the oil bubble, being spherical, may form a strong condensing lens, focusing the light from the microscope, albeit briefly. In fact, the mechanism is still obscure.

## **Silicone Oil Removal**

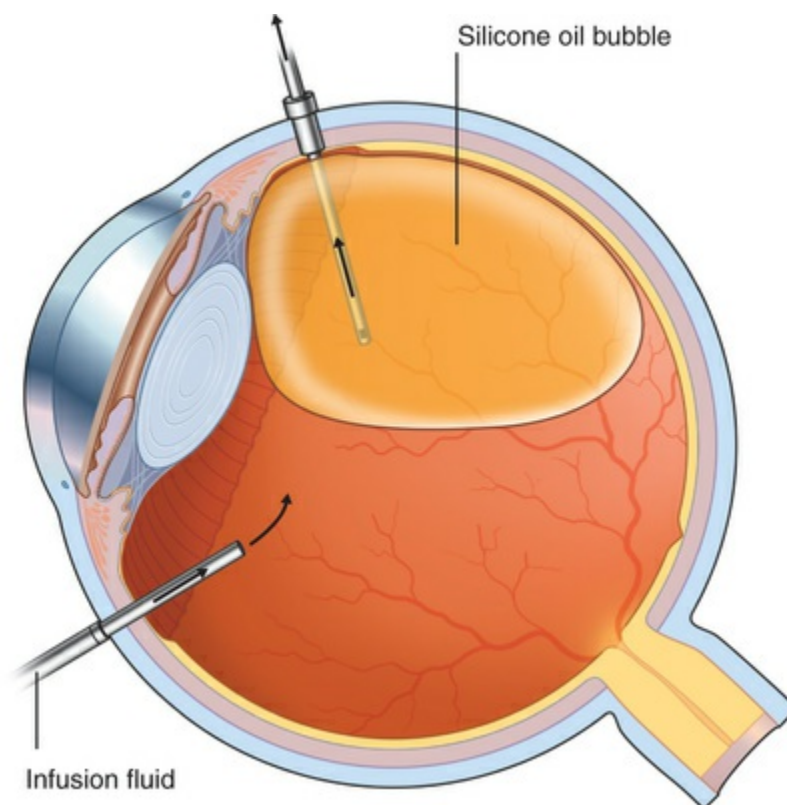

In practice, deciding when to remove SO is difficult. Theoretically, chorioretinal adhesion would have formed certainly by 1 month. However, SO is retained often longer than this, the rationale being that the presence of the oil and the tamponade force might resist

any traction caused by re proliferation. The precise duration of the re proliferating process is therefore less certain if the retina remains attached. The assumption is that the cellular process of PVR would naturally resolve. However, traction may not be clinically manifested. Hiscott and associates introduced the concept of isotonic and isometric contraction; when the retina is attached, epiretinal membrane can cause “isometric” traction, without any surface wrinkling of the retina to indicate the presence of such membranes.<sup>231</sup> It is only when the oil is removed and such traction causes detachment of the retina that this “isometric” contraction becomes manifested as fixed or star-folds. Deciding when to remove the SO and whether it is safe is very much a judgment call.

Removal should be performed when the SO bubble has served its purpose, and when further retention may increase the risk of complications related to its use.<sup>232</sup> In the Silicone Study, SO removal was allowed after a minimum of 8 weeks after surgery. Removal within the first 6 months after surgery is generally recommended. Various techniques have been described for the removal of SO from the eye.<sup>233–237</sup>

In general, an infusion must first be secured at the pars plana to allow saline to replace globe volume as SO is being aspirated. In an aphakic eye, either passive or active egress of SO through a corneal wound could be done. In a phakic or pseudophakic eye, some prefer a two-port system. While one port is used for the infusion, the other port is used for aspiration of SO. The port through which SO is egressed should be placed in the uppermost position because SO floats on top of the infusate (Fig. 108.21). After the removal of the oil, the same port can be used for internal search using a light-pipe combined with scleral indentation using wide-angle optics. Some surgeons feel it is important to do additional maneuvers. These may include removal of epiretinal membranes that might be present or a repeated fluid–air exchange to encourage a more complete removal of the SO. Aspiration of the SO should always be active. It should be understood that the maximum suction that can be generated is not limitless. Even if there were a total vacuum, the difference in pressure in driving the flow of oil out of the eye would be the atmospheric pressure plus the infusion pressure. Therefore, if passive aspiration were used, the aspirating pressure would be

the height of the infusion bottle (for instance 30 mmHg). However, if active aspiration was used, the vacuum driving the flow would be much higher (760 mmHg + bottle height of infusate). This is assuming that a perfect vacuum can be achieved. In fact, for most vitrectomy machines, a maximum aspiration of 600 mmHg is achievable. Another important consideration is the length of the aspirating cannula. Linear extrusion using a length of tubing between the machine and the eye simply does not work. Active aspiration has to be achieved close to the eye with a minimum length provided by a short cannula. In practice, SO injecting syringe drivers or manual aspiration can be used.

**FIG. 108.21** Technique of silicone oil removal with machine-assisted active suction. The draining sclerotomy has to be positioned in the most independent position.

Complete removal of SO is in fact seldom complete. Emulsified droplets adhere to the ciliary processes, zonules, and posterior aspects of the iris. They may only become obvious postoperatively and cause the patient to complain that when they put their head

down, these bubbles come near the line of sight. Emulsified droplets can sometimes adhere to cellular debris such that they are almost density neutral. They may often drift in the visual field giving the sensation of floaters. Multiple air–fluid exchanges has been suggested.<sup>233</sup> The idea is that any residual droplets would be forced to coalesce to form an “oil slick” on the surface of the fluid. However, whether this is effective remains in doubt.

During the removal of SO, it is important that the cannula stays within the main bubble. With aspiration, one could see a “vortex” developing within the oil. If the cannula comes out of the SO bubble, the individual bubble of oil can be isolated and left behind. Therefore, during surgery, the vortex should be closely observed, and the cannula manipulated such that it does not aspirate infusion fluid or come out of the oil.

It is common to use plastic cannulas for aspiration. Plastic, in general, has a greater affinity for SO. Silicone oil bubbles tend to adhere to the outside of the cannula, where they cannot be removed. The adherent oil can be scraped off the outside of the shaft of the cannula, and become free floating in the vitreous cavity, where it becomes difficult to catch. In these instances, a fluid–air exchange would allow easier removal of these droplets.

In cases where phacoemulsification is to be done at the same setting, a posterior capsulotomy could be made for SO removal. This is similar to the technique used in aphakic eyes. Pars plana infusion could be replaced by an AC-maintainer in this case, but the infusion bottle height has to be higher when an AC maintainer is used. In-the-bag intraocular lens implantation could be performed following removal of SO.

## **Permanent Silicone Oil Tamponade**

The decision to remove in situ SO can be affected by factors other than retinal attachment. In eyes that have low or no visual prognosis, when the risk of progression to phthisis cannot be ignored, or when the fellow eye is functioning well, SO could be kept in situ, given that no symptomatic complications have arisen. However, the pros and cons have to be discussed thoroughly between the surgeon and the patient, before arriving at such a decision. SO is used in the eye permanently for more than one

reason. Most frequently, it is because the motivation to remove the SO is not there. This applies to patients with poor visual prognosis. In other circumstances, low IOP deters both the surgeon and the patient. In many instances, patients are simply exhausted by having multiple surgeries. Some surgeons are persuaded against it by patients having only one eye and a bad history of redetachments and therefore, a long-term SO tamponade may be justified. However, close and long-term follow-up is mandatory in these patients.

## Conclusion

Silicone oil has proven itself to be an effective endotamponade agent, especially in the management of complex retinal detachments associated with proliferative vitreoretinopathy. SO is, however, not a cure-all. There are still many unanswered questions, including whether 5000 cSt SO is better than 1000 cSt SO; whether heavy SO has a role to play; whether high-molecular-weight additives can reduce the risk of emulsification; what is the mechanism for visual loss following SO use, and how long is the SO needed? Despite the fact that nearly three decades have elapsed since the Silicone Study, it remains the main evidence-based study that guides our practice today. The efficacy of SO has been proven in the Silicone Study, and it has been found to be equally effective when compared with  $C_3F_8$ . Despite its shortcomings, SO remains a very important and indispensable tool to the retinal surgeon. Both SO and  $C_3F_8$  have their relative advantages and disadvantages, and in the selection of tamponade agent for extended use, the decision should be made on a case-by-case basis. Fundamentally, anatomic success is reliant on the completeness of removal of tractional membranes, and the tamponade agent serves best as an adjunct to it, regardless whether it is SO or intraocular gas.

# The Concept of Heavy Tamponade

## Background

Conventional SOs all have a specific gravity of 0.97 at 25 °C, which is lower than that of water, hence they float. This results in a good tamponade effect to the superior retina, when the patient is in an upright position. However, tamponade effect to inferior retina is often less than ideal. A slight underfilled SO bubble would leave a large area of retina unsupported.<sup>23</sup> PVR has a predilection for the inferior retina. In this regard, a heavier-than-water tamponade agent has long been sought.

Fluorinated SOs developed in the 1980s, were associated with high rates of complications, which included the development of PVR and intraocular inflammation.<sup>238,239</sup> The use of perfluorocarbon liquids (PFCL) is now confined to short- or medium-term tamponade in selected cases, such as that in giant retinal tears.<sup>240</sup> In particular, the use of PFCL as intraocular tamponade has general acceptance in Australia. The main motivation for its use is said to be for the prevention of slippage. PFCL is usually left in the eye for 2 weeks, after which it is exchanged for either gas or SO. However, PFCL causes inflammation and emulsification when left in situ for any length of time, it is not universally accepted as a tamponade agent.<sup>241</sup> Yet another approach, known as the “doublefilling,” combining the use of SO and fluorosilicone oil,<sup>242</sup> SO and PFCL,<sup>243</sup> or SO with perfluorohexyloctane (F<sub>6</sub>H<sub>8</sub>)<sup>244,245</sup> have also been tried. This whole approach is deeply flawed. These liquids are all relatively hydrophobic, and they join to form a single bubble and exclude aqueous fluid from the interface between them. Effectively, they are simply heavier-than-water bubbles. They could not provide simultaneous superior and inferior tamponade. Instead, doublefilling would simply create a new aqueous compartment laterally and superiorly.<sup>242,246</sup> The rationale for their use remains controversial.

Whether retinal toxicity could be caused by the weight of heavy tamponade agents has also been a subject of controversy. In the case of PFCL, it has been suggested that perfluorocarbon liquid is

unsuitable as an endotamponade agent simply because of their high specific gravities. The orthodoxy says that it is the downward force on the retina that gives rise to the histologic changes observed. We have shown that force exerted by the heaviest PFCL amounts to 2–3 mmHg; it is the same order of magnitude as the diurnal variation in intraocular pressure. More importantly, in terms of force acting on the retina, the downward force by PFCL on the lower retina is no more than the upward force of any gas bubble acting on the upper retina.<sup>19</sup>

The semifluorinated alkanes and alkenes have a specific gravity of around 1.35 at 25 °C.  $F_6H_8$  was initially designed as a solvent for SO. The numbers 6 and 8 refer to the number of carbon atoms with fluorine attached (6) as opposed to the number of carbon atoms with hydrogen attached (8).  $F_6H_8$  was found to be well tolerated in rabbits, and it was later tested as a long-term internal tamponade in humans for inferior retinal breaks. Clinically, they have been used for up to 3 months as internal tamponade, but the marked emulsification, inflammation, and PVR were worrying complications.<sup>247</sup> Not all of the semifluorinated alkanes, however, are the same. Mackiewicz et al. have shown that some of the semifluorinated alkanes are more inert than others in rabbit eyes. They speculated that the ratio of the number of carbon atoms with attached hydrogen relative to the number of carbon atoms with attached fluorine might be an important determinant of toxicity.<sup>248</sup> Used on their own, semifluorinated alkanes with their low viscosities, readily disperse into small bubbles.<sup>247,249–251</sup> The authors speculate that these droplets could stimulate macrophage and foreign body giant cell reaction. The inflammation could in turn promote PVR.<sup>252</sup>

Semifluorinated alkanes or alkenes are amphiphilic. For example,  $F_6H_8$  has a straight backbone of carbon. The fluorinated end would be hydrophilic and the alkylated end would be hydrophobic, which means they could partially dissolve in SO. The solubility depends on the individual agent used; the amount that can be dissolved also depends on the temperature, the mixing method and the viscosity of the SO used. The resultant solutions are “heavier-than-water” and are sometimes referred to as “heavy silicone oils.”<sup>248</sup> Their viscosity could be above 1000 cSt, and as such they are much less

likely to disperse and emulsify as compared with the semifluorinated alkanes and alkenes used on their own. This might be one of the reasons that they are relatively well tolerated. The precise nature of the solution has not been fully elucidated. It could be that the fluorinated part of the molecule is on the surface of the solution and in contact with the surrounding aqueous whilst the alkylated part of the molecule is internalized in the silicone. It could be that the  $F_6H_8$  forms micelles inside the oil. Whether it is the higher viscosity or whether it is the molecular arrangement of the  $F_6H_8$ , the fact is that heavy SO is much better tolerated than  $F_6H_8$  when used on its own.

There are a number of agents in the market. These include Densiron 68, Oxane HD, and HWS 46–3000. Table 108.6 shows the comparison of physical properties between the newer heavy tamponade agents with some older tamponade agents. This section aims to provide the reader with a general overview of the current development in heavy tamponade agents.

**TABLE 108.6**

**Physical Properties of the Newer Generation of Heavy Tamponade Agents in Comparison With Other Older Heavy Tamponades**

	Component by Weight	Specific Gravity	Viscosity (cSt at 25 °C)	Surface Tension (mN/m)	Interfacial Tension vs. Water (mN/m)
Densiron 68	$F_6H_8$ – 30.5% PDMS (5000 cSt) – 69.5%	1.06	1349	19.13	40.82
Oxane HD	$RMN_3$ – 11.9% Oxane 5700 – 88.1%	1.02	3300	n/a	44.9
HWS 46–3000	$F_4H_5$ – 55% PDMS (100 000 cSt) – 45%	1.118	2903	18.8	41.3
$F_6H_8$	$F_6H_8$ – 100%	1.35	3.44	19.7	45.3
$C_8F_{18}$	$C_8F_{18}$ – 100%	1.76	0.69	14	n/a
$C_{10}F_{18}$	$C_{10}F_{18}$ – 100%	1.94	2.7	16	n/a

cSt, centistokes;  $F_6H_8$ , perfluorohexyloctane;  $F_4H_5$ , perfluorobutylhexane;  $C_8F_{18}$ , perfluoro-n-octane;  $C_{10}F_{18}$ , perfluorodecalin.

## Newer Generation of Heavy Tamponades

One of the commercially available heavy tamponades, Densiron 68, is a solution of SO (5000 cSt) and  $F_6H_8$ . The clinical experience with this agent is extensively reported. It has a specific gravity of 1.06 (higher than water), and a viscosity of 1350 cSt. Wong and associates conducted a pilot study on 42 consecutive patients with retinal detachments from inferior breaks associated with PVR.<sup>253</sup> Anatomic success (after all tamponade was removed) with one operation was 81%, and this increased to 93% with further surgery.<sup>253</sup> The tamponade agent was removed in 90% of cases at the end of the study. Visual acuity significantly improved from a mean of 1.41 to 0.94 (LogMAR chart). This result was supported by a later study by Herbrig et al., with a similar anatomic success rate of 87.6%.<sup>254</sup>

Another commercially available heavy tamponade, Oxane HD, is a mixture of SO (Oxane 5700) and  $RMN_3$ , a partially fluorinated and hydrocarbonated olefin. It has a specific gravity of 1.02 and a viscosity of 3300 cSt. Wolf and associates first reported a study using Oxane HD for extended tamponade in 33 patients with inferior retinal detachments. Complete retinal attachment was achieved immediately after surgery and macula remained attached at least 12 months postoperatively.<sup>115</sup> In another study, Rizzo and associates used Oxane HD in 28 eyes with inferior detachments. Oxane HD was removed on an average of 88 days, and attachment was achieved in 15 eyes.<sup>255</sup>

$RMN_3$  has a low solubility, and the mixture can separate into its original constituents when temperature is below 23 °C. This can occur during transportation or storage. A study looking at the product using nuclear magnetic resonance showed that Oxane HD is not homogenous.<sup>256</sup> Lai and associates have shown that when Oxane HD emulsifies, the droplets tend to float.<sup>257</sup> The authors have serious doubt whether Oxane HD stays as a solution.

Another heavy tamponade, HWS 46–3000, has been tested in a clinical trial by Rizzo and associates.<sup>258</sup> HWS 46–3000 is a mixture of 45% ultrapurified SO 100 000 cSt and 55% perfluorobutylhexane ( $F_4H_6$ ), a new semifluorinated alkane with viscosity 1.28 cSt; specific gravity 1.254 at 25 °C). The mixture has a viscosity of 3109 cSt and a specific gravity of 1.105 at 25 °C. Among the 36 eyes in their series, retinal reattachment was initially achieved in all. HWS 46–3000 was

removed after 45–96 days, and retinal attachment rate was 84.6% at 6 months with one operation, and 100% with a second operation.<sup>258</sup>

In view of the promising results, there is a need to compare the efficacy of conventional lighter-than-water SO and heavy tamponade, in the treatment of detachments associated with inferior breaks. The heavy tamponade study (HSO Study) was initiated by Jousseaume and colleagues.<sup>259</sup> The hypothesis was that heavy SO would displace any aqueous (containing proliferative cytokines and activated cells) to the superior retina where there were no retinal breaks. This was a prospective, multicentered, randomized controlled trial, comparing the effect of heavy tamponade (Densiron 68) and conventional SO, in eyes with inferior and posterior PVR grade C or above. Eyes were randomized to receive either Densiron 68 or conventional SO of either 1000 cSt or 5000 cSt. All tamponade agents were removed from the eye at 2–3 months after initial surgery. Interim results from the 12-month visit of 93 recruited cases – 46 patients treated with HSO compared with 47 patients treated with standard SO, showed that there was no significant difference between both groups regarding anatomic success as well as visual outcomes.<sup>260</sup> No significant adverse effects were observed during the course of the study, including emulsification of SO.

The investigators concluded that the use of heavy tamponade did not show any significant benefits over conventional SO in cases of inferior and posterior PVR. They also concluded that the results could not be generalized to cases of simple primary inferior rhegmatogenous detachments. Whether heavy tamponade is better than conventional SO as a primary tamponade agent requires further investigation.<sup>261</sup>

The specific gravity of these agents varies according to the molecular density, but all are above 1.0. Higher specific gravity has led to the debate as to whether extended tamponade with these agents will incur damage on the retina. Stolba and associates have shown retinal damage, when the eye is filled with perfluorophenanthrene (having specific gravity almost double that of vitreous) (Fig. 108.22).<sup>262</sup> However, a recent study by Mackiewicz failed to show such findings.<sup>263</sup> In their study, Mackiewicz infused either perfluorohexyloctane ( $F_6H_8$ ) or perfluorodecalin, or a mixture

of both, into vitrectomized eyes of rabbits for a period of 3 months. Histologic results failed to show any damages related to the high specific gravity of these fluids.<sup>261</sup> The changes in the retina might also be caused by exclusion of aqueous from the retinal surface.<sup>19</sup> Winter et al. measured the thickness of the fluid film between the SO bubble and the retina using optical coherence tomography, and they found that the fluid film was so thin that there might not be enough aqueous for ionic exchange.<sup>106</sup>

**FIG. 108.22** Shape of heavy tamponade bubbles in a model eye chamber. (A) Shows a bubble of perfluorodecalin with specific gravity of 1.94. The bubble assumes a more oval shape (the bubble here appeared in black because it was stained with Sudan Black stain). Bubble in (B) has a specific gravity 1.02. Bubble in (C) has a specific gravity of 1.03. Bubble in (D) has a specific gravity of 1.06. The progressive increase in specific gravities from (B) to (D) shows how the shape of the bubble changes as specific gravity increases.

In a laboratory-based study, Williams et al. have produced

another new agent, produced by adding aerosol silica to a phenyl trimethicone, and mixed via a roller, overhead stirring, and ultrasonics. The product, 11% silica, has greater ease of injection than Densiron 68 or Oxane HD. In vivo testings in rabbit eyes showed no apparent toxicity. This product also has good optical clarity, and better tamponade efficiency than Oxane HD and Densiron 68.<sup>264</sup>

## Technique

Heavy SO can be injected following an air–fluid exchange or PFCL/heavy silicone exchange.<sup>247,253,255,260,265,266</sup> In this respect, heavy SO is used much like conventional SO. Heavy SO can also be injected directly. In a giant retinal tear without PVR, it can be injected in the posterior pole. As the bubble gets bigger, the retina unfolds and goes out to length.

It has to be pointed out that some feel that the contact between a heavy tamponade agent and PFCL has the potential of “contaminating” the heavy oil. This might increase the risks of emulsification, inflammation, and sticky SO formation.<sup>267–269</sup> Special note has to be taken when filling an aphakic eye with heavy tamponade. Following complete filling of the vitreous cavity, a superiorly placed peripheral iridectomy should be done.

Conventionally, removal of SO was achieved through active aspiration via a long 18G needle over the optic disc (Fig. 108.23A). Because the oil naturally sinks, this is thought to be necessary. For an 18G cannula, the sclerotomy needs to be suitably large. We have since shown that aspiration over the optic disc is unnecessary (see below).

**FIG. 108.23** How tubeless siphoning enables removal of heavy tamponade agent through a shorter cannula. (A) How conventional removal is done with the extrusion needle held close to the retina. (B) How a shorter needle can successfully remove heavy tamponade agent using the “tubeless siphoning” phenomenon.

As with all removal of silicone, linear extraction using long tubing is not practical. It may work briefly and initially, but once the tubing starts filling with oil, the flow slows to a halt. Poiseuille's Law dictates that flow is inversely and linearly proportion to the length of the tubing. To minimize this length, no tubing should be used. The suction needs to be generated in a syringe connected directly to the aspirating cannula.

Stappler and colleagues have demonstrated that it is possible to remove heavy tamponade using a short small-gauge cannula.<sup>252</sup> With a 20G polyurethane cannula (Venflon), cut to 7 mm in length, it was shown that it was possible to extract heavy oil and it was unnecessary to reach down to the optic disc. The explanation was attributed to the phenomenon of “tubeless siphoning” (Fig. 108.23B). Heavy SO as well as normal SO are viscoelastic fluids. Under aspiration, extensional flow takes place. The bubble of heavy oil could assume a conical shape while being aspirated such that it was possible to remove all the oil in one go using a short cannula.<sup>252</sup>

Using this method, Romano et al. have shown that it is possible to remove heavy oil even with a 23G cannula.<sup>270</sup>

Removing heavy oil using short 20- or 23G cannulas obviates the need to use large sclerotomies. The risk of accidental trauma to the retina from using high suction and a long cannula close to the retinal surface can be avoided. When using a short cannula, it is important for the tip of the needle not to come out of the heavy oil bubble at any stage. Should this happen, a longer cannula needs to be used to reach the bubble.

Consideration should also be given as to the type cannula used. Plastic cannulas are more hydrophobic than metal ones. SO often tenaciously sticks to the outside of a plastic cannula such that it can be difficult to remove the last drop of oil. Removal of the cannula from the vitreous cavity can cause a bit of oil stuck to the cannula to be scraped off and for that tiny amount of oil to remain in the vitreous cavity. Fortunately, with heavy oil, any oil left tends to round up as a droplet and sinks to the posterior pole where it can be visualized and aspirated by passive or active suction.

## Complications

Concerns about inflammation and emulsification have led to slow adoption of heavy tamponade agents.<sup>250,271</sup> Even with the advent of heavy SOs there is conservatism, as there is genuine skepticism as to whether a heavier-than-water tamponade is really safe or indeed necessary. Densiron 68 and, to a certain extent, Oxane HD have been found to be well tolerated in patients, and their use was associated with few complications even when left in the eye for long durations.<sup>253,258</sup>

Densiron 68 shares some of the problems commonly encountered with conventional SO.<sup>238</sup> For instance, it would not conform to the contour of the vitreous cavity; it could not be expected to fit into the nooks and crannies.<sup>23,272</sup> In the presence of high buckles, heavy SO would make contact with the peak of the indent, but leave the retina on the slopes of the indent unsupported.

It is our recommendation that Oxane HD be avoided. It was shown that the olefin RMN3 could come out of solution.<sup>256</sup> The lack of homogeneity of Oxane HD, in the opinion of the authors, should

rule out its use as a heavy tamponade.

## Corneal Toxicity

Corneal damage has been reported with the use of F<sub>6</sub>H<sub>8</sub>.<sup>250,271,273,274</sup> Gerding and Kolck reported in their series of 17 patients, where stromal and epithelial edema was seen in 35% of cases following F<sub>6</sub>H<sub>8</sub> use.<sup>271</sup> Similar problems were also reported by Roider et al.,<sup>250</sup> Schatz et al.,<sup>274</sup> and Vote et al.<sup>273</sup> However, in another report by Kirchof and associates, where 23 eyes were operated on with F<sub>6</sub>H<sub>8</sub> kept in situ for a mean of 76 days, no corneal damage was seen.<sup>202</sup> To date, there has been no report on corneal toxicity from the use of Densiron 68, Oxane HD, or HWS 46–3000. However, there is no reason to believe that heavy SO might not cause oil keratopathy should the AC be filled with heavy oil.

## Cataract Formation

Cataract formation following vitrectomy with heavy oil tamponade can be multifactorial. It can be the effect of surgical trauma, of the vitrectomy *per se*, of the use of tamponade agent, or a combination of all the above factors. Heavy silicone oil is still an oil and therefore, the chance of cataract formation is 100%, as it has been found that the use of conventional SO leads invariably to cataract formation.<sup>275</sup> Wong and associates identified, in their pilot study of Densiron 68, that all patients developed mild nuclear sclerosis with posterior subcapsular changes during the early postoperative period.<sup>253</sup> Similar observation was also reported by Lappas and colleagues.<sup>276</sup> Kirchof et al. noted feathery posterior subcapsular opacification in 90% of their patients following the use of F<sub>6</sub>H<sub>8</sub>.<sup>247</sup> Cataract formation was also observed following the use of Oxane HD and HWS 46–3000.<sup>255,258</sup> Cataract formation was thought to be related to the increase in cellular proliferation in the lens and the change in metabolism of the lens when in contact with the heavy oil.<sup>273,277</sup> In addition to the formation of cataract, progression of posterior capsular opacification has also been seen with the use of heavy tamponade.<sup>278</sup>

As cataract formation with the use of heavy or conventional SO seemed inevitable, some surgeons prefer phacovitrectomy and

intraocular lens implantation at the initial surgery. This has the advantage of facilitating the dissection of membranes at the anterior vitreous. Other surgeons prefer to leave the eye phakic at the time of heavy tamponade injection. There may be valid theoretical reasons to suggest that the tamponade to the posterior retina might be better if the crystalline lens was retained.<sup>279</sup>

## Intraocular Inflammation

Severe intraocular inflammation was one of the main reasons for discontinuation of early heavy tamponade agents. High rates of fibrinous reaction and retropupillary membrane formation had led to the cessation of agents such as O62.<sup>260,271,273,280,281</sup> It was thought that the use of heavy tamponade agents would aggravate PVR by inducing an augmented inflammatory response.<sup>271</sup>

For anterior segment inflammation, Theelen and associates observed keratic precipitates in 37% of eyes in their series of 19 patients who received Oxane HD as heavy tamponade.<sup>267</sup> Among these patients, the reaction was granulomatous and some seemed unresponsive to topical steroid. However, excessive inflammation was not observed in the cases series of Wolf et al. (33 eyes)<sup>115</sup> and in a similar study by Rizzo et al. (28 eyes);<sup>255</sup> only minimal inflammatory reaction was noted in these cases. In the case of Densiron 68, Wong and colleagues observed moderate inflammatory reaction at 1 week after surgery.<sup>253</sup> This was in keeping with the observation by Sandner and Engelmann, where similar reaction was seen in 10 of 48 eyes (21%) of their cases.<sup>282</sup> In the series by Sandner and Engelmann, six cases that had inflammatory reaction eventually progressed to sterile hypopyon formation, which in all of whom resolved with the use of topical steroid eyedrops. Majid and associates reported one case of severe AC uveitis out of 40 eyes.<sup>283</sup> For HWS 46–3000, there are so far no reports of severe intraocular inflammation.<sup>258</sup>

Inflammation can be noted in the posterior segment. In a series of 23 cases with F<sub>6</sub>H<sub>8</sub> as the tamponade agent, Kirchhof et al. noted pigment clumps were seen on the back of the posterior capsule in 17% of cases.<sup>247</sup> Membranes with prominent inflammatory cells have also been noted.<sup>277</sup> Some have suggested that risk factors for inflammation in the posterior segment include emulsification of the

tamponade agent;<sup>277</sup> contamination of the tamponade agent by PFCL during the surgery;<sup>267</sup> and mechanical trauma from the movement of the of low viscosity tamponade agents within the eye.<sup>273</sup> These risk factors apply mainly to the semifluorinated alkanes and alkenes. With heavy silicone oils, there are to date no reports of severe posterior segment inflammation.<sup>115,253,255,258,262,284,285</sup>

## Emulsification

Emulsification is an inherent problem with all liquid tamponade agents. Heavy SO can manifest with: (1) overt emulsification – this may settle as a hypopyon-like fluid level when heavy tamponade agent is used; (2) inflammation – there is some suggestions that heavy SO might give rise to more inflammation although this was not shown in the randomized controlled Heavy Silicone Oil Study; (3) PVR – inflammation could promote PVR. Although, when retinal detachment recurs, it is difficult to know whether PVR is caused by the tamponade agent, or is actually a part of the natural history of the disease process; (4) glaucoma – mechanical blockage of the trabecular meshwork was considered a possible cause of open angle glaucoma in some cases.

In the series with infusion of O62 by Hoerauf and colleagues, 100% emulsification was seen starting from 2 weeks after instillation of the agent.<sup>281</sup> With  $F_6H_8$ , Gerding and Kolck also noted a 100% emulsification rate on removal of the agent from the eye, although only 59% were clinically noticeable, with some as early as postoperative day 1.<sup>271</sup>  $F_6H_8$  has relatively low viscosity of around 1–2 cSt. The heavy SO Densiron 68 has a viscosity of around 1350 cSt. The rate of emulsification reported varies tremendously. With Oxane HD, no emulsification was noted in the series by Rizzo et al.<sup>245</sup> and Wolf et al.<sup>115</sup> In other series, a rate (8–20%) has been reported.<sup>253,266,267,282,283</sup>

The rate of emulsification is dependent on the components that make up the heavy tamponade agent. Viscosity is important. The higher the shear viscosity, the more energy is needed to disperse a large bubble into droplets. Dispersed droplets, however, will tend to coalesce back into one single bubble unless they are stabilized by surfactants. There are individual patient factors, including the extent of blood–ocular barrier breakdown, inflammation, presence

of phospholipids and other potential surfactants that might influence the rate of emulsification.

In a recent report by Chan et al. with a model eye, various factors that may influence shear rate were studied. The authors concluded that indentation within an eye, such as that created by scleral buckling, may have the greatest influence in reducing shear force induced by eye movements.<sup>286</sup> Hence, putting in an encircling band may be equally, if not more, effective in preventing emulsification of the heavy SO. However, this was done on a model eye, and whether this can be entirely applied in in-vivo scenarios requires further testing.

At the present time, it is not possible to identify beforehand which patient will have severe emulsification. We can only conclude that emulsification to a greater or lesser extent is inherent with SO use in all patients.

### **Sticky Silicone Oil**

Silicone oil can stick to the retina surface, posterior surface of the capsule, and undersurface of ciliary body and iris.<sup>238,239,258</sup> It has been speculated that SO adheres to the surface of the retina because of the incomplete removal of the posterior hyaloids.<sup>238</sup> Sticky SO might also be related to the use of PFCL, as a small amount of the PFCL might change the physical property of the heavy SOs.<sup>268,269</sup> Sim and Hero reported a case of sticky SO in a phakic patient, after the use of Oxane HD.<sup>278</sup> There are so far only anecdotal reports of such a problem with the use of Densiron 68 and HWS 46–3000.

### **Adherent Silicone Oil on Intraocular Lens**

It was shown that the SO solvent perfluorobutylpentane ( $F_4H_5$ ) was very effective at removing SO droplets adherent to the posterior surface of the intraocular lens. It is one of the semifluorinated alkanes that is miscible with SO in all proportions. Liang et al. used  $F_4H_5$  on 11 patients and successful removal of all remnants with  $F_4H_5$  was achieved in all cases.<sup>208</sup> In an experimental study, Stappler et al. showed that  $F_4H_5$  was successful in removing virtually all the SO adhering to intraocular lens made from three different materials (silicone, PMMA, and acrylic). By simply rinsing and no mechanical

scrubbing, up to 100% by weight of SO was removed from the surface of PMMA lens (93.7% with silicone lens, and 98.8% with acrylic lens).<sup>209</sup> They, however, also showed that the surface properties of the lenses in terms of hydrophobicity were irreversible, despite virtually complete removal of the oil. Clearly, there was still SO adherent to the lens, even though the layer of oil might only be just a few molecules in thickness.

## Hypotony

Hypotony is one of the most difficult to manage complications. This problem is not unique to the use of heavy tamponade and may be related to the severity of the PVR and the extent of surgical retinectomy. With F<sub>6</sub>H<sub>8</sub>, Gerding and Kolck observed a high rate of hypotony in their series of 16 cases.<sup>271</sup> Others reported rates were only 7% to 11%.<sup>274,279</sup> The rates of hypotony following use of Oxane HD, Densiron 68, and HWS 46–3000 were reported to range from 0–8%.<sup>115,253,255,279,282</sup>

## Raised Intraocular Pressure

The mechanism of an acute rise in intraocular pressure as seen with the use of heavy tamponade agents is theoretically identical to that seen with conventional SO. Pupil block glaucoma could occur in aphakic eyes. Avoiding overfill and performing a superiorly placed peripheral iridectomy might be effective in preventing this complication.

Overfilling of heavy tamponade agent could unwittingly occur when an encircling band is applied after the vitreous cavity has already been filled with silicone. Tightening of the band could raise the IOP, which cannot be compensated for by the outflow of aqueous. Therefore, when an encircling band is to be placed, this should be applied before SO injection.

For chronically raised IOP, the mechanism may include (1) intraocular inflammation; (2) emulsification and blockage of the trabecular meshwork by emulsified droplets; (3) steroid response. Rates of chronically raised IOP following the use of Oxane HD have been reported to be from zero to 18%.<sup>115,255,267</sup> Rates for Densiron 68 were from 8% to 19%.<sup>253,282,284</sup> With HWS 46–3000, only one eye out

of 32 had a chronically raised intraocular pressure.<sup>258</sup> In a report with 100 eyes that received vitreoretinal surgery using heavy SO, the mean IOP before surgery was  $13.3 \pm 5.6$  mmHg. This rose to  $23.3 \pm 8.5$  mmHg after surgery and went back down to  $13.7 \pm 7.2$  mmHg following removal.<sup>287</sup> In general, mild to moderate cases of chronically raised intraocular pressure can be managed with the help of antiglaucoma eyedrops. For severe cases, removal or washout of the remnants or droplets in the AC may be tried but the condition sometimes persists, and may eventually require glaucoma surgery.

## **Redetachment and Proliferative Vitreoretinopathy**

Redetachment following the use of heavy tamponade agents usually occurs in the superior half of the retina.<sup>253,255,271,281</sup> Inferior retinal detachment can also occur.<sup>282</sup> Redetachment can occur while the agent is in situ, or after its removal.<sup>253,255,260,265,271</sup>

With the tamponade agent in situ, total redetachment is uncommon. More often, the inferior retina and the posterior pole remain attached, while the superior retina redetaches because of PVR.<sup>253,255,265,271</sup> Wong and associates suggested that a heavy tamponade might be used in cases of conventional SO failure. They suggested that sequential filling with heavy tamponade followed by conventional tamponade (or vice-versa) might lead to long-term anatomic success.<sup>160</sup> In their series, 10 patients underwent sequential "light" SO and "heavy" (Densiron 68) tamponade. Nine patients had light tamponade first, followed by heavy tamponade, whereas the remaining one patient had the reverse. The retina remained attached in all 10 patients after the removal of all tamponade agents, be it heavy or light. The mean logMAR vision improved from 1.57 before surgery, to 0.82 at the latest follow-up (mean follow-up was 19.5 months).<sup>160</sup> Wong et al. concluded that sequential use of light-heavy tamponades might be a strategy in reducing the number of reoperations in complicated retinal detachments. If retinal redetachment was to occur after heavy SO, then a long-acting gas such as  $C_3F_8$  could be used at the reoperation. This would have the advantage of the gas being absorbed spontaneously, which would obviate the need for a further oil removal surgery.

It has been reported that macular-off redetachments occur less frequently with heavy tamponades than with conventional SO.<sup>160,253</sup> This is perhaps explained by the fact that there is a better tamponade effect of the posterior retina when the patient is supine than when the patient is asleep. The shape of the intraocular bubble between Densiron 68 and conventional SO is very similar. Therefore, there are no theoretical reasons to believe that Densiron 68 is a better tamponade agent than conventional SO.<sup>272</sup>

## Conclusion

Early heavy tamponade agents such as fluorosilicone oil, perfluorocarbon liquids, and  $F_6H_8$ , showed relatively high complication rates and were not acceptable. Of the newer generation of heavy tamponade agents, namely Densiron 68, Oxane HD, and HWS 46–3000, lower complication rates and better in vivo tolerability have been shown, and are comparable with conventional SO in this regard. As mentioned above, Oxane HD is not a homogenous solution, and therefore the authors do not recommend its use. Clinical trials of Densiron so far have shown diversified results. While some noncomparative studies have reported good results,<sup>253,258</sup> others (including the recent multicenter randomized controlled “Heavy Silicone Oil Study”<sup>261</sup>) have demonstrated results that were not superior to conventional SO.<sup>115,282,284</sup> There is sufficient clinical experience with Densiron 68 to indicate that it is well tolerated. Heavy SOs do add to the authors' surgical repertoire, and there are keen advocates for their use. Ultimately, we believe the key to anatomic success lies in careful preoperative evaluation to identify retinal breaks, meticulous planning before surgery and skillful surgery to remove traction and to seal retinal breaks. The tamponade agent, be it heavy or light, is only a minor consideration in the overall approach to patients with retinal detachment.

## Drugs for the Prevention of Proliferative Vitreoretinopathy

## Introduction

With the advancement of surgical instrumentation, reattachment rates have improved over the years. A group of us have reported success rates of 84% with one operation, and 97.9% at 6 months with multiple operations.<sup>288</sup> This is a significant improvement compared with two decades ago, when vitrectomy for retinal detachment was first introduced. Redetachment occurs for various reasons. Missed retinal breaks are seldom eluded to, while PVR is often quoted as being the main reason for redetachment. The incidence of PVR has been reported to range from 5.2% to 11.7%.<sup>164,289</sup>

Different pathogenic mechanisms are involved in the PVR process accordingly, and multiple targets have been tested either in an animal model of PVR or in human clinical trials. The detailed pathogenesis and surgical treatment of PVR are discussed elsewhere in this book (see [Chapter 101](#), Pathogenesis of proliferative vitreoretinopathy, and [Chapter 111](#), Proliferative vitreoretinopathy). This section intends to summarize some the pharmacologic agents that have been tested for the prevention of PVR formation.

## Pharmacologic Agents That Have Been Tested in Clinical Trials

### Corticosteroids

Corticosteroid is being tested for use as an inhibitory agent for intraocular proliferations. It exerts its effect through the inhibition of intraocular inflammation and maintains the integrity of the blood–ocular barrier. Steroids also inhibit fibroblast-like activities. In early animal studies, intravitreal injection of dexamethasone or triamcinolone has been shown to effectively reduce the rate of traction retinal detachment (TRD).<sup>290–294</sup> Methylprednisolone has also been shown to reduce the rate of PVR when injected periocularly ([Fig. 108.24](#)).<sup>295</sup>

**FIG. 108.24** Structural presentation of DNA and the site of action of various chemicals in the prevention of proliferative vitreoretinopathy. The upper portion of the diagram demonstrates the association between purine and pyrimidine pairs contributing to the double-helical structure of DNA. Antimetabolites such as daunomycin intercalate directly into the DNA structure, hence interference with its replication. Others interfere with DNA synthesis by limiting the availability of necessary precursors (fluoropyrimidines) or through their effects on regulatory proteins necessary for the completion of S phase and mitosis (Taxol, colchicine).

The systemic side-effects are such that in the absence of good clinical evidence of their efficacy, the routine use of systemic steroids for the prevention or treatment of PVR does not seem justified. In recent years, however, intravitreal triamcinolone has become part and parcel of vitrectomy. It is not used so much for its pharmacologic effect, but instead, it is used as an intraoperative tool for identification of cortical vitreous or even as a “dye” to assist internal limiting membrane peel. Many of the crystals are left in the vitreous cavity and sometimes purposely, to reduce postoperative inflammation.<sup>290-294</sup>

In a recent retrospective comparative trial, the role of

triamcinolone was being investigated in assisting vitrectomy for pseudophakic retinal detachments associated with PVR.<sup>294</sup>

Although the difference between triamcinolone-assisted and nontriamcinolone-assisted cases was not statistically significant, it did point towards a lower redetachment rate among cases where triamcinolone was used, and highlighted the potential for future prospective studies using triamcinolone. Whether the reduction in redetachment is due to the surgery that could be achieved with triamcinolone, or whether it is due to the pharmacologic effect of the drug, remains speculative.

## Fluoropyrimidines

The fluoropyrimidines, most notably 5-fluorouracil (5-FU), are the first antimetabolites to be investigated for intraocular use to inhibit PVR formation.<sup>296,297</sup> Its relatively low intraocular toxicity and high potency in inhibiting cellular proliferation made it ideal for this purpose. 5-FU exerts its effect on rapidly growing cells through inhibition of proliferation and contraction. There is more than one pathway in which 5-FU acts to serve its purpose. It inhibits protein synthesis by incorporating into ribonucleic acid (RNA), which in turn affects mitosis and cytoskeleton function.

In animal studies, the inhibitory effect of 5-FU has been widely studied. In a rabbit PVR model, a single intravitreal injection of 1 mg 5-FU successfully prevented PVR formation in 41% of animals at 28 days.<sup>298</sup> In another study, 1 mg 5-FU was loaded onto a biodegradable polymer and implanted into the vitreous and maintained for 14 days. Incidence of TRD was significantly reduced in treated animals.<sup>299</sup> Other than being used alone, its use in combination with other drugs have been investigated. 5-FU in combination with triamcinolone or low-molecular-weight-heparin (LMWH) has been injected into rabbit models of PVR.<sup>300,301</sup> Results showed significant reduction in terms of TRD and severity of the PVR.<sup>300,301</sup> As far as toxicity is concerned, no demonstrable damage was seen in the animal eyes.

Blumenkranz and colleagues pioneered its use in humans in the early 1980s. In a study involving 22 patients with PVR, 5-FU injected intravitreally did not seem to cause any toxic effect, and was thought to be potentially effective in preventing PVR

recurrence after surgery.<sup>296</sup> Subsequently, Asaria et al. published the first randomized controlled trial regarding the use of 5-FU in the prevention of postoperative PVR formation.<sup>302</sup> In the study, 200 µg/mL 5-FU and 5 IU/mL low-molecular-weight heparin (LMWH) were added to the intravitreal infusate during surgery. The outcomes of the 174 patients, when divided into the treatment arm and the placebo arm, showed a significantly lower incidence of PVR in the treated group (12.6% vs. 26.4%) at 6 months.<sup>302</sup> The primary success rate between the two groups was not significantly different and, importantly, the rate of complications was not statistically different between the two groups. It seemed that the so-called “British Cocktail” of 5-FU and heparin is safe and efficacious. Both treated and control groups had a similar number of redetachments. It is not known whether the redetachments were caused by PVR or by missed breaks. Nonetheless, when patients with redetachments presented, the control group had twice the rate of PVR as indicated above. It should be further pointed out that all the patients in this group had high-risk characteristics for PVR. Whether patients were at high risk of developing PVR was calculated using a regression formula. This formula was based on a study by the same investigators of patients previously treated. In this regression formula, the number of quadrants of retinal detachment, the presence of early PVR grades A and B, previous cryotherapy, and the presence of uveitis were all important determinants.

Although the study had a randomized design, the unequivocal result was disappointing. The rationale for a PVR treatment is to reduce the redetachment rate, and this was not the result. Perhaps the basic premise was wrong, i.e., that PVR was not the most important cause of redetachment. If it were due to undetected or untreated retinal breaks, no pharmacologic adjunct would be effective. Also, the external validity of the study was an important consideration. The patients were carefully selected according to strict criteria and a regression formula, but what we needed to know was whether the cocktail was effective in cases with established PVR.

In another study by the same group on cases with established PVR, 174 patients undergoing vitrectomy were recruited. Inclusion criteria were as follows: eyes with PVR grade C: anterior or

posterior with at least 1 clock-hour involvement; types 1, 2, 4, or 5. The primary outcome measure was defined as posterior retinal reattachment after removal of SO without any reoperations at 6 months. Secondary outcome measures recorded were posterior retinal reattachment, localized/tractional retinal detachment, visual acuity, macular pucker, hypotony, glaucoma, keratopathy, and cataract. Removal of SO and reoperations were also recorded. At 6 months, 84% of patients had full retinal reattachment and 94% had stable posterior retinal reattachment. There was no significant difference in success in the primary outcome measure (56%, treatment group; 51%, placebo group;  $p=.59$ ) or in secondary outcome measures or rates of complications. Secondary macular pucker occurred less often in the treatment group (6% vs. 17% at 6 months;  $p=.068$ ). The investigators concluded that perioperative infusion of combined 5-fluorouracil and LMWH did not significantly increase the success rate of vitreoretinal surgery for established PVR.

The fact that the drug combination worked in reducing PVR in high-risk groups but not in established PVR might be interesting. In established PVR, the epiretinal membranes would already be maturing. Proliferation might not be such an important feature. In late PVR, the epiretinal membrane might be hypocellular. There may also be a question whether the drugs could penetrate dense membranes. Although the drug combination targeted more than one pathway, it could be that the modulation of the cellular response was the most important. It might also be reasonable to conclude that the cocktail was only effective when given early in the natural history of retinal detachment and by the time that PVR was established, the drugs might not be as effective. This led to the mounting of the third and the largest of the three trials.

The study involved 615 patients with primary rhegmatogenous retinal detachments.<sup>288</sup> The same dosage of 5-FU/LMWH infusate was used. At 6 months, no statistical difference was found between the treated group and placebo, in terms of PVR occurrence. The number of patients who failed due to the development of PVR was not statistically significant: 23 in the treatment group (7.0%) and 14 in the placebo group (4.9%) ( $p=.309$ ). There was no significant difference in the mean visual acuity at 6 months in the placebo

group (0.48) versus the treatment group (0.53;  $p=.072$ ). Of more concern were the visual results of patients who presented with macular-on detachments. The visual acuity at 6 months of patients presenting with a macula-sparing retinal detachment was significantly worse in the treatment group ( $p=.0091$ ). There was no significant difference between the two groups in patients who presented with a macula involving retinal detachment ( $p=.896$ ). The visual results suggested that the drug combination might be slightly retinotoxic. In the past, high doses of 5-FU were used and considered to be safe. They have, however, always been used in patients with poor prognosis. If there was a slight diminution to the visual outcome, this might not have been detected. For the first time, the drug combination was used on some patients with good visual prognosis.

For a summary of the results of all three trials, refer to the recent report from the Cochrane Eyes and Vision Group. Sundaram et al. suggested that no definite conclusion could be drawn from these studies so far, and that further research should therefore be carried out in high-risk patients only.<sup>303</sup> Due to the lack of supporting evidence at present, 5-FU should therefore not be routinely used in the surgical repair of retinal detachments to prevent PVR formation, until evidence from further research, with favorable results, is available.

## **Daunorubicin**

Daunorubicin is an anthracycline antibiotic, and its mechanism of action in the inhibition of PVR formation is thought to be independent of the cell cycle. It has a significant inhibitory effect on proliferation and migration of cells, but the effect on cellular contraction is limited. It has been shown in animal studies to be capable of reducing the PVR rate.<sup>304,305</sup> It has been shown to be more toxic than 5-FU, but a dosage of up to 7.5  $\mu\text{g/mL}$  when infused into the eye during surgery, has been found to be well tolerated.<sup>304</sup>

The first study was performed on patients undergoing vitrectomy for trauma. In 15 patients, there was only one case of proliferation, and there was no sign of toxicity.<sup>304</sup> Results from a later study involving treatment of advanced PVR with daunorubicin and SO agreed on the beneficial effect, in terms of redetachment and vision

improvement.<sup>306</sup>

An RCT was later conducted to investigate the efficacy of daunorubicin in the prevention of PVR.<sup>307</sup> Wiedemann and associates conducted a multicenter RCT on patients with established PVR, where daunorubicin was infused into the vitreous cavity for 10 minutes during vitrectomy, with an aim to reduce postoperative PVR formation. Six months after standardized surgery, complete retinal reattachment without additional vitreoretinal surgery was achieved in 62.7% (89/142) of eyes in the daunorubicin group versus 54.1% (73/135) in the control group ( $p=.07$ , one-sided). However, in the daunorubicin group, significantly fewer vitreoretinal reoperations were performed within 1 year postoperatively ( $p=.005$ , one-sided) to achieve the same overall 1-year retinal reattachment rate (80.2% [105/131] vs. 81.8% [103/126]). The rate of patients with no vitreoretinal reoperations was 65.5% (95/145) in the daunorubicin group versus 53.9% (76/141) in the control group. There was no difference in the best corrected visual acuity.<sup>307</sup>

## Retinoids

In the eye, retinoids play an important role in the metabolism and turnover of visual pigments. It was thought to have an effect on proliferation and cell-mediated contraction of myofibroblasts, as seen in PVR. Laboratory studies involving treatment of human RPE cells with vitamin A showed significant reduction in cellular proliferation and migration.<sup>308</sup> In rabbits, intravitreal injection of retinoic acid (RA) has successfully reduced the occurrence of PVR.<sup>309</sup> In humans, 13-*cis* RA, an isoform of all-transretinoic acid, was found to have an inhibitory effect on excised membranes from PVR patients and did not show toxic effects.<sup>310</sup>

Fekrat and colleagues, in a small group of patients with PVR, conducted the first pilot study. Subjects were given an oral dose of 13-*cis* RA (80 mg/day) for 4 weeks after surgery. Results showed a decreased rate of PVR and an increased rate of retinal attachment.<sup>311</sup> A recent prospective RCT in 35 patients seemed to concur with the results and points towards a protective effect of retinoids against PVR formation. In this study, the treatment arm subjects were given a dose of 20 mg/day for 8 weeks after surgery for retinal

detachment. Results at 1 year showed that in the treatment arm, the retinal attachment rate was significantly higher than in the placebo arm (93.8% vs. 63.2%,  $p=.047$ ).<sup>312</sup> The rate of macular pucker formation was also significantly lower and vision was significantly better in the treatment arm. This was an encouraging result, since this drug has been in wide use in other diseases already and has shown a good safety profile (in acne vulgaris,<sup>313</sup> and in the prevention of second primary tumor in squamous cell carcinoma of the head and neck).<sup>314</sup> Results regarding this drug have so far been promising. Further studies should be conducted to delineate the efficacy profile before it can be incorporated into routine use.

## **Heparin and Low-Molecular-Weight Heparin**

Heparin, a glucose aminoglycan derived from heparin sulfate, is well known for its anticoagulation ability. It acts by binding to and altering the properties of antithrombin, and inactivating thrombin in the end. Other than its anticoagulation properties, heparin also has several other abilities. It binds to a number of growth factors, including fibroblast growth factor, platelet-derived growth factor, and endothelial cell growth factor. It reduces cell aggregation by inhibiting fibroblast adhesion to fibronectin-coated substrates, and gives rise to a change in the cytoskeleton of smooth muscles and pericytes.<sup>315</sup> It also inhibits the polymerization of type I collagen, and reduces the hypocellular gel contraction by fibroblast and RPE cells. It also inhibits the proliferation of scleral fibroblasts and RPE cells.<sup>316</sup>

Despite the numerous functions described, the anticoagulation feature of heparin often causes excessive bleeding, which has limited its clinical use. In view of this, heparin has been broken down into fragments, which have a mean molecular weight of  $\leq 5000$ . These LMWH fragments have increased bioavailability and a longer half-life.<sup>317</sup> They retain the antithrombotic effect of heparin but produce less hemorrhage. This may be due to the fact that LMWH has reduced ability to inhibit platelet aggregation, and some have suggested that, while LMWH can still inhibit factor Xa like heparin, it loses the ability to inhibit activation of thrombin directly.<sup>318</sup> LMWH has been shown to reduce fibrin formation after vitrectomy.<sup>319</sup> LMWH became a better alternative to heparin, while

retaining many of the advantages that heparin confers, especially with respect to prevention of PVR formation. In early animal studies, inclusion of LMWH in the infusate during vitrectomy has successfully reduced the rate of PVR-induced traction retinal detachment.<sup>320</sup> In addition to the effect described, LMWH also reduced the amount of fibrin in the eye after vitrectomy in the rabbit and increased corneal clarity after surgery.<sup>319</sup> More importantly, the rate of postoperative vitreous hemorrhage did not seem to increase.<sup>319</sup>

The mechanism of action of LMWH appears to differ from that of antimetabolites and corticosteroid, with regard to inhibition of PVR formation. Therefore, in clinical studies, LMWH was used in combination with other agents, most commonly with 5-FU or with steroid.<sup>321–323</sup> In a pilot study on 62 patients with severe PVR, vitrectomy with infusate enriched with heparin and dexamethasone did not reduce rate of re proliferation, but rather increased significantly the rate of postoperative hemorrhage.<sup>324</sup> Since the results of this study, the interest in using LMWH instead of the unfractionated heparin has grown. Kumar et al. provide another study that showed some beneficial effect with LMWH-added infusate.<sup>321</sup> However, a recent review by the Cochrane Library looked at two randomized controlled trials with a total of 789 participants using LMWH with 5-FU infusion for the prevention of PVR.<sup>325</sup> However, the authors found inconsistent evidence regarding the efficacy of this regimen in the prevention of PVR.

## Anti-Vascular Endothelial Growth Factor

The ophthalmology world has seen tremendous advances in the use of anti-vascular endothelial growth factor (VEGF) in the treatment of various eye diseases, such as age-related macular degeneration,<sup>326</sup> diabetic retinopathy,<sup>327,328</sup> and retinal vein occlusion.<sup>329</sup> It has also been suggested to be tried as a prophylaxis for PVR inhibition.<sup>330</sup> Platelet-derived growth factor receptor  $\alpha$ , a receptor tyrosine kinase that is key to the pathogenesis of experimental PVR, maybe engaged by growth factors, including vascular endothelial growth factor (VEGF) A, in the process of PVR formation.<sup>325,331,332</sup> Therefore, by inhibiting VEGF, PVR may potentially be prevented.

Ghasemi et al. have performed a study to evaluate the role of bevacizumab in the prevention of PVR, when injected into the silicone oil at the end of the retinal detachment surgery.<sup>333</sup> In their series, 38 eyes with grade C PVR or more were included, and were divided into two groups, one receiving bevacizumab, and the other without. However, their results have shown that the use of bevacizumab did not eliminate the risk of postoperative PVR formation.<sup>333</sup> In another similar trial by Hsu et al., where 20 eyes that had PVR received serial bevacizumab injections into the silicone oil after vitrectomy were compared to historic controls in terms of re-detachment rates, final visual acuity, and epiretinal membrane formation.<sup>334</sup> The authors failed to detect significant improvement in any of the parameters measured, when bevacizumab was being given serially after vitrectomy. Hence, the theory regarding PVR prevention by antagonizing VEGF requires further testing.

## Chemicals yet to Be Tested in Clinical Trials

Many other chemicals have also been proposed for inhibiting PVR formation. These include: taxol,<sup>335</sup> colchicine,<sup>336</sup> immunotoxins,<sup>337</sup> matrix metalloproteinases (MMP),<sup>338</sup> thiotepa,<sup>339</sup> VP16,<sup>339</sup> and vincristine.<sup>339</sup> Although the list is by no means exhaustive, to date none of these has been implemented in clinical practice, either due to toxicity issues or limited efficacy. Details of these chemicals are outlined in [Table 108.7](#).

**TABLE 108.7**

### Various Chemicals Tried in Experimental Models of Proliferative Vitreoretinopathy

Chemical Name	Category	Concentration/Dose	Mechanism of Action	Animal Model
Paclitaxel (Taxol) <sup>335</sup>	Plant-derived mitosis inhibitor	0.0005 mg	Inhibit contraction of collagen gel	Reduced tractional retinal detachment in two rabbit models
Colchicine <sup>336</sup>	Plant-derived alkaloid	1.3–1.7 × 10 <sup>8</sup> mol/L	Inhibit mitosis and cell motility	Inhibition of cell proliferation in a cell culture using cells harvested from pig eyes

Immunotoxin (transferrin-ricin A chain) <sup>337</sup>	Monoclonal antibody	0.002 mg	Inhibit protein synthesis by ribosomal inactivation	Reduced tractional retinal detachment in a rabbit model
Matrix metalloproteinases (Prinomastat) <sup>338</sup>	Enzymes responsible for extracellular matrix remodeling	0.5 mg	Inhibit extracellular collagen remodeling and contraction	Reduced tractional retinal detachment in a posttraumatic proliferative vitreoretinopathy rabbit model

## Summary

The results of pharmacologic adjunct for the treatment of PVR have so far been disappointing. There are three fundamental problems: first, there is a divergence between what basic scientists are aiming for and what the surgeons want. Surgeons want agents that can improve the primary success rate of retinal repair surgery. We may be deluding ourselves in thinking that PVR is the main cause of retinal detachment. At times, it may only be one of the contributing factors. There are other factors that must be taken into consideration, including the surgeon's training, skill and ability, and the technology that we have at our disposal to help identify all causative retinal breaks and to close them. Nonetheless, the clinicians tell the scientists that what we need is an elixir that could suppress PVR. As a result, the elixir may or may not give us what we want; a high primary success rate. Secondly, PVR may be a poor proxy for success and failure of retinal detachment repair surgery. Conversely, if epiretinal membranes were distant from retinal breaks, their contraction and traction might not open retinal breaks and cause retinal redetachment. Equally, if there were no epiretinal membranes, the retinal redetachment might still occur if breaks were not identified and closed during the initial surgery. Thirdly, our obsession with the anatomic success rate of retinal detachment repair might also entirely miss the point. The fact is that even though we have reached over 90% with multiple operations, the visual outcomes in general of macula-off detachments are still disappointing. The poor visual result seems disproportionate to the number of photoreceptors lost through apoptosis. There is a need for greater understanding of why visual recovery is so poor. Recent evidence from spectral domain OCT indicates that some cellular

recovery and remodeling can take place.<sup>340,341</sup> Photoreceptor regeneration or rearrangement could be potentially estimated from the integrity of the inner/outer-segment junction on OCT.<sup>342</sup> If we were to improve the visual prognosis, perhaps pharmacologic agents that confer neuroprotection might be just as important as targeting the process of PVR. After all, visual recovery is ultimately what patients and surgeons desire.

## **Introduction**

Reports of the primary success rate of rhegmatogenous retinal detachment (RRD) repair can range from 64% to 91%,<sup>1-6</sup> a significant improvement from success rates first reported in 1912, where the estimated success rate of therapy was 1 in 1000.<sup>7</sup> The etiology of RRD is now better understood, and most surgeons agree that retinal breaks should be first closed, and then permanently sealed with retinopexy. With advances in vitreoretinal surgical techniques, a broader range of treatment strategies is now available to surgeons to achieve retinal reattachment, allowing them to tailor their approach to improve primary success rates and visual outcomes. This can be seen by the enormous variation between surgeons in their choice of procedure for particular detachments.<sup>8</sup> Factors such as familiarity with the technique, grade of surgeon, and severity of detachment are also important to consider when assessing which procedure to use for any given type of retinal

detachment.

At present there is no large-scale prospective trial showing statistically different outcomes between all the different treatment options for patients presenting with noncomplex RRD. The highest level of evidence exists for horseshoe tear (HST) detachments where the outcomes of vitrectomy versus scleral buckling were compared.<sup>9</sup> The cost of running such trials is likely to be prohibitive given the high success rate of primary surgery, and therefore the numbers required to show a significant difference in success rate. Therefore this chapter aims to examine procedures currently in use, and assist the reader in choosing between them, for eyes with noncomplex RRD.

## Round Hole Retinal Detachment

### Introduction

In eyes with round hole retinal detachment, the causative breaks are small, round holes, often associated with lattice degeneration. Patients affected are typically young, low myopes, presenting with blurring of vision and a visual field defect. Some patients are asymptomatic and picked up on routine examination (Figs. 109.1 and 109.2). Round hole detachments are relatively uncommon, and in a large series of RRD reported by Tillery and Lucier, only 2.8% of cases were found to be secondary to round holes.<sup>10</sup> Other series have reported a higher frequency, with 13.9% being reported by Morse and Scheie,<sup>11</sup> and 21% in a series from Japan.<sup>12</sup> An important clinical finding in these patients is that the posterior hyaloid is usually attached. For example, in a large series of 110 round hole detachments requiring treatment, only eight (7%) of the eyes had a detached vitreous, and in these cases, the associated clinical findings suggested that the retinal detachment predated the posterior vitreous detachment (PVD).<sup>13</sup>

**FIG. 109.1** Typical limited retinal detachment associated with round holes. The patient was asymptomatic and was treated with laser demarcation.

**FIG. 109.2** Extensive retinal detachment associated with round holes. Although the patient was asymptomatic prior to detection of the detachment by her optometrist, she was thenceforth conscious of the temporal field defect and requested treatment. She responded well to scleral buckling surgery.

## Natural History

Much of our understanding of the natural history of round hole detachments comes from the painstaking work of Norman Byer. In a long-term follow-up of patients with asymptomatic retinal

lesions, there were 17 eyes with 18 areas of round hole retinal detachment.<sup>14</sup> The majority (75%) of the patients were followed-up for more than 5 years, and some for up to 12 years. There was no change in 13 of the 18 areas of detachment, and only a minor change in three areas (18%). In a later report, Byer reported on 19 eyes with up to 33 years of follow-up.<sup>15</sup> There were 22 areas of subclinical detachment in the 19 eyes, seven of which showed some form of progression, and only two of which required treatment, which was successful in both. Therefore, it can be stated that none of the patients in this series lost vision as a result of the initial decision to defer surgery.

A common misconception is that a pigment line, or “tide mark” or “demarcation line” posterior to the area of detachment, will prevent progression. This is not the case, though such a line does imply stability of the extent of the detachment for at least some months. Benson studied 66 retinal detachments with demarcation lines (a subset of a larger series all requiring surgery), 20 of which were detected on routine examination. Most of these patients were young (median age 33) and had detachments secondary to round holes. The demarcation line had failed to prevent progression in 51 of the 66 cases.<sup>16</sup>

Brod et al. observed 28 patients (31 eyes) for 0.5–12.1 years (a mean follow-up of 3.4 years). The patients' age range was 17–82 years, with a mean of 49 years. The majority of eyes were myopic, with 76% of patients having refractive errors of  $-2$  diopters or more. A demarcation line was present in 23 eyes (74%). Only one patient progressed to develop symptoms with associated detachment of the macula, and reduction of visual acuity to 20/30, 3.3 years later. Vision returned to 20/20 following successful surgery. Another patient developed a new detachment from a subsequent PVD and a retinal “U” (horseshoe) tear.<sup>17</sup>

Jarrett reported on 16 patients with retinal detachments in whom surgery was delayed or did not occur. Eleven of these patients had round holes or dialyses. Eight patients had buckling surgery up to 8 years after detection, the delay being for a variety of reasons, including reluctance on behalf of asymptomatic patients to undergo eye surgery. Seven eyes progressed, but only one patient who delayed surgery presented later with a detached macula.<sup>17</sup>

## Conservative Management

Conservative management can be considered for patients with peripheral or asymptomatic detachments not threatening the macula. The acceptability of this approach is not dependent solely on the characteristics of the detachment, but rather on patient factors such as the powers of observation of the patient and their ability to attend urgently should they experience symptoms of progression. Many surgeons advocate routine examination at regular intervals, for example every 6 months or annually.<sup>18</sup> However, progression is more likely to occur between follow-up examinations, and if the patient is unable to detect a change, then there is still a risk of the macula detaching before treatment can be applied and the patient suffering long-term visual sequelae. This risk has to be balanced against the possibility of surgical complications in a patient who has presented with an asymptomatic retinal detachment where the risk of progression is small. A patient who develops chronic discomfort, diplopia, or visual loss following surgery for an asymptomatic problem is not surprisingly dissatisfied.

## Treatment

### Laser Demarcation

The use of laser demarcation treatment to create a band of effective chorioretinal adhesion, which completely surrounds the area of detachment, is often recommended in patients with peripheral or small areas of retinal detachment. The area of chorioretinal adhesion acts like a barrier limiting further progression of subretinal fluid<sup>19</sup> but does not resolve the existing detachment, leaving the patient with a scotoma in this area. This may be appropriate in patients with asymptomatic retinal detachments, or those with very minimal symptoms.

Laser treatment is usually applied from ora to ora, just posterior to the edge of subretinal fluid (Fig. 109.3). Although cryotherapy could be used, laser photocoagulation is preferred as it causes less tissue damage and less inflammatory reaction to the external eye. There is evidence that an adhesion stronger than normal appears

within 24 hours of the application of treatment,<sup>20</sup> but maximum strength is achieved between 3 and 14 days later.<sup>21</sup> Therefore, laser demarcation is not suitable for rapidly progressive detachments.

**FIG. 109.3** Localized peripheral detachment secondary to round holes. This was treated with a broad band of laser photocoagulation from ora to ora to “wall off” the fluid and prevent it progressing posteriorly to threaten the macula.

The evidence base supporting laser demarcation for retinal detachment is limited, often being retrospective or consisting of small cohorts. Okun et al. discussed demarcation in 1968. The authors treated 48 eyes, and 42 (88%) were stable after 0.5–6 years' follow-up. Of the remaining six eyes, three developed additional areas of detachment from new breaks, and three were judged at the time of laser to need surgical treatment.<sup>22</sup> Gratton treated 42 phakic patients with limited retinal detachments and attached maculas. Most patients (54%) were myopes. Follow-up was for 1–4 years, during which time only one case progressed. In this patient, surgery was successful in reattaching the retina with no visual loss or complications.<sup>23</sup> In a similar study by Vrabec and Bauml, only one case of progression was reported following inadequate laser reaction, in a cohort of 34 eyes.<sup>24</sup>

Extensive round hole detachments can still be considered for laser demarcation; however, following confluent laser retinopexy, the area of affected retina, and hence the area of visual field defect, will increase. This may result in symptoms where they previously

did not occur. Equally, patients with symptomatic retinal detachments may become more troubled by their symptoms. In patients where subretinal fluid extends posteriorly towards the arcade, the interface between attached and detached retina may become more difficult to determine. In these cases slit-lamp laser treatment may be less technically challenging for the most posterior aspect of the retinal detachment prior to converting to indirect laser for more anterior segments as required.

## **Scleral Buckling**

The primary success rate of scleral buckling in round hole detachments is very high, but there is a risk of ocular morbidity. Tillery and Lucier reported results of buckling surgery in cases with detachments secondary to round holes in lattice (some of whom were asymptomatic). The reattachment rate with scleral buckling was 98%. However, 15% had<sup>10</sup> worse vision postoperatively, and the proportion of eyes with worse postoperative vision in the subgroup of those eyes with 20/40 or better preoperatively was 31%.<sup>10</sup> It should be noted, however, that in this cohort scleral buckles were placed under a scleral flap and supplemented with an encircling band which may have led to greater postoperative morbidity.

Greven et al. reported results of 28 eyes of 27 patients with subclinical detachments. In 16 eyes (57%), the detachment was detected on a routine examination, and in eight patients, the fellow eye had a previous symptomatic detachment. All eyes were treated with segmental scleral buckling, and two were encircled. The initial reattachment rate was 100%, but one eye developed another retinal detachment associated with new breaks after 14 months. One eye lost vision from 20/20 to 20/30 “without obvious cause,” but no mention was made of any other complications.<sup>25</sup>

Ung et al. from Cambridge reported excellent results from scleral buckling in a large series of retinal detachments secondary to round holes. All but one of 110 detachments were repaired with a single procedure, a success rate of 99%.<sup>13</sup>

## **Vitreotomy**

Vitreotomy is not usually recommended for the treatment of round hole retinal detachments due to the potential difficulties in inducing a posterior vitreous detachment over detached retina. However, the increasing use of vitrectomy in some centers combined with the relative reduction in scleral buckling has led to some advocating vitrectomy for round hole detachments. To date no large-scale studies showing the success rates and complications of this indication have been published.

## Detachment Due to Retinal Dialyses

### Introduction

Retinal dialysis denotes a circumferential tear of the retina from its insertion at the ora serrata. Some dialyses are secondary to trauma, and are most commonly found in the inferotemporal quadrant.<sup>26</sup> Nontraumatic idiopathic dialyses may also occur, and tend to be bilateral and inferotemporal,<sup>27,28</sup> and some such cases may be inherited.<sup>29</sup> Retinal dialyses account for a small proportion of retinal detachments presenting to a vitreoretinal unit, approximately 4–17%.<sup>30–32</sup> The majority of patients are young (mean age ~30), with a slight male to female preponderance of 1.3 :1.<sup>30,31</sup> Although trauma is often thought to be the most common precipitating event, a recent retrospective study found that only 22% had a history of significant ocular trauma or findings of ocular trauma on clinical investigation.<sup>33–35</sup> This may also reflect differences in the definition of trauma, with some studies including trauma to the head rather than just direct blows to the globe. The posterior vitreous face is attached in the vast majority of cases with a PVD being present in 2–3% of cases.<sup>31,36</sup>

### Natural History

There is often a long interval between the creation of the dialysis and the development of a symptomatic retinal detachment. In the series of traumatic retinal detachments described by Cox et al., the time from trauma to retinal detachment was up to 40 years, though in 80% of cases, was less than 2 years.<sup>37</sup> In another series of 50

patients, 41% of the detachments due to traumatic dialysis were diagnosed more than 1 year after injury.<sup>34</sup> Late presentation may be explained by slow progression of the detachment, and this may be related to the lack of vitreous detachment. If the detachment is not detected until the macula becomes involved, then the final visual acuity can be compromised. In Ross's series, 84% of eyes had detached maculas prior to surgery.<sup>34</sup> In a report from Northern Ireland on patients with traumatic retinal detachments, patients with delayed diagnosis were found to have a less favorable visual outcome than those who were diagnosed within 6 weeks of the trauma.<sup>38</sup> It is also important to note that patients may present with more than one retinal dialysis; in a series of 63 patients, 29% had more than one dialysis, illustrating the importance of inspecting all quadrants thoroughly.<sup>31</sup>

## Conservative Management

The considerations and options for the management of patients with limited detachment secondary to dialysis are identical to those for patients with round hole detachments. Cases with signs of chronicity, such as tidemarks and retinal cysts, have probably been stable for some time, consequently with a relatively low risk of progression. In one series of 71 detachments secondary to dialysis, three patients had such signs of chronicity and were followed-up without incident.<sup>30</sup>

## Treatment

### Laser Demarcation

Limited detachments secondary to dialysis respond well to laser demarcation. This is particularly true for the majority of detachments from dialyses that are in the inferotemporal quadrant. Walling off of the affected area here results in a permanent field defect superonasally, which is likely to be less important to the patient, than inferotemporal field loss. In Kennedy's series of 71 patients, five were successfully treated with retinopexy in order to demarcate a local detachment.<sup>30</sup>

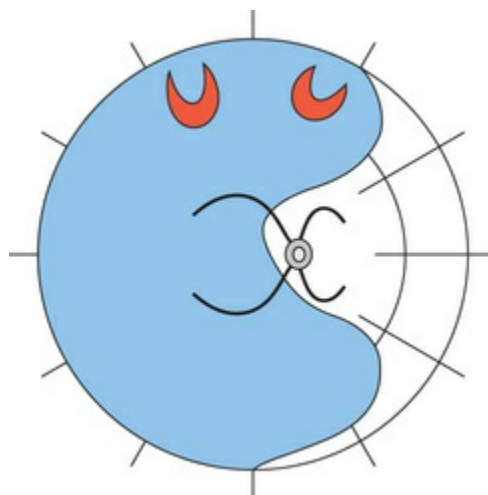

## Scleral Buckling

Dialyses respond well to segmental scleral buckling procedures. In a series of traumatic retinal detachments including 49 cases of dialysis, the primary success rate was 96%.<sup>38</sup> In another series, from France, of 48 cases of retinal detachment secondary to dialysis, the primary success rate was 100%.<sup>36</sup> Ross described a series of 50 eyes with a primary success rate of 94% and a final success rate of 98%.<sup>34</sup> The primary success rate for surgery in Kennedy's series was 97%.<sup>30</sup> The presence of PVR is rare in patients with retinal dialyses; however, in patients with PVR at the time of surgery, the surgical success rate is reduced.<sup>31,32</sup>

## Retinal Detachment Secondary to “U” (Horseshoe) Tears

### Introduction

This category represents the most common group of rhegmatogenous retinal detachments.<sup>32</sup> The detachment is secondary to one or more traction “U” tears, which in turn follow PVD (Fig. 109.4). A typical patient will present with visual loss, a symptomatic field defect, and a history of floaters and flashing lights some weeks previously.

**FIG. 109.4** Extensive detachment secondary to traction tears. At 2 weeks after noticing flashing lights and

floaters, this patient suddenly lost vision “like a curtain coming up from below.” There are two large posterior tears, and the detachment is bullous. It was treated successfully using a vitrectomy and SF<sub>6</sub>.

## Natural History

Retinal detachments associated with HST tend to progress rapidly as a result of continuing vitreous traction on the flap, encouraging further recruitment of subretinal fluid. Fluid currents within the eye also play a significant role in the development and progression of the detachment, as described by Machemer in his Jackson Memorial Lecture in 1988.<sup>39</sup> Subretinal fluid from superior tears spreads more rapidly than that from inferior ones, and this needs to be borne in mind when planning the timing of intervention in eyes with an attached macula. The speed of onset means that patients often complain of PVD symptoms just prior to the onset of visual field loss or at around the same time. However, in pseudophakic patients, there is evidence that chronic traction from a preexisting PVD may lead to new, often small, anterior breaks.<sup>40,41</sup>

The rapid progression of most detachments in this category means that there is an increased risk of macular involvement prior to presentation in these patients. In Burton's series of 953 primary retinal detachments, 69.5% of cases had detached maculas preoperatively.<sup>42</sup> More recently the Scottish Retinal Detachment study reported that 49.4% patients with HST retinal detachments presented with macular involvement compared with 41% round hole detachments.<sup>32</sup> Left untreated, retinal detachment results in severe loss of vision as well as a significant rate of discomfort and cosmetic problems.<sup>43</sup>

## Conservative Management

Conservative management for limited detachments is adopted less commonly than in RRD due to round holes or dialyses. This is because patients usually present with symptoms associated with the PVD, and there are rarely signs of the fluid being longstanding. There is therefore much less confidence that the fluid will remain

stationary or progress slowly. Furthermore, the continuing vitreous traction is an additional factor leading to faster progression.

Occasionally, a small, asymptomatic peripheral detachment from a “U” tear might appear stable, with subsequent development of a tide mark, in which case, careful observation might be appropriate (Fig. 109.5). Since these detachments tend to occur in an older age group, there are also cases whereby severe medical comorbidity precludes any form of treatment.

**FIG. 109.5** Long-standing retinal detachment secondary to a “U” tear. There is a tidemark indicating chronicity. This patient was treated with laser demarcation to reduce the risk of progression.

## Treatment

### Laser Demarcation

Although laser photocoagulation creates an instant adhesion, this is not up to full strength for up to 14 days.<sup>21</sup> Rapidly progressing fluid may extend through the area of demarcation before a strong enough adhesion develops. The distinction between a HST with a cuff of subretinal fluid and an early HST retinal detachment is not always clear in the acute stages following posterior vitreous detachment. The rate of subretinal fluid accumulation and hence retinal detachment progression may be determined by the patient history, location, size, and number of breaks. The presence of a large superior break with a short history is more likely to progress

prior to the formation of adequate adhesion in response to laser, and in these cases laser should be used with caution. In patients where laser treatment is used, sufficient margin should be left between the detachment edge and the placement of laser burns to allow for some progression of subretinal fluid prior to an adhesion developing.

## **Pneumatic Retinopexy**

Modern pneumatic retinopexy (see [Chapter 107](#), Pneumatic retinopexy) was introduced by Hilton and Grizzard in 1986.<sup>44</sup> Expanding gas is injected into the vitreous cavity, followed by application of cryotherapy or laser photocoagulation. The technique can be applied in an outpatient setting under local anesthesia. Postoperatively the patient positions their head so that the gas bubble is opposed to the break or breaks. This limits the flow of fluid into the subretinal space and allows reabsorption of the existing fluid by the retinal pigment epithelium. The technique is most appropriate for detachments with breaks limited to one quadrant, usually superiorly. Complications of pneumatic retinopexy include raised intraocular pressure, and subretinal gas.<sup>45</sup> The expanding gas may also exert traction inferiorly leading to the creation of new, inferior breaks, particularly in the presence of inferior lattice degeneration.<sup>46</sup> New or missed breaks are a common cause of failure following pneumatic retinopexy, accounting for half the failures in one series.<sup>47</sup>

Pneumatic retinopexy was found to have a comparable success rate to vitrectomy with cryotherapy and gas in a prospective randomized control trial in 120 cases.<sup>48</sup> A large multicenter randomized trial compared pneumatic retinopexy with scleral buckling in 198 patients. There was a higher rate of primary reattachment in the scleral buckling group (82% vs. 73%), but this difference did not achieve statistical significance ( $p>.05$ ). There was no difference in the final reattachment rate (98% vs. 99%). However, the patients with pneumatic retinopexy had less morbidity and better final visual acuity.<sup>49</sup> In a more recent study of 422 patients, the primary success rate was 61% with a final success rate of 99.5%.<sup>50</sup>

A recent Cochrane review comparing pneumatic retinopexy to

primary scleral buckling reported that there was some evidence that scleral buckling had a higher primary success rate; however, the reviewers conceded that they could not rule out that there was no difference between the two procedures.<sup>51</sup> Most studies have indicated no difference in the final success rate between the two, and more importantly, no difference in the final visual acuity. There is evidence, however, that pneumatic retinopexy is less effective in aphakic and pseudophakic eyes. In a series of 56 eyes, the primary success rate was 81% in a subgroup of phakic eyes but only 43% in eyes which were aphakic or pseudophakic.<sup>52</sup>

Given that pneumatic retinopexy is a relatively quick and simple procedure, with less morbidity than scleral buckling, it is worth considering as an initial procedure. This is particularly the case for patients who have “classic” indications, as the success rate appears higher in this group. In a subgroup of patients with phakic eyes, single breaks, and fluid confined to one superior quadrant, the primary success rate was 97%.<sup>53</sup> Even if treatment fails, a good final result can be expected following further surgery. Despite this, a recent survey by the American Society of Retinal Specialists showed that preferences toward pneumatic retinopexy as a primary procedure have declined over the past 8 years, commenting that this may reflect a greater confidence in vitrectomy surgery.<sup>54</sup>

Most surgeons who use pneumatic retinopexy apply it as a primary procedure and then employ scleral buckling if it fails. However, pneumatic retinopexy can also be used as an effective method of treating detachments after failed scleral buckling. In most of these cases, there is persistent elevation of the retinal break above the buckle and retinopexy has already been applied. All that is necessary is temporary reduction in fluid flow through the break to allow the retina to settle. In a series of 36 eyes with failed scleral buckling surgery, injection of gas was successful in reattaching the retina in 25 (69.4%).<sup>55</sup> In a more recent study of 42 consecutive cases, secondary pneumatic retinopexy after either scleral buckling surgery or vitrectomy, resulted in a reattachment rate of 100% in the scleral buckle group and 90% in the vitrectomy group.<sup>56</sup>

## **Scleral Buckling**

The aim of buckling surgery is to create an indentation of the sclera

beneath the retinal break. The possible mechanisms of action are well described elsewhere in this volume (see [Chapter 104](#), Techniques of scleral buckling), but the effect is to reduce the rate of flow of fluid into the subretinal space, leading to resolution of the detachment. It is important to understand that buckling achieves only closure, and not sealing of the retinal break, the latter being the role of retinopexy. The implication of this is that buckling alone has the same initial success rate whether retinopexy is applied or not, but if the indentation fades or the buckle is removed, the retinal redetachment will recur. This notion has been confirmed by Chignell, who reported success in 26 of 29 cases of retinal detachment treated with scleral buckling and no retinopexy. Follow-up varied from 6 months to 2 years, and no redetachments were reported,<sup>57</sup> although no buckles needed to be removed during that period. When these cases were followed-up in the long term, late detachments were found in 4 of 46 patients. In all these cases, redetachment occurred because of reopening of the original retinal break, and was associated with progressive reduction of the height of the scleral buckle.<sup>58</sup> In another, larger series of scleral buckling without retinopexy, initial success was achieved in 143 of 175 cases (82%) and final success in 158 cases (90%). Causes of initial failure were all related to malposition of the buckle or the development of new breaks, rather than anything to do with retinopexy. Follow-up was only 6 months, so the long-term effect of buckle fade in these patients is not known.<sup>59</sup>

There is a lack of consensus concerning the best type of buckle to use in any particular circumstance. Limited retinal detachments with single breaks can be treated with a radial element, or a small segmental buckle. Many surgeons supplement the segmental buckle with an encircling band. This has the advantage of helping to maintain the buckle height in the long term. However, if retinopexy has been applied to all the breaks, then this is theoretically unnecessary. Several nonrandomized series have produced good results without encirclement and good long-term follow-up.<sup>60</sup> By contrast, encirclement is associated with a higher risk of motility disturbance and refractive changes, and can also lead to long-term problems, such as erosion of the buckle through the sclera.<sup>61</sup> Singh investigated the role of encirclement in aphakic

patients in a prospective, randomized controlled trial. A total of 84 patients with aphakic retinal detachments were randomized to either local scleral buckling or encirclement. The primary success rate was 90% and 91% in the two groups, respectively.<sup>62</sup> Ho et al. reported no difference in success rates between three different buckling methods in a nonrandomized study of 128 eyes. However, there were more complications in the group of eyes that were encircled.<sup>63</sup>

## Vitrectomy

### Conventional Indications.

Conventional indications for vitrectomy are those where scleral buckling could be technically challenging. Vitrectomy may offer a more successful approach for simple detachments with significant vitreous opacity, or for those with posterior breaks that would otherwise require a large scleral buckle. Other agreed indications include eyes with thin sclera which would make scleral buckling difficult or dangerous (Video 109.1  online).

As surgeons became more comfortable with vitrectomy techniques to manage cases of vitreous pathology and complex retinal detachments, it became clear that the advantages of an internal approach could also be useful for simpler cases. There is now considerable overlap with current indications for scleral buckling surgery, such that vitrectomy is increasingly used in preference to scleral buckling surgery in many units.<sup>8,54,64</sup> In an analysis of Medicare beneficiaries from 1997 to 2007, the use of vitrectomy (with or without scleral buckle) for the treatment of primary RRD had increased by 72% over the study period.

Currently, controversy surrounds the management of medium complexity, bullous, retinal detachments, which represent the majority of cases (Fig. 109.6). Some centers have moved away from scleral buckling towards vitrectomy for the primary management.<sup>8,65</sup> Proponents of vitrectomy argue that it can directly eliminate vitreous traction, remove media opacities, and allow better detection and localization of retinal pathology, particularly when using wide-angle viewing systems. Vitrectomy eliminates the risks of buckle-related complications, such as drainage problems,<sup>66</sup>

choroidal effusions,<sup>67</sup> diplopia,<sup>68</sup> and extrusion of the explant.<sup>69</sup> However, the use of vitrectomy introduces a new set of potential complications, including entry site breaks,<sup>70</sup> postoperative nuclear sclerosis,<sup>71</sup> and proliferative vitreoretinopathy.<sup>72</sup>

**FIG. 109.6** Superior bullous retinal detachment secondary to a posterior vitreous detachment and “U” tears. This type of detachment is difficult to manage by buckling techniques and was treated with a vitrectomy.

Many case series of primary vitrectomy for RRD have been reported. The primary reattachment rate varies between 64% and 100%.<sup>73</sup> A large study from Japan compared 225 phakic eyes with superior retinal detachments associated with “U” tears. Scleral buckling was used in 138 eyes, and 87 eyes were treated with vitrectomy, according to surgeon preference. Primary and final anatomic success rates were identical between the two groups at 92% and 100%, respectively.<sup>74</sup> It is relatively easy to compare reattachment rates between scleral buckling and vitrectomy, and when this is done, the results are similar. However, a valid comparison should also include assessment of the complications, and this is where difficulties occur. This is because the complications are qualitatively different, and there is no scientific method of comparing, e.g., diplopia from a scleral buckle with nuclear cataract from a vitrectomy.

The Scleral Buckling versus Primary Vitrectomy in Rhegmatogenous Retinal Detachment Study (SPR Study) was the first large prospective randomized clinical trial to compare outcomes of two different surgical methods in retinal detachment.<sup>9</sup>

A total of 45 surgeons in 25 centers recruited a total of 681 patients with “medium complexity” detachments. Medium complexity cases were primary RRDs with breaks of size from one to two clock-hours, multiple breaks, superior bullous detachment, central extension of breaks, or marked vitreous traction. Cases were divided into phakic and aphakic/pseudophakic groups before being randomized into scleral buckling or PPV. The protocol allowed the use of a supplementary buckle in cases undergoing PPV at the discretion of the operating surgeon. Surgeons had carried out at least 100 cases using each method before participating in the study. The primary outcome measure was defined as the change in best corrected visual acuity (BCVA) between the initial examination and the final follow-up at 12 months. Secondary outcome measures were the rate of PVR and primary anatomic success. The latter was defined as attachment of the retina central to the equator at the final follow-up visit without additional retinal procedures. With this definition, cases having supplemental laser or treatment of macular pucker would be classified as failures, so it is important to realize that the primary anatomic success rate is not equivalent to what many surgeons might understand as primary reattachment rate, which can be derived from the data for retinal redetachment provided in the study. The key results of the study are shown in [Table 109.1](#), and in summary, there was a better improvement of BCVA with scleral buckling in phakic eyes, and a high primary success rate using vitrectomy in aphakic/pseudophakic eyes.

**TABLE 109.1**  
**Summary of the Main Results From the SPR Study**

Outcome	Scleral Buckling	Vitrectomy
<b>PHAKIC</b>		
Improvement in BCVA	-0.71*	-0.56
Primary success	63.6%	63.8%
Primary reattachment	73.7%	74.9%
<b>APHAKIC/PSEUDOPHAKIC</b>		
Improvement in BCVA	-0.56	-0.65
Primary success	53.4%	72.0%*
Primary reattachment	60.1%	79.5%*

\*Difference statistically significant ( $p < .05$ ).

BCVA, best corrected visual acuity; SPR Study, Scleral Buckling versus Primary Vitrectomy in Rhegmatogenous Retinal Detachment Study.

The SPR Study is a very important contribution to the evidence base of retinal detachment surgery. Since the study was planned, attention has been focused on the “surgeon factor” in surgical trials, because most surgeons have a preferred technique with which they may get better outcomes. Traditional randomization results in only half the patients having a surgeon using their preferred operation, and a better study design for future trials might be expertise-based.<sup>75</sup> However, analysis of the results by surgeon in the SPR Study has found that the majority of surgeons had similar success rates for both operations.<sup>76</sup>

### **Supplementary Buckle.**

Some vitreous remains after vitrectomy, even when shaving of the vitreous base is performed, which may continue to exert traction on retinal breaks, and form a scaffold for later development of PVR. Inferior retinal breaks depend on patient positioning to maintain contact with the tamponade agent. For both these reasons, many surgeons have advocated supplementary scleral buckles. Gartry presented a series of 114 eyes treated with vitrectomy for retinal detachments uncomplicated by PVR. The indication for vitrectomy in the majority was media opacity or large posterior breaks. Supplementary buckles were used for cases that had been operated on previously, and for those with breaks below one clock-hour above the horizontal meridian.<sup>77</sup>

However, a large series of 275 pseudophakic eyes treated with vitrectomy and no buckling showed no evidence of failure resulting from factors associated with lack of a scleral buckle. The anatomic success rate after one operation was 241 (88%), and the final success rate was 265 (96%). No details are given about the distribution of fluid and the position of retinal breaks in this series. However, since the patients were consecutive, it can reasonably be assumed that many of them had inferior breaks. Of the 34 eyes that were not attached with one operation, 17 were associated with new breaks or opening of old ones. Sixteen had PVR and one had a suprachoroidal hemorrhage. Subsequent surgery included a scleral buckle in 12 eyes.<sup>6</sup> A retrospective study of retinal detachments with breaks between 4 and 8 o'clock specifically looked for an advantage of supplementary buckles but failed to find an increased success rate.<sup>78</sup>

In the SPR Study, the use of a buckle in cases randomized to the vitrectomy group was allowed at the discretion of the surgeon. Ancillary analysis found that the use of a supplementary buckle was associated with better success rates in the pseudophakic/aphakic group, but not in the phakic group.<sup>9</sup> A supplementary scleral buckle has the disadvantage of introducing additional risks and complications. Although there may be theoretic advantages in selected cases, there is no evidence base to support its widespread use.

### **Laser Versus Cryotherapy.**

All techniques for retinal reattachment require some form of retinopexy to create a chorioretinal adhesion to seal retinal breaks or wall off areas of detachment. Gonin used thermocautery to achieve this, but today only laser photocoagulation and cryotherapy are widely used. Debate continues about the relative merits of each technique.

Cryotherapy is applied using an external probe, while visualizing the treatment area with the indirect ophthalmoscope or wide-angle viewing system. One practical advantage is that it can be used with moderate degrees of media opacity, and because retinal breaks “light up,” the surgeon has increased confidence that hard-to-see breaks have been treated. Many surgeons prefer the use of laser, either endolaser as part of an internal approach, or the indirect laser ophthalmoscope during scleral buckling surgery. Endolaser is easy to apply, but the use of the indirect laser can be difficult with moderate media opacity, or in the presence of shallow subretinal fluid. This problem can be addressed for scleral buckling by applying indirect laser to the tear postoperatively, once the retina has reattached.

Cryotherapy has been shown to promote dispersion of viable retinal pigment epithelial cells and to cause breakdown of the blood–retinal barrier. Ryan reported two cases of cystoid macula edema, which occurred following uncomplicated scleral buckling procedures for macular-on retinal detachment.<sup>79</sup> Cystoid macular edema, and wrinkling of the inner limiting membrane, has also been reported following cryotherapy alone.<sup>80</sup> It must be remembered, however, that macula pathology, particularly

epiretinal membranes, also occur following PVD without tears, and the association with cryotherapy is not necessarily causative.

Cryotherapy has been shown to cause breakdown of the blood–retinal barrier. In rabbit eyes treated with confluent laser in one eye and equivalent cryotherapy in the other, there was a significantly greater increase in vitreous fluorophotometry readings in the cryotherapy-treated eyes. However, both eyes returned to normal readings after 14 days.<sup>81</sup> Similar findings in man were demonstrated in a randomized trial of cryotherapy and laser photocoagulation in conventional retinal detachment surgery. Patients were treated either with cryotherapy at the time of surgery or with laser photocoagulation 4 weeks postoperatively. Postoperative flare was measured using laser flare photometry and was significantly higher in the cryotherapy group than the laser group. In addition visual recovery was slower in the cryotherapy group. However, at 10 weeks postoperatively, there was no difference in visual acuity between the two groups.<sup>82</sup> Cryotherapy produces more extensive retinal edema and necrosis in treated areas than laser. Lesions are similar at 14 days with atrophy of the retina and choroid, and a pigmented chorioretinal scar.<sup>83</sup>

Many studies have examined risk factors for the development of PVR, but results are contradictory. In a large retrospective study of 65 eyes with PVR and 325 controls, Cowley et al. found that the amount of cryotherapy applied and the use of vitrectomy were independent risk factors for PVR.<sup>72</sup> In another retrospective study comparing laser and cryotherapy, no difference in the rate of postoperative PVR was found in those eyes with round hole detachments or traction tears with no preoperative PVR. However, in eyes with traction tears and some preoperative PVR (“curled posterior edges”), cryotherapy was found to be associated with a higher risk of PVR (13/88, 14.7%) compared with 1/56 (1.7%) in the laser group. Unfortunately, the size and number of the retinal breaks was not included in the multivariate analysis.<sup>84</sup> The importance of including confounding factors was illustrated by the results of another multivariate analysis, which was a prospective study with good data collection, looking at factors associated with success of scleral buckling in a large number of eyes with rhegmatogenous retinal detachment. The vast majority of failures

were due to PVR. While the number of applications of cryotherapy was found to be associated with failure after univariate analysis, it was not found to be a significant factor when the other variables, such as the size and number of breaks, were included.<sup>85</sup> A prospective study looking at PVR in a subgroup of 140 patients undergoing vitrectomy for retinal detachment found that cryotherapy was not an independent risk factor for PVR formation.<sup>86</sup>

In summary, there is no strong evidence to suggest that the use of cryotherapy is inferior to laser photocoagulation. Both techniques have their place, and their selection is largely a matter of surgeon preference.

### **Sutureless Vitrectomy.**

The use of transconjunctival vitrectomy using smaller gauge instruments, 25- and 23-gauge (25G, 23G), has become increasingly popular, but there has been some controversy about the use of these systems in the management of RRD.<sup>87</sup> Most surgeons consider that removal of peripheral vitreous is important, and that indentation of the periphery is helpful in locating retinal breaks. Both these steps are more difficult in 25G surgery, and there were early reports of high redetachment rates. In a series of 53 eyes managed by 25G vitrectomy, the primary success rate was only 74%, the reasons for failure being either new retinal breaks or PVR. In addition, three eyes (6%) in this series developed postoperative choroidal hemorrhage.<sup>88</sup> The authors speculated that the lower flow rate associated with 25G might leave higher concentrations of cytokines in the eye. However, more recently studies have shown success rates with 23G and 25G systems comparable to those reported with scleral buckling and 20G surgery.<sup>89-92</sup> In a study of 133 eyes using 23G instrumentation, the primary success rate was 96.2%.<sup>89</sup> Similarly, recent studies have also reported comparable success rates (primary success over 90%) for 25G vitrectomy and gas, without the use of a supplementary buckle.<sup>91-93</sup>

### **Variations in Practice.**

The same case of retinal detachment might be treated in several different ways depending on which country, or which retinal

surgeon, they present to. Not only are there geographic variations in techniques, but these also change rapidly over time.

The success rate of retinal detachment surgery has improved since the pioneering work of Gonin. A report from a single center in the UK reported three cycles of audit over a 10-year period showing a significant increase in primary reattachment rates, which rose from 67% in Audit 1 (1987–1989) to 87% in Audit 3 (1995–1997) ( $p=.0004$ ).<sup>94</sup> In this audit the increased success rate was attributed to a reorganization of the department whereby retinal detachment surgery was performed solely by vitreoretinal specialists.

The influence of subspecialization in improvement of success rates was also highlighted in a national audit of primary surgery for RRD performed in the UK. Of the surgeons who responded, 38% performed retinal detachment surgery. Of these, 105 (41%) declared a special interest in retinal surgery and were therefore defined as “specialists” for the purposes of the audit.<sup>95</sup> Detachments were graded for severity ranging from 1–4 according to the distribution of retinal breaks and area of retinal detachment, for example, grade 2 detachments were defined as those with breaks within the same quadrant, and/or less than two quadrants of retinal detachment. In grade two detachments, the success rate of specialists was 87% compared with only 70% for nonspecialists ( $p=.001$ ).<sup>4</sup> The primary success rate overall (specialists and nonspecialists) was 77%.<sup>4</sup>

There is an increasing trend towards using vitrectomy as the preferred method of primary retinal detachment repair.<sup>54,96,97</sup> In the 1995 UK audit of primary surgery for RRD, scleral buckling was used in 83% of the sample and the remaining 17% had vitrectomy.<sup>98</sup> Interestingly, no patients in this survey had pneumatic retinopexy, reflecting a significant difference in practice between the UK and the United States. More recently, however, the National Database in the United Kingdom reported that the procedure of choice for primary retinal detachment was vitrectomy in 79.1% cases, scleral buckle in 12.1%, and vitrectomy with scleral buckle in 8.7%.<sup>97</sup> Similar trends have also been reported in the United States, with 53% preferring to treat a RRD secondary to a superior tear with a vitrectomy, 25% a pneumatic retinopexy and 21% a scleral buckle. This survey also observed that use of pneumatic retinopexy as a primary procedure had declined over the past 8 years, commenting

that this may reflect a greater confidence in vitrectomy surgery.<sup>54</sup>

Changes in preferred technique may also reflect a change in the range of pathology, mostly because of the aging population, and the increasing number of patients undergoing cataract surgery.

Among patients with RRDs, the proportion with aphakic/pseudophakic eyes increased to 30% over the 10 years to 1999.<sup>64</sup> These findings were confirmed in a similar study from London. More cases were pseudophakic and fewer aphakic in 1999 than in 1979–1980. Vitrectomy was a primary procedure in 63% of cases in 1999 but in only 1% in 1979–1980. Anatomic success rates were statistically similar: 79.8% primary and 88.8% final success in 1979–1980, compared with 84% primary and 93.6% final success in 1999.<sup>65</sup>

## Conclusion

The treatment of rhegmatogenous retinal detachment has advanced considerably since the pioneering work of Gonin. Both primary and final success rates are now high, and it is only a small minority of cases whose retinas remain detached after one or more operations. There is broad agreement about the best method for some categories of detachment, but for the majority of cases, there is both lack of agreement and lack of an evidence base to make rational choices of technique. The current evidence base suggests that many surgical techniques can achieve similar success rates in specialist units, and that perhaps familiarity and surgeon preference are the more compelling reasons for choosing a particular approach. Despite the contribution of the SPR Study, there remains a need for further evidence from well-conducted trials, and when setting up such trials, it is important to consider factors other than success rate. The goal of treatment should be to choose a method for any particular case that has the best chance of anatomic success, but with the lowest risk of introducing further ocular morbidity. Costs of the respective treatments to both the health care economy and the patient might also be considered. As Wilkinson put it: “The best method of repairing a particular detachment will remain a matter of speculation and bias until more appropriate data are acquired.”<sup>99</sup>

## Acknowledgment

Thank you to Maninder Bhogal MBBS, MD for shooting and editing the video demonstrating surgical techniques used in the treatment of primary retinal detachment with vitrectomy attached to this chapter.

**Prophylactic Therapy In Eyes Undergoing Vitreoretinal Surgery**

**Treatment Methods**

**Results and Complications of Prophylactic Therapy**

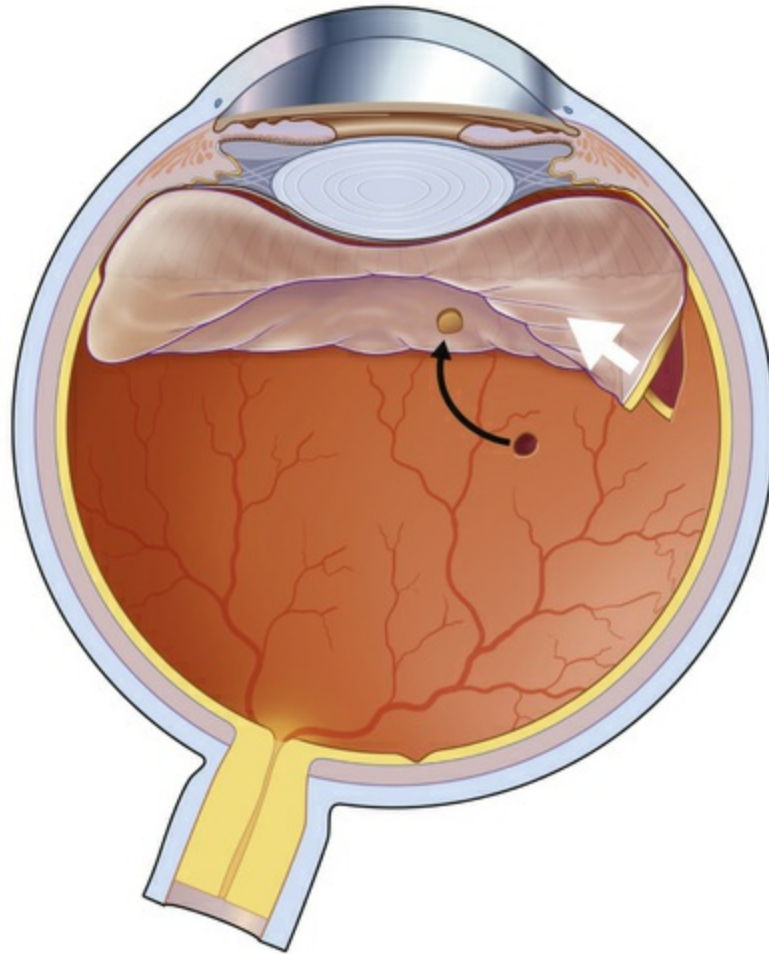

**Conclusion**

## Introduction

Rhegmatogenous retinal detachment continues to be an important cause of reduced visual acuity and blindness. In consecutive series, initial surgical attempts to reattach the retina currently fail in

approximately 10–20% of cases, and reoperations are unsuccessful in as many as 5% of cases.<sup>1–3</sup> Anatomic success is significantly less common in consecutive series of eyes with features suggesting an increased risk of proliferative vitreoretinopathy (PVR).<sup>4</sup> Following anatomically successful surgery, visual acuity returns to 20/50 or better in only approximately 50% of cases.<sup>5</sup> Thus, the prevention of retinal detachment is a worthy goal, and a variety of prophylactic methods have been investigated since the 1920s, when Jules Gonin first described the pathogenesis and treatment of this previously incurable disorder. However, despite a long-standing interest in the ophthalmologic community regarding prophylactic therapy, there have been no optimal clinical trials to test the legitimate value of any form of preventive treatment.<sup>6–9</sup>

Vitreous liquefaction and a retinal break are prerequisites for rhegmatogenous retinal detachment, and the usual pathologic sequence is vitreous liquefaction followed by some degree of posterior vitreous detachment (PVD). Although PVDs were usually considered to be “total” when they occurred, it is now apparent that from a quarter to a half of symptomatic patients may have subtotal PVDs with a continued risk of tears even after the symptomatic event.<sup>10,11</sup> Regardless, vitreoretinal traction at the site of a vitreoretinal adhesion results in the production of a retinal tear (Fig. 110.1). Alternatively, traction may be exerted upon areas of lattice degeneration containing atrophic retinal holes. Continued vitreoretinal traction near retinal breaks appears to be necessary to cause the vast majority of clinical retinal detachments. Thus, retinal detachment might be avoided by (1) preventing vitreous liquefaction and associated PVD; (2) relieving vitreoretinal traction; or (3) creating a chorioretinal adhesion around vitreoretinal adhesions and retinal breaks.

**FIG. 110.1** Traction on the retina (*white arrow*) at a site of abnormal vitreoretinal adhesion has created a retinal tear. If left untreated, liquid vitreous posterior to the vitreous gel will pass through this retinal break into the subretinal space, creating a retinal detachment. Operculated tears typically no longer have traction forces upon them (*black arrow*) unless there is a nearby vitreoretinal adhesion. (Reprinted from Brinton D, Wilkinson CP. Retinal detachment: Principles and practice. 3rd ed. New York: Oxford University Press with the cooperation of the American Academy of Ophthalmology. © 2009, with permission from Oxford University Press.)

No means are available to prevent vitreous liquefaction and later PVD in most eyes, although maintaining an intact posterior lens capsule after extracapsular cataract surgery may reduce or delay these changes.<sup>12</sup> Vitreoretinal traction can be relieved by vitrectomy or by scleral buckling. However, prophylactic vitrectomy is not performed because there are technical difficulties in completely removing the peripheral vitreous gel, and it is relatively hazardous.

Scleral buckling is only rarely employed, such as in particularly high-risk cases in which a nontraumatic giant retinal tear has already occurred in a fellow eye<sup>13</sup> or in cases of posterior segment open-globe injuries.<sup>14</sup> Thus, the primary method of preventing retinal detachment involves the use of laser photocoagulation or cryotherapy to create a chorioretinal adhesion around visible sites of vitreoretinal adhesion and retinal breaks, or alternatively around 360° of the peripheral retina including “normal” zones. Although this is frequently successful in sealing the treated lesion and preventing it from causing a clinical retinal detachment, the genuine value of such therapy related to simple observation remains unclear in most situations since most visible asymptomatic retinal breaks and vitreoretinal degenerative lesions do not cause retinal detachments. Instead, breaks causing detachment more frequently occur in regions of the peripheral retina that appear normal before PVD.<sup>6,7</sup> In addition, relatively extensive prophylactic therapy may cause vitreous changes that increase the chances of subsequent vitreoretinal traction and retinal detachment.<sup>6,15</sup>

## Risk Factors for Retinal Detachment

In any eye with visible retinal breaks or vitreoretinal adhesive lesions that predispose to retinal detachment, a number of additional factors are considered to be associated with a relatively high risk of subsequent retinal detachment (Table 110.1). Symptoms and signs of acute PVD place an eye at particularly high risk. Additional factors include a variety of hereditary, congenital, acquired, and iatrogenic problems.

**TABLE 110.1**

### Risk Factors for Rhegmatogenous Retinal Detachment

<b>Hereditary/congenital/developmental/degenerative</b>
Male gender
Hereditary vitreoretinopathies
Myopia
Lattice degeneration
Cystic retinal tuft
Degenerative retinoschisis
Retinal breaks
<b>Prior ocular surgery</b>

<ul style="list-style-type: none"> <li>• Aphakia/pseudophakia</li> <li>• Nd:YAG posterior capsulotomy</li> <li>• Other surgery involving vitreous gel</li> </ul>
<b>Prior ocular trauma</b>
<b>Inflammatory</b>
<ul style="list-style-type: none"> <li>• CMV retinitis</li> <li>• Acute retinal necrosis</li> </ul>
<b>Other</b>
<ul style="list-style-type: none"> <li>• Fellow-eye nontraumatic retinal detachment</li> </ul>

In evaluating the natural history or risk of retinal detachment in these cases, particular attention must be paid to the way in which both natural history and postoperative data, regarding a variety of retinal lesions, have been collected.<sup>16</sup> The risk of retinal detachment is substantially different among subgroups of eyes, a fact that influences interpretation of both natural history data and treatment results. For example, since an acute PVD is the primary cause of most retinal detachments, and since most retinal tears occur during or soon after PVD, it is likely that eyes without a PVD have a higher risk of later retinal detachment than eyes with a history of prior PVD and no subsequent retinal breaks, regardless of additional risk factors.<sup>17</sup> Similarly, vitreous liquefaction and PVD occur with greater frequency in older patients and in myopic and pseudophakic eyes.<sup>18,19</sup> Thus, data regarding lesions in otherwise normal, young, nonmyopic eyes are not comparable with data from cases with other risk factors that greatly increase the likelihood of PVD. Since more than one factor is often present, data analysis is difficult if all features are not recorded. For example, myopic pseudophakic eyes with lattice degeneration and with a history of retinal detachment in the fellow eye have a substantially greater risk of retinal detachment than otherwise normal eyes with lattice degeneration. No prospective randomized trials of therapy to prevent retinal detachment have been performed.<sup>6-9</sup> The few published studies of treated and untreated comparable eyes have been retrospective, and most reports regarding prophylactic therapy have simply described results of a treatment series.

This chapter briefly discusses published outcomes regarding both the natural course of lesions that predispose an eye to retinal detachment and results of prophylactic therapy for these retinal breaks and vitreoretinal adhesive lesions. The topic of “subclinical retinal detachment” (for one definition, see [Fig. 110.4](#)) will not be

discussed as a separate entity because of the nonspecific nature of the term. This chapter distinguishes symptomatic from asymptomatic cases and is organized according to the type of retinal break or vitreoretinal adhesive disorder and also according to the presence of other high-risk factors. A brief discussion of treatment methods precedes the review of treatment results and complications.

## Symptomatic Eyes

Patients are considered symptomatic if they describe increased vitreous floaters and/or photopsia, which are typically associated with an acute posterior vitreous detachment. Approximately 15% of eyes with a symptomatic PVD develop retinal tears of various types.<sup>20–22</sup> The risk of retinal tears is directly related to the amount of vitreous hemorrhage associated with symptoms, and the finding of pigmented cells in the vitreous is a sign associated with a particularly high chance of associated retinal tear(s).<sup>23</sup> In symptomatic eyes, retinal tears associated with persistent vitreoretinal traction are especially likely to cause retinal detachment, and the likelihood is even higher in cases with additional high-risk factors.

Retinal tears resulting from a symptomatic PVD should be distinguished from preexisting retinal breaks detected after the PVD but not caused by it. Thus, atrophic retinal holes within areas of lattice degeneration are not considered “symptomatic,” even if they were first observed during an examination prompted by symptoms of an acute PVD. Symptomatic retinal tears are subdivided into those with persistent vitreoretinal traction and those in which all traction in the region of the retinal defect has disappeared (Fig. 110.1).

### Tears With Persistent Vitreoretinal Traction

Most symptomatic tears with persistent vitreoretinal traction are horseshoe-shaped and have a high risk of causing clinical retinal detachment. Rarely, a retinal tear with a free operculum may have persistent vitreoretinal traction as a result of a residual vitreoretinal

adhesion near the retinal break, most frequently at the location of a retinal blood vessel (Fig. 110.2).

**FIG. 110.2** Superior temporal retinal detachment, left eye, resulting from a single operculated retinal break. The minimal movement of the operculum during major ocular saccades indicated that persistent vitreoretinal adhesions were present in the vicinity of the retinal hole.

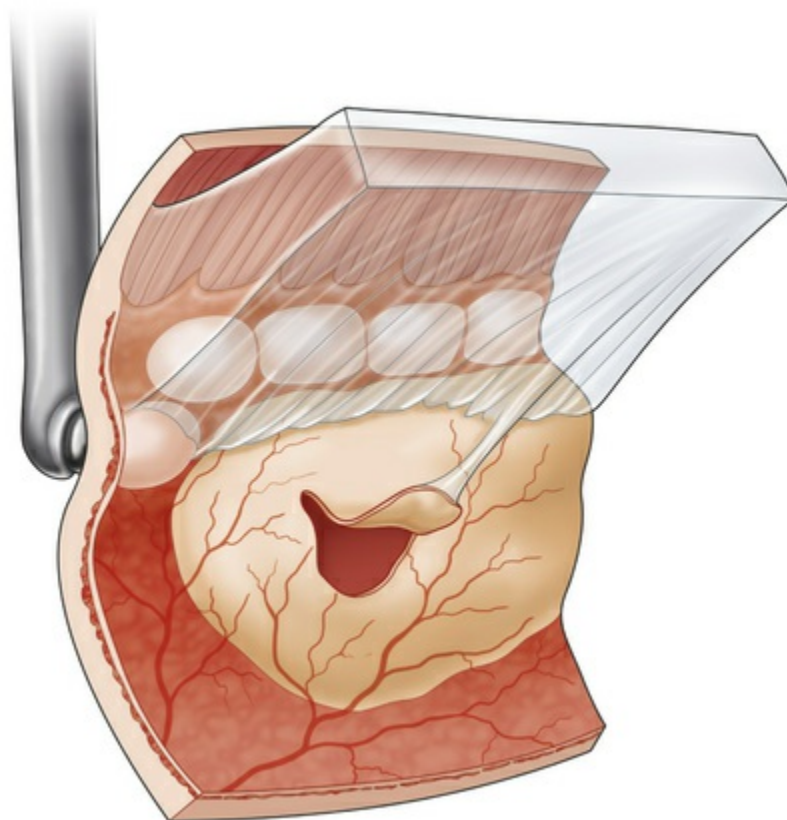

### Horseshoe-Shaped Tears

Untreated symptomatic retinal tears with persistent vitreoretinal traction have been reported to cause retinal detachment in at least 33–55% of cases (Table 110.2).<sup>24,27</sup> Treatment of this type of break substantially reduces the risk of retinal detachment (Table 110.2),<sup>24</sup> and immediate therapy for these lesions is indicated to prevent an accumulation of subretinal fluid.<sup>7,9,25–30</sup> A chorioretinal adhesion is created in flat retina immediately adjacent to localized subretinal fluid (Fig. 110.3). Reviews of treatment techniques have been provided elsewhere in the literature,<sup>31</sup> and these are briefly discussed later in this chapter.

**TABLE 110.2****Progression of Symptomatic Retinal Breaks to Retinal Detachment (RD)**

Type of Break	Authors	Cases (n)	RD (%)
Treated horseshoe-shaped tears	Shea et al. 1974 <sup>24</sup>	48	4.2
	Robertson and Priluck 1979 <sup>15</sup>	88	7.8
	Verdaguer and Vaismon 1979 <sup>25</sup>	74	5.4
	Pollack and Oliver 1981 <sup>26</sup>	74	1.4
Untreated horseshoe-shaped tears	Colyear and Pischel 1960 <sup>27</sup>	20	55
	Shea et al. 1974 <sup>24</sup>	21	48
Treated operculated breaks	Robertson et al. 1981 <sup>28</sup>	47	0
Untreated operculated breaks	Colyear and Pischel 1960 <sup>27</sup>	22	4.5 <sup>a</sup>
	Davis 1973 <sup>29</sup>	6	17 <sup>a</sup>

<sup>a</sup>A single break in each series exhibited persistent vitreoretinal traction upon a nearby retinal vessel and caused a subsequent retinal detachment.

**FIG. 110.3** Cryotherapy is placed to surround and demarcate a peripheral, symptomatic, horseshoe-shaped tear with a subclinical retinal detachment. Photocoagulation can often be applied around the posterior portion of the detachment, but cryotherapy

may be needed anteriorly if laser treatment cannot be extended into the vitreous base. (From Brinton D, Wilkinson CP. Retinal detachment: Principles and practice. 3rd ed. New York: Oxford University Press with the cooperation of the American Academy of Ophthalmology. © 2009, with permission from Oxford University Press.)

## Round Tears

The percentage of operculated retinal tears that are associated with persistent vitreoretinal traction in the vicinity of the retinal break is unknown, but it is quite low. Only two symptomatic operculated retinal breaks have been reported to progress to retinal detachment, and both were associated with persistent vitreoretinal traction on a nearby retinal vessel.<sup>27,29</sup> In unusual cases in which an operculated retinal hole is the only retinal break associated with a clinical retinal detachment, it is presumed that anomalous persistent vitreoretinal adhesions are located in the vicinity of the retinal tear (see [Fig. 110.2](#)). Failures following treatment of operculated retinal holes have not been reported ([Table 110.2](#)).

## Tears Unassociated With Persistent Vitreoretinal Traction

Retinal breaks and vitreoretinal adhesions unassociated with vitreoretinal traction are unlikely to progress to retinal detachment.

## Retinal Tears

Symptomatic operculated retinal tears unassociated with persistent vitreoretinal traction in the vicinity of the retinal break have not been reported to progress to clinical retinal detachment ([Table 110.2](#)). Similarly, although large numbers of these breaks have been treated prophylactically, there are no reports in the literature of a treatment failure ([Table 110.2](#)). Treatment of this type of retinal break appears to be unnecessary unless the possibility of persistent vitreoretinal traction cannot be excluded.<sup>9</sup>

## Retinal Holes and Precursors of Retinal Detachment

Eyes with symptoms and signs of acute PVD frequently contain

atrophic retinal breaks that are not due to acute vitreoretinal traction. For the purposes of this discussion, these lesions are considered to be preexisting and not symptomatic.<sup>21</sup> Similarly, precursors of retinal detachment, including lattice degeneration, cystic retinal tufts, and age-related retinoschisis, are managed as if they were originally discovered in asymptomatic eyes.

## **Asymptomatic Eyes Without High-Risk Factors**

Nonmyopic phakic eyes in patients without a family history of retinal detachment and without previous nontraumatic retinal detachment in the fellow eye are unlikely to develop retinal detachment, regardless of the presence of vitreoretinal pathology. Nevertheless, prophylactic therapy has sometimes been recommended to treat visible precursors of retinal detachment and also asymptomatic retinal breaks.

## **Vitreoretinal Precursors of Retinal Breaks**

Important precursors of retinal breaks and detachment include lattice degeneration, cystic retinal tufts, and degenerative retinoschisis. Of these, lattice degeneration is clearly the most important. Both lattice degeneration and cystic retinal tufts can be sites of retinal tears resulting from vitreoretinal traction at the time of PVD. Atrophic retinal holes commonly occur within areas of lattice degeneration and also in the outer layers of degenerative retinoschisis. However, these holes are a relatively infrequent cause of progressive retinal detachment.

### **Lattice Degeneration**

Lattice degeneration is present in approximately 30% of retinal detachments, and approximately 94% of these detachments occur in primary (nonfellow) eyes.<sup>6</sup>

Because lattice lesions are visible and occur in approximately 8% of the population, they have commonly been considered as candidates for prophylactic therapy. However, Byer's natural

history study of 276 patients and 423 involved eyes, followed for an average of almost 11 years, indicated that lattice lesions in phakic nonfellow eyes were not particularly dangerous.<sup>32</sup> At the end of the follow-up period, atrophic retinal holes were present in 150 (35%) eyes. Subclinical retinal detachments, defined as subretinal fluid extending more than one disc diameter (DD) from the break but not posterior to the equator (Fig. 110.4), were observed in 10 of the eyes with holes. In six of these eyes, the subclinical detachment developed during the observation period, whereas four eyes exhibited the changes at the initial examination. Only one subclinical detachment was considered in need of treatment after a small asymptomatic posterior extension of subretinal fluid.

**FIG. 110.4** Subclinical detachments are defined as those with fluid extending more than one disc diameter on all sides of the retinal break, but the detachment does not extend posterior to the equator. (From Brinton D, Wilkinson CP. Retinal detachment: Principles and practice. 3rd ed. New York:

Four asymptomatic tractional retinal tears were observed in three of these 423 eyes at the initial examination, and symptomatic tractional tears without clinical detachment developed in five additional eyes during follow-up periods of 1.5–18 years.<sup>32</sup> Three of five symptomatic and all asymptomatic breaks occurred adjacent to lattice lesions. All symptomatic breaks were successfully treated; no asymptomatic tractional tears were treated, and none changed over follow-up periods of 7, 10, and 15 years.

Clinical retinal detachments developed in three of the 423 eyes.<sup>32</sup> Two were due to round retinal holes in lattice lesions of patients in their mid-20s, and one was due to a symptomatic tractional tear. These figures clearly indicate that patients with lattice degeneration in a phakic nonfellow eye should not be treated prophylactically unless symptoms occur.<sup>9</sup> However, retinal detachments associated with vitreoretinal traction upon lattice lesions containing atrophic retinal holes are relatively common in eyes with significant amounts of myopia.<sup>33–35</sup> Importantly, a discussion regarding self-examination of peripheral visual fields and periodic follow-up examinations are in order in myopic patients to reduce chances of macular involvement by slowly progressive detachments resulting from round holes in lattice lesions.

## **Cystic Retinal Tufts**

Retinal tears at sites of cystic retinal tufts may be responsible for as many as 10% of clinical retinal detachments associated with posterior vitreous detachment,<sup>36</sup> and they are also associated with asymptomatic small horseshoe-shaped tears and minimal subretinal fluid in the absence of PVD.<sup>37</sup> Byer<sup>36</sup> calculated the chances of clinical retinal detachment in eyes with cystic retinal tufts to be one in 357, and these lesions are not worthy of prophylactic therapy in otherwise normal eyes.

## **Degenerative Retinoschisis**

Clinical retinal detachments occur in association with degenerative retinoschisis in less than 2%<sup>38</sup> to up to 6%<sup>39</sup> of consecutive retinal

detachment cases, whereas the reported prevalence of retinoschisis ranges from 1.65% to 7% among persons age 40 years and older.<sup>38</sup> However, since most cases are asymptomatic and require extensive examination of the peripheral retina, literal retinoschisis is frequently missed on routine examination. However, particularly when it extends posterior to the equator, it is confused with a retinal detachment, and the topic is discussed in detail in [Chapter 100](#).

The presence of retinoschisis, especially when associated with outer layer breaks, has sometimes been considered an indication for prophylactic therapy. However, a natural course study of 218 eyes in 123 patients demonstrated no clinical retinal detachments during a follow-up period averaging 9.1 years,<sup>39</sup> and in a more recent report<sup>40</sup> this complication developed in only 2.2% of cases followed for approximately 14 years. The vast majority of small subclinical detachments that develop in association with outer layer breaks remain small, and prophylactic therapy appears to be indicated only in selected cases in which there is obvious significant progression of subretinal fluid posterior to the equator.<sup>41</sup>

## Asymptomatic Retinal Breaks

In phakic nonfellow eyes, asymptomatic retinal breaks that are routinely discovered during an evaluation of the peripheral retina are extremely unlikely to lead to clinical retinal detachment, even if they are flap tears and even if posterior vitreous detachment occurs.<sup>42</sup> During a follow-up period averaging 11 years, asymptomatic retinal breaks in 235 eyes of 196 patients were studied and horseshoe-shaped tears were present in 45 cases.<sup>42</sup> Acute PVD occurred in nine eyes without adversely affecting the preexisting breaks, although new horseshoe-shaped tears developed in three cases, and these were promptly treated. Subclinical retinal detachments were observed in 19 (8%) eyes. Modest extension of subretinal fluid required therapy in two of these cases, and in a third case a peripheral clinical retinal detachment slowly developed after 14 years of observation.

Prophylactic therapy for asymptomatic retinal breaks in phakic nonfellow eyes is usually not recommended.<sup>9</sup> An occasionally

observed exception to this rule is an inferior retinal dialysis.

These breaks can cause slowly progressive retinal detachments that frequently become symptomatic only after macular involvement.<sup>43</sup>

## Asymptomatic Nonfellow Eyes With High-Risk Factors

Myopia and previous cataract extraction are considered as additional risk factors in patients with vitreoretinal lesions believed to predispose a nonfellow eye to retinal detachment. In addition, a positive family history for retinal detachment is considered important by some authors. The existence of any of these factors in nonfellow eyes has been associated with an increased enthusiasm for prophylactic therapy, despite the absence of appropriate supporting data.

### Myopic Nonfellow Eyes

Myopia is obviously associated with an increased risk of retinal detachment, and there is a direct correlation between amount of myopia and rate of retinal detachment.<sup>38,44</sup> Lattice degeneration associated with retinal holes did not correlate with degree of myopia in the natural course study of Byer,<sup>32</sup> although most slowly progressive clinical retinal detachments associated with lattice degeneration and an absence of extensive posterior vitreous detachment occur in young myopic patients,<sup>33-35,38</sup> as noted above. There appears to be no increased value for treatment of myopic eyes with lattice degeneration in nonfellow eyes, and it is noteworthy that the small favorable effect of preventive treatment of lattice lesions in phakic fellow eyes could not be demonstrated if the degree of myopia exceeded 6 diopters.<sup>45</sup>

Cystic retinal tufts and degenerative retinoschisis are not more common in myopic eyes, and prophylactic therapy is not recommended in the absence of a progressive subclinical detachment.

Asymptomatic retinal breaks are more common in myopic eyes

than in emmetropic or hyperopic cases.<sup>5</sup> However, clinical retinal detachments in these cases are rare in the absence of new symptoms, and prophylactic treatment is usually not advised in nonfellow eyes.

## Aphakic and Pseudophakic Nonfellow Eyes

Removal of the crystalline lens is associated with a substantial increase in the rate of later retinal tears and detachments,<sup>46</sup> regardless of the method of cataract surgery, and this probably is due to vitreous changes in the operated eye, especially the increased incidence of PVD.<sup>19,47,48</sup> An intact posterior lens capsule appears to be associated with a relatively reduced rate of retinal detachment following cataract surgery, whereas Nd:YAG capsulotomy is clearly associated with an increased risk of subsequent detachment.<sup>12</sup>

The natural course of lattice degeneration in nonphakic nonfellow eyes is not well documented, and results of preventive treatment in these particular cases are not available. Similarly, meaningful information regarding cystic retinal tufts and degenerative retinoschisis has not been published. Treatment of these lesions in nonfellow eyes is not advised.

Asymptomatic retinal breaks in nonfellow nonphakic eyes or eyes undergoing cataract surgery have sometimes been regarded as an indication for prophylactic therapy. However, Friedman et al.<sup>49</sup> followed 18 retinal breaks in nonmyopic aphakic eyes for 3–7 years, and none detached. Hyams et al.<sup>50</sup> studied 103 myopic aphakic eyes and discovered 25 asymptomatic retinal breaks in 19 eyes. Although six of the 25 were horseshoe-shaped tears, later retinal detachment occurred in no cases. More thorough reviews of the literature regarding the natural course of asymptomatic nonphakic retinal breaks and therapy for them have been published elsewhere,<sup>6,31</sup> and there are not sufficient data to provide firm guidelines for management of asymptomatic retinal breaks in nonfellow eyes that are nonphakic or scheduled for cataract surgery. Treatment of horseshoe-shaped tears in these cases appears to be frequently recommended despite the lack of appropriate information in the literature.<sup>7,9</sup>

## Family History of Retinal Detachment

Heredity clearly influences the chances of retinal detachment, particularly in families with vitreoretinal degenerative disorders such as Stickler syndrome. Prophylactic therapy is frequently considered in these cases, particularly if retinal detachment has occurred in the primary eye. However, no studies have properly stratified the several high-risk factors associated with retinal detachment and evaluated the natural course and the effects of prophylactic therapy in patients with a familial predisposition to retinal detachment and no detachment in either eye.

## Asymptomatic Patients With Retinal Detachment in the Fellow Eye

Pathologic vitreoretinal changes often occur bilaterally, and patients with retinal detachment in one eye have a significantly increased risk of retinal detachment in the other eye.<sup>51</sup> This risk has been estimated as ranging from as low as 9% to as high as 40%.<sup>31</sup> Thus attempts to prevent retinal detachment in the second eye have received considerable attention, particularly if the outcome of reattachment surgery was poor in the first. Prospective randomized studies have not been performed, but retrospective data regarding precursors of retinal detachments and asymptomatic retinal breaks have been published.<sup>7</sup> These can be further categorized as phakic and nonphakic fellow eyes.

## Asymptomatic Phakic Fellow Eyes

As noted before, phakic fellow eyes have a lower risk of subsequent retinal detachment than comparable pseudophakic eyes. Treatment has been considered for both vitreoretinal precursors of retinal detachment and asymptomatic retinal breaks.

## Precursors of Retinal Breaks

Lattice degeneration is three times more common in eyes in which a retinal detachment associated with lattice degeneration has occurred than it is in the general population,<sup>6</sup> and this entity has

been the most frequently studied indication for prophylactic therapy in fellow eyes. The widely quoted study of Folk et al.<sup>45</sup> retrospectively studied 388 consecutive cases in which phakic retinal detachment associated with lattice degeneration occurred in one eye and lattice degeneration with and without retinal holes was present in the second eye. During an average follow-up period of over 7 years, new retinal breaks or detachments occurred in 31 (20%) untreated eyes (Table 110.3). New tears with retinal detachment developed in nine eyes (5.1%), and new tears without detachment developed in 10 cases. In 10 eyes, new holes developed within areas of lattice degeneration, and atrophic retinal breaks occurred in areas distant from lattice lesions in the remaining two cases.

Group	Eyes (n)	Detachment (%)	New Tears (%)
Untreated	151	5.9	12.6
Partial treatment	73	6.8	16.4
Full treatment	164	1.8	4.9

Reproduced with permission from Folk JC, Arrindell EL, Klugman MR. The fellow eye of patients with phakic lattice detachment. *Ophthalmology* 1989;96:72–9.

Folk and coworkers<sup>45</sup> reported a reduction in the incidence of new retinal tears and detachments in eyes receiving prophylactic therapy for all lattice lesions (Table 110.3). New tears without detachment occurred in five (3.0%) of these fully treated eyes. Retinal detachment occurred in three additional cases (1.8%), compared with 5.1% in the 151 untreated phakic fellow eyes. The small beneficial effect of treating all lattice lesions was apparent when follow-up periods of 3, 5, and 7 years were analyzed separately. Importantly, the beneficial effect was statistically significant for all patient subgroups, *except* in eyes with myopia of 6 diopters or more and in eyes with both high myopia and more than 6 clock-hours of lattice degeneration. In these subgroups, treatment did not reduce the risk of retinal tears or detachment. Conversely, no detachments occurred after full treatment in eyes with less than 6 clock-hours of lattice degeneration or with less than 1.25 diopters of myopia.

In a subsequent evaluation of the same data, Folk et al<sup>52</sup> reported that new horseshoe-shaped tears developed in areas unassociated with lattice degeneration in approximately 30% of treated cases, and Byer<sup>6</sup> has estimated that as many as 58% of retinal detachments in eyes with lattice degeneration arise in areas that exhibit no visible vitreoretinal abnormalities (Fig. 110.5). Because of this reality, some surgeons have recommended prophylactic therapy featuring the production of laser or cryotherapy burns over 360° of the peripheral retina (Figs. 110.6 and 110.7).<sup>6,31</sup> However, the precise indications, intraocular findings, long-term results, and complications of this form of therapy have not been thoroughly described, and remarkably different success rates have been reported. Haut et al.<sup>53</sup> described 109 phakic fellow eyes followed for a minimum of 5 years, and only one retinal detachment and two additional tears occurred posterior to the circumferential chorioretinal adhesion. However, in another study,<sup>54</sup> retinal detachment occurred in five of 10 cases of Stickler syndrome within 15 months of 360° prophylactic therapy. Byer<sup>6</sup> tabulated and reviewed data from 15 reports advocating such treatment, and he concluded that this form of treatment appeared to be both ineffective in preventing subsequent detachment and dangerous in apparently aggravating vitreoretinal traction. The value of this form of therapy to prevent giant retinal tears and tears following vitrectomy and other procedures will be discussed in a separate section below.

**FIG. 110.5** Acute rhegmatogenous retinal detachment occurring despite earlier prophylactic laser photocoagulation for lattice degeneration. Acute horseshoe-shaped tears causing the detachment occurred in an area that previously appeared normal.

Studies of prophylactic therapy of lattice degeneration, with and without holes in phakic fellow eyes, have been of limited value because they have not been prospective and because important information has been missing from available retrospective analyses.<sup>9</sup> In particular, the outcomes have not been studied as a function of the presence of a posterior vitreous detachment. Davis<sup>29</sup> demonstrated that retinal detachments were unusual in phakic fellow eyes if a PVD was present at the time of the initial examination. Retinal detachments occurred in none of 33 such cases. However, if a PVD was not present, retinal detachment subsequently developed in 14 (13%) of 112 phakic fellow eyes with lattice lesions.

Appropriate prospective trials will be required to assess properly the value of treating lattice degeneration in phakic fellow eyes. The relatively low incidence of retinal detachment in untreated cases, the frequency of new tears in normal-appearing retina, the apparent ineffectiveness of therapy in eyes with extensive lattice degeneration and high myopia, and the known success rate following treatment of symptomatic retinal tears and detachments indicate that prophylactic treatment is of limited value. The apparently modest treatment benefit following treatment of all lattice lesions may be of value in selected patients, such as those

with a poor surgical result in the first eye, others who are incapable of recognizing symptoms of vitreous and/or retinal detachment, and patients who live in areas with limited access to ophthalmologic care. In addition, as noted above, patients with atrophic holes in lattice lesions should be evaluated periodically and counseled about loss of peripheral vision because slowly progressive retinal detachments can occur.

Cystic retinal tufts are bilateral in only 6% of cases, so they are not a common cause of bilateral retinal detachment, and there are no data supporting the value of prophylactic therapy.

Degenerative retinoschisis is an unusual cause of progressive retinal detachment, but retinoschisis is both common and frequently bilateral.<sup>40</sup> Thus, patients with both retinal detachment and retinoschisis in one eye frequently have retinoschisis in the fellow eye. An evaluation of the literature regarding prophylactic therapy for retinoschisis in phakic fellow eyes is very difficult because of a lack of complete information regarding the cases.<sup>31</sup> Still, in the unusual case in which outer layer retinal breaks have been responsible for retinal detachment in the first eye, and outer layer breaks and retinoschisis are present in the fellow eye, prophylactic therapy is frequently recommended by some authors.

## **Retinal Breaks**

Asymptomatic retinal breaks in phakic second eyes of patients with previous retinal detachment are frequently cited as an indication for prophylactic therapy.<sup>31</sup> Flap tears appear to be much more likely to cause retinal detachment than round or operculated retinal holes (see [Fig. 110.1](#)).<sup>11,29,55</sup> Merin et al.<sup>55</sup> discovered retinal breaks in 186 (19%) of 966 fellow eyes, 28 of which (15%) later developed retinal detachment. Horseshoe-shaped tears were the cause of the detachment in 20 (71%) of the 28 eyes, whereas only 19% of breaks were flap tears in the 158 eyes that did not progress to retinal detachment. However, Hyams et al.<sup>50</sup> followed 10 untreated asymptomatic horseshoe-shaped tears in phakic fellow eyes, and no retinal detachments occurred. Deficiencies in prior reports have made it difficult to assess both the natural course of asymptomatic retinal breaks that are discovered on an examination of a fellow eye and the results of treatment of these lesions. Most of these breaks

are round and located within areas of lattice degeneration, and these cases were discussed earlier. Data regarding therapy for asymptomatic horseshoe-shaped tears in fellow eyes suffer from a lack of details, including the status of the vitreous gel and the relationship between the original retinal break and the cause of subsequent retinal detachment. An aggressive national program of routine treatment of all retinal breaks in fellow eyes did not reduce the prevalence of retinal detachment in Israel.<sup>56</sup> Still, treatment of horseshoe-shaped tears that are discovered in asymptomatic fellow eyes is sometimes recommended despite the absence of optimal supportive data.

## **Giant Retinal Tears**

Prophylactic treatment is frequently recommended in phakic fellow eyes in which a nontraumatic giant retinal tear has occurred in the first eye. Freeman<sup>13</sup> followed 321 cases for 12 months to 29 years. New giant retinal tears occurred in 14 (4.4%) untreated eyes, 13 of which were highly myopic and had developed “high-risk features” of increased vitreous liquefaction, and “white with pressure” that increased in extent. In a report by Wolfensberger et al.,<sup>57</sup> 48 patients were evaluated following repair of a giant retinal tear in one eye and 360° cryotherapy of the second eye for a mean of 84 months. During the follow-up period, retinal detachment developed in three patients and a retinal tear alone was observed in a fourth.

Ang et al.<sup>58</sup> subsequently described 360° cryotherapy to prevent giant retinal tear in Type 1 Stickler syndrome in a retrospective study (Fig. 110.8). Most of the cases were phakic, and the results indicated that such treatment significantly reduced the risk of later retinal detachment. However, the results of this study were subsequently criticized<sup>59</sup> because of methodology issues. More recently, a larger cohort of 487 cases in the trial were reported, and more convincing favorable outcome data were apparent.<sup>60</sup> Depending on the matched comparison group, the untreated eyes had an increased risk of retinal detachment, ranging from 5 to 10.3 times.

**FIG. 110.8** Treatment scheme for 360-degree cryotherapy prophylaxis in Stickler syndrome. (Reproduced from Fincham GS, Paisea L, Carroll C, et al. Prevention of retinal detachment in Stickler syndrome. The Cambridge prophylactic cryotherapy protocol. *Ophthalmology* 2014;121:1588-97. © 2014 with permission of the American Academy of Ophthalmology.)

## Asymptomatic Aphakic and Pseudophakic Fellow Eyes

All eyes have an increased risk of retinal detachment after cataract extraction.<sup>31</sup> The chances of detachment would be expected to be higher if secondary YAG capsulotomy were required.<sup>9,12</sup> Thus, prophylactic therapy has frequently been recommended for vitreoretinal lesions in fellow eyes that are no longer phakic or that are scheduled to undergo cataract extraction.

### Precursors of Retinal Breaks

Of the precursors of retinal tears that have been considered for prophylactic therapy before or after cataract extraction, only lattice degeneration has been extensively studied, and reviews of the literature have been published.<sup>6,31</sup> However, no prospective randomized studies have compared the natural course in these cases with outcomes following preventive treatment.<sup>7</sup> As is true of phakic fellow eyes, a major problem in treating only visible

pathology is the frequency of new retinal tears that develop in areas of the peripheral retina that appear normal prior to PVD (Table 110.4, see Fig. 110.5). Although treatment of visible lesions appears to reduce the chances of retinal tears occurring at the treated site, the retinal detachments that frequently develop in these fellow eyes are not prevented by this focal therapy.<sup>8,61-63</sup>

**TABLE 110.4**  
**Treatment for Aphakic Fellow Eyes**

Eyes	Detachment Tear in Normal Retina Tear at Lesion Site					
	<i>n</i>	(%)	<i>n</i>	(%)	<i>n</i>	(%)
Initially aphakic ( <i>n</i> = 90)						
Treated ( <i>n</i> = 13)	0	0	–		–	
No treatment ( <i>n</i> = 77)	12	16	10	83	2	17
Cataract surgery during the study ( <i>n</i> = 34)						
Treated ( <i>n</i> = 11)	2	18	2	100	–	
No treatment ( <i>n</i> = 23)	7	30	7	100	–

Studies of prophylactic treatment of lattice degeneration in fellow nonphakic eyes have not been stratified on the basis of posterior vitreous detachment. Hovland<sup>17</sup> demonstrated the critical importance of this variable by studying aphakic eyes of patients with aphakic retinal detachment in the primary eye. Retinal detachment subsequently occurred in one (2.3%) of 43 eyes with a PVD in the fellow eye. In the 40 eyes without a previous PVD, retinal detachment later occurred in eight eyes (21%). Similarly, Davis<sup>29</sup> reported that retinal detachments occurred in five (24%) of 21 aphakic fellow eyes without an apparent PVD (absence of Weiss ring or clearly visible posterior cortical vitreous surface) at the initial examination, but detachments did not occur in 15 additional cases in which a PVD was initially present.

However, as noted earlier, the risk–benefit ratio of this form of treatment in unoperated eyes remains unknown. Treatment of lattice lesions in nonphakic fellow eyes is frequently recommended,<sup>30</sup> despite the lack of supportive data. In eyes in which a PVD has previously occurred, it is doubtful if therapy is particularly effective or necessary. The value of various forms of

prophylactic treatment in eyes without PVD will remain debatable until appropriate trials are conducted.

Cystic retinal tufts and degenerative retinoschisis are unusual causes of bilateral retinal detachment, and data discussing the importance of these entities following cataract surgery are not available. They are managed as discussed under “Asymptomatic phakic fellow eyes” above.

## **Retinal Breaks**

Retinal breaks in nonphakic eyes of patients with a previous retinal detachment in the other eye appear to be followed by a higher rate of detachment.<sup>31</sup> Davis<sup>29</sup> described asymptomatic retinal breaks in 10 aphakic fellow eyes. Subsequent retinal detachments occurred in five of these cases. Four of the five breaks causing retinal detachment were horseshoe-shaped tears, and the type of the fifth break was not reported. The literature regarding the value of treating round holes unassociated with lattice lesions is particularly unclear. Treatment can be expected to prevent retinal detachment resulting from the identified break but not detachment resulting from breaks in other areas of the retina. Treatment of asymptomatic horseshoe-shaped tears in aphakic fellow eyes and in fellow eyes scheduled to undergo cataract extraction is recommended despite the absence of optimal supportive data.<sup>30</sup>

## **Giant Retinal Tears**

Aphakic fellow eyes in nontraumatic giant retinal tear cases have a high risk of retinal detachment. Prophylactic therapy has been recommended for fellow eyes of these patients if significant vitreous liquefaction and progressive “white with pressure” are observed<sup>12</sup> or, alternatively, in all such cases. In the unusual circumstance of a nonphakic eye of a Stickler patient who suffered a detachment due to a giant tear in the first eye, there are compelling data that prophylactic treatment is of value, as noted earlier.<sup>60</sup>

# **Prophylactic Therapy in Eyes Undergoing Vitreoretinal Surgery**

As noted previously, because of the tendency for new retinal breaks to develop in areas of the retina that appear normal, 360° treatment (see Figs. 110.6–110.8) has been advocated during various forms of vitreoretinal surgery.<sup>64</sup>

## **During Silicone Oil Removal in Previously Operated Eyes**

In a nonrandomized retrospective study of eyes following vitrectomy and silicone oil installation, 360° laser therapy appeared to be of value following removal of the oil,<sup>65</sup> and a more recent prospective study<sup>66</sup> demonstrated similar results in apparently comparable eyes following oil removal.

## **During Primary Vitrectomy for Nonretinal Detachment**

In a study of eyes undergoing primary vitrectomy for macular disorders, Koh and coworkers<sup>67</sup> evaluated a consecutive series of 220 eyes in a retrospective analysis. Peripheral 360° laser therapy had been applied in 115 cases, and they were compared with 105 allegedly comparable eyes that had not received treatment. Postoperative retinal detachment subsequently developed in 11.4% of the untreated cases and in 3.5% of those that were treated. However, the eyes were not stratified on the basis of a preexisting vitreous detachment, and 56 cases were lost to follow-up before 6 months.

Another report<sup>68</sup> compared 76 eyes undergoing vitrectomy for macular hole followed by 360° laser therapy with 68 “control” cases in which laser was not employed. At the 1-year postoperative follow-up retinal detachments had occurred respectively in 1.31% and 8.62% of eyes. But again, the data were retrospective, and the validity of matching control cases remains in question. These comments can also be applied to a more recent manuscript on the topic, one that demonstrated a benefit of 360° treatment.<sup>64</sup>

## **During Pneumatic Retinopexy**

Tornambe<sup>69</sup> has advocated 360° laser therapy to prevent later retinal detachment in cases undergoing primary pneumatic retinopexy for retinal detachment, and other authors have described this technique at meetings and in non-peer-reviewed publications. Treated cases have had a lower incidence of subsequent retinal detachments due to new breaks. Still, optimal prospective studies have not been performed.

## Summary Regarding Therapy During Vitreoretinal Surgery

The rationale of preventing later retinal detachment by creating a 360° adhesive bond in peripheral regions of the retina, where persistent vitreoretinal traction would be expected to occur following PVD and a variety of vitreoretinal surgical procedures, is attractive. However, the genuine value of such therapy will remain uncertain until better studies are performed.

## Treatment Methods

Treatment to prevent retinal detachment can be applied in several ways. Usually, chorioretinal adhesions are created around retinal tears or specific vitreoretinal abnormalities that are judged likely to be the site(s) of future retinal breaks. This can be combined with scleral buckling to further reduce vitreoretinal traction, although buckling is rarely used in the prevention of retinal detachment.

The three methods currently available for creating chorioretinal adhesions are diathermy, photocoagulation, and cryotherapy. Diathermy is best applied with scleral dissection, a surgical technique that currently is very rarely employed to prevent retinal detachment, and it can be used to treat localized subclinical detachments when combined with scleral buckling. Nevertheless, contemporary treatment to prevent retinal detachment usually entails a choice between cryotherapy and laser photocoagulation. Photocoagulation was first performed using a xenon arc light source, but this has been replaced by laser treatment. Cryotherapy and laser photocoagulation cause chorioretinal adhesions that seem equally effective in preventing retinal detachment, and choice of a

treatment method depends on individual features of the case. Sometimes both methods are used in the same eye because parts of one or more lesions can be treated best with one modality and other portions are treated best with the other (see [Fig. 110.3](#)).

## Cryotherapy

Cryotherapy is usually applied in a transconjunctival fashion, although it is sometimes necessary to open the conjunctiva and insert the probe in the episcleral space when treating posterior lesions. And in the unusual circumstance when 360° prophylactic treatment appears to be indicated, peritomies are frequently performed, especially in younger patients (see [Fig. 110.8](#)).<sup>60</sup> Visualization is provided by indirect ophthalmoscopy, and this combination is particularly effective in treating far anterior lesions (see [Fig. 110.3](#)) and treating eyes with partial opacities of the ocular media, such as cataract changes or mild vitreous hemorrhage.

Cryotherapy also has certain disadvantages, some of which are theoretical concerns. First, treatment with cryotherapy is difficult for far posterior lesions, unless an incision is created in the conjunctiva. Second, cryotherapy applications do not create an immediately and easily visible effect; therefore, it may be difficult to be certain where the treatment was applied. This can result in areas that are skipped or in refreezing the same area. Third, cryotherapy may cause dispersion of viable pigment epithelial cells through the retinal break into the vitreous cavity, and the dispersion of cells may be further increased if the same area is retreated. Therefore, applications should avoid the centers of relatively large retinal breaks. Cryotherapy also causes breakdown of the blood–retinal barrier, with leakage of serum proteins into the intraocular fluids, and some of the serum components are capable of causing later cellular migration. Cryotherapy applied over the long posterior ciliary nerves can impair accommodation for weeks or months. Finally, chorioretinal adhesions induced by cryotherapy are not as rapidly clinically effective as those that follow laser treatment.<sup>70</sup>

## Laser Photocoagulation

Laser photocoagulation has several advantages, as well as certain

limitations and possible disadvantages. Laser applications cause an immediate visible reaction, which aids both in judging the biologic intensity of each application and in documenting the area of treatment. Each application is precisely focused so that the margins of the break and the surrounding retina can be treated without affecting the pigment epithelium within the open break. The laser applications produce a coagulative effect that seems to cause some immediate adhesion between the retina and pigment epithelium.<sup>70</sup>

Laser photocoagulation is usually applied with either a slit-lamp delivery system using a fundus contact lens or an indirect ophthalmoscopic delivery system. Treatment at the slit lamp is best for posterior lesions. Treatment in the far periphery is considerably more difficult, depending on factors such as the amount of pupillary dilation, and it is sometimes impossible to photocoagulate lesions adequately in this region. Laser delivery systems coupled with binocular indirect ophthalmoscopy have significantly improved the ability to treat the peripheral retina. Routine scleral depression can be employed as laser burns are applied to the crest of the indented area. Considerable practice is necessary to produce burns that are as consistent in size and intensity as those that are created with a slit lamp and contact lens. These techniques are routinely employed in the production of 360° preventive laser therapy (see [Fig. 110.7](#)).<sup>71</sup>

The major disadvantages of laser treatment include the requirement for relatively clear media and adequate visualization of the lesion. Therefore, eyes with a small pupil or media opacities, such as partial cataract or mild vitreous hemorrhage, are not good candidates for laser treatment. The laser energy can also cause specific complications. Anterior segment burns involving the cornea and lens are probably more common during treatment with binocular indirect ophthalmoscopic laser delivery systems than when energy is applied via a slit lamp and contact lens. Excessive energy delivered in any fashion can cause rupture of Bruch's membrane, choroidal hemorrhage, or even retinal hole formation. Laser treatment also causes some breakdown of the blood–retinal barrier, but this is not as significant as with cryotherapy.

## Surgical Techniques

Treatment techniques vary according to the method selected and individual features of each case. However, the general objective is to create a zone of chorioretinal adhesion around each retinal break or area of vitreoretinal abnormality with minimal application of energy and with precise control under direct visualization. The treatment should cause little or no discomfort and minimize potential complications.

## **Cryotherapy**

Cryotherapy is usually applied transconjunctivally using a combination of topical and subconjunctival anesthetic injection, reducing the risk of mechanical damage to the globe or optic nerve with a retrobulbar injection. Also, transconjunctival cryotherapy is easiest when the patient can rotate the eye on command to assist in visualization and to counteract the pressure applied to the globe by the cryoprobe.

The probe tip is properly oriented before being applied to the globe so that the active surface is in direct contact with the eye wall. This prevents accidental freezing in the adjacent meridian. The eye is usually rotated toward the meridian to be treated as the probe is applied, and the probe is moved to indent the sclera beneath the retinal break or vitreoretinal abnormality. If the lesion is located posteriorly or the conjunctival fornix is shallow, the eye is rotated in the opposite direction, thereby permitting placement of the probe in a more posterior location.

The cryoprobe is activated after being positioned beneath or adjacent to the retinal lesion. The freezing effect is permitted to progress until the retina just becomes involved, and then the application is terminated. With experience, the size and intensity of each freezing effect can be anticipated. The probe is moved to an adjacent location, and the freezing mechanism is reactivated. Usually the probe is moved to contiguous locations within the same field of view to minimize the risk of skipping an area or refreezing the same tissue.

Some retinal lesions can be treated with a single application, whereas others require multiple burns. Large retinal breaks are surrounded by contiguous applications while avoiding freezing of the exposed pigment epithelium within the open break, thus

preventing further dispersion of pigment epithelial cells into the vitreous cavity. Areas of lattice degeneration are also surrounded by multiple applications, with each burn straddling the posterior and lateral margins of the lattice lesions where acute retinal tears are most likely. The area anterior to all retinal breaks with persistent vitreous traction is also treated since progressive traction may cause anterior extension of the break (see [Fig. 110.3](#)).

If relatively far posterior lesions must be treated, an incision in the conjunctival fornix is made. A supplemental subconjunctival anesthetic injection is given, the conjunctiva is incised with scissors, and dissection is performed in the episcleral space in that meridian. The posterior edge of the incision is grasped with forceps as the cryoprobe is introduced and positioned beneath the lesion. Closure of the conjunctival incision is usually unnecessary, but it can be closed with an absorbable suture. The patient is told that local swelling and subconjunctival hemorrhage are common after transconjunctival cryotherapy and not to be concerned about the external appearance of the eye.

Patient postoperative activity is determined by the type of lesion treated. Normal activity is permitted after treatment of lattice degeneration without retinal breaks. Marked restriction of activity, sometimes including bed rest and bilateral eye patches, may be appropriate after treatment of an acute retinal tear with localized detachment since an effective chorioretinal reaction may not be present for about 5 days.

## **Laser Photocoagulation**

Laser photocoagulation is usually performed with topical anesthesia. The ability of the patient to move the eye on command is also helpful during photocoagulation to assist in visualization. The greatest difficulty may be in identifying the lesion to be treated when viewing through the slit lamp and fundus contact lens. With the slit lamp, a spot size of 200–500  $\mu\text{m}$  is preferred, although a smaller spot size is used if diffraction caused by the ocular media results in significant divergence of the beam. With an indirect laser system, spot size at the laser source is predetermined, although the burn size in the retina can be modified with variations in employment of the condensing lens. A low-power setting is

selected and gradually increased until a coagulation effect of the desired intensity is obtained. Applications are usually limited to 0.1–0.15 seconds since longer applications often cause pain.

The exact treatment technique varies among surgeons. Some prefer a grid pattern around retinal breaks and other lesions, but most use contiguous applications forming a zone 500–1000  $\mu\text{m}$  wide. All sides of each lesion are treated, with special emphasis on the retina anterior to horseshoe-shaped tears and areas of lattice degeneration where progressive vitreoretinal traction may cause anterior extension of a retinal tear.

Discomfort is usually minimal after laser treatment, but a systemic analgesic can be given during the first several hours if treatment was extensive. Activity restrictions depend on the nature of the lesion treated, as described previously for cryotherapy. The coagulative effect of laser treatment seems to cause an effective adhesion more quickly than cryotherapy,<sup>70</sup> although patient activity might still be limited for a few days if substantial subretinal fluid is present.

## **Scleral Buckling**

A scleral buckling operation is rarely necessary as a prophylactic procedure, although it can be performed if there is prominent vitreoretinal traction and significant subretinal fluid and if a chorioretinal adhesion alone is thought to be insufficient in preventing subsequent clinical retinal detachment. Prophylactic scleral buckling is most commonly used to treat progressive subclinical detachments, and a radial scleral buckle is employed in most of these cases. When scleral buckling is used for only prophylactic purposes for extensive vitreoretinal pathology, an encircling buckle is usually required. This procedure is combined with a broad zone of cryotherapy or diathermy treatment extending from near the ora serrata to a location posterior to the posterior margin of the vitreous base or posterior to other specific areas of chorioretinal traction.

The encircling buckling effect can be produced with a band 2.5–4 mm wide, or a band can be combined with a broader, grooved element. Sutures or scleral tunnels are used to secure the band to the sclera in the middle of each quadrant. Volume reduction can be

difficult in these cases because the eye cannot be softened by drainage of subretinal fluid. Multiple anterior chamber paracenteses are often necessary, and the patient may also be given intravenous acetazolamide and hyperosmotic agents.

## Results and Complications of Prophylactic Therapy

As noted in previous sections, no prospective randomized clinical trial has been performed to evaluate treatment of precursors of retinal tears and retinal breaks, and interpretation of existing treatment results is difficult because the natural course of the respective lesions is uncertain.<sup>7,9,30,67,68</sup> In addition, available studies have not appropriately stratified important variables for comparison of subgroups. However, the most thorough natural course studies of lattice degeneration,<sup>32</sup> degenerative retinoschisis,<sup>39,40</sup> and asymptomatic retinal breaks<sup>6</sup> demonstrate that these conditions rarely cause acute retinal detachment in patients without a previous retinal detachment in the fellow eye.

Of all vitreoretinal lesions causing clinical retinal detachment, the natural course of symptomatic retinal tears with persistent vitreoretinal traction is best known, and there is agreement that prompt treatment of symptomatic horseshoe-shaped tears is indicated.<sup>9,30</sup> The value of treating other types of retinal breaks and visible vitreoretinal adhesions remains unclear, although effective preventive therapy would be particularly desirable in the second eye of patients with previous retinal detachment in the first eye.

Complications of treatment are also difficult to assess. These may include both failure to prevent retinal detachment and pathologic changes caused by the treatment. Some problems that follow therapy may be due to the pathobiology of retinal detachment rather than to genuine treatment complications. Results and selected complications of therapy have been categorized on the basis of the lesion or lesions treated, whereas additional complications have been studied as nonspecific problems.

## Results of Prophylactic Therapy

Results of treatment to prevent retinal detachment are presented in [Tables 110.2–110.4](#). The studies are all somewhat incomplete, as most do not describe information about important variables, including the refractive error, the status of the crystalline lens, the status of the posterior vitreous surface, the type of retinal breaks, and whether there had been a detachment in the fellow eye. In addition, longer-term (e.g., 5–10 years) follow-up information is lacking in most reports. In a 1991 study, Smiddy et al.<sup>72</sup> demonstrated that new retinal breaks continued to occur long after initial prophylactic therapy. In symptomatic eyes that were treated, new retinal breaks were observed in 13% 3 months after therapy and in 21% 2 years postoperatively. The outcomes in this report were not stratified as a function of the type of initial retinal break, so the data are not included in the tables. Another study demonstrated that most detachments that occurred after prophylactic therapy were associated with progression of an incomplete initial PVD,<sup>71</sup> and new tears occur both in “normal” peripheral retina and adjacent to previous chorioretinal burns.<sup>8,10</sup>

## Flap Tears

Horseshoe-shaped tears are mostly responsible for clinical retinal detachment. Symptomatic horseshoe-shaped tears are much more likely to cause retinal detachment than are asymptomatic tears,<sup>30</sup> but many studies have not distinguished between these groups. However, failure of treatment is more common following therapy of symptomatic cases.<sup>30</sup> Early failures are usually due to vitreoretinal traction forces that cause an accumulation of subretinal fluid before establishment of an adequate chorioretinal adhesion or to incomplete or inadequate therapy. Treatment should be placed in flat retina immediately adjacent to the location of subretinal fluid, and treatment should extend well anterior to the “horns” of the tear and into the vitreous base ([Fig. 110.3](#)).<sup>9,30</sup> However, even optimal therapy may be unsuccessful because of extension of subretinal fluid before an effective chorioretinal adhesion develops. This may be more common following cryotherapy than after laser photocoagulation because the adhesion forms more quickly after application of the latter method.<sup>70</sup>

## Lattice Degeneration

There are many difficulties in analyzing results of treatment of lattice degeneration, as mentioned earlier. Results of one study of fellow eyes are listed in [Table 110.3](#). Most new tears following therapy occur in areas not previously treated.

## Retinal Holes

The prognosis for round holes after treatment is substantially better than that for flap tears with persistent vitreoretinal traction. As noted earlier, round holes unassociated with persistent vitreoretinal traction or with lattice degeneration are usually not treated.

## Patients With Previous Retinal Detachment in the Fellow Eye

Fellow eyes of patients with retinal detachment in a first eye have a substantial risk of retinal detachment, and the risk is even higher after cataract extraction. Smiddy et al.<sup>72</sup> demonstrated that aphakia and pseudophakia are statistically significant risk factors for failure after prophylactic therapy for retinal breaks. Results of treatment of aphakic fellow eyes in one report are listed in [Table 110.4](#). It is important to note that treatment of the visible lesions in untreated eyes would have prevented few retinal detachments.<sup>61</sup>

## Complications of Prophylactic Treatment

Complications of preventive therapy include failure to prevent retinal detachment, iatrogenic problems increasing the risk of retinal detachment, and other problems caused by treatment, and they have been reviewed in detail elsewhere.<sup>31</sup> Costs of unnecessary surgery are also a concern. Retinal detachments that occur despite prophylactic therapy are a result of either an inadequate adhesion around a retinal break or a new retinal break. Extension of the detachment is considered a complication of therapy if the treatment is inadequate in extent or intensity, and a particularly common cause of failure in treating horseshoe-shaped tears is an absence of an adequate chorioretinal adhesion surrounding the anterior margins of the break, where vitreoretinal traction persists.<sup>9,30</sup> New

retinal breaks are a complication of prophylactic therapy if the treatment causes excessive damage to the retina, resulting in a break at that location, or if it aggravates vitreous degenerative changes and vitreoretinal traction, causing a tear elsewhere.

Epiretinal proliferation that causes macular pucker has been considered an important complication of prophylactic therapy, but the association between treatment and membrane formation is uncertain. Symptomatic retinal tears are almost always due to a posterior vitreous detachment, and a PVD is present in more than 90% of eyes with idiopathic epimacular proliferation.<sup>18</sup> Also, when vitreoretinal traction causes a retinal tear, pigment epithelial cells are usually liberated into the vitreous cavity, and these may be a source of subsequent epimacular proliferation. The method of creating a chorioretinal adhesion appears to be unrelated to the incidence of postoperative macular pucker.<sup>73</sup>

## Conclusion

Although prevention of retinal detachment is an important goal, the genuine value of prophylactic therapy for most vitreoretinal lesions remains unknown because of a lack of appropriate trials. Treatment of symptomatic flap tears is an accepted method of preventing clinical retinal detachments because the natural course of these breaks and the results of therapy are well documented. In most other instances, treatment of visible abnormal vitreoretinal lesions is of limited value, even in eyes with additional risk features such as high myopia, aphakia, or a history of retinal detachment in the fellow eye. The guidelines offered in this chapter represent an attempt to summarize the literature on this topic, and specific decisions regarding prophylaxis for a given eye should be made on the basis of the features of the case and expanding medical knowledge. In the meantime, patients with high-risk features should be made aware of symptoms of posterior vitreous detachment and loss of visual field, and any patient with such symptoms should be promptly evaluated. In addition, periodic follow-up evaluations at the discretion of the examiner may be indicated.

## Introduction

Proliferative vitreoretinopathy (PVR) is the clinical syndrome associated with retinal traction and detachment in which cells with proliferative potential multiply and contract on retinal surfaces and in the vitreous compartment.<sup>1-4</sup> PVR presents with a spectrum of

severity ranging from subtle retinal wrinkling, to fixed folds and tears with rolled edges and to total rigid retinal detachment, retinal shortening, and advanced periretinal proliferation (Figs. 111.1 and 111.2). PVR is the most common cause of failure in retinal detachment surgery. It can occur in untreated eyes with retinal detachment, especially with vitreous hemorrhage, or after cryotherapy or even laser retinopexy, pneumatic retinopexy, scleral buckling, or vitrectomy, and after a variety of surgical complications. It is common after penetrating injuries and a variety of conditions associated with prolonged inflammation. Although surgical reattachment of retinas associated with PVR can now be achieved in most cases, visual results remain disappointing. Therefore, prevention through early recognition of risk factors and subtle signs of PVR and appropriate modification of standard surgical techniques for retinal detachment remain all-important. Some degree of PVR is found in up to 10% of retinal detachments.<sup>5-7</sup> If PVR is progressive and macula reattachment delayed, then despite complex surgery, low vision is the result in the majority of eyes.

**FIG. 111.1** Retinal detachment with advanced proliferative vitreoretinopathy. Fixed folds are present in all four quadrants (Grade D-2).

**FIG. 111.2** Cross-section of a funnel-shaped retinal detachment with fixed folds posteriorly and a contracted equatorial membrane (Grade D-3).

## Pathophysiology

The pathophysiology of PVR is discussed in detail in [Chapter 101](#) (Pathogenesis of proliferative vitreoretinopathy).

PVR is characterized by proliferation of cells derived from retinal pigment epithelium, glia, or inflammatory recruitment on the retinal surfaces and within the vitreous gel.<sup>8,9</sup> These metaplastic cells transdifferentiate and assume contractile properties through internal cellular contractile proteins and by laying down extracellular collagen.<sup>10</sup> They multiply and grow along available scaffolding, either the retinal surfaces or elements of residual vitreous gel. Mass contraction leads to retinal wrinkles, folds, tears, and traction retinal detachment. The vitreous compartment is normally almost devoid of cellular content with just a few

hyalocytes. It is protected from outside invasion by the internal limiting membrane of the retina and from cytokines and other chemoattractants by the blood–retinal barrier. The process of PVR can start when there is an interruption to the surface lining such as can occur with a posterior vitreous detachment and local preretinal membrane formation or retinal tears in the periphery. Retinal tears with surrounding detachment may encourage inflow of freed-up pigment epithelial cells through the break into the vitreous and onto the retinal surface or onto residual contracted vitreous strands and the vitreous base. Simultaneous breakdown of the blood–retinal barrier with retinal detachment or any cause of intraocular inflammation, including cryotherapy, laser, and the trauma associated with scleral buckling, can all lead to the influx of circulating inflammatory cells and a whole range of proteins associated with inflammation.<sup>11</sup> The process is more likely to be triggered in patients with posterior segment trauma, uveitis, choroidal detachment, or severe diabetic retinopathy in the presence of retinal tears. The PVR process is self-propagating and can be considered an inappropriate excess wound-healing response. Cellular proliferation and contraction increases the breakdown of the blood–ocular barrier, in turn causing more traction and more influx of inflammatory cytokines and inflammatory cells. Macular pucker after retinal detachment repair can be considered a mild form of PVR. PVR most frequently develops in the inferior retinal quadrants, probably because the retinal pigment epithelial and inflammatory cells liberated into the vitreous cavity through retinal tears or those associated with vitreous hemorrhage settle inferiorly with gravity.<sup>12</sup> The PVR process usually takes 4–12 weeks to develop a critical mass of cells and significant retinal traction after retinal detachment surgery or other ocular interference such as trauma. As in normal wound healing, the proliferating cells go through a life cycle, and as they progressively lay down collagen, the membranes become hypocellular leaving contracted collagen sheets, membranes, and cords in the vitreous cavity, or on the retinal surfaces and sometimes under the retina. Contraction of equatorial membranes may lead to a funnel-shaped retinal detachment while shortening of the inferior retina may lead to large, inoperable posterior retinal breaks. Severe PVR may also be

superimposed on diabetic tractional retinal detachment when associated with retinal tears. PVR also may occur in other vascular retinopathies such as Eales disease in the presence of retinal breaks and especially in penetrating ocular trauma. The proliferative/inflammatory process underlying PVR complicating retinal detachment is typically associated with loss of central vision even after successful surgery, and this may be due to inflammation-induced apoptosis of the receptor cells at the macula<sup>13</sup> or degeneration of the receptors associated with prolonged retinal detachment.<sup>14</sup> The cellular and biochemical processes underlying PVR are complex and are explored in detail in [Chapter 101](#) (Pathogenesis of proliferative vitreoretinopathy).

## Risk Factors for Development of PVR

The most common clinical setting is the development of clinically significant PVR a few weeks after previous retinal detachment repair, whether by scleral buckling, primary vitrectomy, or both ([Fig. 111.3](#)). A few eyes develop PVR spontaneously with retinal detachment prior to surgery.<sup>6</sup> Previous trauma, prolonged inflammation of the posterior segment, viral infections of the posterior segment, and prolonged chorioretinitis are also associated with spontaneous PVR. The risks in the presence of retinal detachment are increased with large retinal breaks or giant tears, vitreous hemorrhage associated with retinal tears, multiple previous eye surgery, previous trauma to the posterior segment, and preexisting signs of localized PVR such as fixed folds.<sup>15-17</sup> The risk is increased in retinal detachments with more than two quadrants involved and those with coexisting choroidal detachment. The risk is also increased in retinal detachments associated with a variety of systemic conditions such as Wagner's disease, Stickler syndrome, Marfan syndrome, and familial exudative vitreoretinopathy. A high rate of PVR is reported following a range of novel complex surgical procedures, including macular translocation, retinal prosthesis implantation, and endoresection of ocular tumors. Surgical problems that increase the risk of PVR include vitreous and subretinal bleeding, choroidal detachment,<sup>18</sup> failure to close retinal breaks resulting in prolonged

retinal detachment, incarceration of retina in an external subretinal fluid drainage site, and heavy or excessive cryotherapy.<sup>19-21</sup> Seeding of pigment epithelial cells onto the retinal surface at the time of drainage of subretinal fluid through an internal retinotomy or retinal break may increase the risk. Prolonged inflammation after retinal detachment surgery increases the risk of PVR, especially if associated with postoperative uveitis, residual intraocular blood, or failure to remove all traction off the retina and failure to support it with a scleral buckle. The greatest risk period is 4–12 weeks after detachment surgery. A patient with any of the above predisposing risk factors, either preoperatively or as a result of surgery, should be followed more frequently in the postoperative period to ensure early detection of PVR and recurrence of retinal detachment.

**FIG. 111.3** Recurrent retinal detachment due to proliferative vitreoretinopathy. In this case reoperation may include an encircling silicone buckle, repeat vitrectomy with peeling of membranes and clearance of the vitreous base, aspiration of subretinal fluid, fluid air exchange, endolaser, and silicone oil tamponade.

## Clinical Signs and Diagnosis of PVR

The early signs of PVR are subtle and include cellular dispersion in the vitreous and on the retinal surface and localized fibrocellular membranes, which appear as a white opacification of the retinal surface and small wrinkles or fixed folds (Figs. 111.4 and 111.5). Cellular proliferation at the edge of a retinal tear can lead to local contraction and a rolled posterior edge (Fig. 111.6). More extensive PVR has fixed folds with retinal detachment, especially inferiorly, and fine membranes bridging the valleys between folds, as well as decreased mobility of the detached retina. Advanced PVR with posterior vitreous detachment results in the eventual formation of a funnel-shaped detachment with a contracted equatorial membrane (Figs. 111.1 and 111.2). In some cases, anterior traction at the vitreous base draws retina forward towards the ciliary body or detaches the ora serrata. Diagnosis of established PVR in the presence of rhegmatogenous retinal detachment is made by indirect ophthalmoscopy and slit-lamp biomicroscopy with a +78 or +90 diopter lens or corneal contact lens. In eyes with opaque media, B-scan ultrasonography outlines immobile retinal folds of detachment and prominent vitreous membranes (Fig. 111.7). Early and subtle signs of PVR should always be looked for and noted in the preoperative assessment of retinal detachment as it may result in modification of the choice of surgical techniques outlined below during primary repair. Early recognition of signs of impending PVR following reattachment of a retina in the 1–3-month period following surgery allows more timely intervention. In many cases of early PVR, timely intervention can avoid the substantial visual loss that almost invariably occurs with macula detachment in patients with delayed diagnosis and reoperation.

**FIG. 111.4** Rhegmatogenous retinal detachment with multiple surface wrinkles and folds – an early sign of proliferative vitreoretinopathy, which is associated with retinal stiffness and decreased mobility on eye movement.

**FIG. 111.5** Rhegmatogenous retinal detachment with a fixed star-shaped retinal fold.

**FIG. 111.6** Rhegmatogenous retinal detachment with a superior retinal break with a rolled posterior edge. This is an early sign of proliferative vitreoretinopathy.

**FIG. 111.7** B-scan ultrasound of an eye with rhegmatogenous retinal detachment and proliferative vitreoretinopathy (PVR). A high-intensity echo with a V or funnel shape emanating from the optic disc and lack of mobility of the detached retina are characteristic of advanced PVR.

## Classification of PVR

There is benefit in classifying and recording the extent of PVR in all eyes with retinal detachment. This active process prompts a thorough search for the signs in all patients before surgery and in

the postoperative period. It allows cross-comparison of severity of disease in any clinical series that may be audited or published and is the basis for assessing the effect of various therapies through clinical trials. The most commonly used classification system remains that published by the Retina Society Terminology Committee in 1983.<sup>3</sup> It classifies the appearance of PVR on the basis of clinical signs and geographic distribution into four grades (Table 111.1). A major drawback is that it ignores anteroposterior epiretinal proliferation and hence the importance of anterior traction in PVR. It is also a static classification that says nothing about the degree of cellular proliferative activity at the time of the grading. An inactive Grade D PVR affecting all quadrants may have a better prognosis with surgery than a very cellular, active, proliferating PVR affecting only two or three quadrants as in Grade C. The revised classification of PVR of 1991<sup>4</sup> took into account more detailed information about the location, extent, and severity of PVR in an individual eye and hence is more useful especially for clinical trials (Tables 111.2 and 111.3). Further modifications of the classification of PVR were proposed as part of the multicenter controlled trial of silicone oil (SO) as an adjunct treatment for PVR,<sup>22</sup> but the added complexity was found to be less reproducible between different examiners than the more simplified classifications. An analysis of the actual use of these classifications in publications on PVR over the last 15 years confirm their deficiencies as they omit information on cellular activity, do not record intraretinal fibrosis and retinal shortening and do not correlate well with anatomical success for surgery or visual prognosis.<sup>23</sup> A updated classification has not so far been published. Nevertheless, the description of PVR and accompanying preoperative retinal drawing should always be sufficiently detailed to allow any eye to be graded for clinical research and auditing of results of surgery. Wide-field digital imaging is also useful for this purpose.

---

**TABLE 111.1**  
**Retina Society Proliferative Vitreoretinopathy Classification (1983)**

---

Grade (Stage)	Characteristics
------------------	-----------------

A	Vitreous haze, vitreous pigment clumps
B	Wrinkling of the inner retinal surface, rolled edge of retinal break, retinal stiffness, vessel tortuosity
C	Full-thickness retinal folds in
C-1	One quadrant
C-2	Two quadrants
C-3	Three quadrants
D	Fixed retinal folds in four quadrants
D-1	Wide funnel shape
D-2	Narrow funnel shape (anterior end of funnel visible by indirect ophthalmoscopy with 20 diopter lens)
D-3	Closed funnel (optic nerve not visible)

**TABLE 111.3**

**Updated Proliferative Vitreoretinopathy Contraction Type Classification (1991)**

Type	Location (in Relation to Equator)	Features
Focal	Posterior	Star fold posterior to vitreous base
Diffuse	Posterior	Confluent star folds posterior to vitreous base; optic disc may not be visible
Subretinal	Posterior/anterior	Proliferation under the retina; annular strand near disc; linear strands; moth-eaten-appearing sheets
Circumferential	Anterior	Contraction along posterior edge of vitreous base with central displacement of the retina; peripheral retina

		stretched; posterior retina in radial folds
Anterior	Anterior	Vitreous base pulled anteriorly by proliferative tissue; peripheral retinal trough; displacement ciliary processes may be stretched, may be covered by membrane; iris may be retracted

## Prevention of PVR

Prevention of PVR relies mainly on an understanding of which eyes with or without retinal detachment are at greater risk of development of PVR and a recognition of the early signs of the condition. Increased awareness allows the surgeon to modify the treatment plan and, in most cases, prevent this devastating complication. Eyes with large or multiple retinal breaks or giant tears are more likely to develop PVR as mobilized pigment epithelial cells spill into the vitreous and onto the retinal surface in increased numbers. Likewise, eyes with previous or current penetrating trauma with or without retinal detachment may present with increased cellular content in the vitreous and an enhanced inflammatory response. Eyes with chronic retinal detachment, choroidal detachment, uveitis, viral retinitis, and chorioretinitis associated with detachment all have an increased risk of PVR, particularly if associated with a retinal break. Retinal detachment following cataract surgery with retained lens fragments in the vitreous, or following multiple anterior segment surgeries where there may be an enhanced inflammatory response, are at higher risk of PVR. Most eyes with PVR, however, have undergone a repair of rhegmatogenous retinal detachment in the last 1–3 months, and many of these eyes may have developed PVR regardless of the technique used for initial repair. Intraoperative complications including choroidal hemorrhage, retained vitreous hemorrhage, and intense photocoagulation or especially heavy cryotherapy increase the risks. Laser probably causes less breakdown of the blood–retinal barrier than cryopexy and mobilizes less pigment epithelial cells because of the size of each application and the fact that it is only applied to attached retina. Any eyes with the more

subtle early stages of PVR, including pigment particles in the vitreous, localized fixed folds, retinal breaks with rolled edges, visible vitreous membranes, detached segment of the pars plana ciliaris and ora serrata, and decreased mobility of retinal detachment folds on eye movement during examination, usually require vitrectomy to decrease the chance of progression to the full syndrome. The signs of early PVR may indicate the need for combined vitrectomy and scleral buckling rather than one or the other and also vitreous substitution with long-acting gas or SO.

## Surgery for PVR

There has been substantial improvement in the success rate of surgery for PVR progressively over the past four decades.<sup>24-27</sup> The clinical severity of PVR is very variable, and therefore the extent of surgery is planned accordingly. PVR varies from a single inactive fixed star fold on the retinal surface to a rigid total retinal detachment with a funnel shape and dense equatorial fixed membranes. There may be fixed folds involving only the posterior retina or fibrotic organization of the vitreous base with both circumferential and anterior loop traction dragging the retina forward or detaching the pars plana ciliaris. Fixed folds may tent the retina and be relatively easily divided or peeled to relieve traction, or there may be extensive surface retinal fibrosis and consequent shortening of the retina in the anterior/posterior plane requiring a relaxing retinotomy. The severity of PVR may also differ markedly in terms of current inflammation and cellular proliferative activity or take the form of fixed, quiescent acellular membranes which are unlikely to recur if divided or peeled. These factors may affect the timing of repeat vitreoretinal surgery. It is urgent if the macula is still attached or salvageable. It may sometimes be better to wait a few days and quieten the eye down with corticosteroids if the macular vision is not salvageable until the inflammatory activity is less intense. On the other hand, leaving an eye with a retinal detachment and early PVR almost always will lead to further progression and eventual inoperability, so that most eyes deemed to be operable should be operated on as soon as possible. The objects of vitreoretinal surgery for PVR are to

permanently support the retina from any ongoing traction and to close any open retinal breaks. These goals are achieved by an encircling scleral buckle, meticulous relief of all retinal traction with vitrectomy, and temporary or long-term tamponade of the retina with long-acting gas or SO. These steps must be achieved without causing prolonged ocular inflammation or further cellular access to the retinal surface, or else recurrence is frequent.

## **Scleral Buckling and PVR**

Although complete vitrectomy and vitreous replacement have become the core procedures for PVR, a 360° encircling scleral buckle remains a fundamental requirement for most eyes with established PVR in the view of many vitreoretinal surgeons. That is because the vitreous base, particularly inferiorly, becomes fibrocellular in PVR and continues to contract even after a formal vitrectomy, since it is virtually impossible to remove the whole vitreous base. A high encircling scleral buckle supports the vitreous base against further traction and against leakage from new or missed small retinal breaks in peripheral thin retina. Eyes with localized or relatively inactive PVR may be successfully reattached with an encircling scleral buckle, drainage of subretinal fluid, and peripheral laser photocoagulation alone. Most, however, require a vitrectomy and internal tamponade with SO or long-acting gas. To achieve chorioretinal adhesion, laser photocoagulation is preferable to cryotherapy, but laser is not always possible due to residual subretinal fluid after drainage or an atrophic white background associated with previous surgery.

## **Vitrectomy and PVR**

A comprehensive vitrectomy is essential in the management of PVR. Some surgeons rely on a meticulous vitrectomy and SO tamponade without scleral buckling and report comparable results with a combined procedure.<sup>28</sup> In any event, almost all eyes with retinal detachment and PVR also require a vitrectomy to remove all vitreous gel, cellular and inflammatory material, blood, and fibroblastic membranes. It is necessary to relieve all traction by division and peeling or delamination of fixed membranes and to

remove as much as possible of the vitreous base. It is also important to divide any membranes causing anterior loop traction and to release the tractional effect on scarred shortened retina. This surgery is greatly facilitated by the extraordinary advances in the technology now available. Wide-angle viewing systems are either indirect and attached to the operating microscope, or consist of an operating corneal contact lens and a microscope image inverter. Contact lenses provide a crisper image and easier visual access to the far inferior periphery but need frequent repositioning and replenishing with viscoelastic. Indirect viewing systems provide a less panoramic view, and the view is dependent on precise eye positioning, making angulation more difficult. Wide-field illumination is achieved with a range of fiberoptic light sources or a chandelier arrangement inserted into the eye through a separate pars plana entry site. Vitreous cutting and suction probes (vitrectors) have vastly improved, and the surgeon has a choice of 25-, 23-, and the traditional 20-gauge (G) instruments. Air-driven vitrectors can cycle at up to 5000 cycles per minute and have a variable duty cycle controlled by electronic sensors. This allows faster removal of core vitreous and opacities, but also safer cutting and aspiration close to the retinal surface. Another major advance has been the intraoperative use of heavier-than-water perfluorocarbon fluid which displaces subretinal fluid anteriorly and flattens the bullous posterior retina. This highlights tractional membranes and facilitates peeling and dissection by stabilizing the posterior retina. Sometimes relaxing retinotomy is required to fully relieve traction caused by densely adherent fixed folds or shortened fibrosed retina. Rarely subretinal membranes need to be removed or divided through a small deliberate retinotomy. Internal drainage of subretinal fluid and fluid–air exchange of the vitreous compartment allows the testing of release of all retinal traction. Any persistent retinal elevation after fluid–air exchange means that complete release of traction or retinal shortening has not been achieved. Reattached retina and open retinal breaks are sealed with endolaser photocoagulation or cryotherapy and a decision made as to whether temporary tamponade with perfluoropropane (C<sub>3</sub>F<sub>8</sub>) gas will be sufficient or SO–air exchange is necessary. Although a controlled trial showed the eventual outcomes to be similar, many

surgeons prefer SO to gas because it results in less postoperative inflammation, quicker rehabilitation, and fewer reoperations. The use of heavier-than-water SO can also improve inferior retinal tamponade in severe cases of PVR and is being increasingly used.

## Surgical Steps for Established PVR

Modern surgery for PVR is greatly facilitated by a wide-angle microscopic viewing system and a fully integrated, electronically controlled, surgical system. Vastly improved fluidics and a range of inbuilt modalities improve the efficiency, duration, and predictability of vitreoretinal surgery. High-speed 23G or 25G cutters able to trim vitreous and membranes off the retinal surface at up to 5000 cuts/minute have greatly improved the ability to remove residual vitreous and membranes, particularly around the vitreous base, while avoiding retinal incarceration with the cutter and the creation of iatrogenic retinal breaks (see Video 111.1 online ). Illuminated picks or chandelier endoillumination allow bimanual dissection of intraocular tissue. Endodiathermy probes and small extrusion/suction needles allow the creation of a controlled microretinotomy for endodrainage of subretinal fluid. Flexible endolaser probes facilitate 360° peripheral laser photocoagulation and treatment of any retinal breaks. Laser is superior to cryotherapy in this situation, as it can seal flattened retinal breaks and allow 360° photocoagulation with less postoperative inflammation, and stimulation of repeat cellular proliferation. An integrated fluid–air exchange pump with self-monitoring of intraocular pressure (IOP) facilitates fluid–air exchange and formal checking that the retina is totally mobilized and retinal breaks are completely flat. Difficult visualization still makes cryotherapy necessary in some cases. Soft silicone-tipped fluid extrusion needles (23G or 25G) with active suction facilitate complete drainage of subretinal fluid through a retinal break or intentional posterior retinotomy. 23G and 25G vitreous forceps and scissors have improved the ability to peel, delaminate, and relieve retinal traction in a controlled manner. An integrated pump for the delivery of SO to the vitreous and fluorinated heavy silicone to tamponade the inferior, flattened retina are important additions.

The use of these tools in a stepwise logical manner means that up to 90% of eyes with advanced PVR may be successfully reattached. Advances in instrumentation for phacoemulsification of the lens have also resulted in a shift by many surgeons from posterior lensectomy to formal anterior lens extraction and insertion of an intraocular lens. Planned extracapsular lens removal still enables surgery at the vitreous base, while retaining a barrier to the anterior segment for SO or gas. Eyes left aphakic after pars plana phacofragmentation that are filled with SO risk corneal endothelial damage and secondary glaucoma from emulsified SO bubbles in the anterior chamber or pupil block.

## Anesthesia

As with any vitreoretinal surgery either general or local peribulbar anesthesia is acceptable. If general anesthesia is planned, the anesthetist must be informed if long-acting gas is to be used so as to avoid nitrous oxide. Most cases of PVR can be operated with local anesthesia. The surgery can be prolonged and uncomfortable for the patient, particularly if there is an inadequate deep sub-Tenon block. The block can be supplemented during the operation with further injection and by the attending anesthesiologist with intravenous sedation and analgesia. If a scleral buckle is already in place and the surgery is wholly intraocular, it is not usually painful.

## Operative Technique

The surgery should begin with a well-prepared preoperative plan, which can be modified often during the operation, depending on the findings. Preoperative retinal and biomicroscopic diagrams aid this process by ensuring that all aspects of the pathologic findings are, in fact, examined and taken into account. The conjunctiva is opened by limbal peritomy unless an encircling 360° buckle exists already or is not planned. Any preoperative scar tissue is gently dissected under and around the rectus muscles, which are looped with 4/0 black silk traction sutures. A 360° scleral band is then placed and sutured in position with permanent scleral sutures such as 5/0 polyester. The choice of scleral buckle width depends upon the extent of vitreous base contraction and size of any peripheral

retinal tears. It may vary from a broad 7.0-mm, Style 277 or 276 encircling tire and 40 band through a solid encircling 5.0-mm wide scleral band down to a 2.5-mm wide style 240 encircling band. The trend is towards narrower bands to permanently support the vitreous base and any small peripheral retinal tears. Larger, more posterior tears can be supported by an extra meridional explant placed under the tear at the end of the operation, but in most cases after complete relief of traction, they are closed by an internal tamponade and sealed permanently with laser. The scleral sutures are placed at two-thirds scleral thickness, at least 1 mm anterior and posterior to the encircling buckle, one or sometimes two in each quadrant. The sutures are not tied and the buckle not tightened until the end of the procedure and after vitrectomy. If only an encircling band is employed, some surgeons prefer to anchor it with sclera "belt loops." If an adequate encircling scleral buckle is already present from previous surgery, then the above steps may be omitted and surgery proceeds with transconjunctival insertion of three 23G or 25G entry cannulas. Some surgeons still prefer a 20G system, which requires intraoperative sutured ports. The three entry ports are placed in the inferotemporal, superotemporal, and superonasal quadrants with an angled entry to diminish the risk of leakage of air or fluid from the entry site postoperatively. The first port is placed near the horizontal in the inferotemporal quadrant so as not to impede rotation of the eye downwards during surgery to remove inferior vitreous base. The second and third ports are for the fiberoptic probe and vitrector or other instruments such as endodiathermy, endolaser, vitreous scissors, vitreous forceps, and extrusion needle. If a chandelier is to be used, it is inserted through a fourth port. The entry cannulas are placed 3.5 mm from the limbus above the midline almost opposite each other, again to facilitate superior and inferior rotation of the globe for peripheral visualization during surgery. Care must be taken to check that the pars plana ciliaris is not detached and that the indwelling ports have passed into the vitreous to avoid subretinal or suprachoroidal infusion during vitrectomy. At this point, a decision is made as to the adequacy of visualization of the retina, especially the periphery and vitreous base by switching microscopic illumination to an indirect, non-contact wide-angle viewing system, or by placement

of a wide-angle corneal contact lens. If the pupil is small or the iris stuck down to the lens capsule, the anterior chamber is entered and aqueous replaced with viscoelastic sodium hyaluronate. Synechiae may be broken down by this injection and the pupil dilated, or else it is mechanically dilated using soft disposable iris hooks placed through clear cornea in each quadrant.

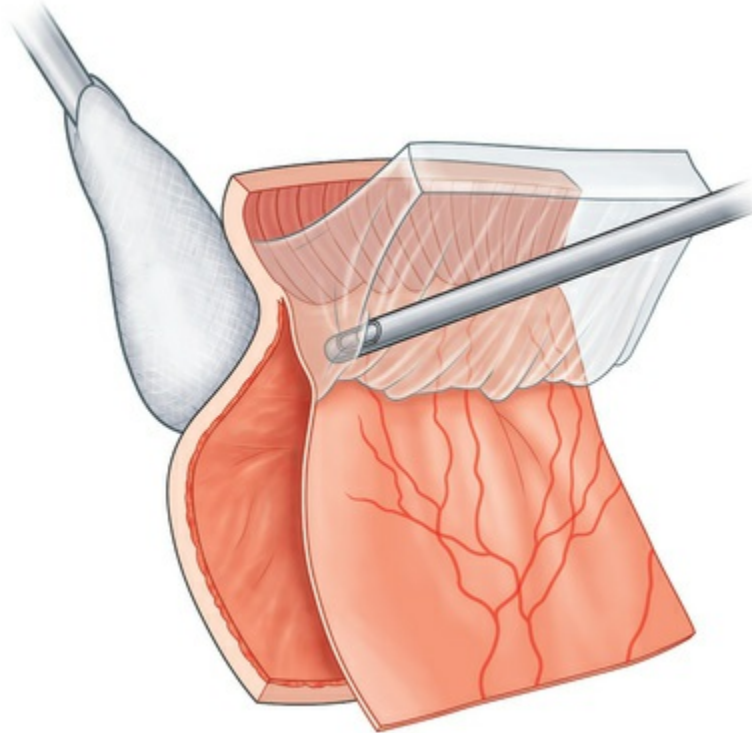

## Management of the Lens in PVR

In most cases, wide-angle viewing systems provide an adequate view of the periphery and the lens is preserved. It always becomes cataractous with SO and is conveniently replaced after phacoemulsification at the time of SO removal or when it becomes visually significant. If lens opacities are sufficient to impede the view of the posterior segment, then the cataract must be removed. Most surgeons now favor a formal phacoemulsification procedure, as this allows insertion of an intraocular lens during the operation. Some surgeons still favor fragmentation of the lens via the pars plana sclerotomy and removal of the whole capsule or retention of the anterior capsule. In this case, the eye is rendered aphakic. If the capsule is totally removed, then there is risk from SO contact to the corneal endothelium in the longer term. An inferior iridotomy reduces this risk.<sup>29</sup> If the anterior capsule is left intact, then it always becomes opaque in the presence of SO and subsequent YAG laser capsulotomy or formal capsulotomy with a sharp instrument is carried out at the time of insertion of an intraocular lens in the sulcus 2–3 months later.

## Core Vitrectomy and Removal of the Vitreous Base

During vitrectomy, the cornea is kept clear by a viscoelastic coating of methyl cellulose and the wide-angle view contact lens if used. The microscope is refocused for internal viewing and after insertion of a fiberoptic light probe and the vitrector. The three available probe sizes are all acceptable. The 25G has the smallest opening and is the safest. It is also the slowest. Because it is more flexible it can be difficult to rotate the eye superiorly enough to comfortably

remove vitreous off a superior retinal break with a mobile detached retina. The 20G probe has the largest opening and most efficient fluidics but the ports need suturing. The 23G probe is the most popular compromise. Most eyes with established PVR already have a posterior vitreous detachment. Any remaining central gel is removed completely and then peripheral vitreous is removed meticulously and as completely as possible, particularly inferiorly where pigment and inflammatory cells tend to gravitate. This process is facilitated by the modern, high-speed, vitrectomy cutters with the port close to the tip. With these cutters, it is possible to shave the attached vitreous off the surface, without engaging the retina. A bimanual technique with an illuminated probe or pic held in the second hand, can also be helpful in protecting the retina. Removal of the inferior vitreous base is also facilitated by having an assistant indent with a scleral depressor, squint hook, or cotton-tipped stick (Fig. 111.8). Formed vitreous attached to the peripheral retina is also very difficult to remove if the retina is detached and mobile, in which case it can be stabilized at this stage by partly filling the vitreous compartment with heavy fluorocarbon liquid (Fig. 111.9, see Video 111.1 online).<sup>30,31</sup> This has the dual effect of flattening the retina by displacing subretinal fluid anteriorly and breaking down invisible microscopic retinal bridges of scar tissue. In cases where vitreous remains attached to the retinal surface posteriorly as well as at the vitreous base, the process of removal may be facilitated by an intravitreal injection of triamcinolone. The white suspension sticks to vitreous membranes and residual vitreous gel, making them both more visible (see Video 111.1 online).<sup>32-34</sup>

**FIG. 111.8** Anterior vitreous and tractional membranes are removed with the high-speed vitreous cutter and low suction. This process may be helped by scleral indentation. Formed vitreous is shaved from the retinal surface to reduce the risk of further postoperative traction.

**FIG. 111.9** Removal of more anterior membranes and vitreous is facilitated by perfluorocarbon heavy fluid injection into the vitreous compartment. This squeezes subretinal fluid forward and stabilizes the posterior retina while the vitrector, a blunt spatula, or forceps are used. Care must always be taken to avoid heavy fluid passing through a retinal break and under the retina.

## Removal of Epiretinal Membranes and Use of Perfluorocarbon Heavy Fluid

After a meticulous vitrectomy, which is as complete as possible, any fixed folds or retinal contraction due to epiretinal membranes must be dealt with. Membranes are peeled from the retinal surface from the posterior pole outwards. If an edge is found, it can be peeled preferably with vitreous forceps. If not, a blunt vitreous spatula or pick may help find a plane and elevate the membrane (Fig. 111.10). Care must be taken to avoid creating iatrogenic retinal breaks. Special attention is given to any fixed folds where contracted membrane tends to fold the retina over underlying valleys. Any membrane involving the macula must be peeled. Some surgeons

advocate the injection of vital dye such as methylene blue at this point to stain and allow peeling of the contracted internal limiting membrane, particularly if the retinal surface at the posterior pole is still stiff or shiny. The degree of adherence of epiretinal membranes to the retinal surface varies so that some may be peeled easily in a single sheet, while many others have to be freed up in a piecemeal fashion or delaminated. Peeling of surface retinal membranes and internal limiting membrane is much easier over attached retina. In many cases, drainage of subretinal fluid through an open retinal break, or if necessary through a small retinotomy away from areas of surface scar tissue, or more often, flattening the posterior retina by the injection of the heavy liquid fluorocarbon facilitates this process (Video 111.1 online).<sup>30</sup> Care must always be taken to avoid the risk of heavy fluid passing through a retinal break under the retina. This can occur if tractional membranes are still elevating a retinal tear. The heavy liquid fill is stopped short of any such retinal break until it is dissected, mobilized, and flattened.

**FIG. 111.10** Elevation of an epiretinal membrane

causing a fixed star fold in the retina using a vitreoretinal pick. Peeling of surface membranes is better carried out with blunt end-on vitreous forceps or a blunt spatula to minimize the risk of creating retinal tears.

## Removal of Anterior Tractional Membranes

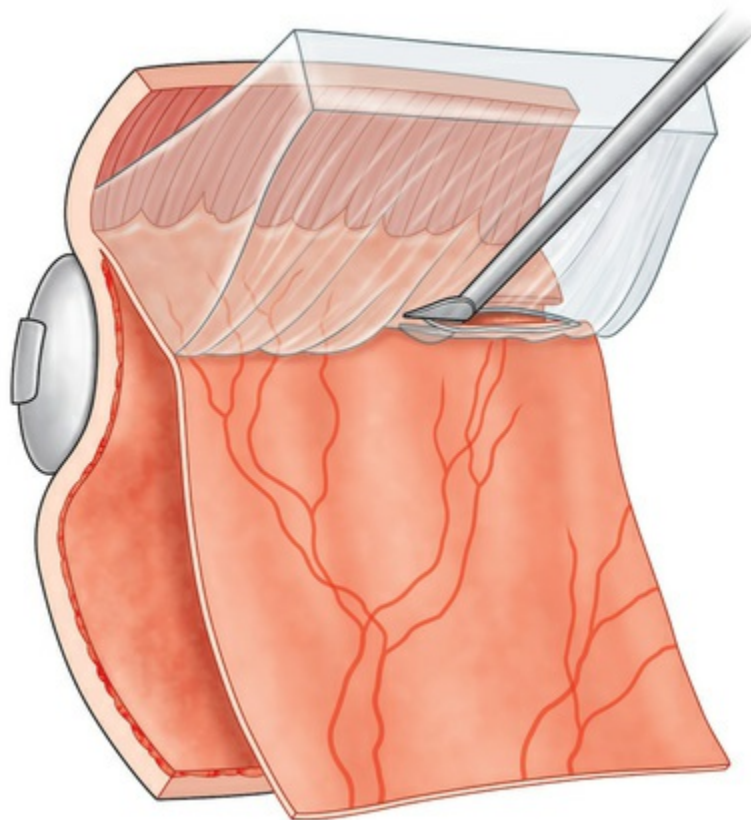

Fibroblastic organization of the vitreous base can cause elevation of peripheral retina and anterior loop traction. This must be sectioned to fully mobilize the retina (Fig. 111.8). As much formed gel as possible must be removed anteriorly also to decrease the risk of recurrence of PVR. High-speed vitreous cutters (23G or 25G) have also greatly facilitated this aspect of surgery so that vertical action scissors are often not needed. Bimanual instrumentation and external scleral depression (Fig. 111.8) may help and wide-angle viewing is very important. Heavy perfluorocarbon liquid is usually needed to stabilize the posterior retina during dissection. If extensive anterior traction is noted preoperatively, then planned lens extraction can also facilitate this dissection, but with modern instrumentation and viewing systems this is no longer usually necessary.

## Testing Adequacy of Relief of Traction and Relaxing Retinotomy

At this point, the adequacy of retinal mobilization can be tested by a complete fluid–air exchange. An extrusion needle is placed through the sclerotomy site, and all vitreous fluid or heavy fluid and any residual subretinal fluid is aspirated by positive suction. Drainage of subretinal fluid is facilitated by a silicone soft tubing extension on the needle. If residual traction is present or the retina shortened by surface or intraretinal gliosis, it fails to flatten completely and air may even pass under the retina. This test informs the surgeon that adequate mobilization of the retina has not been achieved. It may require additional dissection around a retinal tear or a limited peripheral relaxing retinotomy or even a circumferential or radial retinotomy with either vitreous scissors or,

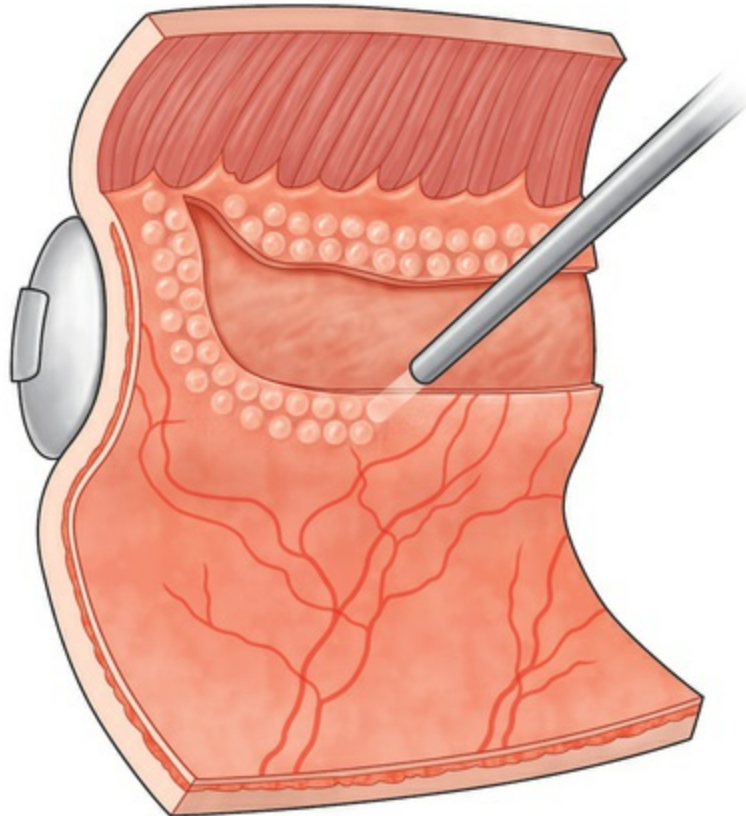

more conveniently, with the vitrector (Fig. 111.11).<sup>35-37</sup> Badly fibrosed, contracted retina may also require local retinectomy to allow reattachment under perfluorocarbon heavy fluid (Video 111.1 online, see also Chapter 112, Retinectomy). Endodiathermy is required to prevent or seal retinal bleeding at the cut edge. The endpoint of this step is a total flattening of the retina under air or heavy fluid. The edges are then thoroughly sealed with endolaser (Fig. 111.12). Failure to relieve all traction prevents the retina from apposing the pigment epithelial surface. This is the most frequent cause of a poor anatomic result. On the other hand, a relaxing retinotomy should not be undertaken lightly. After a large circumferential retinotomy the posterior free edge may contract under SO almost back to the disc and macula and compromise the visual outcome. A radial retinotomy may sometimes relieve residual traction and avoid this posterior retraction of the cut retinal edge.<sup>38-41</sup>

**FIG. 111.11** In severe cases of anterior proliferative vitreoretinopathy retinal shortening occurs. This

prevents the retina being flattened unless the traction is relieved by retinotomy. If extensive retinal scar tissue is present, retinectomy must also be performed.

**FIG. 111.12** After the retinotomy, traction is relieved and the retina flattens with the help of heavy fluorocarbon liquid and/or fluid–air exchange and active aspiration of subretinal fluid. The edges of the retinotomy and any other retinal breaks are then treated with extensive laser photocoagulation.

## Removal of Subretinal Membranes

In a small proportion of eyes, particularly with long-standing PVR and/or excessive prior inflammation, subretinal bands may develop and contract causing tenting of the retina.<sup>42</sup> If these prevent retinal reattachment, then they are removed prior to the fluid–air exchange by creating a small retinotomy with scissors over the tort

membrane, grasping the membrane through the retinotomy with 25G vitreous forceps, and pulling it through the retinotomy into the vitreous compartment.<sup>43,44</sup> It then may be transected or pulled out completely (Fig. 111.13 and Video 111.1 online).

**FIG. 111.13** Subretinal bands are removed if they will prevent retinal reattachment. A small retinotomy is made over the subretinal band and forceps are used to pull it through the retinotomy. It may then be simply sectioned and allowed to retract or pulled free of the pigment epithelium and removed in one piece.

## Fluid–Air Exchange

After complete mobilization of the retina and relief of all traction, fluid–air exchange is done to achieve a totally flat retina. All

subretinal fluid, heavy fluid, vitreous fluid, and residual opacities such as blood are aspirated through a 25G or 23G extrusion cannula, while maintaining a constant IOP with continuous air infusion (Fig. 111.14). Subretinal fluid drainage may be completed in the presence of heavy fluid by suction through an anterior retinal break, or in the case of fluid–air exchange, a small posterior retinotomy may be required. A planned drainage retinotomy is made by first placing a small white diathermy mark on a spot chosen nasal to the disc, away from any fixed fold but over detached retina and avoiding retinal vessels. The 25G or 23G suction cannula is then used to make a small hole in the weakened spot. Care is taken to continuously aspirate the egressing subretinal fluid and to avoid spreading the mobilized pigment cells onto the retinal surface. A soft flexible silicone tip on the aspirator can be passed under the retina either through the retinotomy or a preexisting retinal tear (Video 111.1 online).

**FIG. 111.14** In order to reattach the mobilized retina after vitrectomy and membrane dissection, subretinal

fluid is drained either posteriorly through a deliberate retinotomy or, if present, through a preexisting retinal break. A silicone-tipped extrusion cannula and positive suction facilitates this process as does simultaneous air–fluid exchange. Subretinal fluid is aspirated first to reattach the retina, then remaining intravitreal fluid is replaced by gas. An alternative method if anterior breaks are present is to instil heavy perfluorocarbon liquid and displace subretinal fluid forward where it is aspirated through an open retinal break. (Reproduced with

Louis: Mosby; 1997.)

## Creating Chorioretinal Adhesion and Scleral Indentation

Following complete mobilization of the retina and flattening with air–fluid exchange, extensive endolaser photocoagulation is carried out (Fig. 111.12).<sup>45</sup> All retinal breaks or retinotomies are surrounded with visible retinal burns, and a band of laser is usually extended 360° around the peripheral retina overlying the vitreous base and extending back towards the equator. Endolaser is applied posteriorly almost back to the vascular arcades if an extensive retinotomy or retinectomy has been necessary to flatten scarred contracted inferior retina. Some surgeons prefer to apply laser using an indirect ophthalmoscopic delivery system with scleral depression, particularly if 360°. The settings used tend to be of longer duration (0.3–0.5 seconds) than that used in the clinic with a slit lamp, but care must be made not to increase the energy density excessively, as this may result in choroidal hemorrhage and rupture of Bruch's membrane. Laser photocoagulation is preferable to cryotherapy as it causes less postoperative inflammation and probably is associated with less subsequent complications, namely further breakdown of the blood–vitreous barrier, cellular proliferation, and recurrence of PVR. In some cases, however, cryotherapy is still necessary due to difficulty in dissecting all the membranes in some areas and persisting shallow subretinal fluid under the retina in the far anterior area to be covered by the scleral buckle. Cryotherapy is also necessary if the peripheral view is

compromised. Care should be taken not to overtreat with cryotherapy. If visible laser burns cannot be achieved by endolaser or indirect applications, it usually means that the retina is slightly elevated in the area with persisting shallow subretinal fluid. Once extensive laser photocoagulation and, in some cases, localized cryotherapy is applied, the preplaced scleral buckle is secured by tying each of the preplaced scleral sutures. Indentation is achieved by tightening the encircling element, which is tethered either by a Watzke sleeve or a knotted polyester suture. The resulting scleral buckle should be relatively high to ensure permanent support of the vitreous base. If the eye is left with a low scleral indentation, further proliferation and contraction of residual vitreous base elements can lead to new or reopened retinal tears and recurrence of the detachment. Any large more posterior retinal break should be closed by the buckle if possible. This sometimes requires an additional meridional piece of silicone or even a piece of silicone sponge under the encircling element.

## Intraocular Tamponade

The next step is to decide whether short-term tamponade with a long-acting intraocular gas mixture<sup>46</sup> or more extended or permanent tamponade with SO is preferable.<sup>47</sup> A controlled trial suggested that short-term tamponade for 2 weeks with sulfur hexafluoride (SF<sub>6</sub>) was inadequate but that longer-acting gas tamponade with octafluorocyclobutane (C<sub>3</sub>F<sub>8</sub>) for up to 4 weeks was adequate for many eyes. Results were in general comparable in long-term outlook to those in which SO was inserted.<sup>48,49</sup> In practice, however, most surgeons prefer SO (Table 111.4). This is because the majority of these eyes have already had one or more previous surgeries and SO tends to quieten the eye down much quicker and ensure control of a very difficult clinical situation. A further recurrence with long-acting gas tamponade requires another procedure with SO. It also restricts patients' activities for longer. Long-acting gas prevents airplane flights and useful vision for up to 4 weeks. If octafluorocyclobutane gas exchange is selected, a concentration between 15% and 18% is usually used.<sup>50</sup> This is mildly expansile, running the risk of postoperative ocular

hypertension, but creates an effective gas bubble for tamponade with positioning postoperatively and occupies more than half the vitreous compartment for up to 3 weeks. The gas may be instilled via a modern integrated vitrectomy machine or drawn up separately in a 50-ml syringe and diluted to the appropriate concentration with filtered air. Intraocular gas can be replenished postoperatively if the vitreous fill is inadequate or absorbing too quickly as an outpatient procedure using a push/pull fluid–gas exchange technique.<sup>51</sup> In eyes in which the conjunctiva has been dissected, or if there is thin sclera, myopia or a previous vitrectomy and especially with 23G or 20G vitrectomy, it is usual to suture the sclerotomies (7/0 virgin silk) to avoid early postoperative loss of the vitreous gas or SO. Even 25G vitrectomy ports may leak, and if there is any doubt, they should be sutured.

**TABLE 111.4**

**Comparison of Perfluoropropane Gas Versus Silicone Tamponade for Proliferative Vitreoretinopathy**

	<b>Advantages</b>	<b>Disadvantages</b>
Perfluoropropane gas	Absorbs spontaneously, giving temporary tamponade to retina	Does not last long enough to provide tamponade needed for eyes with epiretinal re proliferation 6–8 weeks after surgery
	Can control duration of tamponade from intermediate to long duration by adjusting concentration of C <sub>3</sub> F <sub>8</sub> with air	Air travel prohibited until bubble absorbed
	Visual rehabilitation occurs more rapidly in eyes with PVR treated with gas	Cataract formation if prone positioning not maintained
	Relatively few long-term complications associated with use	Some short-term complications, such as elevated intraocular pressure Hypotony more likely postoperatively
Silicone oil	Provides extended tamponade for months or years, allowing surgeon to determine if and when to remove silicone oil	Does not prevent re proliferation in inferior retina
	The best tamponade for eyes with numerous retinal tears or large retinectomies	Visual acuity slow to improve and causes substantial changes in refraction
	Better in achieving partial retinal reattachment in eyes with residual traction or re proliferation	Corneal toxicity
	No restrictions on air travel	Cataract formation in phakic eyes
	Better tamponade for eyes with	Silicone oil emulsification

	hypotony	Elevated intraocular pressure
		Must be removed by a second surgical procedure to achieve best acuity

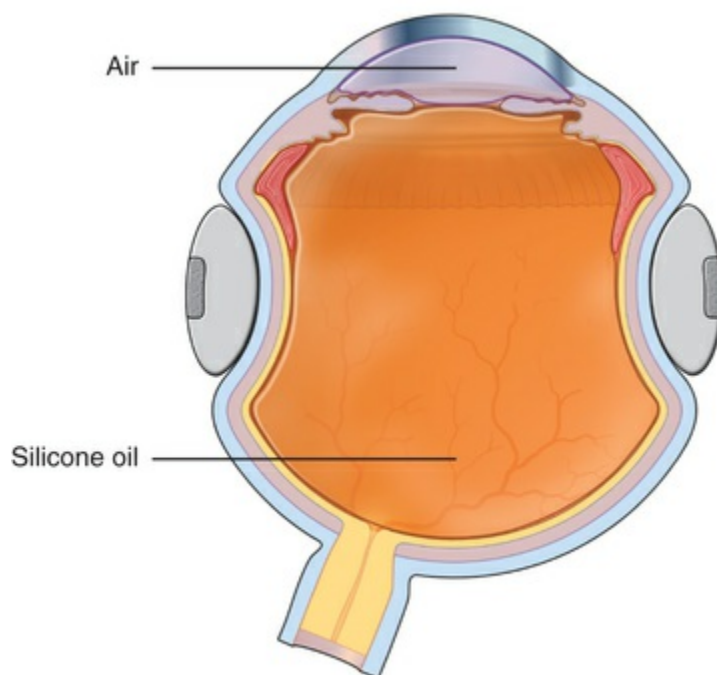

## Silicone Oil

If SO is selected for longer-duration tamponade, as is usually the case, it is injected directly into the air-filled vitreous cavity (Fig. 111.15). If perfluorocarbon heavy liquid has been used during the procedure, some surgeons will do a direct perfluorocarbon–SO exchange, but most prefer the intermediate step of fluid–air exchange before instilling the SO. This is because residual subretinal fluid may be trapped anteriorly by the heavy fluid and it becomes obvious as it migrates posteriorly again with air towards the posterior pole. A specially designed rigid syringe is provided with SO for its injection under pressure from an air pump in the integrated vitrectomy machine. Oil is injected through the surgical vitrectomy port or through the infusion line of 23G or 20G diameter. It is possible, with modern equipment, to force it through a 23G or 25G short needle or cannula,<sup>52</sup> but some still enlarge the sclerotomy to 20G. The oil syringe is then connected to a short plastic catheter fashioned from the range of intravenous disposable trocar/cannulas available, cut to about 1 cm length, and beveled for easy insertion. At this point, most surgeons still cut a basal iridectomy at 6 o'clock in the inferior iris in aphakic eyes using the vitrector under air to prevent postoperative ciliary block and secondary glaucoma.<sup>29</sup> This step is not necessary if the lens/iris barrier is intact. The SO is injected under direct view with the wide-angle viewing system, while air infusion is still connected to the eye. During injection, air passes out of the air infuser port (Fig. 111.15). The infusion pressure is now lowered to 10–15 mmHg as silicone enters the vitreous compartment from the superior site, thus maintaining IOP. Once air infusion stops as the level of the sclerotomy port is reached by the oil, IOP may rise precipitously. At this point, the air infusion cannula is removed and SO injection continued until the residual air is expelled. Care is taken to monitor the IOP during this maneuver with a cotton-tipped stick. Many surgeons would close one of the sclerotomies prior to injecting the SO and then the remaining two are closed. The final aim is to

achieve a complete fill of the vitreous cavity with SO but an IOP that is towards the lower range of normal, between 10 and 15 mmHg (Fig. 111.16). Silicone oil is available in a less viscous form of 1000 or 1300 cSt (centistokes) or the more viscous 5000 cSt variety. Most vitreoretinal surgeons prefer the 1000–1300 cSt oil because of its relative ease of removal. More viscous SO is said to be less likely to pass through retinal breaks, but any oil will pass through if the hole is not properly flattened after relief of traction or supported by the indentation of a scleral buckle.

**FIG. 111.15** Silicone oil (SO) is injected via a pars plana sclerotomy site through a specially designed 10-mL reinforced syringe attached to a 19G, 20G, or 23G intravenous catheter that has been cut to about 1 cm in length. The oil is pumped in under pressure, and as it flows into the eye, air is pushed either through an open sclerotomy site or, with more control, back up the air infusion line. This helps maintain a normal intraocular pressure during SO injection. Once the oil level reaches the infusion cannula, pressure may rise precipitously. This is avoided by removing the air infusion cannula at this stage and gently continuing the SO injection until all the air is expressed out the sclerotomy sites.

**FIG. 111.16** Silicone oil (SO) fills the whole posterior segment after complete vitrectomy, dissection of fibrous tissue membranes, and relief of all retinal traction. The retinal breaks are tamponaded internally with the SO and externally with an encircling silicone buckle. If the eye is aphakic, the anterior segment is temporarily protected from SO by air. SO may have to be left in the eye permanently but is often removed 3–6 months later.

### Heavy Silicone Oil

An additional choice for retinal tamponade is that of heavier-than-water, fluorinated silicone liquid. Standard SO is lighter than water, and therefore once the patient is mobile or sitting upright, there tends to be a small gap between the apposition of the fluid bubble and the inferior peripheral retina. This leads to an accumulation of cellular debris and inflammatory proteins in this pool of aqueous between SO and retina. In combination with the lack of inferior tamponade, this often leads to continued retinal surface proliferation and a recurrence of local traction detachment inferiorly.<sup>53,54</sup> This can be avoided or treated when it occurs

postoperatively with the use of heavy fluorinated SO, which tamponades the inferior retina when the patient is upright (Figs. 111.17 and 111.18). It has been used in combination with light SO but more often as an alternative, particularly after inferior relaxing retinotomy.<sup>54-68</sup>

**FIG. 111.17** Reattached retina 1 week after proliferative vitreoretinopathy surgery with an encircling scleral band, vitrectomy, membrane peeling, endolaser photocoagulation, and tamponade of inferior retina with heavy silicone oil.

**FIG. 111.18** Same eye as in Fig. 111.17, 2 months

later. The retina remains attached, but there has been proliferation of scar tissue posterior to the buckle causing a sharp fold. The retina is weighed down on either side by the heavy silicone oil.

First-generation (fluorinated silicone and perfluorocarbon liquids) and second-generation (partially fluorinated alkanes) heavy tamponades had frequent complications including intraocular inflammation, raised IOP, and emulsification. Three examples of third-generation heavy SO tamponades are reported to have a complication profile similar to light SO.<sup>65</sup> They provide better tamponade of the inferior retina and posterior pole. The toxic effects of long-term retention in the eye are not yet known, and emulsification is frequent.<sup>53-68</sup> Therefore, heavy oil is usually currently removed after 3 months.

Finally, the orbit is rinsed with balanced salt and a long-acting local anesthetic for postoperative pain management. Dilute antibiotics such as gentamicin or a cephalosporin are also added to the sub-Tenon space. The conjunctiva is closed if a peritomy was done, with absorbable 7/0 sutures and an injection of long-acting Celestone or triamcinolone given in the sub-Tenon space.

## **Operating Under Silicone Oil**

Many eyes with PVR continue to develop surface retinal membranes after successful surgery to reattach the retina.<sup>69</sup> These contract and cause complications ranging from premacular pucker to inferior retinal detachment, retinal tears, and retinal shortening. Although some surgeons prefer to remove the SO and peel the scar tissue or relieve the effects of traction with peripheral retinectomy under perfluorocarbon heavy liquid, it is usually possible to operate under the oil.

An infusion port is connected to air to maintain IOP. Membranes are peeled with vitreous forceps off the macula (Figs. 111.19A–B). A secondary retinal tear requires complete relief of traction and further laser. Retinal shortening usually needs a high scleral buckle and/ or peripheral retinectomy. Any residual subretinal and preretinal fluid (in the case of light SO) is drained by active suction, and the SO is topped up as required.

**FIG. 111.19** (A,B) Dense preretinal membrane causing macular and inferior retinal traction after proliferative vitreoretinopathy and retinal reattachment with silicone oil. The secondary macular membrane was peeled with vitreous forceps under the silicone oil without first removing it.

## Removal of Silicone Oil

Both types of liquid silicone are usually associated with poor vision due to the markedly different refractive index even if, as is usually not the case with PVR, there is reasonable macula visual potential.<sup>70</sup> Migration of SO bubbles and slow neuronal degeneration have long been recognized. The wound-healing sequence of PVR matures like any other scar tissue over 3 months, and therefore SO is left in for at least that length of time. The eye is carefully monitored for recurrent traction and retinal breaks, but if the eye is quiet and all peripheral retinal pathology well supported by a high scleral buckle and all retinal breaks closed, silicone liquid may be removed after approximately 3 months. Delayed removal up to 18 months does not improve functional outcomes.<sup>71</sup> However, there is also a significant risk of retinal redetachment after SO removal.<sup>72,73</sup> Additional 360° laser posterior to the encircling buckle may decrease the risk. Many eyes, however, have relatively poor visual potential despite a flat macula, but evidence of persistent peripheral scar tissue or localized retinal detachment. They may have had numerous retinal breaks or extensive retinectomy. Most have had multiple surgeries by this stage, and in all these circumstances it is generally wiser to leave the SO in situ. Depending on the range of severity of PVR for which the surgeon chooses to use SO, the rate of removal will vary from about 50% to 85% of cases. Cataract occurs

invariably after liquid silicone tamponade of the retina, usually within 6–18 months. Combined phacoemulsification of the lens, insertion of an intraocular lens, and removal of the SO is then carried out at the same time. Late glaucoma is common with or without emulsified silicone bubbles in the anterior chamber and is usually an indication to remove all the oil (Fig. 111.20). Band keratopathy may occur in young people in the presence of SO, even if confined in the vitreous. Removal may slow the progression. SO is usually removed in the operating room through a 20G sclerotomy site using a shortened, bevelled intravenous 21G catheter attached to a 10-mL syringe and active suction. A preplaced infusion cannula in the inferotemporal quadrant maintains IOP during the procedure. The last of the silicone is removed by rotating the eye so that the residual bubble floats out. Controlled active suction through a 23G or 25G cannula is a convenient alternative with modern vitrectomy equipment.<sup>74</sup> Many surgeons do one or two fluid–air exchanges to ensure residual small bubbles are removed. This step may also detect small untreated retinal breaks masked by SO tamponade. They can cause local redetachment during the exchanges and can then be treated with laser under air. Heavy fluorinated silicone is more difficult to remove. An automated aspiration system is now available on integrated vitrectomy machines to aid in this procedure. Using a short 23G or 25G cannula continuous suction is applied to draw the heavy SO up to the port. The heavy SO falls back if the suction is interrupted. It then needs to be aspirated with a longer intravenous plastic catheter connected to the aspiration tubing and placed over the optic disc. The vitreous compartment may be left filled with air for a brief postoperative tamponade after removal of SO, or else with saline.

**FIG. 111.20** Emulsified silicone oil (SO) bubbles in the anterior chamber and central corneal stromal haze associated with SO keratopathy. Removal is indicated to prevent secondary glaucoma and further corneal degeneration. It is necessary to remove posterior SO as well in this situation or further emulsified bubbles may pass to the anterior chamber causing the situation to recur. If continued SO tamponade of the retina is necessary, fresh SO is injected in the vitreous compartment.

## Postoperative Management

The postoperative management following surgery for PVR is particularly important. The patient should be nursed face-down in the prone position for at least the first 24 hours after gas or light SO exchange to allow the pigment epithelium to pump out any remaining subretinal fluid and to facilitate initial adhesion at the sites of photocoagulation or cryotherapy. Some surgeons insist on prone positioning for a much longer duration, up to 7–10 days, if there are inferior retinal breaks.

If heavy SO is used, the patient lies supine for 1–2 days and is then mobilized. A rise in IOP is quite frequent after a high encircling scleral buckle and SO injection or gas and it is important that this is monitored regularly. Most surgeons ask the patients to avoid sleeping on their back as this encourages light SO to move forward away from the retinal surface and possibly into the anterior

chamber. Shallowing of the anterior chamber may also occur. Corticosteroid, mydriatic/cycloplegic drops are usually used four times a day for 3–4 weeks, and the patient may in addition require antihypertensive drops and acetazolamide tablets for postoperative ocular hypertension. A rising IOP that persists despite medical therapy usually implies an overfill of the vitreous cavity, and a small amount may even need to be aspirated back in the operating room. If orbital swelling and pain in the absence of a high IOP occurs, oral prednisolone should also be considered in addition to operative sub-Tenon steroid and routine analgesics.

## Complications After PVR Surgery

PVR is a very serious complication of retinal detachment, and patients should be informed preoperatively of the possibility of substantial visual loss despite anatomically successful surgery. There are also risks of significant intraoperative problems and late complications.<sup>75</sup> It is difficult preoperatively to determine how adherent preretinal membranes are to the retinal surface. In some cases, therefore, the membranes cannot be fully dissected and the retina mobilized, and in others, in doing so, retinal breaks can be created. It is now recognized, however, that it is better to relieve retinal traction effectively, even if creation of retinal breaks is inevitable. A deliberate relaxing retinotomy for relief of traction was required in 29% of eyes treated in the Silicone Study.<sup>35</sup> With increasing use of heavy fluids as a surgical aid and for postoperative tamponade, the trend is towards increasingly aggressive intraocular surgery to relieve traction.

## Intraoperative Complications

Intraoperative bleeding may occur during dissection of dense membranes and in creating a retinotomy, and this is controlled by raising the infusion pressure temporarily and, if necessary, endodiathermy. The view may also become obscured by intraoperative corneal edema, pupillary constriction, or lens clouding. The corneal epithelium can be scraped clear or the pupil redilated either with 1 : 10,000 epinephrine in the vitrectomy

infusion, flexible iris retractors, or rarely iridectomy/sphincterotomy using the vitrector. Lens clouding during the operation would necessitate a 20G fragmatome lensectomy via the pars plana. Failure to flatten the retina with internal drainage and fluid–air exchange can be treated either by instillation of heavy fluid to push the subretinal fluid forward to the retinal break or by a discrete retinotomy away from any fibrous tissue and preferably in the superior half of the retina near the optic disc. It may also mean that further relief of traction is required. During surgery, air or heavy fluid or SO may pass through a retinal break and under the retina. Further relief of retinal traction usually allows this to be aspirated and the retina to be reattached again, but it may require a large retinotomy. Choroidal hemorrhagic detachment may occur intraoperatively by laceration of a choroidal vessel when placing scleral sutures, spontaneously in a susceptible eye or if prolonged hypotony occurs. This complication if too large to leave is treated by the temporary insertion of heavy liquid hydrocarbon in the vitreous followed by external drainage of blood through a radial sclerotomy. Sometimes such a choroidal detachment cannot be drained during the surgery and requires a repeat visit to the operating room a few days later. Serous choroidal detachment may occur but is usually due to a misplaced infusion cannula under the retina or in the suprachoroidal space. This is managed by transferring the infusion to another port. The intraocular swelling then subsides, and the offending cannula can be adjusted or replaced. Perfluorocarbon heavy fluid may pass through a retinal break and sink back to the posterior pole if the eye is filled beyond the edge of an open retinal break. A retinotomy may be required to remove it with fluid–air exchange. SO can also pass under the retina if it is not fully relieved of traction. This requires more extensive retinotomy and further exchanges to flatten the retina after complete mobilization.

## Early Postoperative Complications

Multiple early postoperative complications may occur following this complex surgery. Elevated IOP is the most common, occurring in 10–15% of eyes.<sup>48</sup> A rise to about 25 mmHg is treated

conservatively with ocular hypotensive drops and oral acetazolamide. If higher than this, it is often due to angle closure with a forward shift of the iris diaphragm or overfill of the eye with gas or SO. In aphakic eyes filled with silicone, a pressure rise may be due to an incomplete inferior iridectomy or subsequent blocking of it with lens capsule. An overfill of intraocular gas can be readily dealt with in the clinic or at the bedside under topical anesthetic, with removal of 0.2 ml or so through the pars plana with a 30G needle and syringe. Removal of SO is more difficult and requires a trip back to the operating room and aspiration, plus deepening of the anterior chamber. Postoperative inflammation is common following extensive vitreoretinal surgery and fibrin may occlude the pupil or coat the posterior surface of the intraocular lens. This is treated with intensive topical, and sometimes systemic, steroids. Tissue plasminogen activator injection may also be used to break down fibrin in the anterior chamber but is usually not necessary. A common complication where gas is used is an incomplete fill due to mixing errors or leakage through a sclerotomy site. Gas may be topped up or if the subretinal fluid persists, replaced with SO. An incomplete fill of SO with associated fluid inferiorly may require reoperation with top-up of the oil and internal drainage of the residual fluid or possibly supplementation with an injection of heavy silicone liquid. A persistent corneal epithelial defect particularly after the epithelium has been removed from a cloudy cornea during surgery may require extended patching and antibiotic ointment. Endophthalmitis is very rare, but this is a prolonged operation with multiple insertion of instruments, and must always be considered a possibility. The standard injection of intravitreal antibiotics is complicated by the presence of intravitreal gas or silicone. This could be removed and antibiotics instilled in the vitreous, or the surgeon can rely on high-dose systemic antibiotics as a vitreous substitute will exclude entry of inflammatory byproducts into the vitreous cavity and concentrate antibiotic outside the silicone barrier.

## Late Postoperative Complications

There are numerous late complications of surgery for PVR, usually

leading to a disappointing outcome in terms of visual rehabilitation. The commonest is regrowth of surface retinal membranes leading to retinal detachment and tractional retinal tears or, if milder, to macular pucker. Between one-quarter to one-half of eyes undergoing PVR surgery develop recurrent retinal detachment.<sup>72,73</sup> This high incidence has probably improved significantly with the advent of better instrumentation, visualization, and surgical techniques, particularly the intraoperative use of perfluorocarbon heavy fluid as an aid to surgical relief of traction. The commonest situation is inferior recurrence of retinal detachment with or without a new or reopened retinal break inferiorly in association with light SO. Even with a clinically complete fill of silicone, a small meniscus of vitreous fluid remains inferiorly when the patient is upright and the silicone bubble rises slightly superiorly. This is because the shape of the internal eye is not an exact circle like the bubble. The combination of protein, inflammatory, and metaplastic cells and lack of tamponade in this area can lead to further proliferation on the retinal surface in 50–60% of eyes (Fig. 111.21).<sup>75,76</sup> This has been called perisilicone proliferation.<sup>77</sup> It is sometimes advisable to leave this alone and either wall off the local detachment with laser and accept it if the macula stays attached,<sup>78</sup> or alternatively, it can be treated by the supplementation of the silicone with heavy silicone liquid which will press inferiorly with gravity and tamponade the retina (Figs. 110.17 and 110.18). If the fluid is extending towards the posterior pole and threatening useful macula function, then reoperation should be considered. If a retinal break is present, then further dissection of membranes around the edge and indentation with a supplementary radial segment of scleral explant under the encircling band may close it and stop progression. Macular pucker and discrete tractional membranes can be peeled or divided behind SO, without removing it (Figs. 111.19A–B). Macular pucker occurs in PVR eyes subjected to vitreoretinal surgery in 5–15%.<sup>79,80</sup> Peeling is considered if there is significant visual potential and is not difficult under SO.<sup>80</sup> Anterior surface proliferation may gradually interfere with the ciliary body secretory function and lead to hypotony<sup>81</sup> (Fig. 111.22). This is very difficult to treat and, in selected cases, may occasionally justify further surgery to peel membranes off the ciliary body surface

followed by tamponade with SO.<sup>82</sup> Following relaxing retinotomy and retinectomy, the cut edge may fibrose and retract back to the posterior pole (Fig. 111.23). This situation may still allow useful vision. Heavy perfluorocarbon liquid that has passed through a retinal break undetected during surgery localizes under the macula or inferiorly with gravity postoperatively. This can be removed with an additional surgery by suction through a 39G flexible subretinal cannula.<sup>83</sup> Heavy fluid may be left in the vitreous cavity if small in volume, but needs to be aspirated from the anterior chamber.<sup>84</sup>

**FIG. 111.21** Progressive proliferation of scar tissue and inferior retinal shortening behind silicone oil (SO) incompletely filling the vitreous compartment. Progressive retinal shortening may be accompanied by the late development of large inferior retinal breaks and passage of the SO under the retina. Heavy SO formulations show promise of decreasing the occurrence of this condition sometimes called “perisilicone proliferation.”

**FIG. 111.22** Reattached retina after proliferative vitreoretinopathy surgery with inferior relaxing circumferential retinotomy, extensive laser, and silicone oil with no encircling scleral buckle.

**FIG. 111.23** Contraction of cut posterior edge of retinectomy almost back to the macula. Despite this, the macula remains attached under silicone oil with potential for useful vision.

There are many complications of prolonged intraocular SO. Emulsification into fine bubbles is very common, particularly with the lower-viscosity (1000 cSt) material and especially if it has been mixed with inflammatory proteins or blood and in eyes that are aphakic with an incomplete fill where there is a constant fluid/oil surface interaction. If limited in extent and confined to the posterior segment, they can be left alone. Tiny emulsified SO bubbles may pass through the zonules into the anterior chamber (Fig. 111.19) and have also been found in various intraocular and orbital tissues. In particular they can block the angle and lead to late secondary glaucoma. SO in the anterior chamber can also damage corneal endothelial function. If the anterior chamber is full of SO, the cornea does not swell but rapidly does so after removal of the oil if the corneal endothelial function has been damaged. Keratopathy developed in 27% of eyes treated successfully in the Silicone Study,<sup>84</sup> but most of these eyes were aphakic. This incidence is far less in eyes with an inserted intraocular lens and circular capsulorrhexis. Band keratopathy with a degenerative cornea and dystrophic calcification is commonly seen particularly in young people in the presence of long-term SO in the eye even without direct contact to the cornea. Band keratopathy is difficult to treat although the calcium may be temporarily removed by scraping the cornea and applying the chelating agent EDTA. Attempts to remove emulsified SO droplets in the anterior chamber by irrigation and aspiration can be frustrating as further oil tends to flow through from the vitreous cavity. This may be stopped in some cases by replacement of the anterior chamber fluid with viscous sodium hyaluronate and management of any rise in IOP afterwards by intermittent release through a preplaced limbal incision. Otherwise the SO usually needs to be removed completely and, if still required, replaced with fresh SO.

Cataract is universal in phakic eyes following vitrectomy and extended silicone tamponade. Late phacoemulsification of cataract and intracapsular lens implantation presents no special difficulties, and the silicone liquid can be removed at the same time or left in the eye permanently. Some surgeons advocate phacoemulsification and replacement of the lens routinely at the time of surgery for PVR, as this may facilitate dissection of the vitreous base and

anterior loop traction of the retina. With modern systems this is no longer usually necessary and the lens is spared until cataract develops later. Rubeosis of the iris is occasionally seen following surgery for retinal detachment and PVR but is uncommon unless the patient already has coexisting diabetic retinopathy.<sup>85</sup> It is more likely where there is recurrent persisting retinal detachment and intraocular inflammation. Modern SO has fewer impurities and the incidence has decreased. Treatment for rubeosis iridis, if active, rather than low grade and chronic, involves injection of a vascular endothelial growth factor blocker and consideration for subsequent glaucoma surgery if salvageable vision is still present.

Other complications for PVR surgery include late cystoid macular edema with or without preretinal membranes.<sup>79</sup> This can be readily analyzed with spectral domain optical coherence tomography (OCT). Treatment is with topical steroid and nonsteroidal drops, intravitreal triamcinolone injection, and, in special circumstances where vision might be salvageable, peeling of the internal limiting membrane over the macula. Sympathetic ophthalmia must also be considered as a rare complication after multiple vitreoretinal surgeries.

The other group of complications of PVR surgery involves those associated with a scleral buckle. Surface scarring around the muscles may lead to squint and double vision. The scleral buckle may erode through the conjunctiva and lead to chronic low-grade infection. Attempts are often made to retain a scleral buckle rather than remove it in this circumstance. It may be possible to treat the chronic discharge with excision of a local section of the buckle, leaving the band intact and removing the local offending suture, but usually the material all has to be removed. If the buckle does have to be removed, preoperative 360° prophylactic laser immediately posterior to the buckle may be carried out. If persistent membranes are present on the retina and silicone has not been injected previously, then silicone replacement of the vitreous is an additional option to ensure recurrent retinal detachment does not occur. If retinal detachment does recur after removal of an exposed or infected scleral buckle, then SO tamponade is usually the most practical option.

## Medical Adjunctive Therapy for PVR

The devastating effect of PVR on visual prognosis and the expense and difficulty of multiple surgeries has led to sustained efforts to find pharmacologic therapies that may decrease the risk and recurrence after retinal detachment surgery. Systemic prednisolone and sub-Tenon injection of long-acting Celestone or triamcinolone have long been used to dampen down inflammation and its sequelae that predispose to PVR. The very complex cellular and protein factors activated and upregulated in PVR are outlined in detail in [Chapter 101](#) (Pathogenesis of proliferative vitreoretinopathy). Intravitreal triamcinolone acetamide is the most favored agent of those studied, and it is increasingly used as an adjunct during surgery to delaminate fine tissue planes and pockets of formed vitreous and membranes that may not be visible with normal operative systems of illumination. Hopefully, a beneficial dose persists after vitreous replacement. Triamcinolone can also be injected into the SO for slow release.<sup>86,87</sup> As with other steroids, it is thought to have a wide-ranging effect on factors in the inflammatory cascade and hence diminish the stimulus to cellular proliferation and contraction. Antiproliferative agents including 5-fluorouracil<sup>88,89</sup> and daunomycin<sup>90</sup> have been evaluated, but unfortunately the therapeutic window between inhibition of fibroblastic tissue proliferation and toxicity to surrounding sensitive neuronal cells has not been sufficient to demonstrate a clinical benefit in humans.<sup>91</sup> The many biologic signals of PVR found with laboratory investigation of the cell biology and proteomics, for example, with platelet-derived growth factor and connective tissue growth factor,<sup>92,93</sup> will hopefully one day provide a suitable target for a more specific intervention in the process. Early evidence along these lines has been reported with anti-VEGF injections (bevacizumab) into silicone oil.<sup>94</sup> Genetic variations in patients with PVR are starting to emerge, for example, an association with the gene linked to tumor necrosis factor.<sup>95</sup> Hopefully, clinical trials to block specific biologics using humanized antibodies, RNA interference, or gene therapy will emerge.<sup>96</sup>

## Results of Surgery for PVR

The anatomic success, which is defined as retinal reattachment for at least 6 months, has progressively improved over the last 40 years, along with the steady improvement in instrumentation and surgical techniques.<sup>97-122</sup> A summary list of published results is shown in [Tables 111.5](#) and [111.6](#). It is important to note that it is difficult to compare results in case series that may include eyes of different severity and do not define or control enrollment parameters. A scleral buckle without vitrectomy successfully reattached up to 50% of milder cases 30 years ago, while at present, with all the surgical techniques at our disposal, up to 90% of all cases of PVR can be anatomically reattached.<sup>26</sup> However, many eyes need more than one operation because of continuing cellular proliferation and retinal traction. An example of moderate severity successfully reattached and maintained with extensive laser is shown in [Fig. 111.24](#).

Another case requiring extensive retinectomy and long-term SO is shown in [Fig. 111.25](#). Functional success defined as improved visual acuity is more problematic, as any macula detached for more than a few days is unlikely to recover more than 10–20% of central vision<sup>14</sup> which, in the context of the other eye, may be more or less clinically significant. In addition, as outlined in [Chapter 101](#) (Pathogenesis of proliferative vitreoretinopathy), the substantial and multifactorial inflammatory events associated with PVR lead to apoptosis of retinal cells as well as activation and a breakdown in the function of retinal glial cells. If this process is prolonged or particularly severe, then most visual potential is lost. In the multicenter and largely controlled Silicone Study, now almost 25 years old, about half the eyes overall, whether with gas or SO, obtained 5/200 vision or better.<sup>48,121,122</sup> If the process was not so severe that SO was able to be removed, eyes after removal of oil were 19 times more likely to experience a visual acuity improvement of  $\geq 3$  lines. However, removal of SO resulted in recurrent retinal detachment in 19% of eyes, and this was twice the risk of retinal detachment in eyes in which the SO was not removed. The visual results were relatively stable in those eyes that obtained retinal reattachment 6 years after surgery. Visual results were better in those that required only one surgery. There was no statistically significant difference in the

anatomic reattachment rate or visual acuity between 14% perfluoropropane gas tamponade or SO after long-term follow-up of up to 6 years.<sup>122</sup>

**TABLE 111.5**  
**Results of Vitreous Surgery for Proliferative Vitreoretinopathy (1978–2003)**

Reference	Eyes (n)	Anatomic Results: Retina Reattached (%)	Functional Results	Comments
Machemer and Laqua (1978) <sup>97</sup>	47	36	Not stated	Air or 40% sulfur hexafluoride gas

(1989) <sup>44</sup>				required removal of subretinal membranes
Silicone Study Group (1992) <sup>76</sup>	265	61–73	33–45% 5/200 or better	Gas or silicone oil used
Körner and Böhnke (1995) <sup>112</sup>	501	85 stage C PVR, 70 stage D PVR	78% stage C, 65% stage D 5/200 or better	Silicone oil used in 69% of eyes
Coll et al. (1995) <sup>29</sup>	223	78 with one surgery, 96 with multiple surgeries	74% were 20/400 or better	Perfluoro-n-octane used in all eyes, 92% gas, 8% silicone oil tamponade
Scott et al. (2003) <sup>113</sup>	555	78 at 6 months	60% improved acuity at the final exam, perfluoro-n-octane used in all eyes	Proliferative vitreoretinopathy

**TABLE 111.6**

**Results of Vitreous Surgery for Proliferative Vitreoretinopathy (2004–2015)**

Reference	Eyes (n)	Anatomic Results: Retina Reattached (%)	Functional Results	Comments
Charteris et al. (2004) <sup>114</sup>	157	84	Not stated	5-fluorouracil and low-MW heparin made no difference
Tseng et al. (2005) <sup>115</sup>	38	97	Not stated	Relaxing retinotomy, silicone oil
Quiram et al. (2006) <sup>116</sup>	56	93	70% improved or stabilized	Inferior retinotomy, silicone oil removed in 58% and superior to gas
Grigoropoulos et al. (2007) <sup>118</sup>	304	72	VA improved 45%, unchanged in 24%, worse in 29%	Retinectomy
Berker et al. (2007) <sup>55</sup>	21	81	43% improved	Temporary heavy silicone oil tamponade
Lam et al. (2008) <sup>72</sup>	147	82	Correlated with reattachment	Silicone oil removed at 12.4 ± 9.8 months
de Silva et al. (2008) <sup>119</sup>	145	68	49% 20/400 or better; 51% <20/400	Retinectomy
Lim et al. (2009) <sup>38</sup>	30	93	67% improved; 27% same	Combined large radial retinotomy/retinectomy
Chen et al. (2011) <sup>86</sup>	36	97	84%	Silicone oil and triamcinolone 2 mg injected into oil
Stopa and Kociek (2011) <sup>39</sup>	25	96	2.3 logMAR preop improved to 1.00	Retinectomy
Hussain and Banerjee (2011) <sup>66</sup>	12	91	36% 2-4 lines 27% same	Heavy SO
Joussen et al. (2011) <sup>67</sup>	93	48 SO vs 28 HSO	1.24 SO vs 1.27 HSO	First prospective randomized Comparison SO vs HSO

Garnier et al. (2013) <sup>40</sup>	20	70	20% had 20/200 or better	360 degree retinotomy
Hocaoglu et al. (2015) <sup>41</sup>	40	75-79	25% had 20/200 or better	360 degree retinotomy, anterior flap retinectomy and radial retinotomy
Mancino et al. (2015) <sup>120</sup>	33	97	Median 1.28 preop improved to 0.74	previous scleral buckle better outcome

**FIG. 111.24** Reattached retina after extensive proliferative vitreoretinopathy surgery. A wide band of laser 360° decreases the risk of recurrent detachment after removal of silicone oil.

**FIG. 111.25** Reattached retina after proliferative vitreoretinopathy surgery requiring extensive inferior

retinectomy. Although there is a large bare area devoid of retina inferiorly, the retinal edge is held flat with a combination of silicone oil tamponade and laser applications.

## When is Surgery for PVR Not Justified?

Analysis of fellow eyes in 249 patients with PVR showed that more than 50% of fellow eyes have some vision-threatening pathology. Prophylactic laser to any retinal tears or other predetachment changes such as lattice degeneration in the second eye. Therefore, in the opinion of some authorities the most important action to take in this clinical setting, since most patients at this time with PVR achieve what is really only peripheral vision that is often distorted or inducive of diplopia. Judgment is required as to when not to intervene. One cost-utility analysis of surgery for PVR reasoned that it was cost-effective compared with many other medical interventions in ophthalmology and this would be especially so where there is pathology and low vision in the second eye.<sup>123</sup> If the PVR has occurred in the second eye and the first is already afflicted with low vision or blindness, then the complete range of surgical intervention and multiple procedures is justifiable, as a large majority can be expected to recover reasonable mobility vision. Even if retinectomy is required, vision can improve in up to almost half of the eyes and anatomic reattachment in about 70%.<sup>117,118</sup> If the second eye has normal vision and is safe after prophylactic retinal laser, then eyes at the severe end of the spectrum with chronic retinal detachment and no hope of macular redemption, with extensive intraretinal gliosis and inferior retinal shortening, with very large or posterior retinal breaks, or with failure after SO injection, could all be justifiably left alone and further surgery advised against. Eyes with preexisting PVR require a mean of 3.7 operations compared with 1.8 for those with retinal detachment and no PVR in one study.<sup>124</sup> The decision-making process, however, must be flexible and is dependent on the patient and their relatives having a thorough understanding of the expectations and of the

possible outcomes, so that a joint decision-making process can occur. It is to be hoped that the rapidly evolving understanding of the molecular biology and cellular biology of PVR will soon change the outlook beyond the extraordinary therapeutic advances achieved by fine instrumentation, surgical techniques, and current adjunctive therapy (Figs. 111.19 and 111.22).

### **Complications**

## **Introduction**

The term retinotomy denotes cutting the retina, whereas retinectomy means excision of retina. A retinotomy may vary from a small hole created for drainage of subretinal fluid or removal of a subretinal membrane to a 360° cut to release massive peripheral

traction. Retinectomy may mean limited excision of the fixed edge of a retinal flap or total excision of peripheral fibrotic retina. Subjects discussed in this chapter include the indications and techniques for retinotomy and retinectomy, the results and complications of the procedures, and the techniques for managing the retina after a retinotomy or retinectomy.

## Drainage Retinotomy

A drainage retinotomy is a retinal hole created to allow removal of subretinal fluid.<sup>1,2</sup> A drainage retinotomy is most often used in conjunction with treatment of a retinal detachment with vitrectomy techniques. Because of the potential for complications and the availability of other techniques, posterior drainage retinotomy is less frequently used today; if a drainage retinotomy is needed, a peripheral drainage retinotomy can sometimes be used. A drainage retinotomy may be necessary in proliferative vitreoretinopathy (PVR), other complicated retinal detachments, proliferative vascular retinopathy, and primary rhegmatogenous retinal detachment treated with vitrectomy. The drainage retinotomy can be used when a preexisting retinal tear is not present or not adequate for drainage or egress of the subretinal fluid.

### General Principles

The drainage retinotomy is made after as complete removal as possible of periretinal membranes, and should not be created in an area with residual membranes or traction. The drainage retinotomy is most easily created with endodiathermy.<sup>3</sup> Taking care not to close large vessels, the unimanual, bipolar endodiathermy probe is set on a continuous mode and held against the retina in the selected area. A necrotic retinal hole with a well-marked white edge is usually produced. The advantages of creating the retinotomy with diathermy are (1) complete hemostasis of the retinal blood vessels; and (2) whitening of the edge of the hole, which allows easy identification of the retinotomy for laser treatment when the hole is flat against the retinal pigment epithelium. If the diathermy probe does not perforate the necrotic area, the central necrotic area is

perforated with a sharp blade or by suction with the blunt tip of the vacuum needle.

## Surgical Technique in Conjunction With Perfluorocarbon Liquid

The preferred technique for retinal reattachment is to use perfluorocarbon liquid (PFCL). PFCL, heavier than water or saline, can be used to reattach the retina from posteriorly to anteriorly.<sup>4</sup> In addition, PFCL can fixate and stabilize the posterior retina, thereby facilitate removal of peripheral vitreous and membranes.<sup>5</sup> A peripheral retinal break is necessary to allow egress of subretinal fluid when PFCL is injected over the posterior pole. A preexisting retinal break is usually present, but if the break is not located anteriorly enough, subretinal fluid may become loculated beneath peripheral retina, anterior to the anterior-most retinal break (Figs. 112.1A–B). Anterior subretinal fluid can usually be drained through posteriorly located retinal breaks during PFCL–air exchange. However, most surgeons prefer to do laser treatment through PFCL rather than air, so it is desirable to flatten the retina with PFCL. If anteriorly loculated subretinal fluid is present, one of several approaches can be taken to remove it. With PFCL filling the eye to just posterior to the most anteriorly located retinal break, a partial fluid–air exchange can be done to remove the subretinal fluid through the break. Then, if the desire is to do laser treatment through the PFCL, additional PFCL is injected to bring the level anteriorly; anterior air can then be replaced with infusion fluid in order to have a clear view. There is a risk of corneal striate keratopathy or pupillary constriction associated with the air in the aphakic eye that can reduce visualization and interfere with laser treatment and subsequent fluid–air exchange. In the phakic eye, there is the possibility of posterior subcapsular lens opacity induced by the air that could interfere with visualization.

**FIG. 112.1** Retinal reattachment using perfluorocarbon liquid (PFCL). Drainage retinotomy to allow egress of anteriorly loculated subretinal fluid. (A) Detached retina with midperipheral retinal break. PFCL is injected over the posterior pole, and subretinal fluid egresses through the retinal break (*arrow*). (B) Retinal break closed by PFCL. Subretinal fluid loculated beneath anterior retina is unable to escape subretinal space. (C) Anterior drainage retinotomy over anterior scleral buckle allows egress of subretinal fluid and retinal flattening as more PFCL is injected.

An alternative approach that is less time-consuming and more likely to maintain good visualization is to create an anterior drainage retinotomy with endodiathermy in the area where subretinal fluid is loculated in order to allow egress of the fluid into the vitreous cavity ([Fig. 112.1C](#)). If a scleral buckle is not present and will not be used, the retinotomy can be made just posterior to the ora serrata. If a scleral buckle is present, the retinotomy should be made in an area of retina supported by the buckle rather than anterior or posterior to the scleral buckle. It is usually preferable to

perform the retinotomy in an area of superior, rather than inferior, retina. This minimizes the risk of a redetachment caused by complicating fibrosis in the vicinity of the retinotomy. After the drainage retinotomy is created, PFCL is injected to reattach the retina. If the retinotomy is made in an area under traction, there is a risk that the PFCL could go through the retinal break and course beneath the retina; however, if no traction is present, the level of the PFCL can safely be brought anterior to the break to allow laser treatment. The PFCL is usually removed by performing a PFCL–air exchange. Alternatively, a direct PFCL–silicone oil exchange can be done. It is preferable to drain any residual subretinal fluid, if present, through the anterior-most retinal break or retinotomy during the early portion of the exchange. This will prevent trapping of subretinal fluid that can be forced posteriorly as the eye is filled with air or silicone oil.

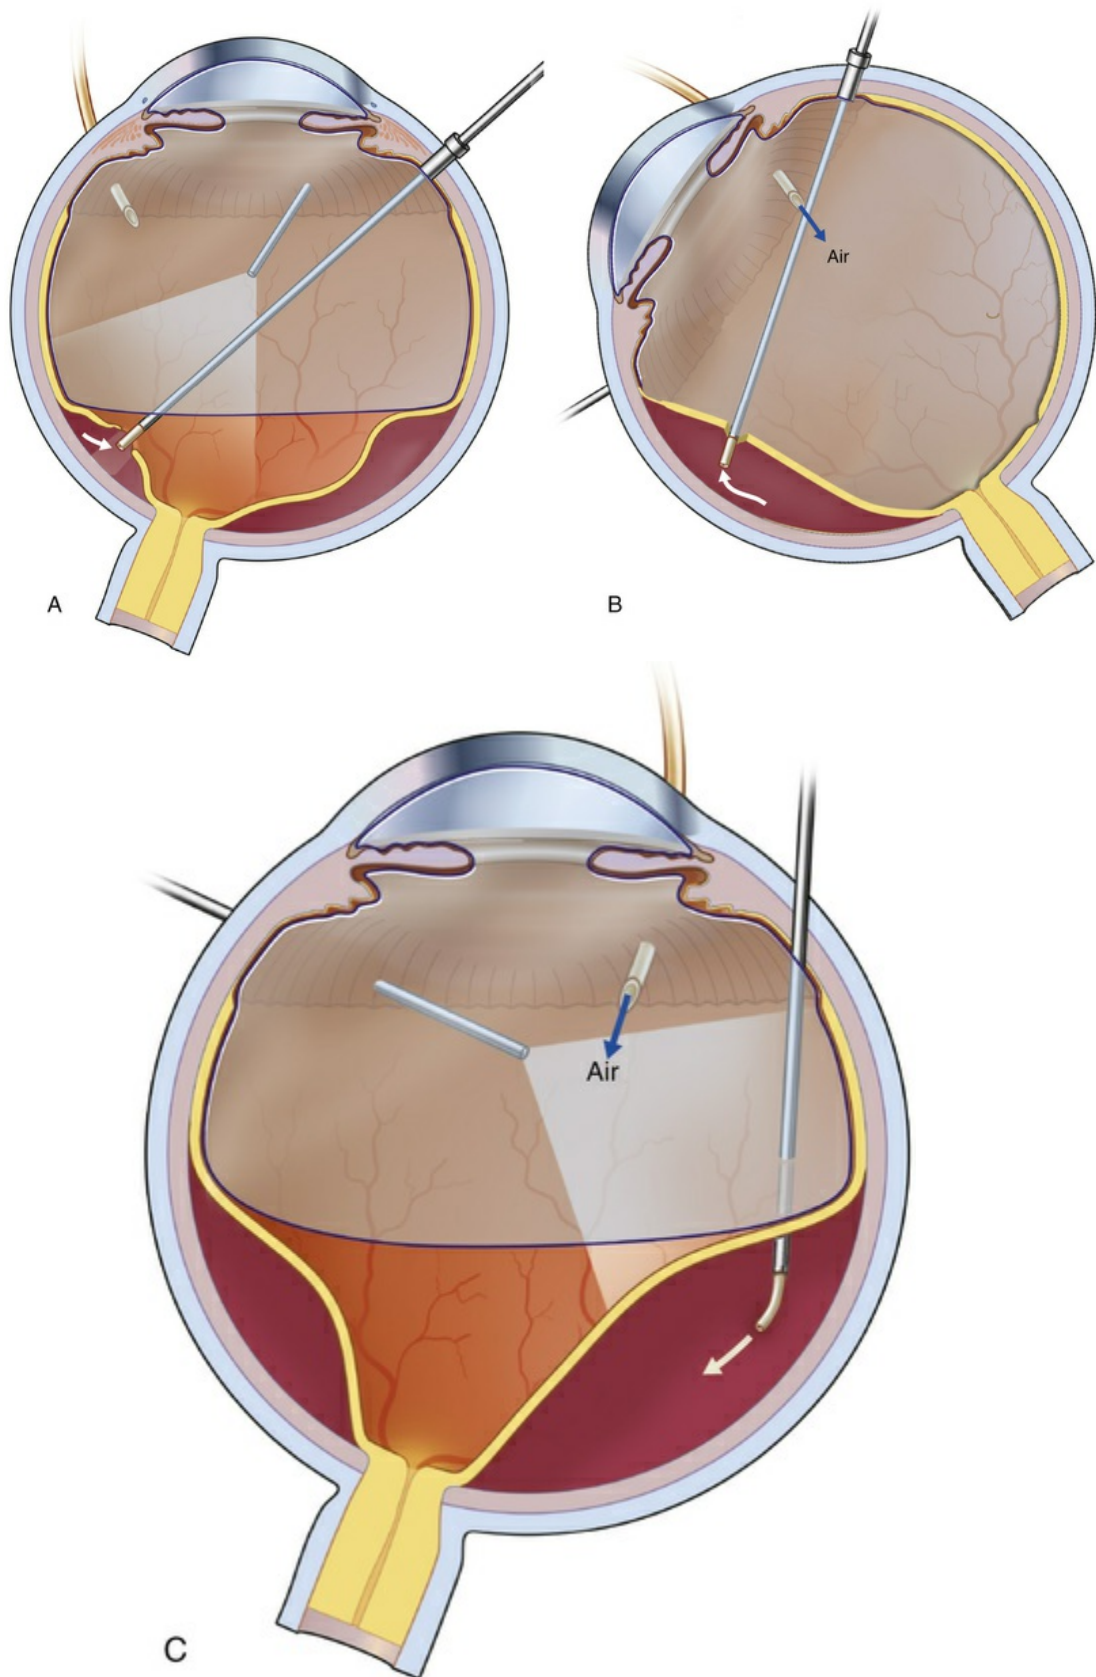

## **Surgical Technique Without PFCL**

### **Posterior Drainage Retinotomy**

Fluid–air exchange was the most commonly used technique to reattach the retina during vitrectomy before introduction of PFCL and is often employed today if PFCL is not used. In the absence of a posterior retinal break or easily accessible peripheral tear for internal drainage of subretinal fluid, a posterior drainage retinotomy can be created. The posterior drainage retinotomy is usually made with diathermy, taking care to make it in a superior quadrant at least 1.5 disc diameters from the optic nerve and avoiding the macula and large blood vessels in order to avoid complications. Our preferred location of the drainage retinotomy, with the least visual impact, is an area 5 disc diameters superotemporal to the center of the macula, just outside the superotemporal vascular arcade. The retina is reattached by suctioning subretinal fluid through the retinotomy while the eye is filled with air supplied by a continuous infusion air pump ([Fig. 112.2A](#)). For fluid–air exchange through a drainage retinotomy, intraocular air pressure is usually set at approximately 30 mmHg. Before air is insufflated, fluid–fluid exchange (internal drainage of fluid through a retinal break or retinotomy in a fluid-filled eye) will

sometimes partially flatten the retina. Air is then insufflated and the air bubble is enlarged to fill the anterior vitreous cavity. In an eye that is partially filled with air, the view is minimized, and it is necessary to refocus the operating microscope on the drainage retinotomy. Place the end of a silicone-tip needle just inside the orifice of the drainage retinotomy and gently aspirate subretinal fluid to reattach the retina. As the retina flattens against the retinal pigment epithelium, fluid ceases to flow into the cannula. Do not push the needle tip forcibly against the retinal pigment epithelium (RPE) because damage to Bruch's membrane and/or choroidal hemorrhage may occur. More fluid often collects in the vitreous cavity, and it is necessary to aspirate fluid from the retinotomy and over the optic disc several times to make sure all fluid is removed. Residual fluid is removed by "dipping" the silicone tip into the fluid meniscus over the optic nerve. A bright reflex appears as the needle tip enters the fluid meniscus; this reflex disappears as the fluid level drops below the needle tip during aspiration. The dipping maneuver is repeated until all of the fluid is removed. Fluid tends to accumulate posteriorly in the vitreous cavity, so the dipping procedure over the optic disc is repeated after several minutes. It is crucial to avoid damage to the optic nerve by not compressing the nerve during this maneuver. When no fluid remains, the margins of the drainage retinotomy are treated with laser endophotocoagulation. Usually one confluent row of laser burns surrounding the margins of the retinotomy is adequate for adhesion.

**FIG. 112.2** (A) Fluid–air exchange through posterior drainage retinotomy. Silicone-tip cannula attached to variable suction through the vitrectomy console is

placed immediately anterior to or into the retinotomy, and the subretinal fluid is aspirated as the eye fills with air from the continuous infusion air pump. After retina is attached and retinotomy is flat against retinal pigment epithelium, retinotomy is treated with laser endophotocoagulation. (B) Fluid–air exchange through peripheral drainage retinotomy. The head is tilted or turned to place the drainage retinotomy at a dependent position in the retinal detachment to remove subretinal fluid as completely as possible. (C) Fluid–air exchange through peripheral drainage retinotomy. A flexible silicone tube from a cannulated extrusion needle inserted through peripheral retinotomy toward posterior retina. Subretinal fluid aspirated during fluid–air exchange (*lower arrow*). Level of fluid in vitreous cavity is below level of retinotomy, and retina is flat over proximal portion of subretinal cannula.

## Peripheral Drainage Retinotomy

A posterior drainage retinotomy can be associated with significant complications, including hemorrhage, fibrosis with traction, choroidal neovascularization (CNV), and visual field loss.<sup>6</sup> In some instances, a peripheral drainage retinotomy can be used instead of a posterior retinotomy to reattach the retina (Fig. 112.2B). Although the same complications can occur in the periphery, peripheral complications are usually less visually significant than posterior complications. Yamaguchi and colleagues reported a 93% single operation success rate in 112 eyes with primary retinal detachments without advanced PVR by draining subretinal fluid through original breaks without the use of posterior drainage retinotomies or PFCL.<sup>7</sup> The essence of their technique, using a non-contact wide-angle viewing system, was to turn the head to make the drainage break as dependent as possible. They were able to internally drain all of the subretinal fluid in 45% of the cases and enough subretinal fluid in the remainder of the cases to be able to treat the breaks with endolaser photocoagulation or cryotherapy.

If the retinal break is in a location where it cannot be placed in a dependent position for drainage, an alternative technique is to make a drainage retinotomy with endodiathermy in a peripheral

dependent position in the area of retinal detachment to maximize subretinal fluid drainage. A risk of incomplete peripheral drainage of subretinal fluid is that residual subretinal fluid can be forced posteriorly to create a retinal fold in the macula.<sup>8</sup> This most commonly happens when the border of a subtotal retinal detachment is near the center of the macula. A posterior retinal fold is less likely to occur when perfluorocarbon liquid is used to reattach the retina or when fluid is drained through a posterior drainage retinotomy; however, it should be possible to prevent a posterior retinal fold during fluid–air exchange. Techniques to avoid a macular fold include first-day positioning on the temporal side (operated eye down) to place the gas bubble against the nasal retina so as not to force fluid into the macula or initial temporal side positioning followed by rolling the patient to a prone position to move the fluid away from the macula and flatten the macula (steamroller maneuver).

An alternative technique for more complete drainage through a peripheral retinotomy or break is to use a soft-tipped cannulated sliding extrusion needle (Universal Soft Tip, Synergetics, Inc., St. Louis, MO) that has a 20- or 23-gauge (G) metal cylinder, a sliding silicone tube within the cylinder, and a handle with a lever for moving the silicone tube in and out of the metal cannula. This technique was originally described by Flynn et al.<sup>9</sup> The instrument can be used with active suction or by extrusion as a fluted needle. The soft silicone tip can be extended through the peripheral retinotomy or break to drain subretinal fluid posterior to the break (Fig. 112.2C). When the retina flattens posteriorly over the silicone tube, the tube is slowly withdrawn from the subretinal space while gently aspirating subretinal fluid. A modified silicone tube has multiple fenestrations near the tip of the tube that reduces the likelihood of retinal incarceration in the tube during aspiration of subretinal fluid.<sup>10</sup> At this point all or most of the subretinal fluid has been removed. Vitreous cavity fluid can be aspirated over the optic nerve to complete the fluid–air exchange; then endolaser photocoagulation is applied to the edge of the retinotomy.

Drainage during fluid–silicone oil exchange is similar to that during fluid–air exchange. For fluid–silicone oil exchange, less viscous 1000 cSt oil is easier to use than 5000 cSt oil, but the former

oil may result in more emulsification. Silicone oil can be pumped through either a 20G or smaller infusion cannula. It is necessary to use a fluted needle to remove the intraocular fluid. A vacuum needle cannot be used because it will collapse the eye during the silicone oil infusion. The silicone oil infusion forces the fluid out of the eye through the fluted needle. The vitreous cavity is filled with silicone oil as completely as possible before the subretinal space is entered. Most of the subretinal fluid can be removed at the orifice of the peripheral retinotomy, and less subretinal penetration by the silicone cannula is necessary compared with that necessary for fluid–air exchange. By repeatedly removing fluid at the retinotomy, then going back and using the dipping maneuver over the optic disc, one can remove most of the subretinal fluid.

## Complications

Intraoperative complications are hemorrhage from the retina or the choroid or enlargement of the retinotomy. By producing the retinotomy with diathermy and by avoiding larger vessels, retinal hemorrhages can usually be avoided. Incarceration of retina beyond the diathermized edge of the retinotomy with the drainage needle tip can sometimes lead to hemorrhage. Hemostasis with diathermy should be obtained as soon as possible.

Choroidal hemorrhage may result from impact of the instruments on the choroid. Silicone-tipped cannulas should be used as they are less likely to damage the choroid than metal-tipped instruments. If the silicone tube does not easily slip into the subretinal space, it should not be forced.

Enlargement of the retinotomy may follow excessive diathermy. The area of diathermy becomes necrotic, and if a wide area is treated with diathermy, the retinotomy may enlarge during fluid–air exchange. Enlargement can also occur due to incarceration of the retina at the edge of the retinotomy in the drainage needle tip during fluid–air exchange.

Postoperative complications of drainage retinotomies are few. McDonald et al.<sup>6</sup> first described cellular proliferation and CNV from drainage retinotomies. Richards and Maberley<sup>11</sup> found that subretinal neovascularization was associated with the retinotomy

site in 1% of 287 cases and focal PVR was associated with the retinotomy site in 2%. Retinal detachment from the retinotomy site is extremely rare. The retinotomy site may even remain attached if the rest of the retina detaches postoperatively. Cellular proliferation from the retinotomy site may lead to periretinal proliferation. In gas-filled eyes, the proliferation usually remains in the local area of the retinotomy site and rarely leads to complications. In silicone-oil-filled eyes, the proliferation may be more extensive and lead to tractional complications. CNV probably results from damage to the underlying choroid and RPE.

An extensive visual field defect may result from a large retinotomy too close to the optic disc or macula. Bourke et al.<sup>12</sup> found visual field defects within 30° of fixation in 12 of 14 eyes with drainage retinotomies. Visual field defects were found in all eyes in which the retinotomy was created within 5 disc diameters of fixation. The researchers recommended that retinotomies be placed more than 5 disc diameters from the fovea and in the superotemporal quadrant to minimize visual field loss.

## **Inner Retinal Fenestration for Optic Pit Maculopathy**

Spaide and coworkers described successful treatment of a case of optic pit maculopathy by creating a partial-thickness retinotomy (fenestration) in the retina just temporal to the optic disc with the bent tip of 25G needle.<sup>13</sup> They theorized that fluid from the optic pit entered the peripapillary retina under pressure and that a small partial thickness hole would allow egress of the fluid into the vitreous cavity. In a subsequent paper, Ooto et al. reported 18 patients treated with inner retinal fenestration, with complete resolution of intraretinal and subretinal fluid in 17.<sup>14</sup> They did not remove cortical vitreous in 12 of the eyes and did not peel the internal limiting membrane (ILM) or treat with laser in any eyes. Only 1 eye was left with an air bubble in the vitreous cavity at the conclusion of surgery.

## **Retinotomy to Gain Access to the**

## Subretinal Space

It is sometimes necessary to create a retinotomy to gain access to the subretinal space. A retinotomy or retinectomy may be necessary to remove a subretinal band or membrane, a subretinal hemorrhage, a subretinal neovascular membrane, a subretinal foreign body, or, rarely, a subretinal mass such as a disciform scar, abscess, or retinal or subretinal tumor.

## Subretinal Membranes

Subretinal bands or membranes complicating PVR are frequent indications for retinotomies and retinectomies. They should be removed or sectioned only if they exert significant traction, preventing retinal reattachment after removal of epiretinal membranes. Subretinal membranes and bands will sometimes relax enough to allow retinal reattachment, so in most cases an attempt to flatten the retina with PFCL or air may be warranted to determine if removal of the membranes is necessary. Details on management of subretinal membranes can be found in [Chapter 111](#) (Proliferative vitreoretinopathy).

## Choroidal Neovascularization and Subretinal Hemorrhage

An indication that has decreased greatly in numbers since the advent of anti-VEGF medications is retinotomy to remove a choroidal neovascular membrane. However, displacement of submacular hemorrhages remains one of the more frequent reasons for a retinotomy. Since both are discussed in [Chapter 122](#) (Surgical management of choroidal neovascularization and subretinal hemorrhage), we will only briefly describe the technique here.

### Removal of Subretinal Neovascular Membrane

A small retinotomy is made adjacent to the neovascular membrane, and the subretinal new vessel membrane is separated from the underlying tissue and retina and extracted with subretinal forceps.

## Displacement of Subretinal Hemorrhage

Subretinal hemorrhages can be caused by trauma or retinal arterial macroaneurysms, but they are much more frequently encountered as a complication of choroidal neovascularization. When the hemorrhage is large and central enough, surgical displacement is warranted. Although multiple techniques have been described, most rely on performing a small-gauge retinotomy adjacent to the subretinal clot to inject beneath the retina 12–50  $\mu\text{g}$  of tPA in 0.05–0.1 mL of saline solution. Intravitreal air or gas tamponade is used to exert pressure on the dissolved blood to displace it away from the macula.

## Macular Translocation Surgery

Macular translocation surgery is still used in some centers for advanced age-related macular degeneration not responsive to medical therapy. Briefly, after detaching the retina by transretinal injection of a balanced saline solution, a 360° peripheral retinotomy is created. When the retina is reattached with PFCL, it is rotated to relocate the macula to a more normal area of retinal pigment epithelium (see [Chapter 123](#), 360-degree macular translocation).

## Subretinal Foreign Body

A rare indication for retinotomy is removal of a subretinal foreign body. A subretinal foreign body may result from perforation of the retina from the vitreal side or, rarely, from perforation of the sclera at an oblique angle, with lodging of the foreign body between the retina and the choroid. If the foreign body is nonmobile and anteriorly located, external extraction through the sclera and the choroid may work quite well. If the foreign body is located posteriorly, or if it is mobile beneath a detached retina, a posterior external extraction is quite difficult. In the latter case, a vitrectomy with retinotomy may be the best approach. If the retina is not detached, the foreign body will usually lie at or near the retinal perforation site. After the vitrectomy, laser endophotocoagulation is applied to surround the foreign body. The retina overlying the foreign body is treated with diathermy, after which a membrane pick is used to remove retina, fibrin, or other material from the

surface of the foreign body. An inflammatory capsule is often present around the foreign body, and this should be opened with the membrane pick and the foreign body dislodged from its capsule if possible. The foreign body can then be grasped and removed with foreign-body forceps or a rare-earth magnet.

If the retina is detached, the foreign body may be mobile. In this case, after vitrectomy, a retinotomy is made with endodiathermy. The retinotomy is made in an area where forceps or the rare-earth magnet will have access to the foreign body. The posterior pole or areas of fibrous proliferation should be avoided when the retinotomy is made. It is often possible to manipulate a subretinal foreign body to the area of the retinotomy before the foreign body is grasped. Joondeph and Flynn described moving the foreign body to the retinotomy site with the soft flexible tip of the cannulated extrusion needle.<sup>15</sup> The foreign body is then grasped and pulled into the vitreous cavity through the retinotomy. Regardless of the method to free-up and grasp the foreign body, it is quite important to be certain that the sclerotomy site for removal is sufficiently large.

## Removal of Subretinal PFCL

An occasional indication for retinotomy is the removal of subretinal PFCL. This indication may arise intraoperatively or postoperatively, subsequent to vitrectomy with use of PFCL. Insufficient release of retinal traction or misdirected injection of preretinal PFCL into a retinal break can result in intraoperative subretinal PFCL. Postoperative retention of subretinal PFCL occurs in up to 12% of cases and is most often associated with large peripheral retinectomies.<sup>16</sup>

Small extramacular bubbles of subretinal PFCL are usually visually insignificant and should not be removed unless they show migration toward the subfoveal region. Migration is more likely to occur with bubbles trapped subretinally superior to the macula, and in the presence of epiretinal membranes. If the PFCL bubble is located subfoveally, or is found migrating in that direction, repeat vitrectomy with small retinotomy is indicated, given PFCL's known toxicity to the photoreceptors and pigment epithelium.<sup>16</sup> Subretinal

PFCL has been found to produce a dense scotoma on microperimetry.<sup>17</sup> Once PFCL is removed, the affected retina tends to regain partial function; the degree of recovery is probably dependent on the duration of its subretinal presence. Large amounts of subretinal PFCL, either intra- or postoperatively, should be removed regardless of location. If the retina is attached, a PFCL bubble can be removed through a small retinotomy given its high fluidity.

A recently reported technique for removal of a subfoveal PFCL bubble is to create a small retinotomy with a sharp needle tip in the thin tissue over the retained subfoveal PFCL, creating a therapeutic macular hole.<sup>18</sup> The retinotomy is created after injecting PFCL into the vitreous cavity overlying the macula; preretinal and subfoveal PFCL are then removed with a silicone-tip backflush needle. After removing the PFCL bubble, the macular hole is closed with complete gas tamponade of the vitreous cavity.<sup>18</sup> Another reported technique is perifoveal insertion of a small-gauge cannula into the subfoveal PFCL bubble and removal of the bubble with active suction.<sup>19–22</sup> When the PFCL is subfoveal, the small-gauge cannula can be inserted through an extrafoveal retinotomy to infuse BSS beneath the fovea in order to move the PFCL bubble to an extrafoveal location where manipulation and suction are safer.

## Retinal or Subretinal Mass

Pars plana vitrectomy and retinectomy have been used to remove a retinal vasoproliferative tumor to treat recurrent hemorrhages and exudation and provide a specimen for histopathologic diagnosis.<sup>23</sup> Gaudric et al. reported retinectomy to treat nine eyes with retinal capillary hemangiomas in von Hippel–Landau disease.<sup>24</sup>

Removal of a subretinal mass is an uncommon indication for retinotomy, although retinotomy can be used for removal of a subretinal mass such as a disciform scar.<sup>25,26</sup> The surgical results of disciform scar removal have been disappointing. Biopsy of choroidal melanomas is now commonly done, sometimes with vitrectomy (see [Chapter 127](#), Vitreous, retinal, and choroidal biopsy). Surgical resection of choroidal melanomas with vitrectomy has been popularized in some centers (see [Chapter 151](#), Surgical

resection of choroidal melanoma). Harris et al. described successfully using extensive retinectomy to remove a subretinal abscess due to *Klebsiella*.<sup>27</sup>

## Retinectomies to Obtain Abnormal Retinal Tissue: Retinal Biopsy

Retinal and choroidal biopsies use retinectomies and choroidectomies to obtain tissue for pathologic diagnosis in difficult diagnostic problems, such as retinitis, uveitis, and neoplastic diseases. (This topic is covered in [Chapter 127](#), Vitreous, retinal, and choroidal biopsy.)

## Retinectomy for Treatment of Intractable Glaucoma

The pressure-lowering effect of anterior retinectomy has been advocated for treatment of intractable glaucoma.<sup>28,29</sup> Of 44 eyes treated by Jousseaume et al, with at least 5 years' follow-up, 52.3% had long-term control of intraocular pressure without complications. Among the remaining eyes, complications were frequent, with a high rate of PVR, hypotony, and phthisis bulbi. Eyes with neovascular glaucoma due to central retinal vein occlusion and eyes with uveitis had a particularly poor prognosis. Because the complication rate was much higher than for more traditional methods to lower the intraocular pressure, others have challenged the use of retinectomy to treat glaucoma.<sup>30</sup>

## Relaxing Retinotomy and Retinectomy

Relaxing retinotomies and retinectomies are used in the presence of retinal shortening that results from retinal incarceration or fibrous proliferation and contraction that prevents contact of the retina with the RPE.<sup>31-36</sup> Usually, the peripheral retina is cut or removed to preserve function of the more visually significant posterior retina. If the retina is cut and not removed, the procedure is technically a

retinotomy; however, in discussing relaxing retinotomies and retinectomies, we will refer here to all retinotomies and retinectomies as “retinectomies.”

The indications for relaxing retinectomies are listed in [Box 112.1](#). Except for retinal incarceration in traumatic or surgical wounds and excision of the inner wall of congenital retinoschisis, all the indications involve PVR or proliferative vascular retinopathy, with fibrous proliferation causing contraction and shortening of the retina. Relaxing retinectomies should only be done if other methods have failed or have no chance of success. A scleral buckle will sometimes adequately relieve traction to avoid cutting the retina. Michels et al.<sup>37</sup> described how a scleral buckle will change the vector force of contraction of proliferative membranes so the force is no longer applied to pull the retina away from the pigment epithelium. A buckle should be considered in the presence of [Box 112.1](#) contraction.

## Indications for Relaxing Retinotomies and Retinectomies

- Retinal incarceration in traumatic or surgical wound
- Proliferative vitreoretinopathy
- Focal contraction (star fold)
- Diffuse contraction
- Circumferential contraction
- Intrinsic retinal contraction
- Anterior retinal displacement
- Extensive fibrous periretinal proliferation
- Contraction and fibrosis of flap of giant retinal tear

- Proliferative vascular retinopathy
- Inner wall of congenital retinoschisis

Factors influencing the decision to perform a retinectomy or to place or revise a scleral buckle include the location and extent of the traction and the difficulty of revising or placing the buckle. Traction that can be easily and efficiently relieved with a scleral buckle (traction usually anterior in location and focal in extent) should be managed in such a manner; however, with extensive traction and fixed folds, a buckle is often not adequate. In addition, the extensive dissection and time required to revise a scleral buckle may sometimes be more harmful to the eye than internally relieving traction with a retinectomy.

Membrane dissection at vitrectomy will relieve most traction. Because posterior membranes can almost always be removed, posterior relaxing retinectomies are rarely indicated. However, peripheral membrane dissection is often more difficult, and if traction cannot be adequately relieved, a retinectomy may be required to reattach the retina.

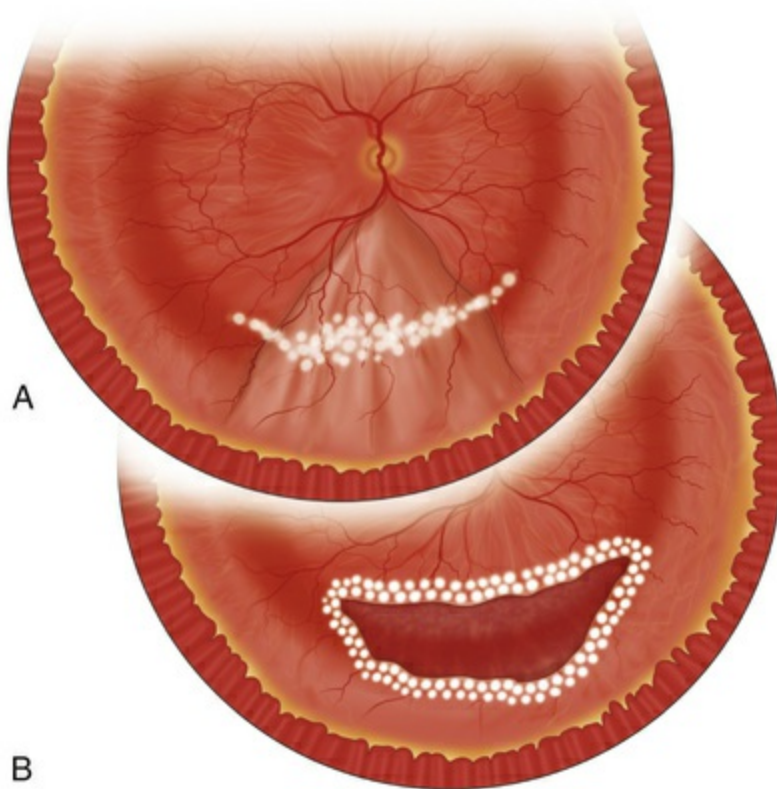

## General Surgical Principles and Techniques

The relaxing retinectomy can be performed after either 20G or smaller-gauge vitrectomy. Newer instrumentation and the ability to inject silicone oil into eyes using microincisional vitrectomy system (MIVS) technology makes the use of smaller-gauge technology possible.<sup>38</sup> The retinectomy should only be performed after complete membrane removal. If the retina is cut or excised before complete membrane removal, further membrane removal will be more difficult and may result in unnecessarily large retinal defects or residual membranes that may lead to redetachment of the retina. Larger peripheral retinectomies are less functionally significant than are smaller posterior retinectomies. Although a large peripheral retinectomy may be more difficult to manage at the end of the operation, the greater preservation of retinal function obtained is usually worthwhile. Circumferential relaxing retinectomies are usually preferred to radial retinectomies. In the

face of circumferential traction, a radial retinectomy that adequately relieves traction may extend too far posteriorly into the central retina.

It is useful to be able to see the full extent of the retina to be cut or excised during creation of a retinectomy. With full visualization, it is easier to assess the best location and the necessary extent of the retinectomy. A wide-angle viewing system is ideal for visualization of the retina during this maneuver. Either a contact or non-contact system can be used. Use of a wide-angle system may reduce the time necessary to do the procedure, improve the ability to apply laser photocoagulation, and reduce the need for scleral depression.<sup>39</sup> Before a relaxing retinectomy is created, diathermy should be applied to the entire area to be cut (Fig. 112.3A). Blood vessels in the area should be occluded. The retina can be cut with scissors or a vitrectomy instrument. Scissors will make the most precise, controlled cut, but 23G and 25G vitreous cutters can be well controlled and are much more precise than 20G instruments. Use of the vitreous cutter is faster than using scissors. The vitreous cutter is used for excising the anterior flap of the retinectomy. For folded retina, sequential cutting and reapplication of diathermy, as described later for release of retinal incarceration, is the preferred method. PFCL may be useful to stabilize the retina posterior to the retinectomy.<sup>5</sup> As a general principle, for maximal relaxation of traction, the retinectomy should extend into normal retina on each end of the area of contraction. With shorter retinectomies, the extension into normal retina needs to be only a few degrees in length. With very large retinectomies, extension into the normal retina may need to be up to 30°. If the normal retina to be cut is attached, care must be taken not to damage the choroid during retinectomy, because bleeding may occur. After diathermy, the retina should be gently pulled away from the pigment epithelium by the scissors tips, a soft silicone tip cannula with or without suction, or a pick before cutting.

**FIG. 112.3** Persistent retinal contraction and shortening after membrane removal. (A) Diathermy applied heavily to vessels and lightly to the remainder of the retina in the area of proposed retinotomy. (B) After retinectomy and reattachment of the retina, the retinal defect is greatest centrally and least at the ends.

The surgeon should pay attention to the pattern of retinal contraction in designing a retinectomy. After retinal reattachment, a circumferential relaxing retinectomy will have an oval configuration (Fig. 112.3B). Relaxation is greatest in the central area where the retinal defect spreads apart the most and least at each end of the retinectomy. For a smaller retinectomy, without extensive traction toward the ends, a simple circumferential cut is usually adequate. For larger retinectomies, especially those with traction toward the ends, the surgical principle of the Z-plasty is useful. By angling the cut anteriorly to the ora serrata or sometimes the pars plana epithelium oblique to the circumferential direction of the relaxing retinectomy, one can relieve residual traction at the ends of the retinectomy (Fig. 112.4).<sup>33</sup> The combination of

circumferential retinectomy to relieve anteroposterior shortening and oblique extension at each end into normal retina to relieve circumferential shortening achieves the greatest retinal relaxation in the face of extensive retinal shortening.

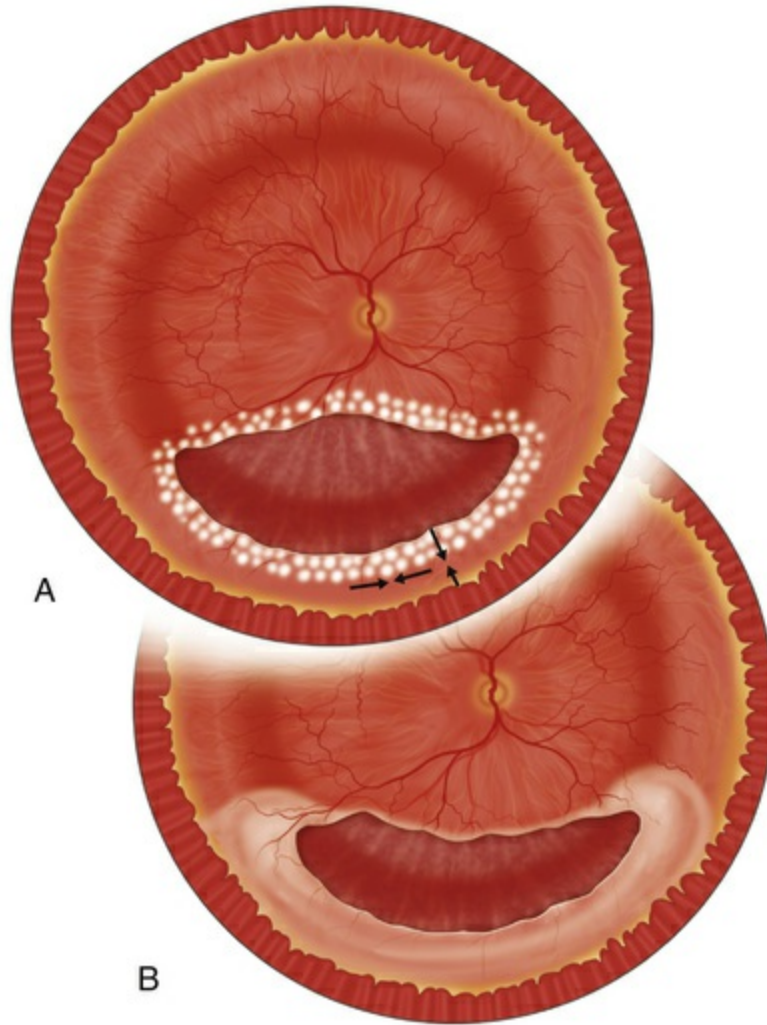

A

**FIG. 112.4** Extensive retinal shortening persists after membrane removal. (A) Arrows indicate both circumferential and radial retinal shortening. Diathermy is applied to the retina and vessels in the proposed retinotomy site. The retinectomy is extended obliquely anteriorly into the uninvolved retina to maximize relaxation. (B) Retina flat following fluid–air exchange. The anterior flap of the functionless retina was excised, which reduces the likelihood of recurrent traction in the area of retinotomy. Note the bare retinal pigment epithelium (*RPE*) anterior to the retinectomy.

The anterior flap of the retinectomy is avascular and nonfunctional. We recommend excision of the retina anterior to a large retinectomy so that fibrin and cellular proliferation do not rejoin the cut edges of the retina or proliferation from the anterior flap does not produce traction on the ciliary body. Excision of the anterior flap is especially important at the ends of the circumferential retinectomy. Failure to extend the retinectomy into normal retina or to excise the anterior flap may allow recurrent proliferation and contraction to redetach the retina (Fig. 112.5).

**FIG. 112.5** (A) Eye in which retinectomy is not extended anteriorly. Arrows indicate forces of recurrent traction, which redetach retina at the ends of the retinectomy. (B) Retinal redetachment around inadequate retinectomy. A larger, more extensive retinectomy is less likely to detach.

If a circumferential retinectomy extends more than  $270^\circ$ , it is usually best to extend it to  $360^\circ$ . Similarly, if a small isthmus of intact retina separates two large retinectomies, it is usually best to cut the intact retina to join the two areas of retinectomy. These small areas of intact retina are of little functional use and may become areas of contraction that elevate the edges of the retinectomy.

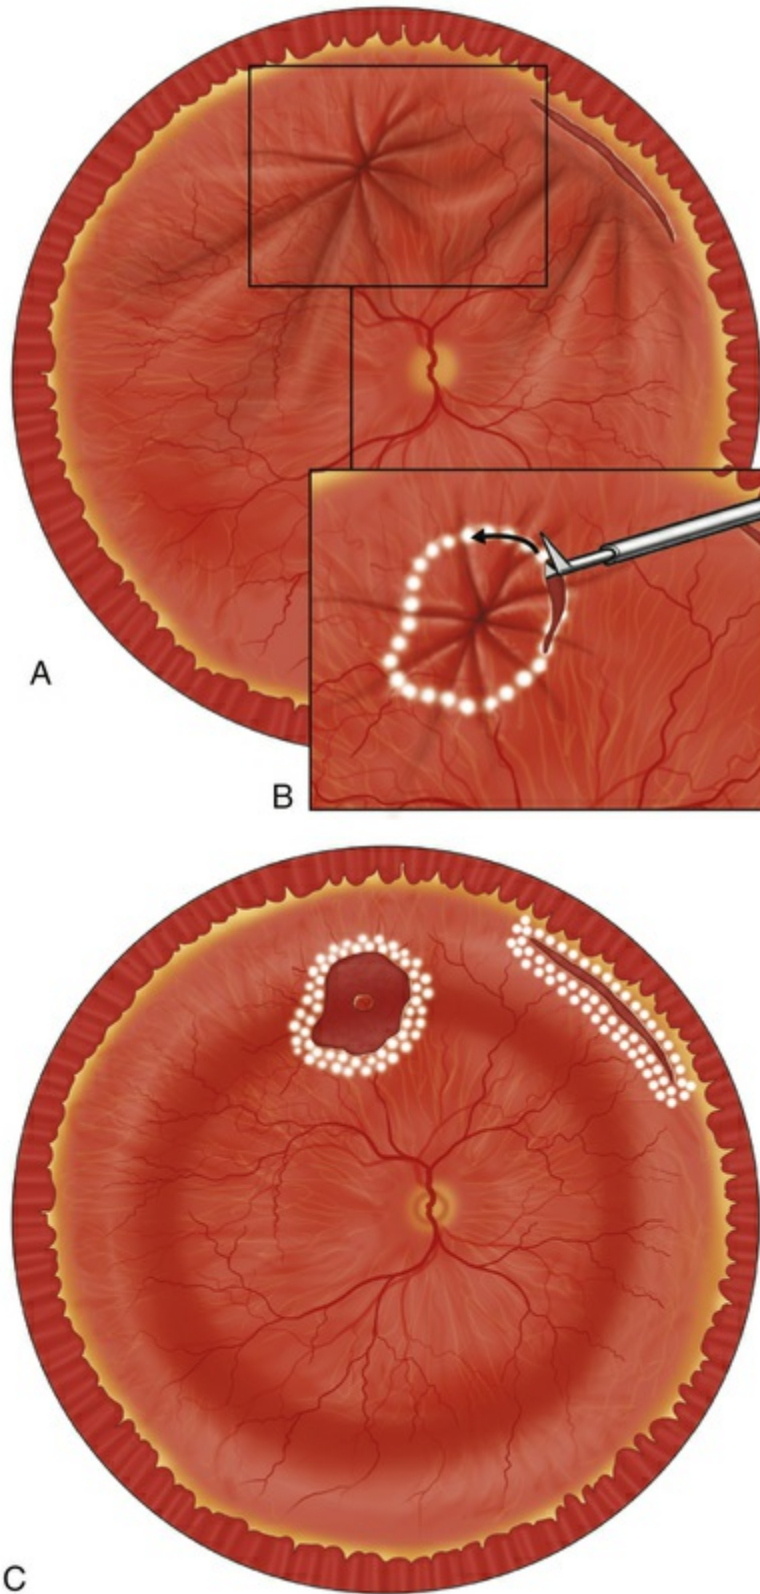

## Retinal Incarceration in Traumatic or

## Surgical Wounds

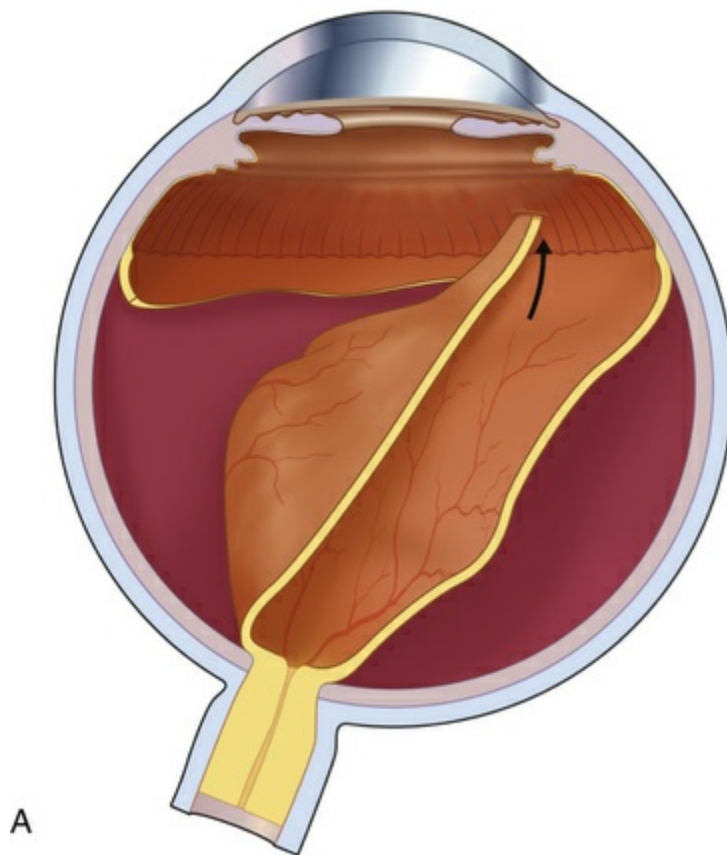

A retinectomy is sometimes necessary for relief of traction that results from traumatic scleral perforation with retinal incarceration.<sup>33,40</sup> Retinal incarceration may result from several mechanisms. Focal (limited) retinal incarceration occurs when local retina is forced or drawn into a penetrating wound. Retina may actually be acutely extruded at the time of injury as vitreous is extruded, or the fibrosis of healing after a penetrating injury may progressively draw retina towards the injury site. In both situations, the final result is overall shortening of the retina with folds radiating toward the central wound (Fig. 112.6). Alternatively, retina may be incarcerated in a sclerotomy site after drainage of subretinal fluid during retinal detachment surgery. Another mechanism of retinal incarceration involves incarceration of retina distant from the penetrating wound (Fig. 112.7). This results from acute extrusion of vitreous out of the wound associated with collapse of the eye during injury. Distant retina attached to the vitreous is pulled into the wound as the vitreous is extruded. The most extreme example of the latter mechanism is total extrusion of the vitreous through a wound with complete avulsion of the anterior retinal insertion. The retina is found in a tight funnel configuration extending from the posterior optic nerve connection to the anterior wound. Incarceration of the retina in an anterior wound such as a cataract surgery wound can result from a massive suprachoroidal hemorrhage in which the vitreous and retina are extruded through the wound by the enlarging choroidal detachment. As the hemorrhage is surgically drained or resolves on its own, the retina may be left incarcerated in the wound.

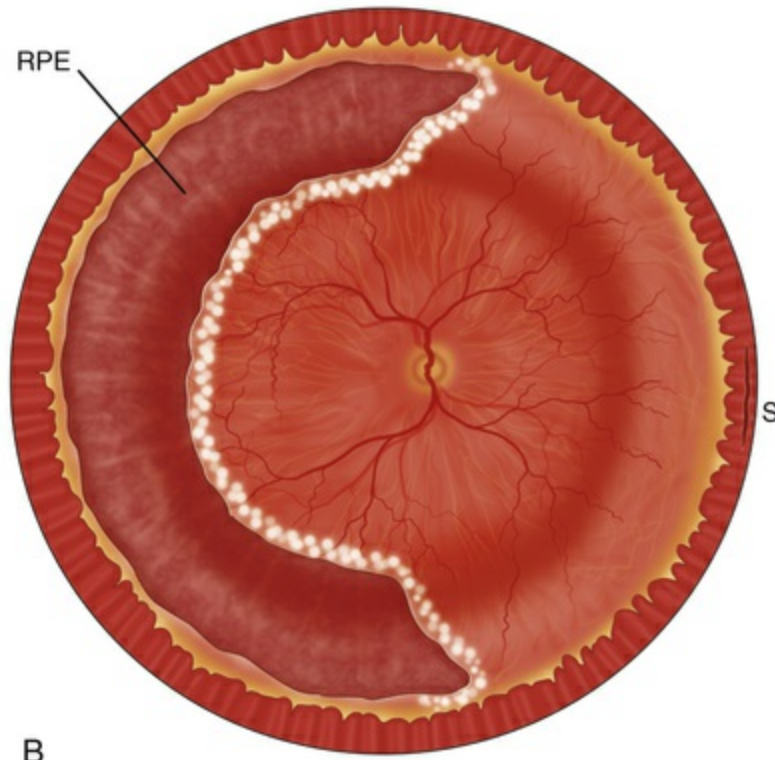

**FIG. 112.6** Release of focal retinal incarceration. (A) Superior traumatic penetrating injury with retinal incarceration and retinal detachment with peripheral dialysis. (B) Endodiathermy applied to retina surrounding incarceration. The retina is cut in layers,

and diathermy is reapplied as deeper retina is uncovered. The retina is cut 360° around the incarceration site. (C) Postoperative appearance. The retinectomy is enlarged after flattening of retina. Laser endophotocoagulation was applied to the edges of the retinectomy.

**FIG. 112.7** Distant retinal incarceration. (A) Torn retina incarcerated in wound on the opposite side of the eye. (B) After excision of the retina from the wound, the retina is flattened. *RPE*, area of bare retinal pigment epithelium after retinal reattachment. Note the scar at the previous incarceration site (S).

In limited incarcerations, the retina has a focal morning-glory configuration at the point of incarceration (Fig. 112.6A). Surrounding retina is usually detached with fixed folds radiating from the area of incarceration. The degree of retinal shortening and contraction is determined by the size of the scleral wound, the amount of retina incarcerated, and the degree and chronicity of fibrous proliferation at the incarceration site. A retinotomy should be performed only if contraction and folds from the incarceration site prevent retinal reattachment.

### **Surgical Technique**

Vitrectomy should be completed and hemorrhage and membranes within the vitreous and on the retinal surface should be removed before retinectomy is considered. If the retina is extruded into an anterior wound, it may be difficult to place the instruments through

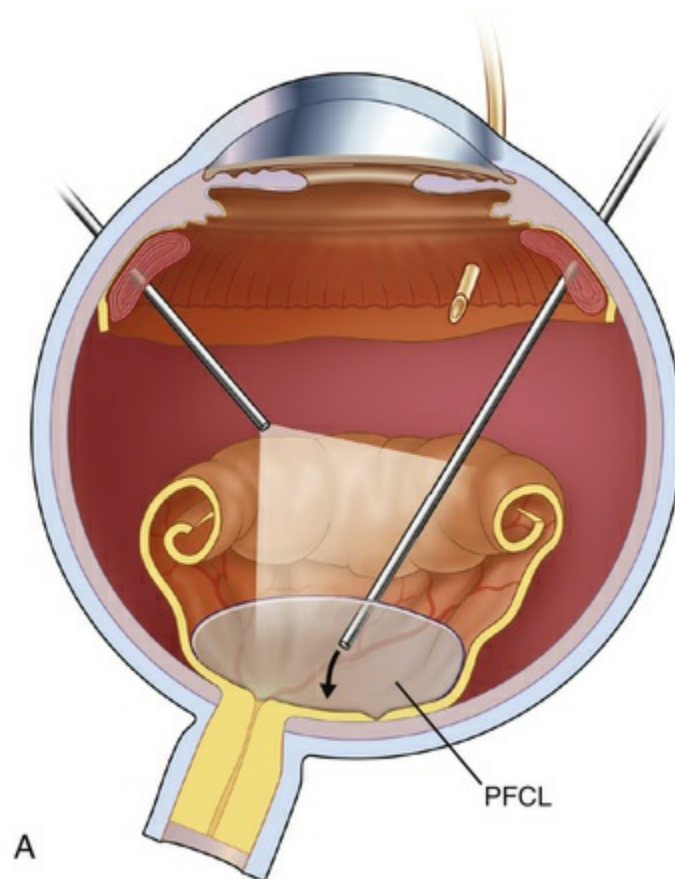

the pars plana in the normal position; the surgeon should be careful to avoid placement of the infusion cannula into the subretinal space. In a fresh wound, the retina may sometimes be teased out of the incarceration site with forceps or repositioned by the injection of a viscoelastic substance. Injection of PFCL over retina posterior to the incarceration may pull retina out of the incarceration. A retinotomy is required if the retina cannot be dislodged from a fresh wound or if it is incarcerated in a fibrotic, older wound. Retina must also be cut if significant shortening and fixed folds persist after a complete vitrectomy and membrane peeling.

Initially, diathermy is applied to the retina at the margin of the incarceration to ensure that all blood vessels are closed (Fig. 112.6B). There may be large vessels within the incarceration site, so it is preferable to cut just peripheral to the incarceration site rather than directly into it. The retina is usually cut with the vertically cutting vitreoretinal scissors 360° around the incarceration site (Fig. 112.6B). Bullous retina posterior to the incarceration site can be flattened and stabilized with PFCL during the retinectomy.<sup>5</sup> If PFCL is used, the retina posterior to the incarceration site should be free of membranes. There should be no open retinal breaks under traction in the area to be covered by the PFCL. The PFCL is injected over the posterior pole and the level of the PFCL brought just posterior to the incarceration.

The retina may be thickened, and parts of the retina may be hidden between folds, making hemostasis with diathermy difficult. It may be necessary to cut the retina in layers, reapplying diathermy as the untreated tissue is uncovered.<sup>33</sup> When the retina is circumcised around an area of incarceration, the defect in the retina will be larger than would initially appear (Fig. 112.6C). Therefore, the closer the cut is made to the area of incarceration, the smaller the potential defect will be. In areas where the retina is closely apposed to the RPE, there is risk of damage to the choroid by the scissors, with resultant hemorrhage. After diathermy, the scissors blade or a membrane pick can usually be placed tangentially through the necrotic retina into the subretinal space. The retina should be lifted away from the RPE before cutting. The retinal defect created by the retinectomy should be treated with laser endophotocoagulation and tamponaded with gas or silicone oil

(Fig. 112.6C).

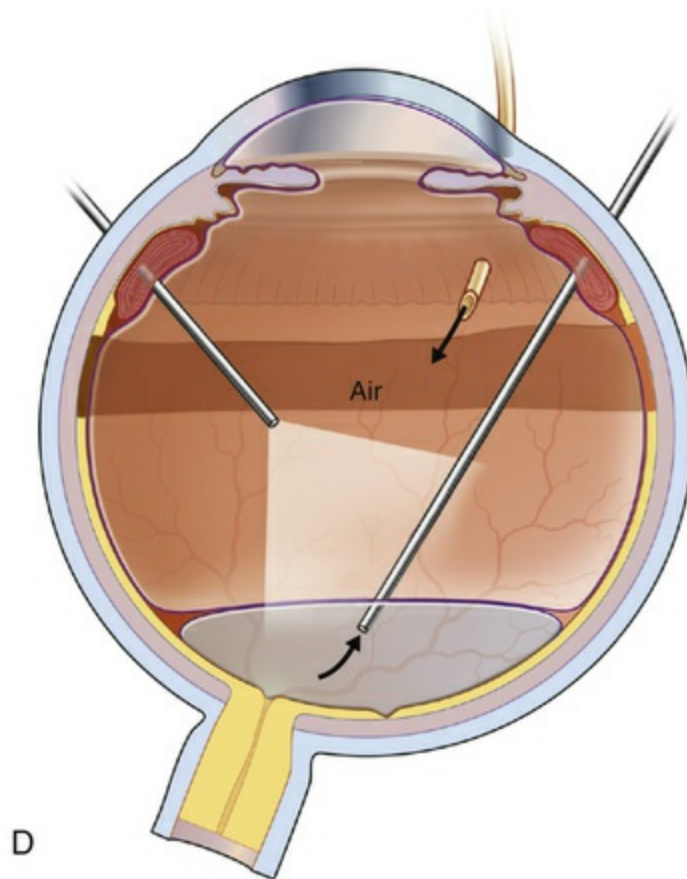

Management of distant retinal incarceration is a special problem. Very large defects are created when the retina is excised from the wound (Fig. 112.7). These eyes may require up to a 360° retinectomy to separate the retina from the wound. PFCLs may be useful in managing extensive distant retinal incarcerations. PFCL might be useful to stabilize the retina during the retinectomy, open the closed funnel of the retinal detachment, and to reattach the resultant giant retinal tear (Fig. 112.8).<sup>4,5</sup>

**FIG. 112.8** Management of giant retinal tear or retinectomy with perfluorocarbon liquid (PFCL). (A) Folded-over giant tear/retinectomy with marked folding of the peripheral retina. PFCL injected over posterior pole after posterior epiretinal membrane removal. (B) Posterior retina reattached. Organized, folded edge of giant tear treated with diathermy, then excised with vitrectomy instrument. (C) Retina completely reattached with PFCL. “Drying” anterior edge of giant tear during initial phase of fluid–air exchange by applying suction with soft-tip needle beneath anterior edge of retina. (D) Continuing fluid–air exchange to remove residual PFCL. No retinal slippage has occurred.

## Retinal Shortening (Contraction) Because of PVR

Retinal shortening in PVR is divided into seven categories ([Box 112.1](#)). In the revised Retina Society Classification of PVR,

contraction posterior to the equator was classified as posterior PVR, whereas contraction at the equator and anteriorly was classified as anterior PVR.<sup>41</sup> The first two categories, focal contraction and diffuse contraction, are similar; both result from contraction of epiretinal membranes and vary mainly in the extent of retinal involvement (see Chapter 112, Proliferative vitreoretinopathy, for further information on classification of PVR).

## **Surgical Technique**

The surgical goals and techniques of performing retinectomies for the various subtypes of PVR are similar. Some modifications in technique are necessary for eyes with the various subgroups of PVR. In all forms of PVR, a complete vitrectomy and aggressive membrane removal are essential to relieve contraction. A scleral buckle may relieve lesser degrees of contraction, but with extensive shortening, a retinectomy is necessary. The size, location, orientation, and configuration of a retinectomy will vary according to the indication.

## **Focal or Diffuse Retinal Contraction**

It is usually unnecessary to cut the retina to manage focal or diffuse contraction. Occasionally when the retina is atrophic, the membranes will not strip from the retina without extensive retinal tearing. Focal retinectomy in areas where membranes cannot be removed is sometimes necessary (Fig. 112.9). Diathermy is applied to the retina surrounding the area to be excised, particularly to the retinal vessels. If the retina is detached, the retinectomy can usually safely be done with a small-gauge vitreous cutter; however, if the retina is partially or completely attached in the area of contraction, the retina is most safely excised with scissors.

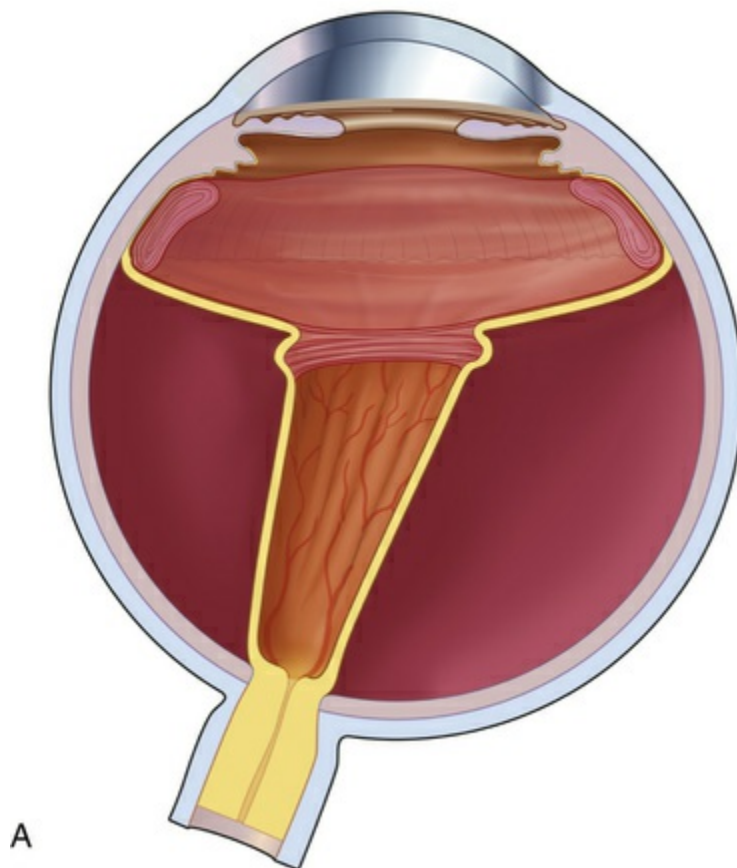

**FIG. 112.9** (A) Diffuse contraction associated with large retinal breaks. Remove all membranes. If all membranes cannot be removed, local retinectomy is performed. (B) Large defect after retinectomy. Traction is relieved, and the retina is reattached. The edge of the break is treated with laser endophotocoagulation.

## Circumferential Contraction

Extensive circumferential contraction may occur because of marked membrane contraction at the posterior aspect of the vitreous base. In the revised Retina Society Classification of PVR, circumferential contraction is a form of anterior PVR.<sup>41</sup> Coronal contraction of the posterior hyaloid pulls the retina centrally into a funnel shape, and circumferential contraction creates tight retinal folds that extend posteriorly in a radial fashion (Fig. 112.10A). Even with excision of the posterior hyaloid and stripping and sectioning of membranes, a ridge of equatorial retina may sometimes remain in a circular contracted state. It is usually visually apparent if circumferential

contraction has not been adequately relieved by membrane peeling and sectioning. If dissection does not release traction, a circumferential retinectomy should be made just posterior to the area of contraction (usually the posterior aspect of the vitreous base) (Fig. 112.4). The relaxing retinectomy is best made with PFCL stabilizing the retina posterior to the area of contraction (Fig. 112.11). With the posterior retina held in place by the PFCL, the retinectomy is extended circumferentially into normal-appearing retina on each end of the retinectomy, and then extended anteriorly to the ora serrata (or the ciliary body if the pars plana is involved with traction) (Figs. 112.4 and 112.11). The retina anterior to the retinectomy should be excised with the vitrectomy instrument. Once all traction is released by the retinectomy, the PFCL can be brought anterior to the level of the retinectomy to reattach the remaining retina without fear of subretinal PFCL.

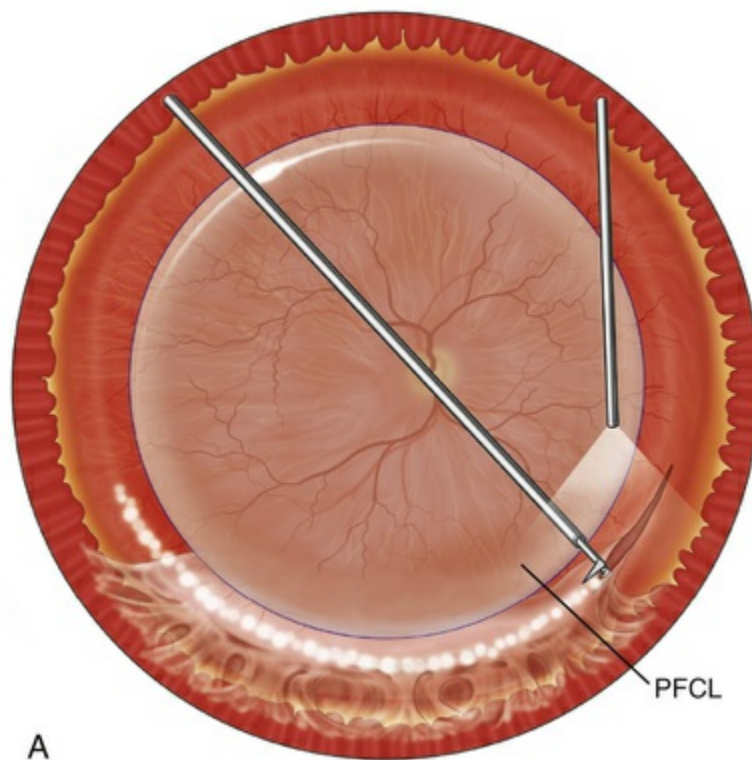

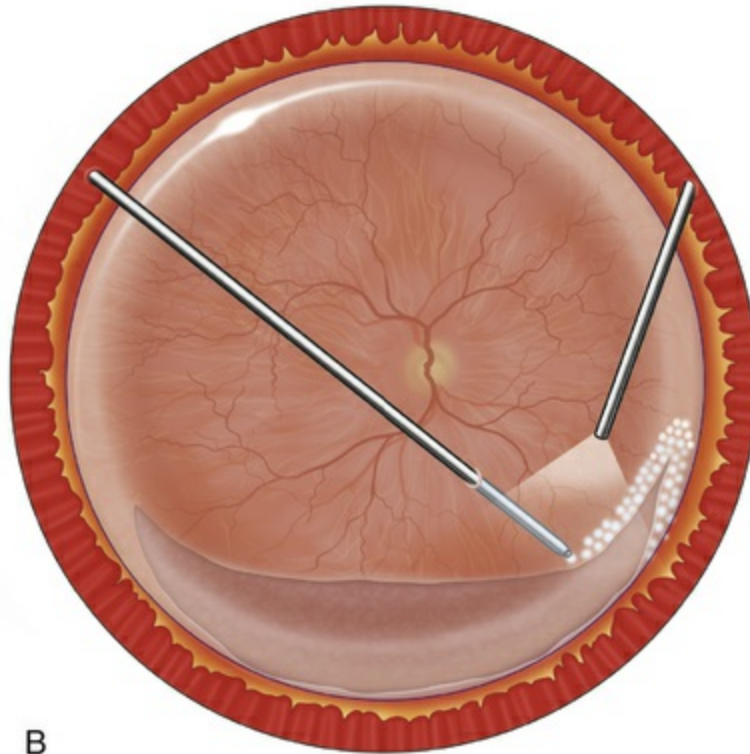

**FIG. 112.10** Contraction of posterior aspect of vitreous base. (A) Retina pulled into funnel configuration.

Circumferential contraction of posterior vitreous base with radial folds in retina. (B) After vitrectomy, membrane removal, scleral buckle, and fluid–air exchange, air (A) courses subretinally through the retinal break. Dashed line indicates location of proposed retinectomy. (C) Circumferential retinectomy is performed under air, and the retina flattens. Extend retinectomy into attached retina on each end.

**FIG. 112.11** (A) Anterior proliferative vitreoretinopathy extends from 5 to 8 o'clock. The posterior retina is held in place by perfluorocarbon liquid (PFCL). Retinectomy anterior to the PFCL extends into unaffected retina at each end of the retinectomy. (B) The full extent of the retinectomy is now flattened by PFCL and is large because of excision of anterior flap. Laser endophotocoagulation is applied to the margin of retinectomy.

Alternatively, the need for a relaxing retinectomy at the posterior aspect of the vitreous base may be noted during injection of PFCL or after fluid–air exchange. The surgeon may notice persistent circumferential tenting of the retina or the air or PFCL may course subretinally through retinal breaks elevated by traction. It is best to try to determine if contraction has been adequately relieved before air or PFCL goes subretinally, as both situations further complicate surgery. If PFCL goes under the retina, it will be necessary to retrieve it with a fluted needle or suction cannula, often requiring folding the retina over in order to visualize the subretinal PFCL. If air has gone under the retina, the air may delineate most of the area of residual traction ([Fig. 112.10B](#)). It is important to extend the relaxing retinectomy well beyond the point that allows the retina to

flatten because the surface tension of the air may overcome residual traction that might redetach the retina as the gas bubble resolves. Subretinal air will coalesce with air in the vitreous cavity when the retinectomy is made and the retina will reattach (Fig. 112.10C).

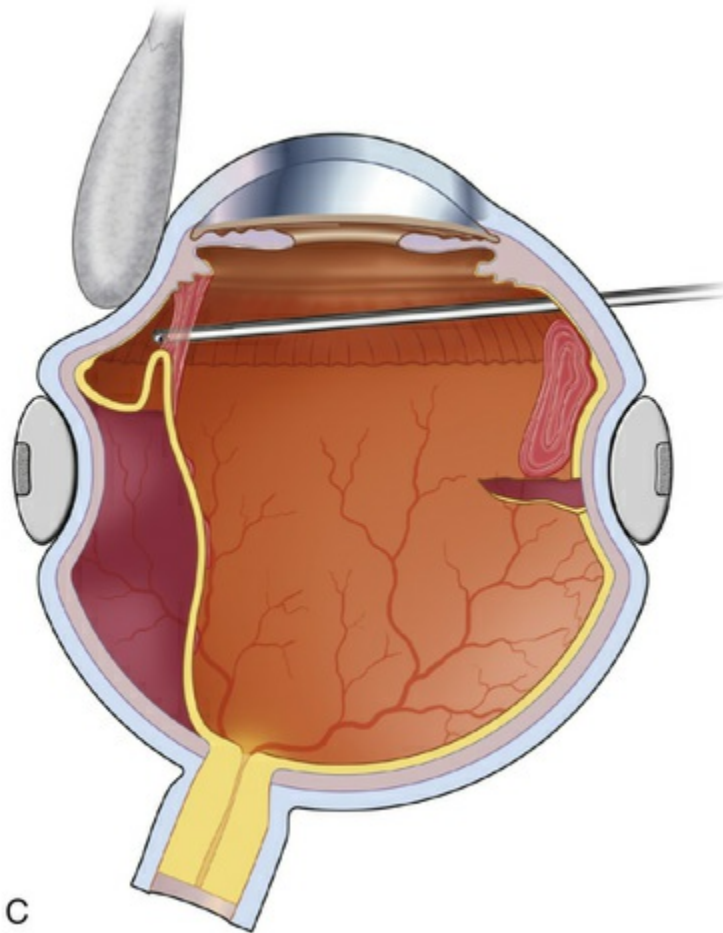

## Anterior Retinal Displacement

Anterior retinal displacement is an important cause of retinal detachment with PVR and is primarily found in patients who have undergone a previous vitrectomy.<sup>41-43</sup> In these cases, fibrous proliferation and contraction of membranes at the vitreous base pull peripheral retina anteriorly to the pars plana, pars ciliaris, or even to the posterior iris. This may lead to anterior retinal detachment, recurrent posterior retinal detachment, or to ciliary body detachment and hypotony (Fig. 112.12).

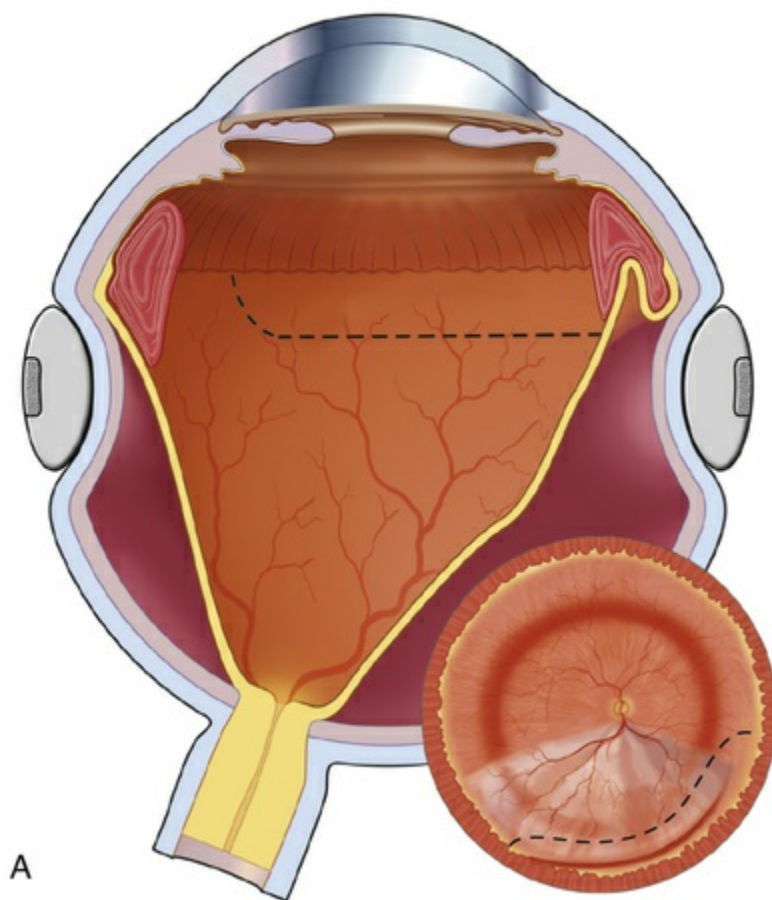

B

C

**FIG. 112.12** Anterior retinal displacement (ARD) after previous vitrectomy and scleral buckle. (A) Proliferation of cells onto the retina and residual peripheral vitreous. (B) Recurrent retinal detachment after contraction of proliferative membranes. Note ARD (*arrow*) with peripheral retina pulled in a fold toward the ciliary body by contracting vitreous base. (C) Release of ARD with scissors by cutting membrane.

If excessive traction persists after membrane dissection, an anterior retinectomy is necessary (Figs. 112.11 and 112.13). The retinectomy is performed after all posterior membranes have been removed and is made just posterior to the anterior retinal traction. The retinectomy is performed in a manner similar to that described for extensive equatorial contraction.

**FIG. 112.13** Relaxing retinectomy for localized anterior retinal displacement. (A) Area of contraction not released by membrane dissection. *Dashed line* indicates proposed retinectomy. Extend anteriorly into unaffected retina. (B) After retinal reattachment. Retinectomy with anterior flap excised.

## Intrinsic Retinal Contraction

Intrinsic retinal contraction is retinal contraction in the absence of epiretinal or subretinal membranes and is most often found in eyes with chronic retinal detachments. Retinectomy for intrinsic retinal contraction is similar to retinectomy for other forms of contraction, but intrinsic retinal contraction is often only recognized after injection of PFCL or insufflation of air. If the area of intrinsic retinal contraction is in the peripheral retina, a circumferential retinectomy is made posterior to the area of contraction. With intrinsic retinal contraction, the area of involvement is often extensive, so the retinectomy may need to be quite large. The retinectomy should be

extended circumferentially into normal retina at each end and anteriorly to the ora serrata.

Intrinsic retinal contraction involving the posterior retina is more difficult to manage. When there is annular contraction involving the posterior retina, if no subretinal membrane is found as a cause, a retinectomy is necessary to relieve traction. A circumferential retinectomy in the posterior pole is problematic because of loss of visual field. Several radial cuts in retina will sometimes adequately relieve the traction; however, these cuts may extend too far posteriorly toward the optic nerve. Excision of a section of nasal retina may adequately relieve traction and allow the more visually significant temporal retina to be reattached.

## **Extensive Periretinal Fibrous Proliferation**

Extensive periretinal fibrous proliferation may occur in eyes after extensive traumatic retinal contusion or necrosis. The retina may be replaced by fibrous tissue with further fibrous proliferation on the anterior and/or the posterior surface of the retina. With longstanding PVR and chronic retinal detachment with severe fibrous proliferation, the retina may become very thin and atrophic in areas of fibrous proliferation, making membrane removal impossible. Perisilicone proliferation may involve widespread fibrous proliferation, especially at the margin of a previous retinectomy. The peripheral retina may become so encased in fibrous tissue that the tissue cannot be separated from the retina.

In all these instances, the dense, white fibrous tissue cannot be separated from the retina. The retina in these areas becomes nonfunctional and should be excised if it prevents retinal reattachment. These membranes are often quite contracted, causing marked folding and shortening of the retina. The involved areas may be vascularized, although sometimes they are avascular. Diathermy should be applied along the posterior edge of the area to be excised, and then excision is carried out with the vitreous cutting instrument in a technique similar to that described for diffuse retinal contraction ([Fig. 112.9](#)).

## **Prophylactic Removal of Anterior Flap of**

## Horseshoe Tears

One of the most common forms of retinectomy is the removal of the anterior flap of a horseshoe tear. These flaps always have strong vitreoretinal adhesions, and the flap is removed because of the possibility of progressive traction on the edge of the tear by vitreous contraction in the postoperative period. Traction may lead to lifting of the retina away from the pigment epithelium and/or anterior extension of the horseshoe tear. The tear should be left in a rounded shape, which is more likely to withstand vitreous traction without experiencing extension or elevation. If present, the operculum of a retinal tear is also commonly excised as part of the necessary peripheral vitrectomy. Sometimes retinal vessels bridge the operculum or flap of the tear. Diathermy should be applied to the vessels prior to removal of the flap or operculum with the vitreous cutting instrument.

## Contraction and Fibrosis of Flap of Giant Retinal Tear

The posterior flap of most giant retinal breaks shows inward curling of the edge because of the normal contractility of the retina. With chronicity and the onset of PVR, this folding may become permanent and prevent reattachment of the edge of the flap ([Fig. 112.14A](#)). The inwardly folded retina may become fixed with proliferative membranes, and the edge may be thickened, fibrous, and taut. Even after removal of membranes, the edge may remain folded, requiring retinectomy to allow complete flattening of the flap of the giant break.

**FIG. 112.14** (A) A 180° giant retinal tear with folded rolled edge, which prevents complete unfolding. The *dashed line* indicates the limit of the edge to be excised. (B) Retina relaxed and reattached.

There is often both anteroposterior shortening because of inward rolling of the edge of the break and circumferential shortening as a result of fibrous contraction. Membranes are removed on both the anterior and posterior surfaces of the retina. The flap is unfolded mechanically using two instruments. If the flap will not unfold, it is often best to excise the folded edge of the flap.<sup>44</sup> Alternatively, a series of radial cuts may be placed approximately every 30° along the margin of the flap to allow unfolding.<sup>44</sup> However, the irregular edge created by this series of cuts is more difficult to manage, and excision of the edge is the preferred approach (Fig. 112.14B).

After removal of posterior membranes, PFCL is injected over the posterior pole and the level is brought to a level posterior to the fibrotic edge of the giant tear (Fig. 112.8B).<sup>4</sup> The PFCL fixes the retina and makes excision of the organized edge easier. Diathermy is applied to the edge of the flap throughout the extent to be

excised. Excision is usually with the vitreous cutting instrument, being careful to apply low suction so that excessive retina is not excised. If radial cuts are to be made, diathermy is applied only locally in the area to be cut.

## **Inner-Wall Retinectomy for Complications of Congenital Retinoschisis**

Congenital retinoschisis can be complicated by combined schisis–traction retinal detachment, combined schisis–rhegmatogenous retinal detachment, vitreous hemorrhage, and obscuration of the macula by the overhanging inner wall of a schisis cavity. Ferrone et al. reported pars plana vitrectomy with excision of the inner wall of the peripheral schisis cavity in nine eyes with various complications of congenital retinoschisis.<sup>45</sup> The retina was attached postoperatively in eight of nine eyes; six had improvement in visual acuity (VA), and one had stabilization of VA. Two eyes had a decrease in VA. An alternate technique with posterior hyaloid dissection, a small retinotomy, fluid drainage with a 42G cannula, laser photocoagulation, and silicone oil injection was successful in one reported case.<sup>46</sup>

## **Retinal Shortening Because of Proliferative Vascular Retinopathy**

Retinectomy is sometimes indicated for the repair of longstanding traction retinal detachment associated with diabetic retinopathy and other proliferative vascular retinopathies such as branch retinal vein occlusion, proliferative sickle-cell retinopathy, and retinopathy of prematurity.<sup>47</sup> The indications and techniques for relaxing retinectomy are similar to the indications and techniques for PVR.

## **Management of Retinectomy**

Production of a relaxing retinectomy can create problems in closing the tear and managing what may be a giant retinal break that can invert or retract posteriorly. Small retinectomies can usually be

flattened with air and treated with laser endophotocoagulation without slippage or inversion of the posterior flap. Larger circumferential retinectomies need to be treated as a giant tear.

PFCL is the best method for managing a large circumferential retinectomy. The PFCL is injected over the optic disc and reattaches the retina from posteriorly to anteriorly. The anterior edge of the retina should be carefully monitored during PFCL injection. If the retina is completely mobile, the level of the PFCL can be safely brought anterior to the edge of the retinectomy. However, if traction remains on the anterior retina, the PFCL may go beneath the retina. Therefore, if traction remains, the anterior edge of the flap should be excised before further PFCL injection. With traction relieved, the meniscus of the PFCL can safely be brought anterior to the flap of the tear to completely reattach the retina. The PFCL interface should not be brought in contact with the infusion cannula because small bubbles of PFCL will be created that can migrate under the edge of the retina if the edge is still elevated. The use of valved cannulas will reduce overall fluid flow and decrease production of PFCL bubbles.

Laser photocoagulation can be applied to the edge of the retina either before or after exchanging the perfluorocarbon for air or silicone oil. The view is usually superior through PFCL than through either air or silicone oil. The fluid anterior to the PFCL maintains good corneal clarity and pupillary dilation, whereas air sometimes causes striate keratopathy, pupillary miosis, and a minimized view. Small bubbles suspended in silicone oil can sometimes interfere with visualization through silicone oil. If the anterior edge of the retinectomy has been completely flattened by PFCL, it is easier to apply laser through the PFCL than through air or silicone oil. However, if it is not possible to flatten the edge of the tear completely with PFCL, laser treatment should be delayed until after exchanging the PFCL for air or silicone oil. Alternatively, an anterior drainage retinotomy can be made to allow egress of loculated anterior subretinal fluid into the vitreous cavity (Fig. 112.1).

Exchange of the PFCL for air or silicone oil is an important step that can lead to problems if not performed correctly. There is often a small amount of subretinal fluid beneath the anterior edge of the

retina, and there can be small bubbles of PFCL beneath the retinal edge. Unless this fluid is removed, it will be forced posteriorly during the exchange and can lead to posterior slippage of the retina and/or to accumulation of subretinal PFCL. During PFCL–air exchange, the fluid anterior to the PFCL should first be replaced with air. “Drying” of the anterior edge of the retina is accomplished with either a backflush brush or other soft-tipped extrusion or suction cannula placed just anterior to the retinal flap (Fig. 112.8C). The exchange is completed (Fig. 112.8D) after all subretinal fluid is removed and the anterior edge is thoroughly “dried.”

Posterior retinal slippage can occur during PFCL–air exchange for giant tears or retinectomies. Slippage most commonly occurs in large, highly myopic eyes and is due to fluid behind the anterior edge of the retina being forced posteriorly during the exchange. Inadequate removal of that fluid (inadequate drying of the anterior edge of the retina) is the most important cause of posterior slippage. Sometimes it is possible to manipulate the anterior edge of the retina with the backflush brush to pull the retina to its proper position. However, if the retina cannot be brought to its normal position, the air should be removed and the retina once more flattened with PFCL. Thorough drying of the anterior edge of the retina during exchange usually prevents further retinal slippage. Laser treatment to the retinal edge prior to PFCL removal anecdotally appears to exert a small immediate protective effect against slippage, perhaps by dehydrating the retina-RPE interface. Exchange with silicone oil rather than air is less likely to cause slippage of the retina.

## Results

In the Silicone Study,<sup>48</sup> group 2 eyes (previous vitrectomy) were twice as likely to undergo retinectomy as group 1 eyes (no previous vitrectomy) (42% vs. 20%;  $p<.0001$ ). Variables identified with stepwise logistic regression analysis that were associated with the need for retinectomy were (1) membership in group 2 and (2) the presence of >6 clock-hours of anterior retinal displacement. Group 1 eyes undergoing retinectomy had a significantly poorer anatomic prognosis than eyes not undergoing retinectomy (50% attached vs.

69% attached at 6 months,  $p = .03$ ; 38% vs. 69% at 24 months,  $p = .01$ ) regardless of whether perfluoropropane gas or silicone oil was used. In group 2, this difference was only significant at 24 months (52% attached with retinectomy vs. 70% attached without retinectomy;  $p = .052$ ). Group 1 eyes (but not group 2 eyes) undergoing retinectomy were more likely to have visual acuity less than 5/200 than eyes not undergoing retinectomy (32% vs. 59%,  $p < .01$  at 6 months; 28% vs. 55%,  $p = .03$  at 24 months), regardless of tamponade modality. In group 1 (but not in group 2), hypotony (intraocular pressure  $\leq 5$  mmHg) was about twice as prevalent in eyes that had a retinectomy than in those that did not (35% vs. 17% at 6 months,  $p < .05$ ; 24% vs. 14% at 12 months, not significant) regardless of tamponade. It is probable that eyes with poorer anatomic and visual prognosis underwent retinectomy, which might explain some of the results.

More recent series report better anatomic and visual results than those reported in the Silicone Study and lower rates of hypotony. Bovey et al.<sup>49</sup> reported excellent anatomic and visual results following peripheral retinectomies of 180° or more. Of 33 eyes reported (all managed with silicone oil), silicone oil was permanently removed from 24. The final VA was 5/200 or better in 85% and 20/200 or better in 51%. Only one eye had hypotony (intraocular pressure  $\leq 5$  mmHg) at the last follow-up examination, although two eyes required reinstillation of silicone oil because of hypotony.

Eckardt et al.<sup>50</sup> reported silicone oil removal from 32 eyes that had peripheral relaxing retinectomies for proliferative vitreoretinopathy. Only three eyes developed retinal detachments following silicone oil removal and 28 eyes obtained a VA of 0.1 or better and 15 eyes 0.2 or better. One eye was hypotonus and 11 eyes were treated for glaucoma.

Tseng et al.<sup>51</sup> looked at the influence of relaxing retinectomy on surgical outcomes in PVR. They found that silicone oil was significantly superior to gas for long-term tamponade in eyes with a relaxing retinectomy, confirming the results of the Silicone Study.

Quiram et al.<sup>52</sup> reported complete reattachment in 93% of 56 eyes with recurrent retinal detachment with PVR treated with retinectomy. Patients undergoing radical anterior vitreous base

dissection and lensectomy at the time of first retinectomy had a higher success rate than those who did not. Hypotony was present in 5.4% at the last follow-up.

Grigoropoulos et al.<sup>53</sup> reported the results of 304 eyes managed with retinectomy. The cause of retinal detachment was rhegmatogenous retinal detachment with PVR (78%), posterior trauma (17%), and vasoproliferative diseases, acute retinal necrosis, and endophthalmitis in the rest. A total of 51% were completely reattached with one operation and 72% with more than one operation. A final VA of 6/24 or better was significantly associated with better preoperative vision, shorter duration of silicone oil tamponade, silicone oil removal, and smaller size of retinectomy.

Of 145 patients managed with retinectomy, de Silva et al.<sup>54</sup> reported visual acuity of 20/60 or better in 16%, between 20/60 and 20/400 in 33%, and <20/400 in 51%. There was complete retinal reattachment in 68%. They found with each stepwise increase in the grade of preoperative PVR, there was an approximately 15% increased risk of final visual acuity of <20/40. They found that the use of 360° prophylactic laser retinopexy prior to removal of silicone oil was associated with a higher rate of final retinal reattachment.

Tan et al.<sup>55</sup> advocate retinectomy without a scleral buckle for eyes with anterior PVR without an existing scleral buckle. Of 123 eyes, the single operation success rate was 77% with a final reattachment rate of 96% after one or two additional procedures. They demonstrated significant improvement in visual acuity, and hypotony was present in only 4.1%.

There are several reports of the results of 360° retinectomy. Faude et al.<sup>56</sup> reported 30 eyes with advanced PVR or proliferative diabetic retinopathy treated with 360° retinectomy. Silicone oil tamponade was used in all eyes. At 10 months, VA had improved in 47% and the retina was attached in 83%. Hypotony was present in six eyes.

Zhang and Jiang<sup>57</sup> reported 26 cases with more than 6 months follow-up after 360° retinectomy following severe ocular trauma. The retina was reattached in 77%, and visual acuity was 4/200 or better in 70%, 20/400 or better in 35%, and 20/200 or better in 11.5%. In a mixed series of 30 eyes with more than half secondary to ocular trauma, Kolomeyer et al.<sup>58</sup> reported the retina attached at 6 months

in 83% of 30 eyes with 360° retinectomies, but only 11% with ambulatory vision. Garnier et al. reported similar results in 20 eyes.<sup>59</sup> Only 10% recovered visual acuity of 20/200 or better.

Williamson and Gupta reported a technique of planned delayed retinectomy for PVR in 27/87 eyes operated on for advanced PVR.<sup>60</sup> In the first operation, they partially reattached the retina with vitrectomy and silicone oil, then returned to surgery at a later date to do a relaxing retinectomy and completely reattach the retina. Following silicone oil removal, 24/27 eyes (89%) had complete retinal reattachment.

Stopa and coworkers, in a nonrandomized study, compared the anatomic and visual results of 25 adult patients and 20 pediatric patients, each group managed with vitrectomy and retinectomy for retinal detachment.<sup>61</sup> Reattachment rate was higher in adults than children (88% vs. 60%,  $p=.041$ ), and visual acuity was better in the adult group. Children required more reoperations ( $p=.008$ ) and postoperative PVR was significantly more frequent in pediatric eyes ( $p=.003$ ).

## Complications

Relaxing retinectomies can have several potentially serious complications. Because these complications can sometimes lead to surgical failure, retinectomy should not be taken lightly and other methods should be used if possible. The major complications of retinectomy are hemorrhage, inability to unfold and reattach the retina, visual field loss, hypotony, fibrous proliferation from the retinectomy site, and persistent traction leading to retinal detachment when the retinectomy is too small.

Hemorrhage may result from inadequate diathermy of the vessels. Relatively heavy diathermy should be applied to close the blood vessels within the area of retinectomy. Although the retina between the vessels may not bleed in some cases, there may be oozing from smaller vessels in other cases. Optimal control of systemic blood pressure might reduce the chances of hemorrhage.

Because of the potential for hemorrhage, we prefer to treat the retina with a row of diathermy before cutting. Fibrotic retina may have many blood vessels requiring more extensive diathermy.

Raising the infusion bottle temporarily, causing an increase in intraocular pressure, can usually control intraoperative hemorrhage. Use of a combination diathermy and fiberoptic light source (fiberoptic tissue manipulator, Alcon Laboratories, Fort Worth, TX) will allow readily available diathermy in the event of hemorrhage during a retinectomy.<sup>62</sup> This manipulator, currently only available in 20-gauge, has infusion capability, so a small stream of fluid can be injected and directed toward the bleeding site to uncover the bleeding vessel and allow precise placement of diathermy.

Complete hemostasis is essential because inadequately diathermized vessels may reopen later, causing a significant postoperative hemorrhage. Postoperative hemorrhage under silicone oil can lead to severe fibrous proliferation. In gas-filled eyes, recurrent hemorrhage can sometimes be removed with repeat postoperative fluid–gas exchange.

Inability to unfold and reattach the retina may occur after retinectomy when the retina retracts posteriorly and resists unfolding because of retinal contraction in longstanding PVR or other conditions such as retinopathy of prematurity. Most flaps can be manipulated and unfolded with PFCL. Only rarely does one encounter an eye in which contraction is so severe that the retina cannot be unfolded with any method.

Anterior retinal neovascularization, probably secondary to ischemia in avascular retina anterior to the retinectomy, is a possible late complication that can result in hemorrhage.<sup>63</sup> Complete removal of residual anterior retina or its ablation with laser is necessary to avoid this adverse event.

Hypotony is seen in some eyes after large retinectomies. In the report by Morse et al.,<sup>64</sup> hypotony (intraocular pressure  $\leq 5$  mmHg) developed in 43% of reattached eyes. In the Silicone Study,<sup>48</sup> the incidence of hypotony following retinectomy was 24% at 12 months. More recent series have reported a much lower incidence of hypotony following retinectomy.<sup>49–52,55</sup> This complication is probably most often related to the PVR process with fibrosis and detachment of the ciliary body associated with anterior proliferation. Another possible etiology of hypotony is increased absorption of intraocular fluid from the large area of exposed RPE.

Whether the latter is a significant factor in the production of hypotony is unknown.

Subretinal retention of PFCLs occurs in up to 12% of cases, usually associated with large peripheral retinectomies.<sup>16</sup> Posterior small to medium-size retinotomies rarely lead to this complication. Saline wash after removal of PFCLs may have a preventive role in both preretinal and subretinal retention. As discussed above, the need to remove retained postoperative subretinal PFCL depends upon the amount and location.

Visual field loss may occur if a retinotomy or retinectomy is made too close to the optic nerve or macula.<sup>12</sup> Relaxing retinectomies should be made in the periphery, and it is better to make a larger peripheral retinectomy, even to the extent necessary to fold the retina over to gain access to more posterior pathologic processes, than to make a posterior retinectomy that may produce marked loss of visual field.

Retinal pigment epithelial and choroidal damage can occur during retinectomy because of trauma due to scissors, vitrectomy instruments, endolaser probes, or other devices. This complication is most likely to happen if the retina is attached or only shallowly detached, such as in retinectomies near the ora serrata during macular translocation. It may lead to immediate choroidal hemorrhage that needs to be controlled by raising intraocular pressure or cauterization. Sometimes damage to Bruch's membrane will lead to development of choroidal neovascularization in the postoperative period.<sup>65</sup>

Fibrous proliferation from the retinectomy site most commonly follows the use of silicone oil. Reproliferation often occurs if there is hemorrhage beneath the silicone oil. The fibrous proliferation may bridge between the edge of the cut retina and more anterior structures, and occasionally retraction of fibrous tissue will redetach the retina. In patients with diabetes, the membranes may be vascular and cover a large section of retina. There may also be a release of cells from a large bed of exposed RPE, leading to fibrous proliferation elsewhere. The surgeon should try to avoid re proliferation by meticulous control of hemorrhage.

Postoperative fibrin may be a matrix for re proliferation, so accumulation or deposition of fibrin should be prevented if

possible. Preoperative and postoperative corticosteroids and nonsteroidal antiinflammatory agents may play a role in preventing deposition of fibrin. Tissue plasminogen activator will lyse postoperative fibrin.<sup>66</sup> If significant re proliferation and traction are seen, early reoperation with removal of the membranes may be successful in stabilizing the eye.

Persistent traction leading to retinal detachment when the retinectomy is too small is not a complication of the retinectomy but rather a complication of inadequate retinectomy. It is important to extend the retinectomy into more normal retina beyond each end of the area of traction. Extension of a large circumferential retinectomy obliquely anteriorly to the ora serrata on each end of the retinectomy and excision of anterior retina should allow maximal release of traction.

One of the major limiting factors in visual recovery following vitrectomy with retinectomy is abnormal macular status following surgery. Stopa and Kociecki<sup>67</sup> found optical coherence tomography evidence of macular abnormalities in 75% of 25 patients following retinectomy including retinal pigment epithelium irregularities, cystoid macular edema, epiretinal membranes, subretinal fluid, and subretinal PFCL. Fluorescein angiographic studies of the retina in eyes with healed retinectomies showed that the attached retina had very little change as a result of the retinectomy.<sup>65</sup> An intact blood–retinal barrier was found in areas of uncovered RPE. Complications noted on angiography included occasional choroidal neovascular membranes at the retinotomy site, cystoid macular edema, optic atrophy, pigment fallout, depigmented tracks, and choroidal folds. Most complications were believed to be nonspecific findings following vitrectomy and retinal detachment surgery.

In a nonrandomized comparative study, Odrobina et al. compared two groups, each with vitrectomy and retinectomy  $\geq 180$  degrees.<sup>68</sup> Group A had peeling of the ILM in the posterior pole and group B did not have the ILM peeled. Although visual results were similar, the group with ILM peel had significantly less macular pucker formation (0/33, 0% vs. 9/51, 17.6%,  $p=.008$ ).

## **Introduction**

Giant retinal tear by definition is a retinal tear of more than 90° circumferential extent.<sup>1</sup> Since the posterior vitreous is detached, the vitreous gel is adherent to the anterior flap. Hence the posterior flap has a tendency to fold over. In contrast, in a giant retinal dialysis the retina is either torn at the ora serrata or there is a break in ciliary epithelium, with the vitreous being adherent to the posterior

retina.<sup>2</sup> Thus the posterior flap does not have the tendency to fold over, since it is supported by the vitreous gel.

The management of fresh giant retinal tear is an emergency. The delay in surgical intervention could lead to significant proliferative vitreoretinopathy (PVR) changes jeopardizing reattachment of the retina and eventual visual gain. Before the introduction of perfluorocarbon liquids by Stanley Chang,<sup>3</sup> the management of giant retinal tear was challenging and resulted in limited success. The present day management of giant retinal tear is reasonably straightforward with predictably good success rate.<sup>4</sup>

## Etiology

Most giant retinal tears are idiopathic in origin with males being at higher risk. Traumatic giant retinal tears are commonly located in the upper nasal and lower temporal quadrants and are again commoner in males. In a population-based study in the United Kingdom, Ang et al. have reported an annual incidence of 0.091 patients per 100,000 population.<sup>5</sup> Most of the cases were idiopathic (54.8%) and males predominated (71.7%).<sup>5</sup>

The association with high myopia is well established.<sup>6</sup> Of all retinal detachments in Marfan syndrome, 11.3% have been reportedly caused by giant retinal tears.<sup>7</sup> Retinal detachment, especially due to giant retinal tear, has been identified as an important complication of Stickler syndrome.<sup>8,9</sup> Other diseases associated with occurrence of giant retinal tear include the Ehler-Danlos syndrome,<sup>10</sup> lens coloboma,<sup>11</sup> and aniridia.<sup>12</sup> Giant retinal tears can also occur following acute retinal necrosis<sup>13</sup>

## Iatrogenic Giant Retinal Tear

Special mention should be made of the occurrence of giant retinal tear during/after intraocular surgery.

1. During a cataract surgery misadventure.<sup>14</sup> If attempts are made to fish around for the dislocated nucleus, giant retinal tear can easily occur due to the uncontrolled vitreous traction.

2. During vitreoretinal surgery.<sup>15,16</sup> Circumstances that predispose to such an occurrence are:

- a) Inadvertently large leaky sclerotomies with prolapsing vitreous gel.
- b) During extraction of a foreign body, especially a large one with irregular surface that can engage the gel vitreous in the vitreous base area.
- c) Too frequent exchange of instruments prior to good vitrectomy.

Use of minimally invasive vitrectomy and wide-angle visualization have definitely reduced the incidence of the iatrogenic giant retinal tears.

1. Giant retinal tear has also been reported after pneumatic retinopexy and has been attributed to partly detached vitreous that exerted traction following the expansion of the bubble of expansile gas.<sup>17,18</sup>

2. Shinoda et al. have reported the occurrence of giant retinal tear due to jamming of the 25G instruments in the cannula, while operating on eyes with vitreous hemorrhage.<sup>19</sup>

3. Giant retinal tear has also been described after refractive surgery in the form of LASIK<sup>20</sup> and phakic IOLs,<sup>21</sup> although the cause and effect relationship remains debatable.

4. Barrage laser for subclinical retinal detachments in rare instances may lead to giant retinal tear along the line of treatment.<sup>22</sup> The occurrence of giant retinal tear has been attributed to a combination of thin retina due to high myopia and heavy treatment.

5. During surgery for retinal detachment with PVR, giant retinal tear may be the result of a deliberate relaxing retinotomy.

## Pathogenesis

Schepens first described the important role played by the vitreous in giant retinal tear. Central vitreous liquefaction is associated with condensation in the peripheral vitreous base that leads to traction on the peripheral retina.<sup>1</sup> As traction progresses, it is evident clinically as spreading white without pressure. Later, transvitreal contraction of the cortical gel occurs, tearing the retina along the vitreous base in a zipper fashion. Sometimes, multiple horseshoe-shaped tears may form along the posterior vitreous base and coalesce to form a giant retinal tear. Radial extensions (horns) can occur at the two ends of the giant retinal tear. Eyes with radial extension invariably have some amount of vitreous hemorrhage since the tears cut across larger blood vessels posteriorly.

A giant retinal tear nearing 180° in circumferential extent has a tendency to fold over. The size of the giant retinal tear also has an effect on the amount of retinal pigment epithelium (RPE) that gains access to the vitreous cavity, thus increasing the risk of PVR. Giant retinal tear occurring after penetrating injuries has high risk of PVR while giant dialysis tends to progress very slowly.

## History of Management of Giant Retinal Tear

The management of giant retinal tear can be divided conveniently into pre- and post- perfluorocarbon liquids (PFCL) eras. Most techniques used in the pre-PFCL era are of historic importance. However, a brief mention of these techniques is relevant in the overall understanding of the management of giant retinal tear. The primary problem faced by the surgeon was the gravity-driven tendency of the flap of the retinal tear to fold and fall back. Scleral buckles have been done for tears of smaller extent (around 90°). A relatively shallow but broad buckle was aimed at so that the tendency for the flap to slip back is reduced and the inevitable central sagging of the flap is accommodated on the broad buckle.<sup>23</sup> Attempts were also made to rotate the patient and reposition the retinal flap with the help of an air bubble.<sup>24</sup> Vitreoretinal surgery

helped mobilize the inverted flaps of large giant retinal tears, but the surgeon still faced difficulty in unrolling the same and fixing it in position. One strategy was to divide the giant retinal tear into smaller segments by pinning the edge of the tear down to the RPE/choroid complex using retinal tacks<sup>25,26</sup> or sutures.<sup>27</sup> This enabled routine fluid–air exchange to fix the retina without slippage of the retinal flap. Another technique involved fluid–air exchange in prone position. After a vitrectomy (and sometimes placement of buckle), the sclerotomies were closed and the patient was turned prone. Without contaminating the operative field, fluid–air exchange was then performed, with the air injection being done in front of the optic disc and fluid being evacuated from the anterior chamber.<sup>28</sup> The air progressively attached the retina posteroanteriorly. The patient was repositioned in the supine position, and internal tamponading agent was injected – gas or silicone oil as the case may be. Among all these techniques, perhaps the best attachment of the retina with no folds or slippage was seen with prone fluid–air exchange following vitrectomy.

However, with the use of PFCLs the surgery has become much simpler.

## Preoperative Evaluation and Planning

A thorough evaluation of both the anterior and posterior segments is important to plan the surgery properly. Corneal and lens status must be noted. Perforating injury-related retinal detachments with vitreous incarceration and giant retinal tear can have associated corneal problems such as generalized haze due to edema, opacity, Descemet membrane folds, etc. The lens could be subluxated due to the blunt trauma and could be also cataractous.

Pseudophakic eyes can also have specific problems. The IOL could be tilted or subluxated (especially in eyes that had capsular dehiscence and vitreous disturbance during cataract surgery). Deposits on the IOL and posterior capsule opacification can interfere with surgery. A decision as to the need to remove the IOL should be taken based on this evaluation. There is, however, no justification to remove a well-placed IOL.

The intraocular pressure (IOP) could be low, normal, or high. A

low to very low IOP is seen in relatively recent giant retinal tears and often associated with choroidal detachment. One may choose to treat such cases with a course of systemic steroids for a few (3–5) days before performing the surgery. High intraocular pressure is rare at the time of presentation with acute giant retinal tear even in eyes with preexisting glaucoma. However, eyes with traumatic dialysis can have persistent high pressures despite presence of retinal detachment. Following reattachment of the retina, one should anticipate an acute rise in intraocular pressure. Hence arrangements for frequent IOP monitoring must be in place. It is only rarely that a glaucoma surgery needs to be combined with the retinal reattachment surgery.

The posterior vitreous will be found to be detached in cases of giant retinal tear, unlike in dialysis. In eyes that had blunt injury, the vitreous base can be avulsed and is seen as a rope-like structure near the pars plana. In eyes with perforating injury or following cataract surgery misadventure, the vitreous could be incarcerated in the wound and is seen as a transvitreal membrane. The giant tear or dialysis is seen usually in the opposite quadrant.<sup>14</sup>

The extent of retinal detachment can vary. A dialysis can be associated with chronic partial detachments of the retina with high-water marks, while giant retinal tear is usually associated with a more rapidly spreading retinal detachment. Eyes with around 90° tears are characterized by sagging of the center of the tear posteriorly but do not show inversion of flap. However, if the two ends of the giant retinal tear trail significantly posteriorly (horns), the retinal flap that is enclosed in between can fold back. Retinal tears that are nearing 180° circumferentially will show a tendency to fold back. The inverted flap can sometimes obscure the disc (Fig. 113.1). The edge of the tear usually is scrolled inwards despite lack of obvious PVR elsewhere. The pars plana epithelium can be detached in the area of tear and sometimes beyond, due to the vitreous base traction. The anterior flap of the retina can harbor lattice degeneration. Additional horseshoe tears can be seen in other quadrants near the posterior vitreous base. A macular hole can coexist – especially in eyes that are highly myopic or where the giant retinal tear is a result of blunt injury. Significant pigment dispersal is seen in the vitreous cavity, and pigment is often seen

adherent to the surface of the retina. A traumatic dialysis is often associated with evidence of damage to the RPE and choroid at the site of the ora serrata.

**FIG. 113.1** Fundus photograph showing giant retinal tear with inverted flap that is obscuring the optic disc. Note the retinal blood vessels seen through the thickness of the edematous inverted retina.

## Ultrasonographic Diagnosis of Giant Retinal Tear<sup>29</sup>

In eyes with opaque media, giant retinal tear can be suspected on ultrasonography. A suggestive feature is a discontinuity in the retinal echo anteriorly and extending more than one quadrant. Double linear echo would be seen near the disc due to the close proximity of the two layers of the retina – one representing the flap of the giant retinal tear and hence discontinuous with the globe contour and the other representing the detached retina and hence continuous with the globe contour (Fig. 113.2).

**FIG. 113.2** Ultrasonography in an eye with giant retinal tear. Note double linear echo close to the optic disc: the inner layer is discontinuous while the outer layer is continuous with the globe contour.

## Proliferative Vitreoretinopathy (PVR)

The vitreous base can contract circumferentially and anteroposteriorly causing a significant anterior loop, evident in the peripheral retina that is not involved in the giant retinal tear. The inverted flap of the retina can get adherent to the opposite detached retina, especially when vitreous is incarcerated in a wound.

Extensive membranes can form on both sides of the retina – both focally and diffusely. In badly traumatized eyes, the anatomy can be fairly distorted and the true nature of the detachment and the presence of giant retinal tear will be evident more during the surgery than preoperatively. A 360° retinal tear with PVR has the worst-looking configuration. The entire retina can be seen to be lying posteriorly, crumpled around the disc, and wrapped around by fibrotic tissue. It is not possible in all such cases to assess the operability or otherwise of the retina preoperatively.

Eyes with acute retinal necrosis can develop giant retinal tear at the posterior edge of the retinitis patch. There will be tell-tale signs of the previous retinitis anteriorly, characterized by very thin, atrophic, parchment-like retina in the involved area.

## Role of Nonsurgical Treatment

### Laser Barrage Photocoagulation

Very occasionally one may get an opportunity to barrage the dialysis/tear with laser photocoagulation if the lesion is detected before it has resulted in clinical retinal detachment. Such an event is more likely with a dialysis where clinical retinal detachment takes some time to develop. Laser treatment would involve production of 2–3 rows of retinal burns along the posterior limit of the dialysis/tear and continuing the treatment anteriorly to meet the ora on the either side. Indirect delivery of laser assisted by scleral indentation would be needed to complete the treatment satisfactorily. Cryopexy is also an option but is best avoided in view of increased risk of PVR.

### Outpatient Fluid–Gas Exchange Followed by Cryopexy or Laser Photocoagulation

Fresh giant retinal tears noted following a vitreoretinal surgery can sometimes be managed by outpatient fluid–air exchange followed by retinopexy with laser or cryo, thus avoiding a major resurgery. A push–pull technique or a two-needle technique can be used to inject 12–14%  $C_3F_8$  gas while removing the vitreous fluid. A two-needle technique has the advantage of not permitting gross fluctuations in the intraocular pressure and has less risk of the uncut vitreous gel or the giant retinal tear flap getting caught in the needle. Following the fluid–gas exchange, laser would be possible by the next day, by which time the retina is well attached and the gas has formed a single bubble (without frog eggs).

## Role of Simple Scleral Buckling

In the present era, where vitreous surgery has become the desired approach to fix even simple retinal detachments with horseshoe tears, most surgeons would not perform simple scleral buckling for giant retinal tear of any degree. The role of scleral buckling is perhaps restricted to cases of giant retinal dialysis. In the absence of

a vitreous detachment and in these usually younger patients, a vitrectomy approach may not be ideal in cases with dialysis. Scleral buckling would suffice in most such cases.

## Technique of Simple Scleral Buckling

After the recti muscles are tagged, the two ends of the dialysis are localized. It is expected that the center of the dialysis will sag to some extent, hence a broader than anticipated tire is used to accommodate the expected sag in the center. The surgeon should aim for a shallow buckle. Cryo is done to the posterior edge of the dialysis and is connected to the ora serrata at both ends. Most dialysis-related retinal detachments tend to be chronic in nature and are best drained. The drainage is done as posteriorly as possible to avoid the vitreous tracking into the perforation site through the open dialysis. It is also useful to indent anteriorly with a cotton-tipped applicator, so as to effectively approximate the dialysis edge to the underlying RPE while permitting the posteriorly trapped SRF to exit without danger of vitreous finding its way to the perforation site.

A similar technique can be potentially adopted with a giant retinal tear of about 90°. The risk of central sag of the retina is even more than with the dialysis. Gas injection would help smooth the folds on the buckle. Cryopexy of the edge of the giant retinal tear could also pose a problem if it is lifted significantly away from the RPE. The risk of excessive treatment of the bare RPE/choroid exists.

## Vitreous Surgery

In the current scenario, most cases of giant retinal tear would be managed by a vitreoretinal approach.

## Role of Encircling Band With Vitreoretinal Surgery

Many surgeons feel comfortable placing an encircling band even in eyes undergoing vitreoretinal surgery.<sup>30</sup> An encircling band is expected to support the vitreous base and reduce the risk of

recurrent detachment taking place from the quadrants where there is no retinal tear. However, there are reports that the success rate of surgery for fresh giant retinal tear is not reduced by not placing the buckle.<sup>31</sup> In addition, minimally invasive sutureless vitreous surgery is possible if one is not placing the buckle.<sup>32</sup> The trick is in the use of a wide-angle system of visualization and radical vitreous base removal.<sup>33</sup> In the presence of some degree of PVR, placement of an encircling band is desirable.

## Lens Management

The options for lens management are (1) leave it untouched; (2) lensectomy and leaving the eye aphakic; (3) lens removal and keeping the posterior capsule intact for future IOL placement; and (4) lens removal and IOL placement same time. The exact approach would depend on the individual case, the surgeon's choice, and the ability to be reasonably certain of the power of the IOL to be implanted. In general, IOL placement would be avoided in eyes with severe PVR. In fresh giant retinal tears, IOL placement is possible, especially if a buckle is not being placed. Guidance from previous refractive status and fellow eye measurements would be needed to calculate the IOL power. In eyes with gross subluxation of the lens, scleral fixation of IOL is an option, but is best deferred to a later date. In eyes where silicone oil is being used as a tamponading agent, one can leave the eye aphakic at the first sitting and implant the IOL at time of silicone oil removal.

## Management of Intraocular Lens

A well-positioned IOL is not an issue in the management of giant retinal tear. However, IOL can be associated with problems such as deposits of pigment and inflammatory precipitates on the IOL surface, posterior capsule opacification, tilt, and displacement of IOL (especially if the cataract surgery had been eventful). As long as the visualization is not hampered, the IOL need not be disturbed. Simple maneuvers, such as creating an opening in the posterior capsule or gently scraping the precipitates on the IOL surface under viscoelastic fill of the anterior chamber, can greatly improve the visualization. Silicone IOLs can be associated with problems when

silicone oil is injected, especially if there is posterior capsule opening. The oil tends to stick to the posterior exposed surface of the IOL, and at the time of silicone oil removal, a film of oil remains permanently adherent to the IOL surface. This, however, is not an absolute indication to remove the IOL.

Explanting the IOL is best done through a scleral tunnel rather than a clear corneal wound. With scleral entry, there is much better maintenance of corneal clarity during the subsequent vitreoretinal surgery. A scleral wound is also less prone to leak even when the eye is distorted, e.g., during scleral indentation.

## Visualization

With the advent of wide-angle viewing systems, the management of giant retinal tear has considerably improved. It is a tremendous advantage to be able to visualize the periphery without losing view of the posterior pole, especially while exchanging the PFCL with gas or silicone oil. Landers lens system even with prism lenses would be a poor substitute. However, a Landers lens or similar contact lens would be useful for internal limiting membrane (ILM) peeling, if there is associated macular hole.

Handheld illumination and three-port vitrectomy will suffice in cases of fresh giant retinal tear. In badly traumatized eyes with giant retinal tear (especially when the tear is 360°), and in eyes with severe PVR, bimanual surgery would be required. The choice is between using a combined instrument such as an illuminated pic or making a fourth sclerotomy and placing a chandelier light pipe.

## Vitrectomy

Vitreous removal is perhaps the easiest of the steps in giant retinal tear surgery. With a total PVD that is most often associated with a giant retinal tear, all the vitreous lies anteriorly and can be easily removed. In fresh giant retinal tear, the flap tends to be mobile and care should be exercised to prevent accidental unnecessary nibbling of the flap. While placing the infusion cannula one should be aware that some eyes with profuse hypotony can have significant ciliochoroidal edema/detachment. Placement of a 6-mm infusion cannula can reduce the risk of suprachoroidal infusion, but the

surgeon must ensure that the tip is seen inside the vitreous cavity before switching on the infusion. If the cannula tip is not seen, a MVR blade introduced through one of the upper sclerotomies can be used to cut the tissue overlying the tip of the infusion cannula. A loose pars plana epithelium can also drape round the infusion cannula but can be easily removed with the cutter.

In eyes with vitreous in the anterior segment wound and a giant retinal tear, the first step would be to excise the incarcerated vitreous and allow the retina to fall back before performing the rest of the vitrectomy.

## **Radical Excision of the Vitreous Base**

The vitreous base is debulked to the maximum extent possible. However, to be able to perform this step adequately, the posterior pole and the retinal flap should be kept down with a bubble of PFCL. Otherwise the retinal flap will keep getting sucked into the port even while working in the opposite quadrant. Even in phakic eyes, a good amount of debulking is possible without lens sacrifice by having the assistant indent the sclera.

## **Mobilizing the Retina and Management of Anterior Retinal Flap**

The anterior retinal flap to which the vitreous is adherent should be excised as much as possible. If the same is left behind, it can get fibrosed and also exert traction on the ciliary body. As mentioned, the edge of the giant retinal tear tends to scroll in, and this does not necessarily indicate fibrosis along the edge. However, if the edge is stiff, it can be excised. Inspection of the retina should include the assessment of PVR and the location of the fibrosis – pre- and subretinal. In cases of fresh giant retinal tear, the retina will be freely mobile and the inverted flap can be lifted up with the intraocular instruments. Despite absence of frank PVR, one very often sees pigment deposition on the surface of the retina, especially inferiorly. The pigment clumps can be relatively adherent to the surface of the retina and could indicate early attempts at proliferation. One may have to use fine instruments such as a

membrane scratcher (rake) to remove these immature membranes. Loose pigment can be removed with a brush needle. Meticulous removal of such immature membranes can reduce the risk of recurrent retinal detachment.

## Eyes With PVR

In eyes with PVR, the anatomy could be varied depending on the severity. Some description on the pathoanatomy has been given in the section on preoperative evaluation. In general, the posterior pole is cleared first, a bubble of PFCL is placed to stabilize the posterior pole, and then the rest of the dissection is carried out. A combination of spatula, scratcher, and forceps would be needed. As one proceeds with the dissection, more membranes become evident, especially by placing the retina on stretch with additional PFCL. Injecting too much PFCL in the initial stages without adequate relief of posterior traction will result in the bubble finding its way into the subretinal space. The subretinal PFCL may need to be removed before further dissection. Subretinal fibrosis is identifiable once most of the preretinal traction is relieved. In the presence of giant retinal tear, removal of the subretinal membranes should not be difficult. The ease of attaining complete relief of traction would depend on the severity of the PVR. Anterior circumferential traction would usually need bimanual dissection while keeping the posterior pole down with PFCL.

In eyes presenting with 360° giant retinal tear and PVR, picking up the membranes with forceps could become difficult, since the retina does not offer any resistance and moves with the forceps. With bimanual surgery, the dissection can be done comfortably. Appearances can be deceptive and what looks like an apparently inoperable bunched up retina lying in the posterior pole can open up to reveal a relatively healthy posterior retina. Delay in performing surgery after penetrating injury greatly increases the risk of the retina becoming contracted and inoperable.

## Conversion to 360-Degree Tear

If peripheral traction relief is not adequate, it is best to excise the peripheral retina along with the fibrosis, rather than trying to

compromise, by placing a buckle underneath an area of unrelieved peripheral traction. Converting a giant tear to a 360° tear does not worsen the prognosis.

While excising the peripheral retina, it may be worthwhile to leave behind tags of attachment to the ora, till PFCL is placed up to the arcade. Then the residual tags can be cut to convert it into a 360° tear. This may sometimes permit proper orientation of the macula. In view of the extreme distortion of the retina due to the PVR, there can be tendency for the macula to be shifted to abnormal locations, necessitating manipulation of the retina under the PFCL. On occasions, areas of residual traction are identified after reattaching the retina with PFCL. Some of these membranes can be removed under PFCL. If not, one should not hesitate to remove the PFCL to facilitate removal of the newly identified membranes and then reinject the PFCL. The edge of the giant retinal tear can be folded under the PFCL. As long as there is no fibrosis, these edges are easily smoothed with the help of a spatula. A silicone brush can also be used to stroke the edge into position. Fibrosed edges must be excised.

## Perfluorocarbon Liquids

Several properties make these liquids well suited for vitreoretinal surgery, namely the specific gravity (greater than water), transparency (can see and treat the retina underneath), low viscosity (easy to inject and easy to remove), excellent tamponading effect (good retinal flattening), and a refractive index that is different from the infusion fluid (visible interface). PFCLs are useful at several stages of the surgery: (1) during membrane dissection to stabilize the posterior pole; (2) for facilitating internal limiting membrane removal around macular hole in detached retina; (3) for reattachment of the mobilized retina without fear of posterior slippage; (4) for medium-term tamponade.

### Injection of PFCL

Wide-field visualization is very useful in this step. The initial bubble of PFCL is injected over the optic disc to unfurl the folded retina. Further injection is done into the main bubble to prevent

formation of multiple bubbles. Forceful injection should be avoided since the jet of the liquid can tear through retina and can even cause choroidal bleed. The PFCL bubble is injected till it flattens the edge of the giant retinal tear. One should be cognizant of the fact that there is subretinal fluid anterior to the bubble in the areas where the retina is not torn from the ora serrata.

In eyes with 360° retinal tear and some intrinsic contracture of the retina, injection of the PFCL may not result immediately in a smoothly attached retina. There will be tendency for the retina to form circumferentially oriented folds around the disc. If the contracture is not severe, the folds can be smoothed with help of a blunt instrument – used to massage the retina gently. A flat retinal spatula, a knob spatula, or even the tip of the vitreous cutter can be used for this purpose. In eyes with severe retinal contracture, there will be a tendency for the PFCL bubble to roll off the retina, leaving it bunched up around the disc. At this stage one may have to accept the inability to reattach the retina.

## **Retinopexy**

Endolaser is the preferred modality of retinopexy. By tilting the eye to the same side, the edge of the giant retinal tear can be kept entirely under PFCL, thus facilitating the application of the laser along its edge. In general, about 3–4 rows of burns are applied along the margin. It is best to treat 360° including the peripheral retina, beyond the area of the giant retinal tear.<sup>34</sup>

The peripheral retina beyond the giant tear will still have subretinal fluid anterior to the PFCL bubble, and this would make it difficult at this stage of surgery to produce burns till the ora serrata in this area. Treatment of this anterior retina is easier done once the PFCL is exchanged with silicone oil or gas and the residual anterior subretinal fluid is removed. In phakic eyes, anterior treatment is done with laser delivery by indirect ophthalmoscope (LIO). Only very rarely is cryo resorted to.

## **Internal Tamponade**

The choice of internal tamponade is between long-acting gases such as 12–14% C<sub>3</sub>F<sub>8</sub> or silicone oil. SF<sub>6</sub> and air are not suited, in view of

the large extent of the tear and the need for extended period of support.

### **PFCL–Air Exchange**

This is the step when slippage of the retinal flap can potentially occur. The edge of the tear should be dried frequently before removing the main PFCL bubble. In view of the relatively rapid sequence of events (unlike with silicone oil), there is a tendency for fluid pockets to be trapped anteriorly and then getting pushed under the retina as the PFCL is removed – leading to retinal slippage characterized by circumferentially oriented folds in the quadrant of the tear. Depending on the extent of the tear and the amount of residual subretinal fluid, the extent of slippage varies. The macula can be involved in these folds in cases of temporal tears. Attempts at drying the edge of the tear at this stage does not usually succeed since the air keeps the fluid trapped posteriorly. Some surgeons suggest leaving behind some vitreous fluid and then positioning the patient prone to permit postoperative smoothing of the folds. Posterior retinotomy is not recommended. It is perhaps best to reinject the PFCL and perform the exchange with gas more carefully or opt for silicone oil–PFCL exchange.

### **PFCL–Silicone Oil Exchange**

Directly exchanging PFCL with silicone oil has the least chance of retinal slippage. One should understand the fluid dynamics during this process to obtain best results with least complications.

1. As the silicone oil is being injected it forms initially a circular bubble. Once it comes in contact with the central part of the upper meniscus of the PFCL, further injection flattens the anterior surface of the PFCL bubble, thus spreading it over a larger surface of the retina.
2. The balanced salt solution (BSS) will slowly be pushed into a circumferential ring all round, sandwiched between the oil and PFCL. One should not forget the rim of subretinal fluid that is trapped anterior to the PFCL in the area outside the giant retinal tear ([Fig. 113.3](#)).

**FIG. 113.3** Drawing demonstrating the concept of circumferential ring of fluid trapped between silicone oil and perfluorocarbon liquids (PFCL). Unless this fluid is completely removed before removing the PFCL, slippage of the giant retinal tear flap can occur.

3. BSS, subretinal fluid, as well as PFCL can be easily sucked with both active and passive suction devices. Silicone oil will tend to block the suction device. Hence while injecting silicone oil, sudden rise in IOP can occur if suction port is located within the silicone oil bubble. Failure to notice the raising IOP can result in some unpleasant consequences such as (1) the edge of retinal flap getting sucked into the port of the suction device, (2) snapping of corneal sutures in eyes with recently repaired corneal wounds, or (3) iris prolapse through a gaping scleral or corneal wound that has been made for IOL explantation.

4. Intermittent injection of silicone oil coupled with careful positioning of the suction tip at the edge of the giant retinal tear and just beyond the PFCL bubble margin will result in slow evacuation of the circumferential ring of BSS. Even the fluid located in the opposite quadrant will find its way to the site of suction and the subretinal space becomes totally dry. It is easy to distinguish between the residual fluid and silicone oil by the ease with which it finds its way into the suction port. Once all the fluid is removed, the PFCL bubble can be removed. Intermittently one can go back to the edge of the giant retinal tear to make sure that it is dry. Slow injection of the silicone oil will permit controlled removal of the

PFCL, and the endpoint is clearly visualized.

5. If the suction port is blocked with silicone oil, the IOP will rapidly rise as evidenced by appearance of central retinal artery pulsations and rapidly developing corneal edema. If the suction port is now shifted to the PFCL bubble, the block reopens as the PFCL washes the silicone oil out and one can clearly see the perfusion returning.

[Figs. 113.4](#) and [113.5](#) show pre- and postoperative photographs of a case of giant retinal tear. Note the postoperative photograph shows early PVR inferiorly.

**FIG. 113.4** Preoperative photograph of an eye with 180° giant tear and folded flap.

**FIG. 113.5** Postoperative photograph of the eye in Fig. 113.4 showing attached retina and early proliferative vitreoretinopathy (PVR) inferiorly. Note the reflexes due to silicone oil.

## Alternative Techniques

1. *PFCL as medium-term tamponade*: In this technique, PFCL are injected during the first stage and retained for 5–10 days, during which period the patient is encouraged to lie supine. A second procedure is then performed to exchange the PFCL with gas or silicone oil.<sup>35,36</sup>
2. *Air–PFCL exchange followed by air–silicone oil exchange*: Some surgeons are not comfortable with direct silicone oil–PFCL exchange and perform first air–PFCL exchange followed by silicone oil–air exchange. This, however, retains the risk of retinal slippage during the first step of the procedure.
3. *Use of heavy silicone oil*: Densiron is heavier than water and is made up of perfluorohexyl octane ( $F_6H_6$ ) and conventional silicone oil. This mixture has a specific gravity of 1.06 and a viscosity of 1480 mPas. It can be used both to settle the retina (since it is heavier than water) and can serve as internal tamponade. Unlike silicone oil, the inferior retina is better supported. There have been conflicting reports of its utility. The major concern appears to be that of significant emulsification that has been reported with Densiron even within 12 weeks of injection, leading potentially to

inflammation and membrane formation.<sup>37,38</sup>

## Additional Steps

1. Once the whole retina is reattached following PFCL–air or silicone oil exchange, the untreated anterior retina can be treated comfortably.

2. In aphakic eyes, a peripheral iridectomy is done inferiorly to reduce the risk of pupillary block. This step is best done before exchanging the PFCL with silicone oil. In oil-filled aphakic eyes, iridectomy can still be done by filling the anterior chamber first with BSS and then nibbling away the iris at 6 o'clock by placing the cutter behind the iris.

3. Where phacoemulsification has been done at the beginning of the surgery and IOL implantation is planned, this step is best done just before PFCL–air or silicone oil exchange. Alternatively, one can implant the IOL as the first step of the surgery along with the phacoemulsification and then proceed with the vitreoretinal surgery. However, the additional optical interfaces are avoided if the IOL is placed subsequent to reattachment of the retina.

4. *Management of associated macular hole:* Macular hole not uncommonly coexists with giant retinal tear, especially in traumatized eyes and highly myopic eyes. Once the retina is mobilized, internal limiting membrane can be peeled around the macular hole. A small bubble of PFCL placed on the macular area helps achieve this goal. Staining of the ILM can be done with brilliant blue under the PFCL bubble. By injecting small quantities of the dye with the PFCL bubble in place, one can avoid the migration of the dye into the subretinal space. Some eyes with high myopia and extensive chorioretinal atrophy in the macular area may develop large macular holes. In these eyes, the aim of treatment would be to seal the hole with laser since there are high chances of recurrence of retinal detachment.

## Results

In the previtrectomy era, Schepens and Freeman could achieve successful reattachment in only 2 out of 14 eyes.<sup>39</sup> Machemer et al. have reported a final success rate of 43% following vitrectomy with prone fluid–gas exchange and use of SF<sub>6</sub> gas, although intraoperative success was achieved in 12 of the 14 cases.<sup>40</sup> Aylward et al. reported a success rate of 89% in traumatic giant retinal tears using vitrectomy and silicone oil tamponade.<sup>41</sup> Batman et al. have reported no difference in success rate between silicone oil and long-acting gas tamponade.<sup>42</sup>

The routine use of encirclage continues to be debated, with Goezinne et al. reporting higher failure rate in the absence of encirclage,<sup>30</sup> while Kreiger et al.<sup>31</sup> (11 eyes) and Hoffman<sup>43</sup> (6 eyes) have reported success without buckle. Loewenstein et al. compared perfluoro-perhydro-phenanthrene and perfluoro-octane and found no statistically significant difference between the two groups.<sup>44</sup> The overall success was 71.7% and 78.3% respectively in the two groups. But the authors found greater incidence of retained perfluorophenanthrene compared to perfluoro-octane. This was attributed to its (perfluorophenanthrene) greater specific gravity, lesser vapor pressure, and less prominent interface with BSS. Al-Khairi et al. analyzed the prognostic factors associated with surgical results and identified phakic/clear lens at presentation, unfolded flap of the giant retinal tear, absence of postoperative cataract, and absence of postoperative PVR to be associated with better than 20/200 vision.<sup>45</sup> They also found that placement of encircling band and silicone oil tamponade were associated with higher anatomic reattachment with one procedure. In a series of 24 eyes with giant retinal tear greater than 180° Dabour used the technique of direct PFCL–silicone oil exchange in addition to encirclage. There was no incidence of slippage, and the final anatomic success was achieved in 83.3%.<sup>46</sup>

In unpublished data of management of 36 children (age group 4–16 years) with giant retinal tear, 41.7% were found to have severe PVR at presentation, suggesting a delay in diagnosis.<sup>47</sup> Nearly 50% of them had an abnormal fellow eye (phthisis in 16.8%, anophthalmic socket in 8.3%, history of repair of retinal detachment

in 19.4%, and history of giant retinal tear-related retinal detachment in 5.7%). Twenty-five percent needed more than one surgery to achieve anatomic success. The final rate of reattachment was 91.6%, but visual acuity of >20/200 was achieved in only 58.3% of the eyes.

## Management of the Fellow Eye

In a study of the natural history of the fellow eyes, Freeman has reported a 14% incidence of giant retinal tear and 36% incidence of other retinal tears.<sup>10,48</sup> High-risk fellow eyes include high myopia, eyes with progressively increasing white without pressure areas with sharp posterior margin and increased vitreous condensation, and patients with Wagner–Stickler syndrome. In a series of 204 patients with Type 1 Stickler syndrome, Ang et al. reported a risk reduction from 73% to 6.5% by performing prophylactic 360° cryopexy posterior to the ora serrata. Posterior lesions were not treated in this study.<sup>8</sup> Wolfensberger et al. have reported a series of 48 eyes with giant retinal tear wherein the fellow eye was prophylactically treated with 360° cryopexy.<sup>49</sup> They found an 8% (4 eyes) incidence of retinal breaks (3 with retinal detachment) over a 84-month follow-up period, of whom 1 patient had giant retinal tear posterior to the treated area. Based on their data, the authors believe that there is justification for prophylactic treatment.

While Freeman advocated prophylactic buckling along with cryopexy,<sup>48</sup> most surgeons have resorted to only cryopexy or laser photocoagulation without scleral buckling.<sup>45,49,50</sup> Laser has the advantage of being an outpatient procedure and can be spaced over two or more sittings in an attempt to reduce the inflammation caused by the treatment.

Despite these publications, one has to admit that there is still no consensus on (1) the need for prophylaxis; (2) modality of treatment (cryo or laser); (3) where to treat (ora or equator); and (4) what to treat (visible lattice degenerations/visible areas of white without pressure or just 360° treatment). In a review of literature on interventions for prevention of giant retinal tear in the fellow eye, Ang et al. did not find conclusive evidence to support or refute the value of prophylaxis.<sup>51</sup> In Stickler syndrome, however, the evidence is more strongly in favor of offering prophylaxis for the fellow eye.<sup>8</sup>

## Extent of Ocular Injuries

It is estimated that 1.6 million blinding ocular injuries occur worldwide each year, with an additional 2.3 million people sustaining bilateral low vision from trauma, and almost 19 million with unilateral blindness or low vision.<sup>1</sup> Ocular trauma is second only to cataract as the most common cause of visual impairment in the United States. Of 2.4 million eye injuries sustained each year, up to 50,000 people are left with significant impairment.<sup>2</sup> Nearly 1 million Americans are visually impaired due to ocular trauma, of whom 7% have severe impairment and about 5% are blind in one eye. The annual cost of ocular trauma in the United States is estimated at between US\$175 million and US\$200 million for hospital care alone.<sup>3</sup> Based on data published in the United States from 2000 to 2010, the estimated total economic cost attributable to military eye injuries exceeded \$25 billion during that decade. This figure included direct costs of medical care and vision rehabilitation, federal disability benefits, and projected costs over the remaining lifetimes of visually disabled service members.<sup>4</sup>

According to trauma registries in the United States and abroad, ocular injuries are more common among younger people, males, and those with less education and wealth.<sup>5</sup> Statistics from the

National Institute for Occupational Safety and Health on work-related diseases and injuries indicate that more than 800,000 work-related ocular injuries are reported annually in the United States. The impact of these injuries is compounded by the personal and national financial burden incurred. Total costs (direct workers' compensation claims and indirect costs such as time lost by noninjured workers and production slowdowns) exceed US\$4 billion.<sup>2,6</sup>

## Ocular Trauma Classification

In 1996, Kuhn et al. published a terminology for ocular trauma, with the intention of establishing a standardized and unambiguous language for ocular traumatology (Table 114.1).<sup>7</sup> In 1997, the Ocular Trauma Classification Group incorporated this new terminology into a more extensive classification scheme designed to improve consistency and accuracy in clinical practice and research.<sup>8</sup> In this “classification system for mechanical injuries of the globe,” the group incorporated anatomic and physiologic variables that had been shown to be prognostic of visual outcome after ocular injury. In addition to mechanism and extent of injury, these variables included visual acuity, presence or absence of a relative afferent pupillary defect, and zone of injury (external, anterior segment, or posterior segment). These classification schemes have improved communication between physicians and have been incorporated into many subsequent retrospective studies.

**TABLE 114.1**  
**New Standardized Classification of Ocular Trauma Terminology**

Term	Definition
Eyeball	Sclera and cornea
Closed-globe injury	The eyeball does not have a full-thickness wound
Open-globe injury	The eyeball does have a full-thickness wound
Rupture	Full-thickness eyeball wound caused by a blunt object; the impact results in momentary increase of the intraocular pressure and an inside-out injury mechanism
Laceration	Full-thickness wound of the eyeball, usually caused by a sharp object; the wound occurs at the impact site by an outside-in mechanism

Penetrating injury	Single laceration of the eyewall, usually caused by a sharp object
Intraocular foreign body (IOFB)	Retained foreign object(s) causing body injury and entrance laceration(s)
Perforating injury	Two full-thickness lacerations (entrance + exit) of the eyewall, usually caused by a sharp object or missile

## Closed-Globe Injuries

### Hyphema

Traumatic hyphema, or anterior chamber hemorrhage, can often manifest after blunt trauma. Most hyphemas clear spontaneously and do not cause residual visual impairment. However, permanent visual impairment can arise from complications of hyphema. These complications include (1) corneal blood staining;<sup>9</sup> (2) ghost cell glaucoma as a result of blocked outflow from clogging of the trabecular meshwork by erythrocytes;<sup>10</sup> or (3) central retinal artery occlusion from elevated intraocular pressure.<sup>11</sup> All these complications are more common when secondary bleeding occurs, usually 48–72 hours after the injury.

The laboratory workup for traumatic hyphema is tailored to the specific patient. While laboratory evaluation is not indicated in most patients with a hyphema, blood coagulation tests should be considered in patients with a known bleeding diathesis or pertinent review of systems. African American patients should be questioned about a family or personal history of sickle-cell disease or trait. If unknown, a sickle preparation or hemoglobin electrophoresis should be obtained. Patients with sickle-cell hemoglobinopathies and traumatic hyphema present special problems because of their decreased ability to tolerate modest rises in intraocular pressure. Optic atrophy may result in this setting due to decreased perfusion pressure, sludging and sickling of erythrocytes, and subsequent infarction.<sup>12</sup> In addition, because of its lower likelihood to cause systemic acidosis that promotes sickling, methazolamide (Neptazane) rather than acetazolamide (Diamox) should be used to decrease intraocular pressure in these patients. Mannitol should be used once only to avoid hemoconcentration.

Primary management of traumatic hyphema is directed at

prevention of rebleeding, which can complicate up to 35% of cases.<sup>13</sup> Previous clinical studies have demonstrated the benefits of shielding the injured eye to prevent accidental repeat trauma, using atropine for cycloplegia, and daily checking of visual acuity, corneal status, and intraocular pressure.<sup>14</sup> On the other hand, no benefit in the prevention of rebleeding has been proven for hospitalization with enforced bed rest or for bilateral patching to reduce eye movement.<sup>15</sup>

Several pharmacologic measures have been used to prevent rebleeding. Corticosteroids, both topical (prednisolone acetate 1% q.i.d.) and systemic (prednisone 0.5–1.0 mg/kg per day), reduce iritis and ciliary spasm, increase patient comfort, and theoretically stabilize the clot formation, thereby decreasing the rate of rebleed. Clinical trials have demonstrated the efficacy of oral epsilon-aminocaproic acid, both systemic (Amicar, Lederle Laboratories, Pearl River, NY, given 50 mg/kg every 4 hours for 5 days) and topical (Caprogel, ISTA Pharmaceuticals Irvine, CA, given every 6 hours for 5 days) and tranexamic acid (Cyklokapron, Pfizer, New York, NY) in reducing the incidence of secondary bleeding.<sup>16,17</sup> These antifibrinolytic agents reduce clot degradation from traumatized blood vessels by inhibiting the conversion of plasminogen to plasmin, the protein responsible for clot breakdown.

A recent review and meta-analysis examined the use of antifibrinolytic agents, corticosteroids, cycloplegics, miotics, aspirin, conjugated estrogens, traditional Chinese medicine, unilateral or bilateral patching, elevation of the head, and bed rest. In this review, traumatic hyphema in the absence of other intraocular injury uncommonly led to permanent loss of vision. No intervention had a significant effect on visual acuity, whether measured at  $\leq 2$  weeks after the trauma or at later time points. Systemic aminocaproic acid reduced the incidence of recurrent hemorrhage but prolonged the time needed for the hyphema to clear and was associated with increased nausea, vomiting, and other adverse events compared with placebo. The evidence to support an associated reduction in the risk of complications from secondary hemorrhage (i.e., corneal blood staining, peripheral anterior synechiae, elevated intraocular pressure, and development

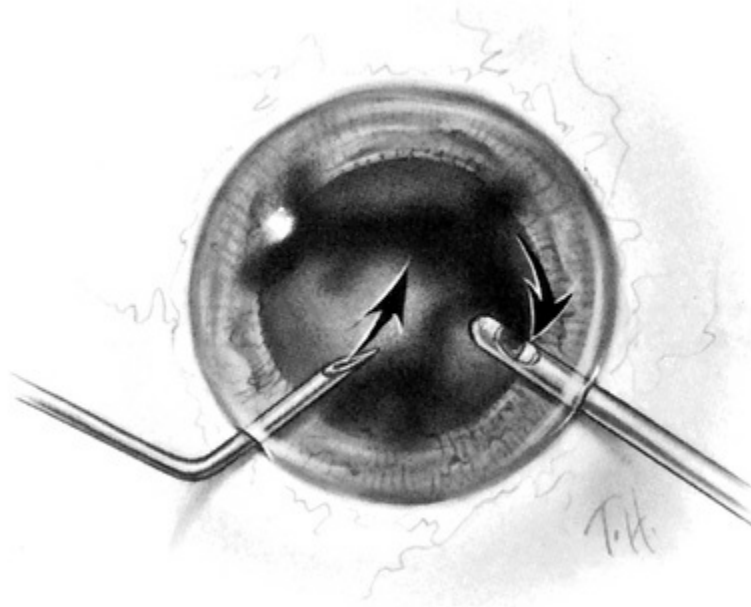

of optic atrophy) by antifibrinolytics was limited by the small number of these events.<sup>18</sup> Since no solid evidence was found to support the use of cycloplegics, corticosteroids, or nonpharmacologic interventions such as eye patching, head elevation, or bed rest, these measures should be individualized to patient needs and circumstances.

In most cases the hyphema improves with medical management. However, empiric criteria for surgical evaluation have been developed.<sup>14,19,20</sup> (1) intractably elevated intraocular pressure (IOP) despite medical therapy (>60 mmHg for 2 days in sickle-negative patients; or >24 mmHg for more than 1 day in sickle-positive patients); (2) total hyphema for more than 5 days with IOP >25 mmHg; (3) corneal bloodstaining; (4) persistence of hyphema occupying at least one-half of the anterior chamber volume. Several surgical techniques have been suggested to manage this problem, including paracentesis, anterior chamber washout with a one-needle irrigation or irrigation–aspiration technique,<sup>21</sup> washout with a two-needle technique, clot evacuation with a forceps or cryoprobe through a large limbal incision,<sup>22</sup> or clot evacuation associated with a trabeculectomy filtering operation.<sup>23</sup>

The concerns of shallowing of the anterior chamber with concomitant intraoperative fluctuations in intraocular pressure and renewed bleeding can be mitigated by the use of an anterior chamber maintainer (ACM). In this technique, an inferotemporal corneal paracentesis is made to accommodate the ACM connected to balance saline solution. A second paracentesis is then made in the superior cornea to allow evacuation of clot and blood.<sup>24</sup>

A two-instrument bimanual technique using vitrectomy instrumentation inserted through limbal incisions permits controlled removal of anterior chamber hemorrhage (Fig. 114.1).<sup>25,26</sup> The surgeon inserts through one incision a blunt infusion cannula (20-gauge (G), or smaller) or a bent needle (typically 23G) connected to balanced salt solution and a vitreous cutter through the second incision. Using both the aspiration and cutting functions of the cutter, as much of the clot and free blood is removed as possible. Care is taken to avoid damaging the crystalline lens and corneal endothelium. It is not uncommon to leave some residual blood at the end of the procedure. The incisions are closed with “X-

type” sutures using 9–0 or 10–0 monofilament nylon with knots buried in the incision. With the newer small-gauge (23G or 25G) vitrectomy instruments, self-sealing incisions may be feasible.

**FIG. 114.1** A two-instrument bimanual technique permits controlled removal of anterior chamber hemorrhage. An angled, blunt, 20G infusion cannula is inserted through a nasal limbal incision, and the vitrectomy instrument is inserted temporally. Careful aspiration and cutting are used to evacuate the clot.

The instruments can be transposed to reach hemorrhage inaccessible in the primary position. Alternatively, smaller gauge infusion and vitrectomy instrumentation can be used for the same procedure.

## Lens Subluxation and Dislocation

Blunt trauma can lead to either subluxation or dislocation of the crystalline lens. In lens subluxation, zonular filaments are broken, and the lens is no longer held securely in place but remains in the pupillary aperture. Lens dislocation occurs following complete disruption of the zonular filaments and displacement of the lens from the pupil. Trauma is the leading cause of lens dislocation.<sup>27</sup>

The dislocation or subluxation is not a problem in itself. Patients

can have normal visual acuity with a totally dislocated lens and aphakic correction. However, the contusive impact can lead to cataract formation. Special considerations and techniques are required when extracting a subluxated or dislocated cataractous lens.

In the evaluation of a patient with a cataractous lens after blunt trauma, it is important to remember that the lens may be subluxated. During the slit-lamp examination, evidence of iridodonesis or phacodonesis must be sought. This usually is more apparent in the undilated state, when the remaining intact zonular filaments are under less tension. Phacodonesis can be detected by having the patient look quickly from side to side or up and down, or by jarring the slit-lamp table. If an associated iridodialysis is present, the absence of zonular fibers can be identified by looking through the area of absent iris (Fig. 114.2). Presence of vitreous in the anterior chamber is proof of zonular rupture and probable lens subluxation.

**FIG. 114.2** This 13-year-old boy suffered an iridodialysis and subluxated lens with zonular rupture from a nonpenetrating BB pellet injury. A cataract developed within 2 weeks of the injury.

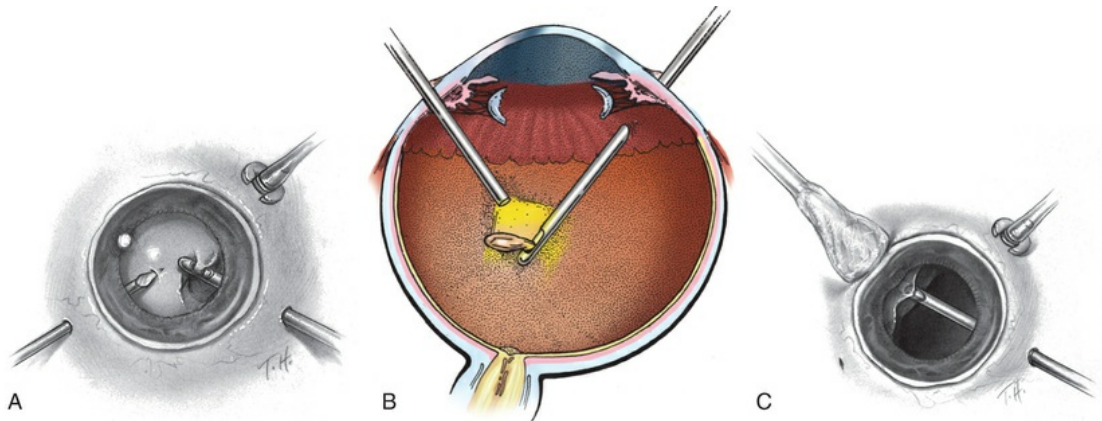

Extraction of a subluxated or dislocated cataractous lens should be considered only when the cataract is causing significant visual impairment. Urgent intervention is indicated for cases of pupillary block glaucoma, intractable uveitis, or lens–corneal touch leading to corneal decompensation. In children, the possibility of amblyopia may necessitate surgery. Lens extraction also may be necessary if visualization of the fundus is impaired and ultrasonography is equivocal with regard to retinal status. When surgery is planned for a subluxated or dislocated cataractous lens, vitreous loss is likely, and the success of surgery most likely depends on the care with which the vitreous is managed.

For cases with minimal lens instability, the traditional phacoemulsification techniques through a corneal limbal or scleral tunnel incision may be used, with a thorough hydrodissection and care taken to minimize the stress on the zonule and vitreous. A capsular support device, such as a capsular tension ring, may increase the safety and ease of phacoemulsification by stabilizing the capsular bag. Alternatively, a larger capsulorhexis may be used, and the lens may be prolapsed into the anterior chamber for phacoemulsification. Of great concern is vitreous prolapse through the cataract wound, and if vitreous is pulled on, traction transmitted to the vitreous base can cause retinal tears, giant retinal tear, and retinal detachment.<sup>28</sup> Consequently, the surgeon must recognize that vitreous prolapse through the wound is probable and be prepared for its management.

A pars plana approach using vitreoretinal instrumentation avoids many of the risks associated with limbal extraction ([Fig. 114.3](#)). Using a two- or three-port system, a myringotomy blade or a bent 21G or 23G butterfly intravenous needle connected to irrigation is inserted through the pars plana into the lens for fixation, and either a vitrectomy or a phacofragmentation instrument is inserted through the opposite pars plana to digest the lens. If the lens is soft, as in children and young adults (the most frequent victims of trauma), the entire lensectomy can be performed with the vitreous cutter. Vitreous around the lens can be managed with high-speed cutting and low vacuum to prevent traction on the vitreous base. Should the lens nucleus be harder and require phacofragmentation, care should be taken to perform either a limited vitrectomy around

the lens before introduction of the phacofragmatome or to use the phacofragmatome only when inside the lens capsule. This avoids unintentional aspiration pressure on the vitreous that could lead to retinal damage.

**FIG. 114.3** Technique for pars plana lensectomy for subluxated cataractous lens. (A) A pars plana infusion cannula is sutured in place in the inferotemporal quadrant, and the lens is fixated with a myringotomy blade inserted through a pars plana sclerotomy. A vitrectomy instrument (if the lens is soft) or phacofragmentation instrument (if the lens nucleus is harder) is inserted into the lens through the opposite pars plana. (B) If any lens material falls posteriorly, a fiberoptic probe is inserted in place of the myringotomy blade, and the lens material is removed using standard two-hand vitrectomy techniques. (C) Residual peripheral lens material is removed with the use of careful scleral indentation to bring the pars plicata area into view.

If any lens fragments fall posteriorly, a fiberoptic probe can be inserted through a sclerotomy and the lens material can be removed using standard vitrectomy techniques. In order to minimize vitreous traction during manipulation, all vitreous surrounding the lens must first be carefully removed. Lens material on the retinal surface should then be brought into the middle or anterior vitreous cavity before fragmentation. Removal of residual peripheral lens material can be facilitated by gentle scleral depression to bring the pars plicata area into view. Vitrectomy (including mechanical

dissection of the posterior hyaloid) should be as complete as possible in order to decrease the chance of postoperative retinal detachment, posterior hyaloid contraction, or vitreomacular traction. However, even though the induction of a posterior vitreous detachment (PVD) is ideal, the surgeon should not risk iatrogenic retinal damage in an attempt to create a vitreous separation.

If enough zonular filaments remain intact to support a sulcus-fixated intraocular lens (IOL), primary placement of an IOL can be considered. If minimal capsular support remains, the residual capsule should be removed, as this may increase the risk of late postoperative anterior fibrous proliferation and traction on the ciliary body and retina. Complete capsular removal is most easily performed using a two-handed technique: in one hand, an end-grasping microforceps engages the capsule, gently pulling it centrally, and in the other hand, a vitrector aspirates and cuts the residual capsule and zonular filaments. In these cases, the resulting refractive error can be corrected either by use of an aphakic contact lens following surgery or by implantation of an intraocular lens at the time of lensectomy. Options for lens implantation include an open-loop flexible anterior chamber intraocular lens (AC-IOL), iris-fixated lens, or a posterior-chamber lens (PC-IOL) secured in the ciliary sulcus or pars plana by a variety of means (suture, fibrin glue, or sutureless scleral fixation).<sup>29,30</sup>

Pars plana vitrectomy and pars plana lensectomy (PPV/PPL) with implantation of IOL can be used for cases of subluxated traumatic cataract with extensive zonular damage. Kazemi et al. reported on nine such eyes, in which an anterior chamber IOL was placed. Best corrected visual acuity of better than 20/40 was achieved in six of the nine eyes.<sup>31</sup>

Kodjikian et al. reported on nine consecutive cases of traumatic cataract with zonular dialysis of at least 180° and visual acuity of 20/100 or worse. Following PPV/PPL and implantation of an iris-fixated Artisan IOL, all patients achieved best corrected visual acuity of 20/30 or better.<sup>32</sup> Other authors have reported similar results using PPV/PPL and sutured sulcus IOLs.<sup>33</sup> A consistent finding in these studies is that the primary determinant of postoperative visual acuity is posterior segment pathology related

to the original injury<sup>34</sup>

An iridodialysis can be repaired at the end of the case using a 10–0 Prolene suture introduced through the cornea in a modification of the technique described by McCannel<sup>35</sup> to fixate IOLs to the pars plana (Fig. 114.4). At the end of the procedure, the peripheral retina should be carefully inspected with scleral depression to identify retinal breaks, dialyses, or areas of retinal detachment. Inspection can be performed either with binocular indirect ophthalmoscopy or through the microscope equipped with wide-field viewing. Should retinal breaks or detachment be present, they should be treated immediately with retinopexy and, if necessary, scleral buckling and endotamponade.

**FIG. 114.4** An iridodialysis can be repaired with a modification of the McCannel suture technique. A curved needle attached to a 10–0 Prolene suture is introduced through the limbus. With the iris grasped with a microforceps and pushed back into place, the needle is passed through the iris and back out through the limbus. The needle is then tied, reapproximating the iris in its original position.

## Vitreous Hemorrhage

Vitreous hemorrhage may result from damage to blood vessels in

the ciliary body, retina, or choroid. Vitreous hemorrhage from blunt trauma may be associated with a retinal tear, and meticulous indirect ophthalmoscopy with scleral depression should be performed to identify retinal abnormalities. Fundus visualization is usually best at the initial exam, as diffusion of hemorrhage or further bleeding may compromise later examinations. If occult scleral rupture is suspected, then scleral depression should be deferred.

Ultrasonography is critical in decision-making in cases of fundus-obscuring hemorrhage. With combined contact A-scan and B-scan techniques, many details of the posterior segment can be determined, including presence of retinal detachment, PVD, occult scleral rupture, hemorrhagic or serous choroidal detachment, and giant retinal tear (Fig. 114.5). For example, if ultrasound demonstrates vitreous strands emanating from an equatorial location, an occult scleral rupture with vitreous incarcerated in the wound can be inferred, requiring conjunctival peritomy and exploration.

**FIG. 114.5** In the presence of vitreous hemorrhage, contact B-scan ultrasonography can demonstrate a retinal detachment and can sometimes also identify the causative retinal tear.

In general, patients with a nonpenetrating ocular injury and a vitreous hemorrhage without associated retinal tear or detachment

should be observed. In cases of minimal diffuse hemorrhage, indirect ophthalmoscopy may be sufficient to establish retinal attachment. However, if the blood does not settle, the patient should be followed every few weeks with ultrasonography repeated to confirm retinal attachment. If retinal detachment is seen or suspected on ultrasonography, pars plana vitrectomy should be performed.

If pars plana vitrectomy is performed for a nonclearing vitreous hemorrhage caused by nonpenetrating trauma, we recommend a standard three-port technique. After the infusion cannula is secured in place and confirmed to be in the vitreous cavity, a core vitrectomy should be performed to remove hemorrhagic vitreous. In most cases a PVD will have developed in the time between injury and surgery. After one cut through the detached posterior hyaloid face with the vitrectomy instrument, subhyaloid blood can be aspirated from the preretinal space. A blunt cannula connected either to the vitrectomy system for powered extrusion or to a fluted handle for passive extrusion will allow controlled removal of the blood. Residual vitreous, including posterior hyaloid, is then excised with the vitrectomy instrument. The retinal periphery should be examined carefully to identify retinal tears or dialyses that could have led to the original vitreous hemorrhage.

If a PVD is not present, the surgeon should attempt to induce one. We have found that induction of a PVD can be made significantly easier and safer with the instillation of triamcinolone (either full-strength or diluted 20% in balanced salt solution) after a brief core vitrectomy. With this method, residual adherent cortical vitreous is marked by the triamcinolone particles and can be clearly visualized. The posterior hyaloid can then be engaged over the optic nerve with gentle suction from the vitrector or a powered soft-tip extrusion cannula and carefully stripped from the retinal surface. Other techniques for initiating posterior vitreous separation include incising the posterior hyaloid with a vitreoretinal pick, myringotomy blade, or diamond-dusted scraper over the periphery of the optic nerve. The vitreous detachment can be extended using an illuminated vitreoretinal pick while the hyaloid is elevated with either the extrusion cannula or vitrectomy instrument. If the posterior hyaloid remains adherent in certain locations, it should be

freed from surrounding vitreous so that all localized vitreoretinal traction is relieved. If traction persists, it may be necessary to place a local scleral buckle. Areas of persistent vitreoretinal traction should be scrutinized carefully because they may represent sites of occult scleral rupture and vitreous incarceration.

Smaller-gauge vitrectomy instrumentation can be used successfully for cases of traumatic vitreous hemorrhage, even those with associated retinal detachment and proliferative vitreoretinopathy. The surgeon should remember several aspects of transconjunctival small-gauge surgery that are especially relevant to traumatized eyes. First, since the infusion cannula is not sutured in place, it may slip backward into the suprachoroidal space, even after being well-visualized at initial placement. This risk is higher in eyes with choroidal hemorrhage, choroidal congestion, or dense accumulation of blood or fibrin at the anterior vitreous base. This risk can be minimized by preoperative ultrasonographic confirmation of an absence of choroidal detachment, by choosing a quadrant of the eye with a relatively clearer periphery, and by selecting the longest infusion cannula available. Second, smaller-gauge vitreous cutters (especially earlier-generation 25G cutters and 27G cutters) may become clogged with dense hemorrhage or vitreous debris. Third, additional instrumentation (such as intraocular forceps, scissors, lighted instruments, or equipment for oil infusion) may be required for treatment of associated vitreoretinal pathology. The surgeon must have as much information as possible regarding the ocular anatomy and have readily available the requisite surgical instruments.

The visual prognosis for eyes with vitreous hemorrhage associated with nonpenetrating trauma depends on associated macular damage (from choroidal rupture, traumatic macular hole, Berlin's edema, or macular contusion), retinal dysfunction from associated retinal detachment, and occlusional amblyopia in young children. In a study of 33 eyes with severe vitreous hemorrhage associated with closed-globe injury, best corrected visual acuity following resolution and/or treatment of hemorrhage was <20/200 in 54%. The most common cause of poor visual outcome was macular scar. Poor prognostic factors included presenting visual acuity of light perception or worse, hyphema, traumatic cataract,

and age 55 years or younger.<sup>36</sup>

## “Commotio Retinae,” Avulsion of the Vitreous Base, and Retinal Tears

Blunt trauma can damage the retina in many ways, ranging from retinal edema to retinal detachment. “Commotio retinae” is commonly seen after a contusive injury to the globe and appears ophthalmoscopically as retinal whitening (Fig. 114.6A). Edema involving the macula (termed Berlin's edema) can impart an appearance similar to a cherry-red spot. Experimental and histopathologic studies suggest that disruption of the photoreceptor cell outer segments and damage to the retinal pigment epithelium account for the retinal whitening.<sup>37</sup> Vision can be markedly decreased with commotio retinae, but vision most often improves as the swelling resolves over several weeks. Long term, however, vision can remain decreased as the macula develops an atrophic appearance with granular hyperpigmentation or if cystoid areas coalesce to form a macular hole (Fig. 114.6C).

**FIG. 114.6** This 40-year-old helicopter pilot suffered closed-globe trauma to the left eye when struck with an air-pressure hose. (A) Color fundus montage at presentation shows dispersed vitreous hemorrhage,

intraretinal and subretinal hemorrhage, and diffuse retinal whitening (commotio retinae). Visual acuity was counting fingers. (B, C) Color fundus montage and spectral domain optical coherence tomography (SD-OCT) 2 months later shows resolution of retinal whitening and reduction in intraocular hemorrhage, but the patient has now developed a full-thickness macular hole, with best corrected visual acuity of 20/400. Given the lack of spontaneous closure of the macular hole after 6 weeks, the patient underwent pars plana vitrectomy, removal of the internal limiting membrane, gas-air exchange with 14% perfluoropropane, and 3 days of prone positioning. (D) SD-OCT taken 6 weeks postoperatively shows complete closure of the macular hole. Visual acuity was 20/60 with eccentric fixation and will likely remain limited by disruption of outer retinal anatomy.

Blunt trauma can lead to large areas of irregular, jagged retinal holes. These breaks have been observed almost immediately after the contusive injury and are believed to be the result of mechanical disruption and fragmentation of the retina. Similar-appearing breaks have been produced in an experimental model of concussive injury to the globe.<sup>38</sup> This syndrome has been given a variety of names, including “acute retinal necrosis”<sup>38</sup> and “chorioretinitis sclopetaria.”<sup>39</sup> We prefer the term “contusive or traumatic retinopathy,” as it more precisely describes the etiology and mechanism of the clinical finding and avoids confusion with the acute retinal necrosis inflammatory syndrome of herpetic viral origin.

In eyes with chorioretinitis sclopetaria, it is tempting to intervene in some way because of the frightening size and often posterior location of the retinal breaks (Fig. 114.7). However, the retina rarely detaches in this situation, presumably because inflammation at the edges of the necrotic retina leads to a firm chorioretinal adhesion. Therefore, we do not recommend routine prophylactic retinopexy to areas of chorioretinitis sclopetaria. If a retinal detachment occurs, it is usually from another site and typically within the first few weeks of injury.<sup>40</sup> Patients with this condition often have poor visual acuity because of the effects of the severe blunt force on the

macula.

**FIG. 114.7** (A) Color fundus montage showing inferior retinal detachment caused by a giant retinal tear (GRT) along the inferior arcade with overlying vitreous hemorrhage. The inferior peripheral retina is white from presumed infarction arising from arteriolar transection. Posterior segment injuries often result from contrecoup forces and vitreoretinal traction. As the vitreous was forcefully separated from the retina, abnormally strong perivascular vitreous traction over the postequatorial retina may have contributed to the unique location of the GRT in this case. (B) Color montage taken 10 months following vitrectomy, scleral buckling, endolaser, and gas endotamponade.

Blunt trauma can also cause retinal breaks by transmission of the force to the vitreous base, leading to acute severe vitreoretinal traction. Rapid displacement of the vitreous can tear the retina in various ways, including retinal dialysis with or without avulsion of the vitreous base, operculated retinal tear, macular hole, and horseshoe-shaped retinal tears at the posterior margin of the vitreous base, at the edge of a meridional fold, or at the equator.<sup>41,42</sup> A study by Cox<sup>38</sup> concluded that the different forms of retinal abnormalities are a result of the point of impact of blunt trauma.

A retinal break that commonly follows trauma (and considered pathognomonic for blunt ocular trauma) is a retinal dialysis. This is

seen most commonly in the superonasal and inferotemporal quadrants because of blunt trauma frequently striking the globe inferotemporally.<sup>43</sup> The blunt force causes equatorial stretching of the globe, leading to traction on the vitreous base at the site of impact and diametrically opposite. Cox et al.<sup>41</sup> reviewed 160 patients with retinal detachment caused by contusion. In that series, retinal dialyses larger than one oral bay were found to be the most common retinal break.

It is important to perform careful indirect ophthalmoscopy with scleral depression on all patients with a history of blunt trauma. The authors recommend prophylactic cryopexy or photocoagulation to any retinal dialyses or tears that are identified, in the hope of decreasing the likelihood of subsequent retinal detachment.

## Retinal Detachment and Macular Hole

It is uncommon for a patient to develop an acute rhegmatogenous retinal detachment after blunt trauma. Most trauma victims are young with solid vitreous, providing internal tamponade to the retina despite retinal tears or dialyses. However, with time the vitreous liquefies, allowing fluid to form in the vitreous cavity, which can pass through the retinal breaks and detach the retina. By careful examination of the retina shortly after the injury and treatment of areas of retinal damage, detachment can be prevented in many cases.

Most traumatic retinal detachments can be treated with conventional scleral buckling techniques. Because of the potential for retinal damage 180° from the impact site, an encircling element is recommended. The selection of chorioretinal adhesive procedure and determination of the need to drain subretinal fluid should be made by the surgeon using the same principles as for nontraumatic detachments. Johnston<sup>44</sup> reported 77 eyes with retinal breaks after contusive injury; 65 developed rhegmatogenous detachment. Surgical treatment restored or maintained retinal apposition in 96% of the eyes.

In rare cases, blunt trauma may cause a rhegmatogenous retinal detachment from a macular hole or giant retinal tear (a tear greater

than 3 clock-hours). Although these detachments have been repaired successfully in the past with a variety of scleral buckling techniques, modern vitreoretinal surgery has significantly increased the rate of anatomic reattachment. Vitreous surgery allows mobilization of the flap by excising adherent vitreous. With the aid of surgical adjuvants, such as perfluorocarbon liquids, and current surgical techniques (as described in [Chapter 109](#), Optimal procedures for retinal detachment repair), the rate of successful retinal reattachment for such cases has greatly improved.

Traumatic macular hole formation is uncommon. Like idiopathic macular holes, traumatic holes can be rehabilitated with vitrectomy. However, a significant number of traumatic macular holes may close spontaneously. In a consecutive series of 18 such cases, spontaneous closure and accompanying visual improvement were seen in eight (44%) and occurred between 1 week and 4 months following injury.<sup>45</sup> In a retrospective study of 27 patients with traumatic macular hole observed for at least 6 months, multivariate regression analysis was performed to identify factors predictive of spontaneous closure. Holes with smaller inner diameter (mean of 245  $\mu\text{m}$ ) and fewer intraretinal cysts were more likely to close without surgery.<sup>46</sup> Although the visual outcome may be limited by associated macular damage (such as a macular choroidal rupture), there are encouraging reports of successful anatomic and functional outcomes with vitrectomy. Since patients with traumatic macular hole are typically younger and phakic, we elect to use long-acting gas endotamponade with 14% perfluoropropane to optimize the chance of hole closure ([Fig. 114.6D](#)). It has been suggested that surgical adjuvants such as autologous plasmin enzyme<sup>47</sup> or removal of internal limiting membrane<sup>48,49</sup> may improve the rate of anatomic success. Improvement in visual acuity of at least 2 Snellen lines has been reported in 69–94% of cases.<sup>48–50</sup>

## Open-Globe Injuries

### Preoperative Evaluation

It is important to obtain a history from any patient being evaluated for a possible eye injury. Although many trauma patients will be

poor historians because of associated shock, intoxication, or neurologic problems, the history can give important clues about the ocular damage. For instance, if a patient felt something flying into the eye while hammering a nail but did not note any visual disturbance, the physician must carefully search for evidence of an intraocular foreign body (IOFB), even if there is no evidence of obvious ocular laceration. Furthermore, since many of the medical malpractice cases brought against vitreoretinal specialists involve trauma, careful documentation of the details surrounding the injury may prove valuable in case of future litigation.<sup>51</sup>

Careful evaluation can also aid in prognostication of visual outcome when used according to the ocular trauma score (OTS). The OTS was developed by Kuhn et al.<sup>52</sup> following review of over 2500 registered cases of ocular trauma and has since been validated in adult and pediatric populations.<sup>53,54</sup> The OTS provides a single probability estimate that an eye trauma patient will obtain visual acuity within a specific range by 6 months after injury.<sup>52</sup> In the OTS, a numeric score is derived by adding or subtracting points on the basis of initial visual acuity, presence of rupture, endophthalmitis, globe perforation, retinal detachment, or afferent pupillary defect. Higher OTS scores are associated with better visual prognosis.<sup>52</sup> The OTS can thus be used as an aid in patient counseling and in identifying ocular injuries with a poor visual prognosis.

The initial step in examination is determination of visual acuity (VA) with either a near vision card or a Snellen acuity chart. When a retrospective review of penetrating injury patients was subjected to multivariate analysis, VA was the most important determinant of final visual outcome. Patients with initial VA of 5/200 or better had a 28 times greater chance of salvaging acuity at this level than those with vision worse than 5/200.<sup>55</sup> Two subsequent prospective studies of penetrating injuries have confirmed this finding. In the first of these series, 94% of patients with initial VA of 20/200 or better achieved a final VA of 20/200 or better.<sup>56</sup> In the second series, multivariate analysis revealed that presenting visual acuity of 5/200 or worse was the most important factor contributing to poor visual outcome; statistically insignificant factors were time since injury, cataract, and presence of IOFB.<sup>57</sup> In one review of 167 open-globe injuries, only 3% of eyes presenting with vision better than light

perception ultimately underwent enucleation, as compared with 39% of eyes presenting with light perception and 89% of eyes presenting with no light perception.<sup>58</sup>

The presence or absence of an afferent pupillary defect (APD) is a strong predictor of outcome.<sup>59,60</sup> A multivariate analysis of 240 traumatized eyes found 69% of eyes without an APD obtained a final VA of 20/200 or better, as compared with 34% of eyes with an APD ( $p<.00001$ ).<sup>59</sup>

On rare occasions, the surgeon may contemplate primary enucleation when encountering a totally disorganized globe with prolapse of intraocular contents, including retina. In these cases it is important to determine carefully whether the patient can perceive light. This is best done with the uninjured eye covered, with the indirect ophthalmoscope light at maximal intensity, and with the light held at sufficient distance so that the patient cannot perceive the heat of the ophthalmoscope light. Unfortunately, since many patients with injuries of this severity often are either intoxicated or have other injuries affecting their mental status, determination of light perception is questionable. Additionally, there are several reports of eyes with preoperative measurement of no light perception achieving visual acuity of light perception or better following reconstructive ocular surgery.<sup>61-63</sup> For these reasons, primary enucleation is rarely performed.

It is important to perform an examination sufficient to determine the extent of injury but not so extensive as to cause further damage to the globe. Pressure on the globe that could cause further prolapse of ocular contents must be avoided. Lid retractors may be used with care when lid swelling precludes visualization of the globe. If the history is highly suggestive of a penetrating injury and the examination is inconclusive, possibly because of poor cooperation, an examination under anesthesia should be performed, at which time repair can be performed if needed.

Occasionally, a scleral rupture can be occult (hidden under conjunctiva, Tenon capsule, or rectus muscles). Diffuse chemosis or subconjunctival hemorrhage suggests the presence of occult rupture. An open globe often has low IOP, but normal or elevated IOP does not rule out the possibility of a rupture. On occasion, slit-lamp biomicroscopy or ultrasonography of the anterior vitreous can

demonstrate vitreous strands directed toward a hidden scleral rupture site (Fig. 114.8). Computed tomography (CT) can also show occult rupture, with flattening of the posterior contour of the sclera (“flat tire” sign).<sup>64</sup>

**FIG. 114.8** In cases of occult scleral rupture, slit-lamp biomicroscopy can demonstrate vitreous strands directed toward the rupture site.

Confirming the presence or absence of a retained IOFB is critical to management. An IOFB can often be identified by slit-lamp biomicroscopy or indirect ophthalmoscopy (Fig. 114.9). However, if the ocular media are clouded by corneal damage, hyphema, cataract, or vitreous hemorrhage, ancillary techniques (typically ultrasonography and CT) are necessary. Ultrasonography can accurately localize foreign bodies, particularly with a systematic approach providing transverse and longitudinal views in all meridians (Fig. 114.10). When the globe is open, however, the resolution of ultrasound may be limited, as the examination often must be performed gently through closed lids. The usefulness of echography is also limited by shadowing caused by highly reflective surfaces such as air, reverberation artifacts created by some IOFBs, and by the user's skill and familiarity with ocular pathology.<sup>65</sup>

**FIG. 114.9** This patient suffered an intravitreal foreign body while shooting at a rifle range. The intraocular foreign body was nonmagnetic and was successfully removed via vitrectomy with foreign body forceps.

**FIG. 114.10** Contact B-scan ultrasonography can demonstrate a metallic intraocular foreign body. The foreign body has a characteristic triangular shape because of its absorbance of the sound waves and the resultant trail of artifact behind it. The foreign body is highly reflective and remains visible even at low gain.

CT has emerged as the imaging technique of choice in the evaluation of IOFBs, as it requires minimal patient cooperation and

can image radiolucent and radiopaque foreign bodies (Fig. 114.11). By assembling many consecutive orbital slices that demonstrate the ocular anatomy, and by using computer-generated reconstructions in three dimensions, the location of an IOFB can be determined. In an experimental study to determine the size of CT cuts required to detect small IOFBs, Dass et al. concluded that with modern spiral CT scanning both 3-mm and 1-mm cuts were effective (100% sensitivity) in detecting a 0.5-mm metallic, glass, or stone IOFB.<sup>66</sup> The absorption characteristics of the foreign body are quantitated in Hounsfield units and can be compared with the absorptions of various known materials. Zinreich et al.<sup>67</sup> have shown that wood is the least dense of the nonmetallic foreign bodies, followed by plastic and then glass. Unfortunately, all metallic foreign bodies have the same absorptions and are impossible to differentiate. CT scanning does have limitations, in that metallic IOFBs often create significant scattering artifact that may obscure their precise location. This can be particularly bothersome when attempting to determine whether a foreign body is intraretinal or intrascleral. In addition, identifying some of the lower-density foreign bodies, such as wood, may be difficult with CT scanning.<sup>68</sup>

**FIG. 114.11** This computed tomography (CT) scan demonstrates an intraretinal shotgun pellet in the patient's left eye.

Magnetic resonance imaging (MRI) is useful for imaging

intraocular tumors and other lesions. However, the magnetic fields and heat generated during MRI scanning preclude examination of patients with suspected intraocular or intraorbital metallic foreign bodies, as these objects can move within the suprachoroidal or vitreous spaces when subjected to the torsional forces of MRI.<sup>69</sup> Another disadvantage of MRI is its inability to image bone. MRI's principal advantage over CT is its detection of wood and plastic IOFBs.

The possibility of intraocular infection must also be addressed during the initial evaluation. Endophthalmitis is a devastating complication of penetrating injuries, and its prognosis is related to a number of factors, including time to diagnosis. Classically, eyes with endophthalmitis will be painful and have swollen conjunctiva and marked intraocular inflammation, including hypopyon. However, since these signs may be more difficult to identify in an already traumatized globe, infection can be diagnosed only if the physician remembers it as a possibility. Traumatic endophthalmitis is discussed in greater detail later in this chapter.

In many parts of the world, even in developed countries, there are limited numbers of emergency departments and medical centers with the requisite personnel and resources to provide complete care for the patient with ocular trauma. Thus, many patients will require transfer to a separate, specialized center after initial evaluation. At least one study has suggested that, with appropriate education as to key examination criteria, emergency physicians and general surgeons can determine the need for ophthalmic intervention with accuracy comparable to that of a general ophthalmologist.<sup>70</sup> The vitreoretinal specialist can be invaluable in advising the initial evaluation and streamlining the timely delivery of definitive treatment. We recommend, for example, in cases of suspected open-globe injury, that when feasible the evaluating physicians confirm the patient's medical and neurologic stability, shield the injured eye, evaluate for additional injuries, check toxicology screen, administer broad-spectrum systemic antibiotics with high intravitreal penetration (preferably fourth-generation fluoroquinolone), administer tetanus toxoid, and perform noncontrast CT of head and orbits to detect foreign body and determine any deformation of the globe. In parallel with this

initial evaluation, the ocular trauma surgeon can plan appropriate treatment and mobilize appropriate surgical personnel and services. If this initial evaluation cannot be performed with adequate quality or timeliness, then we recommend direct and immediate transfer of the patient.

## Repair of Laceration

Principles guiding the repair of a laceration or rupture of the globe are the same whether confronting a straightforward corneal laceration or a complex corneoscleral laceration with prolapse of ocular contents. First, the structural integrity of the globe must be restored, providing a watertight closure of all wounds and restoration of normal IOP. Second, iatrogenic damage to the eye must be avoided. Efforts should be made to protect the visual axis but not if this sacrifices the previous principles.

Before repair of a laceration, it is critical to determine the extent of the injury. If a corneal laceration extends to the limbus, a limited conjunctival peritomy is necessary to evaluate for any scleral extension. After establishing the extent of injury, the presence or absence of iris or vitreous incarceration must be determined.

A simple corneal laceration without tissue incarceration should be closed with interrupted 10-0 nylon sutures. Tissue bites should be placed roughly two-thirds deep into corneal stroma on either side of the laceration. Closure can be attained by starting at one end and working to the other, starting at both ends and working toward the center, or starting at the middle and continually bisecting the laceration until the wound is watertight. We prefer the last approach. It is often necessary to replace some of the earlier sutures if they become loose as the wound is pulled together more tightly. In some cases it may be helpful to use larger sutures during initial approximation of the wound, similar to the way cardinal sutures are used for penetrating keratoplasty surgery. Placement of cardinal sutures may be particularly helpful in repair of jagged lacerations. If the edges of the corneal wound are edematous, the suture bites need to be placed at a greater distance from the wound edge. After tying the knots, the surgeon should try to bury them, but this may not be possible when the cornea is edematous.

A watertight closure can be difficult to achieve with stellate lacerations. In some cases the wound leaks even with multiple sutures crisscrossing the laceration, and a purse-string closure may be necessary. The suture is placed in a circle through the various portions of the cornea involved in the laceration and then tied to itself with the knot buried in the laceration. If this technique does not work, corneal tissue may have been lost, and tissue adhesive can seal the leakage site. When there is too much tissue loss for glue to work, a corneal patch graft can be used.

When iris is incarcerated in the corneal wound, it can be repositioned in most cases. We advocate excision of uveal tissue only if it looks extremely necrotic, usually having been externalized for more than 24 hours. Reposition of incarcerated iris usually can be accomplished with introduction of an iris or cyclodialysis spatula or a 27G cannula connected to viscoelastic through a limbal stab incision made about 90° away from the laceration. This maneuver is best done after the corneal integrity has been partially restored by the first few sutures and the anterior chamber has been reformed with balanced salt solution, air, or viscoelastic substance. When there is positive pressure or in the presence of a hyphema, the surgeon may be helped by having the assistant reposit incarcerated iris while the surgeon places the suture. The success of subsequent surgical iridoplasty and pupillary reconstruction is directly related to the amount of iris that is preserved at the time of primary repair. The surgeon, therefore, should be meticulous in salvaging as much iris tissue as possible, resisting the understandable urge simply to excise all prolapsed tissue.

Whereas the location and extent of corneal lacerations are obvious, scleral lacerations require deliberate exploration. Therefore, good exposure is important. Lid sutures can be useful for lid retraction without putting excessive pressure on the globe. A conjunctival peritomy should be performed for 360°, followed by sharp dissection of the conjunctiva and Tenon fascia from the sclera in the four quadrants to avoid undue pressure on the globe.

Scleral lacerations should be repaired with 8-0 or 7-0 nonabsorbable sutures. We prefer spatulated needles similar to those used for placement of sutures for scleral buckling. In general, we use interrupted sutures to close the laceration, working from

anterior to posterior. If a scleral laceration is well delineated, a running shoestring suture can provide a watertight closure.

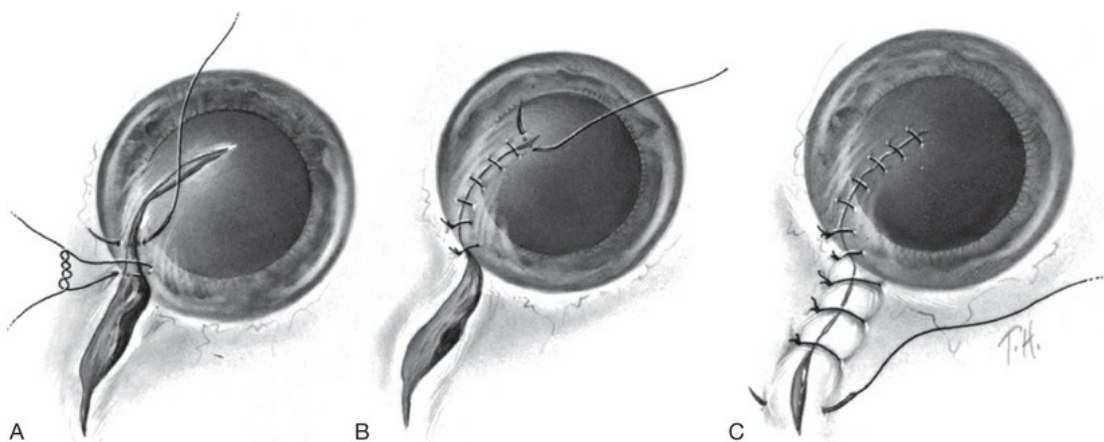

In some cases a scleral laceration may either be located under the rectus muscles or extend under the muscles. In these cases the area under the muscle can be exposed by gently passing a muscle hook under the muscle and using the hook to lift it out of the way. If this is unsuccessful or is causing too much pressure on the globe, the muscle should be isolated on a 6-0 Vicryl suture and cut from the globe. After repair of the laceration, the muscle is resutured to its original insertion. If a scleral rupture has resulted in extensive loss of tissue, such as with large missile injuries, it may be necessary to use a scleral patch graft.

Uveal tissue often extrudes through scleral lacerations. In most cases this tissue can be repositioned by the assistant while the surgeon closes the overlying sclera. Even when the tissue appears necrotic, cutting the tissue can cause significant bleeding; rarely should extruded tissue be excised if the repair is performed within 24 hours of the injury.

Vitreous that has prolapsed through the laceration must be removed to decrease the chance of incarceration and subsequent vitreoretinal traction. Typically, extruded vitreous is cut with sharp scissors placed flush against the sclera. Alternatively, a vitreous cutter at high cutting speed and low vacuum can be used. This approach, if available, is preferable because of the reduction in traction placed on the vitreous and transmitted to the retina. The vitreous cutter should not be inserted into the eye through a scleral laceration to remove extruded vitreous because of the potential for damaging the choroid or retina. If the surgeon suspects extrusion of retina, every attempt should be made to reposit the retina, avoiding excision or incarceration if possible.

In some cases, the scleral laceration extends posterior to the ora serrata and may have an associated retinal laceration. Because of associated vitreous hemorrhage, it is rare to identify a retinal laceration during primary repair. Cryopexy should not be performed prophylactically unless a specific retinal tear can be visualized, since cryotherapy may cause excessive inflammation that may promote the development of later traction retinal detachment.<sup>71</sup>

In cases of lacerations involving both the cornea and sclera, the extent of the laceration must be determined first. To restore structural integrity, the limbus is the best place to start, as it provides a recognizable anatomic landmark. Limbal wounds are closed using 9–0 nylon sutures (Fig. 114.12). After the limbal portion of the laceration is closed, it is easier to repair the corneal laceration first, then the scleral laceration. The same techniques and principles described for lacerations limited to the cornea or sclera should be employed.

**FIG. 114.12** Repair of a complex corneoscleral laceration begins with exploration of the globe to determine the extent of the injury. (A) The limbus is then reapproximated with 9–0 nylon sutures. (B) The corneal laceration is then repaired with 10–0 nylon sutures. (C) Subsequently, the scleral portion is sutured with nonabsorbable interrupted sutures.

In some cases, a hyphema or cataract is identified at the time of laceration repair. Because of the possibility of causing additional damage to the eye by attempting significant intraocular manipulations at the time of primary repair, we generally advocate deferring the anterior chamber washout or lensectomy to a secondary procedure. These issues are discussed in greater detail below.

The value of scleral buckling at the time of primary open-globe repair has been examined by several retrospective studies.<sup>72–74</sup> The justification for prophylactic scleral buckling (typically only considered in eyes with lacerations extending >5 mm posterior to

the limbus) is that support of the vitreous base may reduce vitreoretinal traction and subsequent retinal tears or detachment, which occurs in up to two-thirds of cases.<sup>75</sup> Placement of a buckling element at the time of primary repair is easier because the rectus muscles are often already isolated during exploration of the open globe, and there is no scarring of the wound, Tenon fascia, or conjunctiva. A matched cohort study from two US institutions<sup>73</sup> and a recent retrospective case–control study of 38 patients in Israel<sup>74</sup> have addressed this question. According to these studies, as with our experience, in selected high-risk eyes treated with scleral buckling at the time of globe repair, there was a significantly lower rate of proliferative vitreoretinopathy and a trend toward a lower incidence of later retinal detachment.

## Management of Intraocular Foreign Body

Conventional wisdom has held that an IOFB be removed at the time of repair of the entry site or soon afterward. This recommendation was based on several concerns: (1) because of the inflammation caused by IOFBs, they often are rapidly surrounded by a fibrous capsule that can make delayed surgical removal more difficult; (2) metallic foreign bodies containing copper or iron may cause inflammatory damage to intraocular structures; (3) traumatic endophthalmitis, particularly associated with the *Bacillus cereus*, is more commonly seen with IOFBs than with other forms of penetrating injuries,<sup>76</sup> and IOFB removal within 24 hours of injury has been advocated because of the increased risk of endophthalmitis.<sup>76,77</sup> In these series, however, it was not clear that systemic antibiotics were administered.

On the other hand, in certain cases, IOFB removal must be delayed because of inaccessibility to appropriate specialized resources, surgeon inexperience with foreign body removal, or because of systemic medical instability. In a recent report of military soldiers sustaining ocular trauma with IOFB, none of 79 eyes developed endophthalmitis despite a median delay of 38 days in IOFB removal. Since 97% of patients received antibiotics (most commonly by systemic administration, and most commonly levofloxacin), the authors contended that prompt antibiotic use was

helpful in reducing the chance of endophthalmitis.<sup>78</sup> It is reasonable, therefore, to consider for some patients that IOFB removal be intentionally delayed, especially in cases without access to adequate equipment or personnel at the time of primary repair. Such a paradigm of deliberately staged procedures may be considered in patients presenting immediately after injury with no signs of endophthalmitis, in whom appropriate systemic and/or intravitreal antibiotics can be administered, and in whom compliance and timely follow-up are assured. In cases involving an IOFB, it helps to determine preoperatively whether the object is magnetic. If it is not known whether the IOFB is magnetic, the surgeon may attempt to extract the foreign body with the magnet. If the foreign body does not move when the magnet is turned on, an alternative approach must be used.

Three instruments are commonly available for IOFB extraction: external magnets, intraocular forceps, and intraocular magnets. External magnets are best reserved for cases in which extraction can be performed immediately (success rates fall when the IOFB becomes encapsulated<sup>79</sup>) and when there is good fundus visualization with minimal associated posterior segment injury. (In a study of eyes with comparable damage, significantly better anatomic and functional results were achieved in eyes managed with vitrectomy and intraocular magnet.<sup>80</sup>)

Our surgical approach to IOFBs is summarized in [Table 114.2](#). When a magnetic intravitreal foreign body can be well visualized, extraction with an external electromagnet is usually effective ([Fig. 114.13](#)). This should be done through a pars plana sclerotomy after repair of the entry site. It is important to make the sclerotomy large enough so that the foreign body can pass out of the globe without becoming incarcerated in the pars plana. If the scleral laceration site is used for extraction, then it should be enlarged, since the elastic sclera and ocular tissues will have stretched after initial IOFB entry and made the wound smaller than the longest dimension of the IOFB. A magnetic extraction is best performed with an assistant holding the magnet over the sclerotomy while the surgeon visualizes the IOFB with indirect ophthalmoscopy and controls the magnet's foot pedal. If a large sclerotomy is needed, it is helpful to pre-place a mattress suture so that it can be closed quickly after

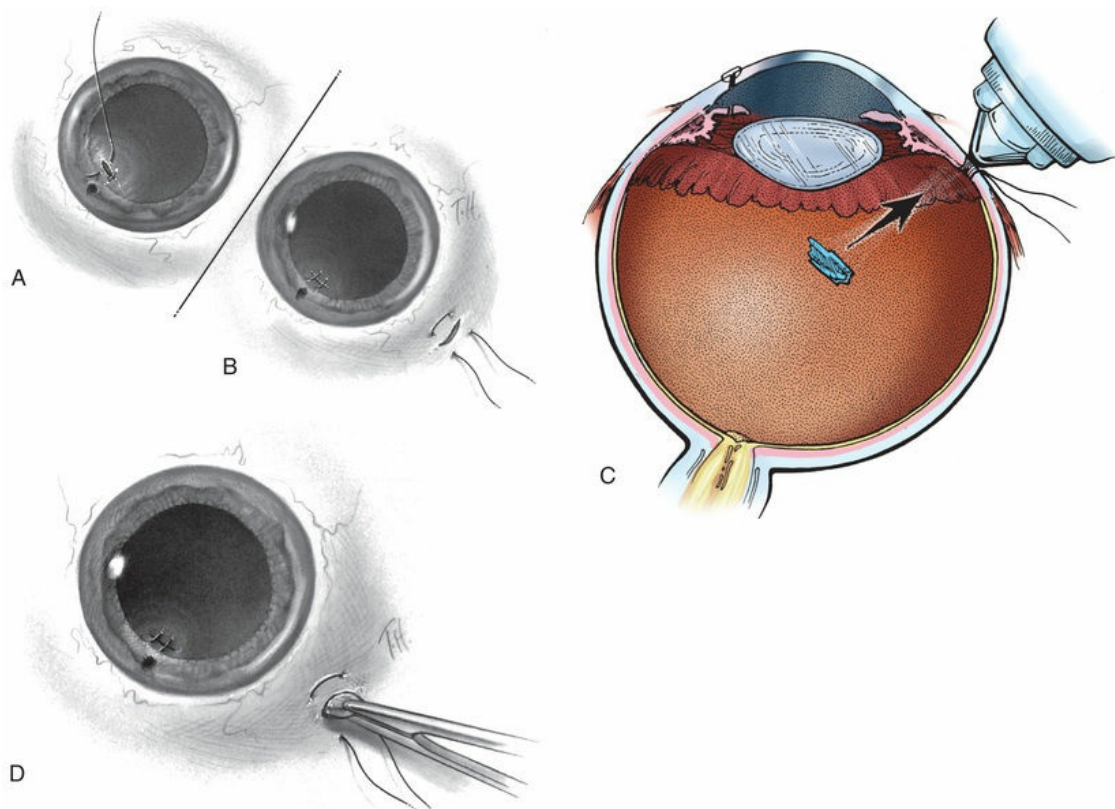

removal of the IOFB to decrease the period of hypotony. We do not advocate prophylactic cryopexy or scleral buckle in these patients.

**TABLE 114.2**

**Management of Intraocular Foreign Bodies**

	Well Visualized	Poorly Visualized
<b>INTRAVITREAL</b>		
Magnetic	External magnet	Vitrectomy, forceps/REM

REM, rare earth magnet.

**FIG. 114.13** Management of magnetic intravitreal foreign body. (A) Suturing of entry site. (B) Creation of a pars plana sclerotomy with a preplaced mattress suture. (C) The external magnet is held over the sclerotomy while the surgeon visualizes the foreign body with indirect ophthalmoscopy and controls the magnet's foot pedal. (D) Occasionally, the foreign body

must be grasped at the sclerotomy site with a forceps and pulled out.

When the magnetic intravitreal foreign body is poorly visualized because of cataract or vitreous hemorrhage, one must perform a pars plana vitrectomy and/or lensectomy (Fig. 114.14). The foreign body can then be removed by a number of techniques. The IOFB can be removed with greatest control using IOFB forceps inserted through the pars plana sclerotomy or with the rare earth intraocular magnet. If the intraocular magnet is used to grasp the foreign body and bring it into the anterior vitreous, it often helps to transfer the IOFB to foreign body forceps to pull it through the sclerotomy.

**FIG. 114.14** Management of magnetic intraocular foreign body in the presence of vitreous hemorrhage. (A) A pars plana vitrectomy is performed to remove the vitreous hemorrhage in order to visualize and mobilize the foreign body. (B) The foreign body is grasped with the intraocular rare earth magnet and brought into the anterior vitreous. (C) The foreign body is transferred to a foreign body forceps and removed through a sclerotomy.

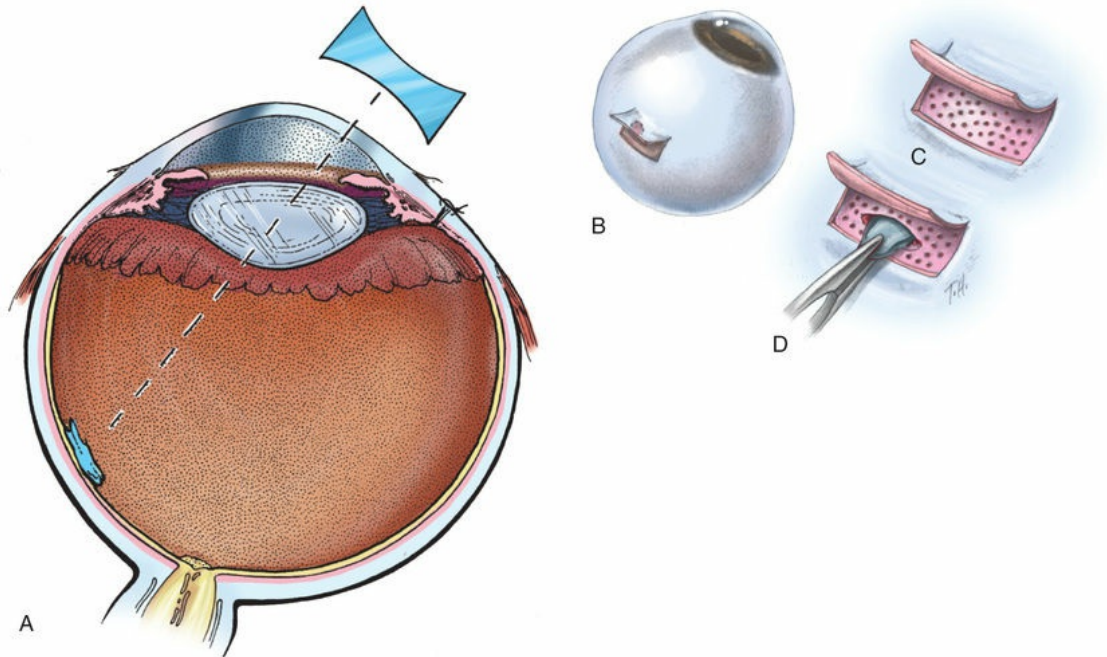

The surgeon must have the foreign body grasped firmly when removing it through the sclerotomy. If the foreign body is dropped, it will likely strike the macula. Injection of liquid perfluorocarbon has been recommended as a means to protect the macula in this setting. However, experimental studies suggest that these heavier-than-water agents will not support a metallic foreign body.

Removal of intraretinal foreign bodies is more difficult and more hazardous because of the risk of retinal detachment (Fig. 114.15). If

the ocular media are clear and the IOFB can be localized by indirect ophthalmoscopy, it can be removed by a transscleral approach (Fig. 114.16). A trapdoor scleral flap is created, the choroidal bed is treated with external diathermy, the choroid is incised, and the foreign body is removed with either forceps or an external magnet. If retinal incarceration occurs, then scleral buckling should be performed. The choice of buckling element is determined by the extent and location of vitreoretinal traction. For example, if a vitrectomy has been performed and all traction in the transvitreal vector has been relieved, then a localized segmental element over the area of incarceration is sufficient. If transvitreal traction has not been sufficiently eliminated, then an encircling element should be placed in order to reduce traction that may develop on the retina diametrically opposite the site of incarceration. Because the surrounding area has already been treated with diathermy, it is unnecessary to add cryopexy.

**FIG. 114.15** This patient was striking a chisel with a hammer when he suffered a penetrating ocular injury. The metallic intraocular foreign body is located within the retina. Inflammatory retinal whitening developed within 6 hours of the injury.

**FIG. 114.16** Transscleral approach to intraretinal foreign bodies. (A) The foreign body is localized with indirect ophthalmoscopy. (B) A trapdoor scleral flap is created. (C) The choroidal bed is treated with external diathermy and the choroid incised. (D) The foreign body is removed with either forceps or an external magnet.

Intraretinal foreign bodies can also be removed via a transvitreal approach, particularly when they cannot be well visualized (Fig. 114.17). After a pars plana vitrectomy is performed, the foreign body should be gently mobilized with the foreign body forceps. In many cases the foreign body will be somewhat adherent to the retina or choroid. If the IOFB has been surrounded by a fibrous capsule, the capsule may be incised with a myringotomy blade before removal. All these manipulations are made to avoid further tearing of the retina. After the IOFB is freed, it can then be removed with either the forceps or intraocular magnet using the method described above.

**FIG. 114.17** Management of an intraretinal foreign body in the presence of vitreous hemorrhage. (A) A pars plana vitrectomy is performed removing vitreous blood. (B) If a posterior vitreous detachment is not present, one is created by gently aspirating the posterior hyaloid with suction or a vitreoretinal pick. (C) The foreign body is grasped with the foreign body forceps and removed from the eye.

When it is necessary to perform a vitrectomy to remove an intraretinal foreign body, it is important to remove the posterior hyaloid overlying the incarceration site. In some cases a PVD will be present; otherwise one must be created. Residual posterior hyaloid may lead to the postoperative development of vitreoretinal traction or formation of epiretinal membrane (Fig. 114.18). In an early report describing the use of pars plana surgical techniques for removal of intraretinal foreign bodies, 90% of eyes developed either macular pucker or proliferative vitreoretinopathy.<sup>81</sup> The authors believe the frequency of this complication can be decreased by careful attention to removal of the posterior hyaloid. In a more recent series of 34 eyes undergoing vitrectomy for removal of intraretinal foreign body, macular pucker and/or scarring developed in one-fourth of eyes and sclerotomy-associated retinal breaks were seen in one-third. Postoperative visual acuity was 20/200 or better in two-thirds of eyes and was unrelated to the size, shape, or type of foreign body.<sup>82</sup>

**FIG. 114.18** This 19-year-old man suffered a penetrating injury from hammering metal. A metallic intraocular foreign body was lodged in the inferior sclera (A). Following placement of an encircling band, the foreign body was extracted from the exit wound (B,C), which was then closed and supported by the scleral buckle. Vitrectomy, endolaser photocoagulation, and silicone oil infusion were then performed to repair the inferior retinal detachment. Postoperative photograph taken 3 months later following removal of silicone oil shows retinal reattachment and the old exit wound inferiorly (D).

There has also been controversy over the optimal management of a retinal tear caused by the foreign body. Some surgeons emphasize the necessity of creating a chorioretinal adhesion at this site with either cryopexy or photocoagulation. In our experience the inflammation caused by the foreign body impaction has been adequate to prevent retinal detachment, particularly if the surgeon pays close attention to proper management of the posterior hyaloid.

There has also been discussion of the need to place photocoagulation around the intraretinal foreign body preoperatively to decrease the risk of retinal detachment at the time of foreign body removal. Again, it has been our experience that this is unnecessary. Ambler and Meyers<sup>83</sup> reported five eyes with intraretinal foreign bodies managed without retinopexy or fluid–air exchange without developing retinal detachment or preretinal fibrosis. If, however, a retinal detachment does occur at the time of extraction, it is particularly important to attempt removal of adherent posterior cortical vitreous before fluid–gas exchange to reattach the retina. In these cases, endphotocoagulation should be placed around the retinal break. If the surgeon is unable to remove all adherent vitreous, then the retinal tear should be supported on a scleral buckle. We perform prophylactic encircling scleral buckles in all eyes receiving vitrectomy for management of penetrating injuries, as discussed later in this chapter.

Nonmagnetic intravitreal foreign bodies require extraction with intraocular forceps whether they are well visualized or partially hidden by vitreous hemorrhage or cataract.<sup>84,85</sup> In these cases, we perform a vitrectomy with or without a lensectomy, depending on the lens clarity. The foreign body is grasped with the IOFB forceps and removed through the pars plana sclerotomy site. Inert nonmagnetic foreign bodies such as glass or plastic can be observed without immediate removal. However, since it is difficult to know whether they are infected, we advocate treatment with systemic antibiotics prior to IOFB removal.

Extremely large foreign bodies can pose great difficulty for the surgeon attempting removal via a pars plana approach. The foreign body forceps designed to pass through the 20G or 19G sclerotomy sites is unable to grasp large IOFBs, such as BB gun pellets. When they can be grasped, they are too large to be removed through the sclerotomy and must be removed through a second incision created at the limbus. When one suspects that a foreign body cannot be removed by way of pars plana surgery, a scleral tunnel, a limbal opening, or even an open-sky approach should be considered. In many of these cases, there is severe corneal damage with a stellate laceration that makes visualization of the posterior structures difficult. By removing a corneal button and performing an open-sky

vitrectomy, one can identify and remove the foreign body.

Intralenticular foreign bodies usually must be removed in concert with lens extraction. However, if the anterior capsule tear is small and the foreign body is composed of a nontoxic material, the capsular wound may fibrose, resulting in a localized, visually insignificant cataract that can be observed.<sup>86</sup> If cataract formation has occurred, or if the object is metallic, then lens and foreign body extraction should be performed using standard extracapsular cataract extraction methods. We also recommend lensectomy for small capsular defects when endophthalmitis is suspected or if the foreign body was dirty (e.g., rural trauma).

Overall, patients with IOFBs can have an excellent outcome, with approximately one-half of eyes achieving visual acuity of 20/50 or better.<sup>87</sup> Worse outcomes are typically associated with IOFBs of greater mass, uveal prolapse, and injury with a BB or other pellet.<sup>88,89</sup>

## Perforating Injury

Perforating injuries represent a small subset of ocular trauma, occurring in only 4.4% of lacerated globes.<sup>90</sup> Until the introduction of vitreoretinal surgery, these eyes had a uniformly poor prognosis because of ingrowth of fibrovascular tissue through the posterior exit site, leading to severe retinal detachment. Our current management of this type of injury is guided by experimental studies of Topping et al.<sup>91</sup> Scleral wounds had self-sealed by day 7 following injury, after which the degree of transvitreal proliferation (and subsequent risk of traction retinal detachment) increased dramatically.

Ideally, vitrectomy would be performed early enough to prevent transvitreal proliferation,<sup>92</sup> but it is impossible unless the scleral rupture sites are sealed. The entry site can be repaired by the surgeon using standard techniques described earlier in this chapter. However, attempts to close posterior rupture sites can be difficult, as well as hazardous, causing excessive traction on the globe and optic nerve and possibly leading to extrusion of intraocular contents. Having learned from the experimental studies that the scleral wounds seal by day 7, we routinely delay vitrectomy until

this time or later. We do advocate suturing the anterior “entry site” promptly after injury (see [Chapter 102](#), Pathophysiology of ocular trauma).

We employ the standard three-port technique for vitrectomy, proceeding from anterior to posterior, clearing vitreous opacities ([Fig. 114.19](#)). As in vitrectomies for penetrating injuries, it is important to identify the posterior hyaloid and, if it is still adherent to the retina, create a PVD. The stump of proliferation growing through the exit site should be reduced but not eliminated, so that the posterior exit site is not reopened. When planning surgery and choosing one's vitrectomy setup, the surgeon should remember that this fibrovascular ingrowth can often be exceedingly thick and difficult to cut with smaller-gauge vitreous cutters. Thus, in the eventuality that fibrous ingrowth may be encountered, the surgeon is well served to have access to a cutter or scissors strong enough to transect and trim stiff fibrous tissue. Retinal breaks are managed with air–fluid exchange and endophotocoagulation or scleral buckling with cryopexy. We advocate an encircling scleral buckle, even in eyes without retinal detachment.

**FIG. 114.19** Penetrating injuries are managed with primary repair of the entry site. At 7–10 days later, pars plana vitrectomy is performed with removal of the posterior hyaloid. The proliferation growing through the exit site should be reduced to a stump but not eliminated.

Overall, the prognosis for these eyes appears to be improved by this management ([Fig. 114.20](#)). In a case–control study of penetrating injuries, a beneficial trend was demonstrated for those eyes managed with vitrectomy.<sup>93</sup> Martin et al.<sup>94</sup> achieved anatomic success in 41 of 51 eyes, with functional success (visual acuity better than 5/200) in 32 eyes (63%). The location of the exit site has profound influence on the final visual acuity. If the exit site is through the macula or optic nerve, the final vision is obviously limited. The location of the exit site also affects the success of hyaloid removal. Complete removal is more easily achieved when the exit site is located posterior to the vitreous base.

**FIG. 114.20** This child suffered a perforating injury with a whittling knife. Following emergent repair of the corneal laceration (A), lensectomy and vitrectomy were subsequently performed. He returned 2 months later with (B) traction retinal detachment associated with fibrous ingrowth at the exit site.

More recently, it has been demonstrated that chorioretinectomy (removal of the choroid and/or retina at the impact or perforation site) may improve final visual acuity and increase the chance of globe salvage.<sup>95</sup> In this technique, first advanced by Zivojnovic nearly three decades ago,<sup>96</sup> any retinal or uveal tissue incarcerated into the perforation site is removed with the vitrector, with diathermy destruction of the retina/choroid in a 1-mm ring around the exit wound/impact site. High cutting speeds (up to 7500 cpm) with low vacuum are typically used. Bleeding, though uncommon from necrotic incarcerated tissue, is controlled with endodiathermy or transient elevation of infusion pressure. In a small pilot series of such a “proactive technique” reported by Kuhn et al. in 2004, chorioretinectomy was performed in five consecutive eyes within 100 hours of perforating globe injury. Their strategy involved limited vitrectomy (performed while looking through the binocular indirect ophthalmoscope) at the time of primary repair, intensive topical corticosteroid therapy, and followed 3 days later by complete vitrectomy, localized retinectomy, evacuation of subretinal blood, laser retinopexy, and placement of silicone oil.<sup>97</sup> Two retrospective series comparing eyes with perforating injury treated with early vitrectomy and chorioretinectomy and those treated with later vitrectomy alone have since been reported.<sup>98,99</sup> In eyes treated with chorioretinectomy, higher rates of globe survival

and retinal reattachment and lower rates of proliferative vitreoretinopathy were observed. This technique should only be considered, however, by surgeons with the requisite experience and in cases with adequate visualization of the posterior segment and confirmation that there is minimal retinal or choroidal detachment.

## Vitreous Hemorrhage and Retinal Detachment

Despite advances in the management of eyes with penetrating injuries, a large group of patients still have a poor prognosis. These more severe injuries most often have posterior segment involvement. A seminal study evaluating the outcome of penetrating ocular injuries identified several factors other than initial visual acuity that correlate with a poor final visual outcome. These include presence of an afferent pupillary defect, wounds involving the sclera or extending posterior to the insertion of rectus muscles, wounds >10 mm, and vitreous hemorrhage.<sup>55</sup> The study emphasized that the prognosis following penetrating injury is strongly influenced by the nature of the injury and the location and extent of initial damage. Functional loss of these eyes is caused by either inoperable retinal detachment or damage to ciliary body function, arising from intravitreal fibrovascular and fibroglial proliferation. This proliferation seems to occur more commonly in injuries with lacerations of the ciliary body and retina and in injuries with vitreous hemorrhage. These initial conclusions were corroborated in a prospective observational study of 69 eyes with penetrating injury.<sup>57</sup>

In a study of retinal detachment following open-globe injury, Stryjeski et al. reported the clinical course of 893 cases of open-globe injury repaired emergently at the Massachusetts Eye and Ear Infirmary. The overall incidence of retinal detachment in this cohort was 29%. Of these, roughly one-fourth were identified within 24 hours of injury, roughly one-half were identified within one week of injury, and roughly three-fourths were identified within one month of injury.<sup>100</sup> (In most cases, especially within the first week, the diagnosis was made by ultrasonography.) By multivariable regression analysis, the factors associated with occurrence of retinal

detachment (at any timepoint) were poorer visual acuity at presentation following injury, higher zone of injury, and presence of vitreous hemorrhage. The authors constructed a useful model (the RD-OGI, or Retinal Detachment after Open Globe Injury, score) that incorporates these three clinical variables to estimate the probability of retinal detachment.<sup>100</sup>

The importance of vitreous hemorrhage in the pathophysiology of retinal detachment following penetrating ocular injury has been recognized for decades. Additionally, early case series suggested the efficacy of vitreous surgery in management of severe penetrating ocular injury.<sup>101-103</sup> Vitrectomy for penetrating ocular trauma was first advocated by Coles and Haik<sup>104</sup> in 1972 when, on examining several eyes enucleated after trauma, they noted fibroblastic tissue in areas of vitreous hemorrhage within several hours of injury. Beginning in 1979, Cleary and Ryan<sup>105</sup> published a series of papers in which they described an experimental model for penetrating ocular injury with vitreous hemorrhage. Invariably, a traction retinal detachment resulted. In subsequent animal studies, they demonstrated that vitrectomy performed 1–14 days after injury could significantly reduce the risk of traction retinal detachment.<sup>106</sup> These elegant translational studies support collective clinical impressions that vitrectomy may reduce the incidence of severe visual loss after penetrating injuries by removing the scaffold for intraocular fibrocellular proliferation and by lowering circulating levels of profibrotic chemokines.

Vitreous surgery should be performed in all eyes with light perception vision, lacerations involving the sclera, and moderate to severe vitreous hemorrhage. Growing clinical experience also supports the utility of secondary vitreoretinal surgery in eyes with no light perception at presentation. In several series of such patients treated with vitreoretinal surgery (typically performed after the initial repair), light perception was restored in 23–83% of patients and visual acuity of 20/200 or better was attained in 7%. By contrast, eyes in which secondary vitrectomy was deferred almost uniformly progressed to phthisis or enucleation.<sup>62,63,107-109</sup> In eyes undergoing secondary vitrectomy, favorable outcome (i.e., an anatomically restored eye with at least light perception) was associated with recovery of light perception after initial globe repair and vitrectomy

within 14 days of initial repair. Eyes with unfavorable outcome (NLP, phthisis, enucleation) were more likely to have sustained globe rupture (rather than laceration), zone III injury, ciliary body damage, choroidal detachment, and/or closed funnel retinal detachment.<sup>107,108</sup>

While there may be general consensus on the indications for vitrectomy in patients with penetrating injuries, the appropriate timing of vitrectomy has not been clarified.<sup>110</sup> Some experienced surgeons favor operating within the first 48–72 hours, and others prefer delaying surgery up to 14 days after injury.

Advantages of earlier intervention include prompt visualization of the fundus and immediate retinal surgery when indicated; reduction in complications related to vitreous incarceration in the laceration; and eliminating the need for a second operation by combining vitrectomy with primary repair.

Delaying vitreous surgery beyond 72 hours after the injury permits further diagnostic evaluation, including ultrasonography and electrophysiology, which may assist the surgeon in determining prognosis, counseling the patient about realistic expectations, and formulating a surgical plan. It also permits the operation to be performed under conditions more favorable than emergency circumstances. Furthermore, excision of the posterior cortical vitreous (a critical step in the vitrectomy) may be easier when vitrectomy has been delayed.

In addition, there is a concern of severe hemorrhage when attempting early vitrectomy, presumably secondary to uveal congestion associated with acute injury. Hemorrhagic choroidal detachment can cause extreme difficulty with insertion of an infusion cannula or other vitrectomy instruments without damaging the retina. Delaying surgery may decrease the risk of uncontrollable intraoperative hemorrhage, as well as allow choroidal hemorrhage to recede or to be drained more easily.

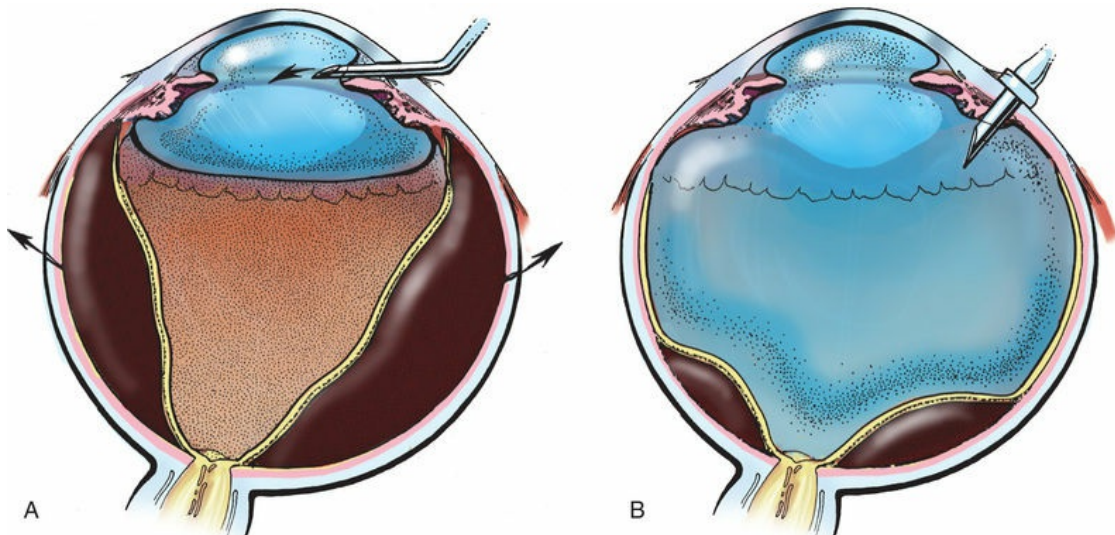

Most authors agree, however, that vitrectomy for severe penetrating injuries should not be delayed beyond 14 days.<sup>103</sup> First, if the vitrectomy is unsuccessful, these eyes may be at risk for developing sympathetic ophthalmia and require enucleation to prevent its development. The risk of sympathetic ophthalmia may be reduced if enucleation is performed within 14 days of injury.

Second, histologic studies of penetrating eye injuries show intraocular cellular proliferation within 1 week of injury with membrane formation already occurring by 2 weeks.<sup>111</sup>

Once the decision has been made to perform a vitrectomy, the surgeon has the following goals: (1) to clear the ocular media through removal of cataractous lens or vitreous hemorrhage; (2) to remove the vitreous scaffold from the scleral laceration site; (3) to remove the posterior hyaloid that could provide a future scaffold for epiretinal membrane formation and vitreoretinal traction; and (4) to identify and treat retinal breaks and detachment.

In most cases, general anesthesia with endotracheal intubation is employed for vitrectomy following trauma. Peribulbar or retrobulbar anesthesia has the risk of increasing orbital pressure leading to extrusion of intraocular contents, but has been used successfully in selected patients, typically those with short corneal or limbal wounds and a formed anterior chamber.<sup>112</sup> Historically, succinylcholine chloride has been avoided during induction. However, in an experimental study, succinylcholine administration resulted only in forward displacement of the iris and lens without extrusion of intraocular contents, suggesting that some of the historical fears of its use may be unwarranted.<sup>113</sup> In most cases, the wound will have been closed prior to vitrectomy, but the globe should still be inspected, with open or leaking wounds resutured to make the eye watertight.

At the onset of surgery, the surgeon must make several critical decisions that can profoundly influence the success of the procedure. First, the presence or absence of hemorrhagic choroidal detachment must be determined. This is best done by preoperative ultrasonography. If present, the blood can often be drained through scleral incisions while simultaneously infusing air or balanced salt solution into the eye. Infusion maintains normal IOP and can be done through a cannula or short needle inserted either through the limbus (in aphakic eyes) or through the pars plana (in phakic eyes) (Fig. 114.21). After drainage of the choroidal hemorrhage, a long pars plana infusion cannula (6 mm) may be inserted, but infusion should not be turned on until the cannula tip can be visualized in the vitreous cavity.

**FIG. 114.21** Vitrectomy for vitreous hemorrhage with hemorrhagic choroidal detachment after penetrating injury. (A) Scleral cutdown incisions are made to drain choroidal blood while air is infused into the eye through a cannula inserted through the limbus. (B) After drainage, a 6 mm pars plana infusion cannula is inserted and infusion started only when the cannula can be visualized within the vitreous cavity.

Second, the surgeon must decide whether surgery can begin through the pars plana or whether it must be started through limbal incisions. For instance, in the presence of total hyphema, where the status of the retina is unknown, the hyphema can be evacuated through a limbal incision with an irrigating infusion needle inserted through a second incision (Fig. 114.22). The same problem can be managed in aphakic eyes by inserting a long irrigating infusion needle through a pars plana incision and into the anterior chamber where it can be visualized and then turned on. Similarly, the vitrectomy instrument can be inserted through a pars plana sclerotomy and brought anteriorly to evacuate the hyphema. It is essential that all sclerotomies be deep enough to ensure penetration through the uveal tissue into the vitreous cavity. Recent improvements in the stiffness of smaller gauge (23G and 25G) vitrectomy instrumentation, and the accompanying expansion of available instrumentation, allow the surgeon to use these systems successfully in the treatment of traumatized eyes. One must be cognizant, however, that in the preparation of sclerotomies, the insertion of a 25G trocar imparts significantly more force on the

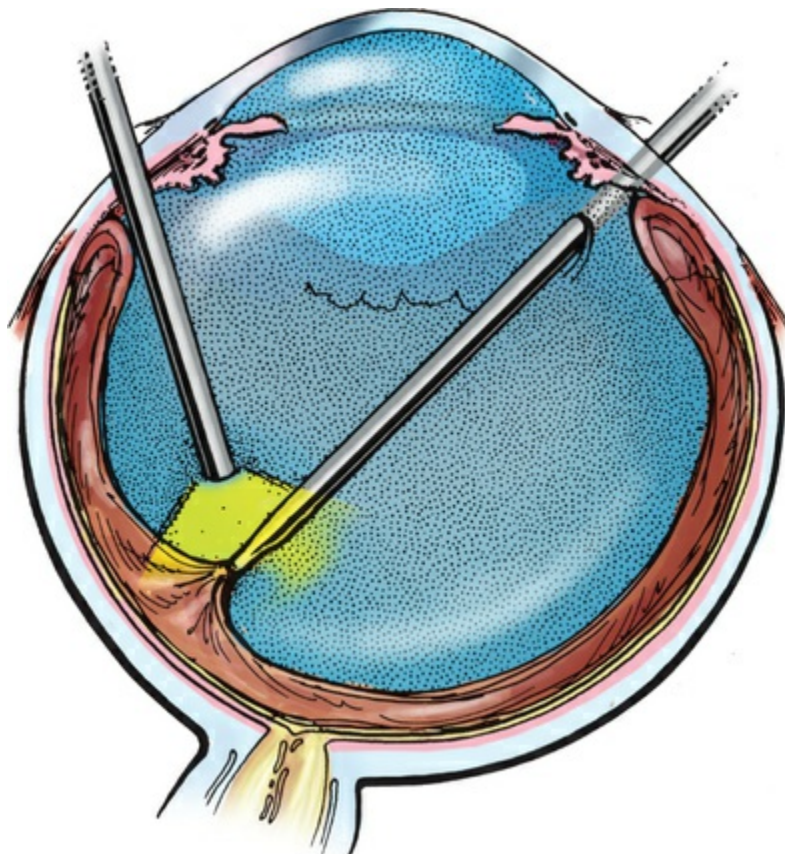

globe than a 20G blade. The correspondingly high IOP may cause leakage of freshly sutured rupture sites. To avoid the potential for leakage or hypotony, therefore, one can use a 25G MVR blade to create the initial sclerotomy prior to placing the small-gauge cannula or inserting instruments.

**FIG. 114.22** When anterior chamber hemorrhage precludes visualization of the infusion cannula at the beginning of a vitrectomy for vitreous hemorrhage after penetrating injury, a blunt 20G infusion needle can be inserted through the pars plana, maneuvered into the anterior chamber where it can be visualized through the cornea, and infusion turned on. The vitrectomy instrument can be brought into the anterior chamber in a similar manner to remove the hyphema and begin the vitrectomy. When the anterior chamber hemorrhage has been cleared to adequately visualize the pars plana infusion cannula, the blunt infusion needle can be removed and replaced with a fiberoptic probe.

Third, a decision must be made on the necessity of lens removal. Often, the lens has been lost at the time of the injury. In other instances, the lens will have become opacified, subluxed, or dislocated and will need to be removed. If the lens interferes with visualization of the posterior segment because of cataract or blood on its anterior or posterior surface, then it must be removed. In cases with cyclitic membranes, transvitreal sheets extending to an anterior injury site or to anterior hyaloid hemorrhage, the lens must be removed to achieve the objectives of the procedure. In most cases the lens is removed through the pars plana using either the vitrectomy probe or an ultrasonic fragmenting device.

After the anterior segment is cleared, the vitrectomy can be performed, proceeding from anterior to posterior. It is critical to remove the posterior cortical vitreous (Fig. 114.23). The peripheral retina is then carefully inspected for retinal tears and detachment. We routinely place a 3.5-mm or 4-mm encircling band to support the vitreous base and decrease the risk of subsequent retinal detachment.

**FIG. 114.23** When a vitrectomy is performed for ocular trauma, it is critical to remove the posterior cortical vitreous. When a posterior vitreous detachment is not present, one can be created by either suction, a vitreoretinal pick, or carefully incising the posterior hyaloid with a myringotomy blade and then lifting it with the pick.

When retinal tears are identified, they are treated by endophotocoagulation. Cryopexy should be avoided due to concern about the increased inflammatory response and release of profibrotic cytokines. Placement of a posterior radial scleral buckle is recommended in cases with persistent traction adjacent to a posterior retinal tear.

When retinal detachment is present, it is essential that all tangential and anteroposterior vitreoretinal traction on the retinal break be relieved either by membrane peeling, delamination, or segmentation. If this traction cannot be relieved, it will be necessary to place a scleral buckle of adequate size to alleviate traction or to perform a relaxing retinectomy. Subretinal fluid usually is drained transvitreally during a fluid–gas exchange either through a posterior retinal break or through a posterior retinotomy created in an area free of traction, ideally superonasal to the optic nerve. In some cases, extrusion can be used to flatten the retina by drainage of posterior subretinal fluid through a peripheral retinal break. Long-acting gases, such as sulfur hexafluoride or perfluoropropane, or silicone oil can be injected to provide a longer-lasting internal tamponade.<sup>114</sup>

Retinal incarceration in the scleral laceration site can produce complicated retinal detachments. In many cases this situation can be managed with vitrectomy and scleral buckling, particularly when the incarceration is located anteriorly. However, when the incarceration is more posterior, scleral buckling is more difficult and retinotomy may be necessary. Han et al.<sup>115</sup> reviewed their experience with this problem and recommended retinectomy when a scleral buckle is insufficient to relieve the traction or when the incarceration is located too posteriorly to be treated with a scleral buckle. In the former situation, they performed a circumferential relaxing retinectomy. In the latter situation, they performed

retinotomies circumscribing the retinal incarceration site. Endodiathermy was placed to provide hemostasis before the retinotomy. With these techniques, they achieved anatomic success in 11 of 15 eyes (73%), but only six eyes regained visual acuity of 5/200 or better. Eyes with traumatic retinal detachment associated with retinal incarceration appear to carry a poor prognosis even when managed aggressively.

Intraocular bleeding is a frequent intraoperative hazard of vitrectomy for penetrating injuries and, if massive and uncontrolled, can preclude successful vitrectomy. Intraoperative bleeding can be managed by a number of maneuvers, including raising the infusion pressure to increase the IOP, endodiathermy or endophotocoagulation to areas of active hemorrhage, fluid–air exchange, injection of viscoelastic substance (i.e., sodium hyaluronate), or injection of heavy liquids (i.e., fluorinated hydrocarbons such as perfluoro-n-octane or perfluorodecalin). Control of bleeding by infusion of a thrombin solution at a concentration of 100 U/mL has been reported.<sup>116</sup>

Visualization of the posterior structures must be preserved. When the cornea becomes cloudy because of epithelial edema, the epithelium can be carefully removed with a surgical blade. Folds in Descemet's membrane can be overcome by coating the corneal endothelial surface with sodium hyaluronate.<sup>117</sup> In some cases, visualization through a scarred cornea can be improved with the use of a wide-angle viewing system. In cases in which the cornea is grossly edematous, markedly distorted by a stellate laceration with multiple sutures, or damaged with tissue loss requiring a patch graft, vitreoretinal surgery can be performed with a temporary keratoprosthesis or with endoscopic visualization. The first temporary keratoprosthesis, the Landers–Foulks device, is a clear cylindrical polymethylmethacrylate lens that fits into a trephinated corneal bed and permits excellent visualization of the vitreous and retina without an additional contact lens.<sup>118</sup> Though a great advance, this keratoprosthesis has a concave lens that minimizes the retinal image and a long optical cylinder that obstructs visualization of the anterior retina and vitreous base where much of the significant pathology in traumatized eyes exists. Our preference is the Eckardt temporary keratoprosthesis,<sup>119</sup> which is made of clear

silicone rubber and has normal magnification and a short optical cylinder, allowing visualization for anterior vitreoretinal dissections, as well as posterior segment pathology. In a series of 11 traumatized eyes surgically rehabilitated with the aid of an Eckardt keratoprosthesis, five (45%) obtained a visual acuity of 20/400 or better.<sup>120</sup>

Penetrating keratoplasty (PKP) can be combined with vitrectomy and temporary keratoprosthesis to reconstruct severely traumatized eyes. However, functional outcomes are usually disappointing, often due to graft failure and hypotony from ciliary body dysfunction. In a recent series of 34 eyes managed with combined PKP and vitrectomy, fewer than one-third achieved vision of better than hand motions at any time postoperatively and fewer than 15% of grafts remained clear more than 1 year postoperatively.<sup>121</sup>

An alternative to temporary keratoprosthesis in eyes with impaired visualization due to corneal opacity is endoscopy.<sup>122</sup> This approach may be particularly useful in cases in which a donor graft or corneal surgeon may not be readily available or in cases in which silicone oil placement is planned and there is concern of corneal graft failure. Disadvantages of endoscopy include the need for specialized equipment, mandatory additional surgery for corneal transplantation, and a steep learning curve.

No prospective controlled study has evaluated the efficacy of vitrectomy in penetrating ocular injury. Large series of patients treated with vitrectomy have been published, with the comment that favorable results would not have been possible without vitreoretinal surgical techniques. The frequency of obtaining functional visual acuity of 5/200 or better ranged from 52% to 78%. A 1984 case–control study matched eyes managed with vitrectomy with similar eyes that did not undergo vitrectomy.<sup>93</sup> A trend toward benefit with vitrectomy was demonstrated in severe injuries in which initial visual acuity was worse than 5/200. In a more recent retrospective series of 36 eyes treated with immediate vitrectomy and silicone oil endotamponade for coexisting penetrating injury and retinal detachment, ambulatory vision was achieved postoperatively in 64%. Patients were most likely to attain ambulatory vision if they presented preoperatively with ambulatory vision and without macular detachment.<sup>123</sup>

## Endophthalmitis

Endophthalmitis is a potentially devastating complication of penetrating injury. The reported incidence has ranged from 1–16% of penetrating injuries.<sup>124–126</sup> but there has been a steady decline over the past few decades.<sup>127</sup>

Ocular signs associated with traumatic endophthalmitis are similar to those with a postoperative infection: aqueous cell and flare, hypopyon, and vitreous cell and flare exceeding that expected from the injury itself. Aqueous or vitreous fluff balls are characteristic of fungal infections. However, the initial diagnosis of posttraumatic endophthalmitis can be difficult because the considerable postoperative inflammation and pain that commonly occur in these eyes can obscure infectious endophthalmitis. Delay in diagnosis, compounded by the virulent bacteria involved in these cases, makes the prognosis for recovery particularly grim.

In one retrospective investigation, risk factors for endophthalmitis after penetrating ocular trauma were subjected to univariate and multivariate analysis.<sup>128</sup> Factors such as scleral wounds, hyphema, uveal prolapse, retinal detachment, suprachoroidal and vitreous hemorrhage, lens rupture, and IOFB were investigated. Only lens rupture was independently significant for the development of endophthalmitis, carrying a relative risk of infection of 15.8. In a more recent comparative cohort study, patients developing posttraumatic endophthalmitis were ascertained prospectively and compared with historical controls of patients with open-globe injury. Delay in primary repair, ruptured lens capsule, and dirty wound were each independently associated with the development of posttraumatic endophthalmitis.<sup>129</sup> The presence of an IOFB had a relative risk of infection of 1.9, but this did not reach statistical significance. In the National Eye Trauma Study, conducted between 1985 and 1991, there was a statistically significant increased incidence of endophthalmitis for eyes with retained IOFBs, particularly if surgical intervention occurred more than 24 hours after the injury (13.4% versus 3.5%,  $p < .0001$ ).<sup>130,131</sup> One must not infer from this study, however, that prompt IOFB removal is always the preferred treatment, since it was not clear which patients (if any) received prompt systemic antibiotics, and the study was conducted before the widespread availability of antibiotics

with high vitreous penetration.

Three more recent series have reported lower rates of endophthalmitis, and the authors attributed this reduction in part to the systematic use of antibiotics.<sup>78,125,126</sup> In one of these series, intravenous vancomycin (or clindamycin if allergic) and ceftazidime (or a fluoroquinolone if allergic) were administered promptly and continued for at least 48 hours.<sup>125</sup>

While the majority of cases of postoperative endophthalmitis are caused by less virulent coagulase-negative staphylococci (especially in injuries associated with metallic foreign bodies), posttraumatic endophthalmitis is frequently caused by virulent organisms such as *Bacillus*, *Streptococcus*, and Gram-negative organisms.<sup>132</sup> *Bacillus cereus* is most commonly associated with penetrating ocular injuries that occur in rural areas and, while rarely seen in postoperative endophthalmitis, accounts for 25–46% of cases of posttraumatic endophthalmitis.<sup>126</sup> The multiple enzymes and exotoxins elaborated by this organism lead to blindness or enucleation in the vast majority of eyes,<sup>126</sup> although several cases of successful management and retained useful vision have been reported.<sup>133</sup> Gram-negative bacteria are responsible for up to 20% of cases of posttraumatic endophthalmitis.<sup>75</sup> These cases also carry a poor prognosis, with one-third of eyes ending in no light perception or enucleation.<sup>134</sup>

Management of traumatic endophthalmitis parallels that described for postoperative endophthalmitis. Cultures of the aqueous and vitreous are obtained, any retained foreign body is removed, and antibiotic therapy is administered. Cultures should include blood agar, chocolate agar, thioglycolate broth incubated at 37°C for bacteria, and Sabouraud agar incubated at 25°C for fungi. Gram stains should also be obtained and may provide useful information for antibiotic selection. The patient's history of immunization against tetanus should be evaluated, especially in injuries involving contact with soil or rust, and appropriate booster or vaccination should be given.

We recommend antibiotic delivery via systemic, subconjunctival, intraocular, and topical routes. Although the Endophthalmitis Vitrectomy Study (EVS) did not show a benefit to using intravenous ceftazidime or aminoglycosides, it should be noted that

the EVS studied only patients with acute endophthalmitis following cataract extraction or lens exchange.<sup>135</sup> In posttraumatic endophthalmitis, we still consider systemic antibiotic use the standard of care. We prefer a third- or fourth-generation fluoroquinolone (levofloxacin 500–750 mg or moxifloxacin 400 mg daily for 7 days) because of its broad coverage of common pathogens and its excellent vitreous penetration following intravenous or oral administration.

Intraocular antibiotics in cases of suspected endophthalmitis should target a broad range of gram-positive and gram-negative organisms, and intraocular toxicity must be negligible. Vancomycin is active against gram-positive bacteria, is bactericidal, rarely promotes resistance, and is well tolerated by the eye in efficacious dosages (1.0 mg/0.1 mL). Ceftazidime (2.25 mg/0.01 mL) is a  $\beta$ -lactamase third-generation cephalosporin with excellent activity against most gram-negative bacteria and some gram-positive bacteria, including penicillinase-producing *Staphylococcus aureus*. Alternative intraocular antibiotics include clindamycin phosphate (1 mg/0.1 mL) and amikacin (400  $\mu$ g/0.1 mL).

Prophylactic intraocular injection of antibiotics to prevent endophthalmitis in patients with penetrating injury is controversial. However, when there is high suspicion of injury from a contaminated foreign body, or early signs of endophthalmitis are present (e.g., significant anterior chamber cells, perivascular retinal sheathing), prophylactic treatment with intravitreal antibiotics should be considered. In a prospective study of eyes with penetrating injury, patients were randomized to receive either intraocular injection of antibiotics (40  $\mu$ g of gentamicin sulfate and 45  $\mu$ g of clindamycin sulfate) or balanced saline solution. The rate of endophthalmitis within 2 weeks was significantly lower in the group treated with antibiotics (2.3% versus 0.3%), but this difference was driven by the high incidence of infection in eyes with IOFB (28% in the control group versus 0% in the antibiotic group).<sup>136</sup>

Prognostication for cases of traumatic endophthalmitis is difficult because of the compounding effect of the penetrating injury. Prognosis also relates to the specific organism and to the interval to diagnosis. Overall, Brinton et al.<sup>124</sup> reported 42% of cases obtaining

final VA of 20/300 or better and 26% with 20/30 or better. Affeldt et al.<sup>137</sup> reported only 22% of their patients with 20/400 or better. Lieb et al. reported final VA of 20/400 or better in only 50% of open globes with a positive bacterial culture and overt signs of endophthalmitis.<sup>138</sup>

## Cataract

Management of cataract after penetrating injury is controversial. Diagnosis of cataract at presentation can be difficult, as fibrin in the anterior chamber almost immediately after the injury can simultaneously obscure visualization of the lens and give the appearance of a cataract. In such settings, we rarely perform a lensectomy at the time of repair of the corneal laceration. In some cases, however, a rent can be identified in the anterior lens capsule accompanying an opacified lens. It is in this situation that cataract extraction at the time of primary repair of the laceration may be considered to reduce the chance of postoperative inflammation and infection.

After deciding to perform a primary lensectomy, the surgeon should first repair the laceration using the techniques and principles described earlier in this chapter. One must then decide whether the cataract extraction can be performed through a limbal incision or via the pars plana. When the laceration is limited to the cornea and the posterior lens capsule is believed to be intact, a limbal incision should be created and lens aspiration or phacoemulsification performed. If, during the course of the surgery, it becomes apparent that the posterior capsule has been damaged, it is critical to manage the vitreous loss properly, making sure there is no vitreous incarcerated in either the laceration site or the limbal incision. Primary placement of an IOL has been shown to be well tolerated in selected cases and does not appear to increase the risk of endophthalmitis or other postoperative complications. However, the IOL power selection may be inaccurate, and the surgeon may misjudge the intactness of the posterior capsule. Echography with a 20-MHz probe has been shown to be highly accurate in assessing the integrity of the posterior lens capsule in eyes with dense traumatic cataract.<sup>139</sup>

In one series, 64% of patients who underwent lensectomy and IOL implantation at the time of primary repair of a penetrating ocular injury obtained 20/40 or better visual acuity.<sup>140</sup> Therefore, if capsular support allows, one can proceed with IOL placement. If too little capsule remains, an anterior chamber IOL, or sutured posterior chamber IOL, should be deferred as a second procedure. Implantation of an IOL in children has also become an accepted means of visual rehabilitation. In children 4–17 years of age, up to 87% of penetrating ocular injuries primarily managed with lens aspiration and IOL implantation obtained 20/40 or better visual acuity.<sup>141</sup> IOL implantation in infants, however, is still controversial and should probably be deferred to a secondary procedure.

Cataract surgery is more easily performed following primary repair. Deferral of surgery permits clearing of fibrin and intraocular inflammation and allows proper determination of the extent of the cataract, position of the lens, capsular integrity, and IOL power.

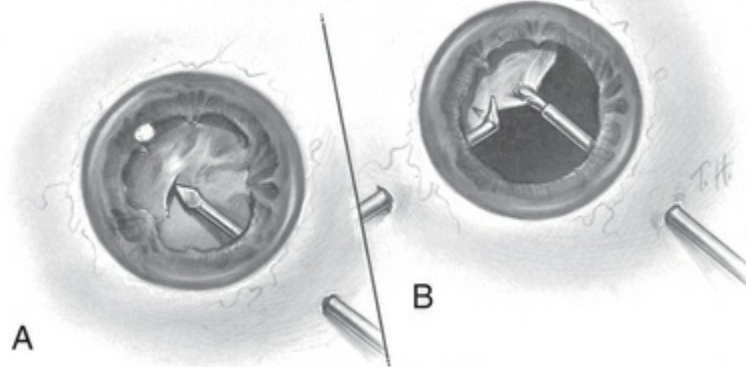

When cataract surgery is planned, the choice between a limbal or a pars plana approach depends on the extent of zonular support. If the lens is in place with no signs of iridodonesis or phacodonesis, standard cataract surgery through a limbal or clear corneal incision can be performed. If the lens is believed to be dislocated or subluxated, the surgery should be performed through the pars plana with vitrectomy instrumentation as described for cataracts associated with nonpenetrating injuries. Because of the high incidence of damage to anterior chamber angle structures in eyes with penetrating injuries, we routinely do not advocate anterior chamber IOL implantation when pars plana lensectomy has been performed. However, the evolution of techniques for sulcus fixation of posterior chamber IOLs presents a potentially acceptable alternative to contact lens fitting for the aphakic patient.

## Late Complications of Penetrating Injury

Despite excellent repair of corneoscleral lacerations and proper vitreoretinal surgery for vitreous hemorrhage, cataract, and other immediate complications of penetrating injuries, a variety of late complications can arise.

Fibrotic membranes result from organization of residual lens

material after a traumatic cataract. In this situation, the material is often quite difficult to cut with the vitrectomy instrument alone (Fig. 114.24). However, after segmentation with a myringotomy blade or scissors, the material may be more easily removed with the vitrectomy probe. When this fails, the segments of tissue can be grasped with intraocular microforceps, cut with microscissors, and removed from the eye through the sclerotomy. If the tissue has become vascularized, it may be necessary to use endodiathermy for hemostasis. With these techniques, a clear pupillary space can be achieved in nearly all cases. Final visual acuity depends on the anatomy of the posterior segment and, in children, the presence of amblyopia.

**FIG. 114.24** Residual lens material can cause an opaque pupil. This material can be difficult to remove with vitrectomy instrumentation. In these cases the material is incised (A) and then grasped with a microforceps held in one hand and cut with an intraocular scissors (B) or vitrectomy instrument held in the other hand.

Some aphakic eyes develop an occluded pupil (Fig. 114.25). This often is caused by residual lens material but can also result from contraction of a vitreous sheet incarcerated in a corneal or limbal laceration. In the latter situation, the pupillary space can be recreated by freeing the vitreous from the wound and excising it, although cutting of the iris with the vitrectomy instrument may be necessary in some instances.

**FIG. 114.25** This patient developed an occluded pupil after an extensive corneal laceration with extrusion of the lens.

Pupillary membranes can occur after penetrating injury in the absence of residual lens material. These presumably develop either from proliferation through an anterior scleral laceration that grows in the retropupillary space or from proliferation of tissues as a result of the inflammation associated with a penetrating injury. Although some of these membranes simply impair visualization of posterior structures, more advanced cyclitic membranes can cause ciliary body detachment and hypotony.

In general, we advocate surgery through the pars plana for these membranes, using techniques similar to those described for residual lens material. However, if one suspects a cyclitic membrane, care must be taken to avoid infusing into the subretinal or suprachoroidal space. Surgery should be performed with a bent infusing needle until the sutured pars plana infusion cannula can be visualized. The use of a smaller-gauge vitrectomy instrument may be contemplated in these cases; however, the larger 20G probe may be necessary for effective cutting and ingestion of the often thick cyclitic membranes.

Macular pucker can develop after penetrating injuries and is managed in a manner identical to that for idiopathic macular pucker. Retinal detachment, either traction or rhegmatogenous, can also be a late complication of a penetrating injury<sup>142</sup> and can be managed similarly to nontraumatic detachments. However,

additional care should be taken when one is performing the conjunctival peritomy and isolating the rectus muscle because of the possibility of areas of scleral thinning associated with the laceration.

## Sympathetic Ophthalmia

Sympathetic ophthalmia is a bilateral inflammation of the uveal tract characterized by nodular or diffuse infiltration with lymphocytes and epithelioid cells. Its onset is insidious, and its course is characterized by exacerbations and remissions. Although the cause is unknown, almost all reported cases are associated with a penetrating injury to the globe.<sup>143</sup> The risk of sympathetic ophthalmia following nonsurgical trauma is estimated at 0.3% to 1.9%.<sup>144</sup> In a prospective surveillance study for sympathetic ophthalmia performed in the UK and Ireland, an incidence of 0.03/100,000 was calculated. Interestingly, the most common cause in the 23 cases reported was retinal surgery.<sup>145</sup>

The inflammation appears in the injured (exciting) eye usually within 4–8 weeks. The injured eye does not quiet readily, remaining injected with a persistent, low-grade uveitis. The iris is thickened, is unresponsive to light, and can have nodules at the pupillary margin. Keratic precipitates can be seen. Eventually, phthisis bulbi may develop.

The sympathizing eye becomes involved simultaneously or shortly thereafter. It usually develops mild uveitis with pain, photophobia, and keratic precipitates. The iris will become thickened and immobile with posterior synechiae, leading to a vascularized pupillary membrane and possible secondary glaucoma. In some cases, the disease begins in the posterior segment with small whitish choroidal lesions (histopathologically termed “Dalen–Fuchs nodules”), retinal and choroidal swelling, and possibly exudative retinal detachment.

Evidence suggests that the risk of sympathetic ophthalmia is extremely low if the injured eye is enucleated within 2 weeks of the injury. Thus, we recommend secondary vitreoretinal surgery within this timeframe to allow determination of whether an injured eye is salvageable. If it is believed that the eye has no visual potential after

vitrectomy, enucleation (rather than evisceration) is performed. However, isolated cases of inflammation in the sympathizing eye isolated cases have been reported at 5, 8, and 10 days after injury.<sup>146</sup>

Once the diagnosis of sympathetic ophthalmia has been made, enucleation of the exciting eye should seldom be done because this eye may turn out to be the better of the two. However, if there is little or no vision, enucleation may be beneficial, particularly if it is performed within 2 weeks of the onset of symptoms.

Corticosteroids remain the treatment of choice for sympathetic ophthalmia, though steroid-sparing immunomodulating agents, such as infliximab, may be necessary because of side-effects of corticosteroids or the need for long-term use. High doses of prednisone (up to 200 mg/day) over the first 7–10 days may be particularly critical to the patient's prognosis. Frequent topical corticosteroids should be used in cases with anterior segment inflammation. In patients whose disease does not appear to respond to corticosteroids, cytotoxic agents may be effective. Use of corticosteroids beginning at the time of injury does not appear to prevent development of sympathetic ophthalmia.<sup>147</sup>

Although there is little consensus on the optimal method of treatment, it is generally agreed that prompt recognition and treatment of sympathetic ophthalmia are crucial for preservation of vision. Kilmartin et al. reported 1-year visual acuity of 20/40 or better in 12 of 16 patients treated initially with systemic corticosteroids, although 11 received additional immunosuppression.<sup>145</sup> In a larger series of 85 patients drawn from three tertiary-care uveitis centers, 59% maintained visual acuity of 20/50 or better in the sympathizing eye and 75% maintained visual acuity of 20/200 or better.<sup>148</sup>

## **Application of Online Resources and Newer Technology to Ocular Trauma**

Numerous online resources regarding the incidence, scope, and prevention of eye trauma are available to patients and general medical practitioners. We recommend the following two sites, sponsored by the American Academies of Ophthalmology and

Pediatrics, respectively: (1)

<http://www.geteyesmart.org/eyesmart/living/eye-injuries/preventing.cfm>; and (2)

<https://www.healthychildren.org/English/tips-tools/Symptom-Checker/Pages/Eye-Injury.aspx>.

The advent of smartphone technology has allowed the concept of ophthalmic telemedicine to approach realization. In this scenario, smartphone-based ophthalmic examination devices (such as a funduscope or portable slit lamp) are used to perform ocular examination. Image data are sent wirelessly for real-time analysis (either by trained readers or by artificial-intelligence algorithms) and stored for later complete analysis by specialists as needed. The Professional Eye Exam Kit ([www.peek.org](http://www.peek.org)) is a smartphone-based platform through which a variety of vision tests and ocular imaging can be performed. Such a paradigm allows real-time examinations in remote settings in which access to necessary diagnostic services is impossible. In the context of ocular trauma, for example, real-time telemedical evaluation would assist onsite field personnel to determine the relative urgency of referral and the appropriate destination for definitive treatment.

## Prevention

As the vast majority of ocular trauma is preventable, physicians should reinforce the importance of eye protection for all occupational or recreational activities that may lead to eye injury. The primary occupational risks include metalworking and use of powered tools. Sports with a higher risk of injury included basketball, baseball, pool sports, and racquet sports.<sup>149</sup> In a joint policy statement, the American Academy of Ophthalmology and the American Academy of Pediatrics recommend the mandatory use of protective eyewear for all young athletes with best-corrected vision worse than 20/40 in one eye or those who have undergone eye surgery.<sup>150</sup> Various styles of goggles, face shields, face guards, and masks tailored to individual sports are readily available. Sports eyewear should conform to the requirements of the American Society for Testing and Materials (ASTM), which provides standards of protection appropriate for specific sports. In the

United States, the Protective Eyewear Certification Council (PECC) has begun certifying protectors that comply with the ASTM requirements. Lenses made of polycarbonate material (or CR-39, an allyl/resin plastic, for stronger prescriptions) are recommended.

Legislation in a given country has a major impact on the incidence of serious eye injuries caused by a particular object. For example, the rate of injury from firearms, BB guns, and fireworks is 10-fold greater in the United States (where their use is legal) than in Hungary, where their use by individuals is illegal.<sup>151</sup> Similarly, a mandate in 2011 by the National Federation of State High School Associations to require high school field hockey players to wear protective eyewear led to a threefold reduction in orbital and eye injuries among players.<sup>152</sup> Thus, legislation directed at regulation of behaviors or restriction of items known to be associated with ocular injury may reduce incidence and severity of ocular trauma.

# Surgery for Proliferative Diabetic Retinopathy

---

*Simon Brunner, Susanne Binder*

**Introduction**

**Indications and Timing of Surgery**

**Preoperative Evaluation and Informed Consent**

**Surgery**

**Surgical Procedure**

**Postoperative Care**

**Complications**

**Results of Surgery as Indicated by Evidence-Based Trials**

**Conclusion**

## Introduction

Surgery for non-life-threatening diseases always has to be carefully balanced against conservative treatments. Similarly, the decision to recommend surgery for complications of diabetic retinopathy

depends on many factors. The present and possible future visual function has to be determined and compared with the patient's expectations and needs. All potential surgical benefits and unwanted side-effects, as well as consequences of alternative strategies including observation, must be discussed in detail with each patient.

Pars plana vitrectomy was originally developed by Machemer in 1971 as a closed system, allowing for a safe intraocular manipulation and constant viewing of the retina.<sup>1</sup> At that time, indications were mainly nonclearing vitreous hemorrhages of greater than 1-year duration and complicated retinal detachments with macular involvement. However, in the past decades, improvements in technique and instrumentation have broadened the use of vitrectomy.<sup>2-5</sup> Today, it has an established role in the management of many severe complications of diabetic retinopathy, together with many other surgical procedures.<sup>6,7</sup> The principal underlying pathology in this disease is retinal ischemia, which may finally lead to the development of fibrovascular proliferations and membranes with the risk of secondary glaucoma, vitreous hemorrhage, and/or retinal detachment. The principles and techniques described in this chapter may be applied to the medical and surgical treatment of other proliferative vascular retinopathies as well, e.g., retinal vein occlusions, Coats disease, or retinopathy of prematurity (ROP).

Following the pathogenetic evolution of proliferative diabetic retinopathy, the cornerstones are progressive retinal microvascular closures with ischemia (see also [Chapter 50, Nonproliferative diabetic retinopathy and diabetic macular edema](#), and [Chapter 51, Diabetic proliferative retinopathy](#)). They are the main causes of tissue hypoxia with subsequent development of macular edema and/or retinal and iris neovascularizations. These processes are triggered by diverse local proangiogenic factors, as insulin-like growth factor 1 (IGF-1), basic fibroblast growth factor (bFGF), and others.<sup>8-12</sup>

The conversion from nonproliferative to proliferative diabetic retinopathy was assumed to involve recruitment and proliferation of retinal vascular endothelial cells, eventually promoted by locally activated cytokines, as vascular endothelial growth factor (VEGF).

This cytokine provokes endothelial cell growth and permeability,<sup>8-12</sup> being associated with higher white blood cell counts and other inflammatory markers. The VEGF protein was found to be expressed in glial cells of the retina and optic nerve, retinal astrocytes, pigment epithelial cells, vascular endothelial cells, and ganglion cells.<sup>12</sup> VEGF is also suspected to mobilize and augment endothelial progenitor cells (EPC) from bone marrow by acting as a chemoattractant protein.<sup>13-16</sup> Circulating EPCs then are assumed to directly go to the sites of ischemia or neovascularizations to initiate new vessel and tissue formation.<sup>13,14</sup> The new (fibro-)vascular tissue may then proliferate in the space between retina and vitreous. With further ingrowth it may contract, potentially resulting in vitreous hemorrhage, which may stimulate further fibrosis and vitreous contraction, leading to retinal breaks or tractional detachment.<sup>12</sup>

## Indications and Timing of Surgery

### Cataract

Extracapsular cataract surgery with intraocular lens (IOL) implantation is usually well tolerated in advanced diabetic retinopathy, when there are no anterior segment neovascularizations.<sup>17,18</sup> The removal of an opacified lens allows for a better fundus evaluation and visualization, e.g., for panretinal photocoagulation. In the past, a higher incidences of iris neovascularizations, secondary glaucoma, and vitreous hemorrhage were reported after intracapsular cataract extraction in association with proliferative diabetic retinopathy, notably by Aiello et al.<sup>19</sup> However, in recent times, as small incision cataract surgery, photocoagulation, and anti-VEGF drugs are widely used, anxiety has shifted from iris and retinal neovascularizations to diabetic macular edema (DME). Progression may be lower when grid/focal lasers are applied before cataract surgery, or when panretinal photocoagulation is applied after lens extraction instead of before.<sup>20</sup> In general, proliferative diabetic retinopathy should be treated with panretinal photocoagulation with/without intravitreal anti-VEGF medication before cataract surgery whenever possible, but panretinal photocoagulation may also be applied at time of surgery

or shortly thereafter.<sup>21</sup> Along with improvements in vitrectomy surgery techniques, an increasing trend for simultaneous vitrectomy and cataract surgery has been observed in recent decades; lensectomy may be particularly helpful in revision vitrectomy surgery or in eyes with much reduced prognosis.<sup>22,23</sup> The advantages of any cataract extraction are a better intraoperative view and access to the vitreous base, which is of utmost importance in cases of fibrovascular proliferations in diabetic retinopathy or proliferative vitreoretinopathy; there is also evidence from Schiff et al. that reoperation rates seem to decrease when the lens has been removed during vitrectomy.<sup>24</sup> Similarly, fear of iris neovascularizations after combined surgery has been reduced by careful application of panretinal photocoagulation and anti-VEGF drugs during surgery.<sup>24</sup> In younger patients with clear lenses, the loss of accommodation has to be weighed against possible intra- and postoperative complications, such as earlier cataract formation requiring another surgery.<sup>17,24</sup>

## High-Risk Retinal Neovascularization

### Fibrovascular Proliferations

Severe fibrovascular proliferations in proliferative diabetic retinopathy can produce a major threat of profound loss of vision without surgical intervention. A progressive proliferation of fibrovascular preretinal tissue may occur, despite panretinal photocoagulation, as described by Hutton, Smiddy, and Ho (Figs. 115.1–115.3).<sup>17,18,25</sup>

**FIG. 115.1** Proliferative diabetic retinopathy with extensive neovascularization.

**FIG. 115.2** Progression of fibrovascular proliferation and vitreous hemorrhage despite panretinal photocoagulation.

**FIG. 115.3** Postoperative appearance after vitrectomy for severe fibrovascular proliferation.

The Diabetic Retinopathy Vitrectomy Study (DRVS)<sup>26,27</sup> established the definition of “advanced, active, neovascular, or fibrovascular proliferation” based on a review of studies of the natural history. The term “severe” for new vessels or fibrovascular proliferations was defined in the DRVS according to standard photographs and size definitions.<sup>26</sup> Basically, the benefit of surgery tends to increase with increasing severity of neovascularization. Eyes most suitable for early vitrectomy are those with both severe fibrovascular proliferations and at least moderately severe neovascularizations despite extensive panretinal photocoagulation.<sup>6,27</sup> More recent papers reported similar favorable surgical results for severe diabetic fibrovascular proliferations.<sup>28,29</sup>

Stable or improved visual function may be achieved in 78% of cases on average. Good prognostic factors include younger age at baseline (<40 years), preoperative panretinal photocoagulation, better visual acuity (>5/200), no iris neovascularizations, and no iatrogenic breaks at surgery.<sup>26,30</sup> Therefore, extensive panretinal photocoagulation and/or anti-VEGF medications are recommended prior to early vitrectomy to improve the patient's outcome.<sup>25,31–33</sup> In patients with relatively asymptomatic pathologies, intensive counseling is essential, as some eyes lose vision despite careful surgery.

## Vitreous Hemorrhage

Nonclearing vitreous hemorrhage in diabetic retinopathy was the earliest indication for vitrectomy in the 1970s, representing 70% of cases at that time.<sup>2</sup> Today, it is still one of the most common indications for vitrectomy, although surgery may be avoided or at least postponed in many cases. Waiting, head elevation, or intravitreal injection of hyaluronidase may lead to spontaneous blood clearing, thus allowing for panretinal photocoagulation to induce regression of active retinal neovascularizations.<sup>34,35</sup> Diode laser systems, eventually delivered by indirect ophthalmoscopy, might be more effective than argon laser in some cases.<sup>25</sup> Early vitrectomy, defined by the DRVS as within 1–4 months from onset, results in earlier recovery of vision and better functional outcome after 2 and 4 years.<sup>27</sup> The benefit is greater in patients with type 1 diabetes mellitus, compared to type 2. This difference might be influenced by a greater incidence of maculopathy and posterior vitreous detachment in elderly type 2 diabetic patients.<sup>36</sup>

In proliferative diabetic retinopathy with dense premacular (subhyaloidal) vitreous hemorrhage, blood is trapped between the posterior hyaloid interface and the internal limiting membrane. The hemorrhage is usually well demarcated, resulting in significant visual loss. It may be associated with fibrovascular proliferations, preretinal membrane formation, or tractional macular detachment, which are common indications for an early vitrectomy (Figs. 115.4 and 115.5).<sup>26</sup> Less-invasive treatment methods include observation, laser membranotomy, or intravitreal injections with recombinant tissue plasminogen activator (r-tPA) or gas. When those methods are not successful, vitrectomy may improve functional recovery or decrease the risk of complications.<sup>26,32,37</sup> Again, a longer delay than a few months for surgery is not recommended, as the proliferative process may advance and surgical dissection become more difficult.<sup>25,38</sup> Another relatively urgent indication for vitrectomy in nonclearing vitreous hemorrhage is rubeosis iridis and/or severe progressive proliferation of the fellow eye, especially when no panretinal photocoagulation has been applied.<sup>25,27</sup>

**FIG. 115.4** Dense premacular hemorrhage. Note extensive fibrovascular proliferation, contraction, and distortion of retinal vessels.

**FIG. 115.5** Postoperative appearance after vitrectomy, membranectomy, and removal of preretinal hemorrhage.

## Macular Traction and Macular Edema

Vitreomacular traction syndrome, vitreopapillary traction, diabetic macular edema, epiretinal membrane, or macular hole formation in patients with proliferative diabetic retinopathy have specific features in their presentation and management, representing newer indications for vitrectomy.<sup>39-43</sup> Opacification of posterior vitreous cortex or preretinal membrane formation alone results in substantial visual loss, sometimes associated with metamorphopsia or diplopia.<sup>31,44</sup> These changes may occur after premacular hemorrhage or extensive panretinal photocoagulation.<sup>26</sup> Vitreomacular traction may be associated with more complex vitreoretinal adhesions than in nondiabetic patients, eventually resulting in tractional retinoschisis.<sup>45</sup> Vitreopapillary traction is a relatively new, controversial indication for vitrectomy, with limited evidence for functional improvement.<sup>46</sup> In eyes with coexistent macular edema, a causative role of vitreopapillary traction has been suggested.<sup>47</sup> Diabetic epiretinal membranes are more likely to have more focal attachments to the macula and more proliferative activity than idiopathic epiretinal membranes.<sup>41,42</sup> In cases of diabetic macular edema, tangential traction, or former intravitreal surgery, macular holes may develop.<sup>39,40,48</sup> To avoid progression of diabetic macular edema, panretinal photocoagulation may be divided into smaller sessions or be applied after intravitreal injections of anti-VEGF drugs.<sup>49,50</sup>

All these pathologies are relative indications for early, extensive, and meticulous surgical treatment, usually featuring vitrectomy combined with central membrane peeling.<sup>51</sup> Generally, the functional outcome is negatively associated with preoperative visual acuity and the degree of maculopathy.<sup>39,52</sup>

## Retinal Detachment

### Traction Retinal Detachment

As neovascular membranes in proliferative diabetic retinopathy grow within the cortical vitreous gel attached to the retina, they may produce firm vitreoretinal adhesions and contract over time,<sup>43,53</sup> resulting in tractional retinal detachment.<sup>54</sup> Diabetic tractional macular detachment, therefore, has been the most common indication for vitrectomy.<sup>25</sup> However, the management of

peripheral retinal tractional detachment seems to have changed in recent times. Traditionally, those cases were observed for a while as the risk of complicated vitrectomy seemed to exceed the low progression rates.<sup>55</sup> As anatomic and functional results after vitrectomy substantially improved, an earlier surgical approach in cases with peripheral tractional detachment seemed reasonable.<sup>56,57</sup> Still, functional results after successful vitrectomy in severe macular tractional detachment remain rather poor (Figs. 115.6 and 115.7).<sup>57</sup> Also, chronic cases of diabetic tractional detachment may be a lesser indication for surgery, as the retina under tractional fibrovascular proliferations usually becomes atrophic.<sup>6,18,57</sup> In general, vitrectomy reoperation rates in diabetic tractional detachment are between 24% and 47%.<sup>58-60</sup>

**FIG. 115.6** Tractional retinal detachment involving the entire macula. This patient had severe fibrovascular proliferation and traction along the arcades with recent extension of the detachment to involve the macula.

**FIG. 115.7** Postoperative appearance after vitrectomy, membranectomy, and retinal reattachment.

Factors with a more favorable outcome in the literature are age <50 years; preoperative panretinal photocoagulation; visual acuity >5/200; no or few iris neovascularizations or retinal proliferations; macular detachments <30 days; and no iatrogenic breaks.<sup>6,25,61</sup>

### **Combined Tractional–Rhegmatogenous Retinal Detachment**

Severe fibrovascular proliferations in proliferative diabetic retinopathy may result in progressive traction and membrane contraction leading to the development of posterior retinal breaks. The shape of the retina appears convex in contrast to tractional detachment, and the dimensions of detachment are often greater, extending over the ora serrata.<sup>43,62,63</sup> The retinal surface often shows white hydration lines, which are diagnostic of retinal breaks. These are often small, located posteriorly, paravascular or immediately adjacent to vitreoretinal tractions and retinal elevations.<sup>63,64</sup> Sometimes, subretinal hemorrhage may be present.<sup>65</sup> Vitrectomy combined with silicone oil tamponade is frequently indicated in particularly severe cases, especially when the second eye shows a poor visual function (Figs. 115.8 and 115.9).<sup>63,66</sup> Reports of silicone oil surgery generally show a high rate of reattachments with just a moderate chance of functional improvements (see below). Silicone oil finally helps to reduce the incidence of further complications

such as neovascular glaucoma and phthisis in those desperate cases.<sup>63,66</sup>

**FIG. 115.8** Combined tractional–rhegmatogenous detachment with dense fibrovascular proliferations over optic nerve and arcades.

**FIG. 115.9** Postoperative appearance after successful vitrectomy, membranectomy, endophotocoagulation,

and silicone oil tamponade/removal.

## Neovascular Glaucoma

Neovascular glaucoma is a very severe complication in proliferative diabetic retinopathy. It is assumed that the ischemic retina is the source of vasoproliferative growth factors that may diffuse into the anterior segment. Consequently, growth of neovascularizations and fibrovascular membranes in the chamber angle obstruct aqueous outflow and intraocular pressure rises; different stages of neovascular glaucoma have been described.<sup>67,68</sup> Therefore, the first therapeutic target should be the cause of the neovascular stimulus, indicating extensive panretinal photocoagulation or cryotherapy.<sup>69</sup> Intravitreal or intracameral anti-VEGF medications, such as bevacizumab, may be helpful as short-term adjunct to panretinal photocoagulation or when panretinal photocoagulation fails to cause regression of rubeosis.<sup>70-72</sup> This treatment alone usually induces regression of neovascularizations; however, fibrovascular proliferations in the chamber angle may contract and the pressure remain high.<sup>62</sup>

In cases of opaque optical media, as vitreous hemorrhage or cataract, controlled panretinal photocoagulation can only be performed after vitrectomy and/or cataract extraction, which has been shown to reduce rubeosis and improve neovascular glaucoma.<sup>73,74</sup> In addition, silicone oil tamponade prevents recurrent vitreous hemorrhage and may induce regression of rubeosis.<sup>75</sup>

Vitrectomy may be combined with endocyclophotocoagulation of ciliary processes or partial retinectomy to improve perfusion and reduce intraocular pressure.<sup>76,77</sup> Patients with higher-stage neovascular glaucoma with synechial angle closure almost always need some sort of glaucoma surgery.

Filtering surgery in diabetic neovascular glaucoma has significantly lower success rates than surgery for primary or secondary open angle glaucoma.<sup>78</sup> The intraoperative use of antimetabolites, such as 5-fluorouracil and mitomycin C, is strongly recommended; in addition, intensive perioperative antiinflammatory and antiproliferative treatments, as well as anti-VEGF injections and panretinal photocoagulation, can improve the

outcome.<sup>71,79</sup>

The implantation of glaucoma-drainage tubes (as Molteno, Baerveldt, or Ahmed implants) is also very common, although the drainage capacity can be compromised by epibulbar scarring or recurrent intracameral or intravitreal hemorrhages.<sup>80,81</sup>

Nonpenetrating glaucoma surgery, as well as argon laser trabeculoplasty, is generally not recommended in diabetic neovascular glaucoma, as angle closure due to the rubeotic process can deteriorate postoperatively.<sup>78</sup>

Additional vitrectomy surgery should be considered at earlier stages of proliferative diabetic retinopathy and not be reserved for only advanced neovascular glaucoma.<sup>82</sup> It should be combined with panretinal photocoagulation ab interno; in addition, a pars plana glaucoma drainage implant may be considered to stabilize the glaucoma.<sup>80</sup>

Cyclodestruction, with transscleral cryo- or diode-laser cyclocoagulation, is a helpful, widely used method in advanced neovascular glaucoma. However, this treatment is usually reserved for eyes with low visual function at presentation.<sup>83,84</sup> Blind, painful eyes may still need retrobulbar alcohol injections or, in the worst case, evisceration or enucleation.<sup>85</sup>

## Preoperative Evaluation and Informed Consent

As the presence of advanced diabetic retinopathy may indicate significant macro- and microvascular disease, all patients should be referred to an internist or endocrinologist before surgery. It is important to evaluate the patient's medical and glycemic status, as well as coexistent problems such as hypertension, hyperlipidemia, or cardiovascular or renal disease. Those findings will influence the decision for the extent, timing, and prognosis of surgery.<sup>86,87</sup>

Optimal blood glucose management may be protective against perioperative infection.<sup>88</sup> Patients should be well informed about adjustments of medications, especially those for blood glucose and blood pressure control. Anticoagulants, as well as antiplatelet medications, may be stopped or substituted at the surgeon's

suggestion. Another issue is that of patients needing renal dialysis. In those cases, surgery has to be arranged between dialysis sessions. In any case, an optimal medical control will optimize surgical success and reduce intra- and postoperative complications in diabetic patients.

Every patient must undergo a thorough ophthalmic evaluation before surgery to determine all anatomic abnormalities, as well as actual and possible future visual function. It is important to correlate the history of visual decrease with possible anatomic changes, which can be discovered by anamnesis or the referring ophthalmologists. This correlation is a major prognostic factor for surgical success. A complete ophthalmic status, with best corrected distance and near acuity, pupillary function, intraocular pressure, and visual field tests, is essential. Slit-lamp biomicroscopy of all anatomic abnormalities, and, if possible, fundus examination with indirect binocular lenses, provides further important information to plan the surgical approach.<sup>89,90</sup>

Silicone IOL implants should be avoided, as intraocular silicone oil tamponades would firmly adhere to silicone lenses, thereby affecting intra- and postoperative fundus visualization and visual function.<sup>91,92</sup> If applicable, fluorescein angiography and optical coherence tomography (OCT) may add further details, as the presence and extent of retinal or iris neovascularizations, macular or retinal ischemia, macular edema, vitreoretinal tractions, and epiretinal membrane formation.<sup>87,89,93</sup>

In cases with opacified media preventing fundus visualization such as cataract or intracameral or intravitreal hemorrhage, ophthalmic echography should be performed; it can provide most relevant information, as the presence or absence of vitreoretinal adhesions, vitreoschisis, retinal detachment, or other subretinal opacities and tumors.<sup>90,94</sup>

Preoperative electrophysiologic testing (visually evoked potentials, VEP, or electroretinography, ERG) is another tool to evaluate function in those cases. However, in clinical practice it is not routinely used, as results in predicting postoperative outcome are sometimes contradictory.<sup>95</sup>

Prior to surgery, possible infections of the lid, conjunctiva, cornea, or ocular adnexae must be treated. Antibiotic prophylaxis

may be reasonable when the risk for endophthalmitis is increased, although there is no evidence-based general recommendation.<sup>43,96</sup> The presence of iris neovascularizations or massive fibrovascular proliferations is an indicator for an early surgical intervention, with preoperative intravitreal or intracameral application of anti-VEG medications and panretinal photocoagulation, if possible.<sup>97,98</sup> Especially in severe proliferative diabetic retinopathy in type 1 diabetic patients, there is strong evidence of the value of performing adequate panretinal photocoagulation, especially in the anterior periphery to minimize the risk of further anterior neovascularizations or fibrovascular proliferations.<sup>6,31,99,100</sup>

Before any treatment, the patient, his/her family, and/or responsible persons should be thoroughly informed about the nature of the disease and the scheduled surgery, as well as possible alternative treatments or nontreatment. This important decision-making process is dependent on the physician's knowledge of all general and ocular conditions, as well as on the patient's understanding of the impact of surgery. A promising final decision can only be made on the basis of all the patient's needs and expectations. It is always necessary to obtain a written informed consent, which should include a detailed description of all information. Preprinted forms may be used, favorably including some additional graphic illustrations.

## Surgery

### Education and Training

Surgery for complications of diabetic retinopathy, notably vitrectomy, requires advanced surgical judgment and skills and the use of highly developed instruments and equipment. Technical advances in the development of instruments and surgical techniques require regular and frequent trainings of surgical skills of all operating personnel, as well as modernization and proper maintenance of all surgical equipment and instrumentation.<sup>87</sup> Wet laboratories using animal models play an important role in modern ophthalmology surgical residency training. In recent times, new virtual reality simulators can be used as a gated, quantifiable

performance goal to expert-level benchmarks (Fig. 115.10).<sup>101,102</sup>

**FIG. 115.10** An EYESI simulator, for training of intraocular surgery in a virtual reality system. The simulator is equipped with a binocular microscope and an eye phantom model to train or improve skills as visual coordination and digital micromanipulations.

## Anesthesia

Surgery in proliferative diabetic retinopathy can be performed under local or general anesthesia, sedoanalgesia, or a combination of those. The adequate form of anesthesia depends on many factors, as the extent and duration of surgery, the patient's mental or physical condition, or simply the patient's and surgeon's choice. It also depends on geographic and economic factors, as there are diverging anesthesia standards in different countries. The patient's vital signs should be continuously monitored by experienced operating staff members, even during local anesthesia. The advantage of local anesthesia is a minimal disturbance of the diabetic metabolism; however, the patient may feel some pain or

move during surgery. Local anesthesia can also be applied during sedoanalgesia or general anesthesia to minimize the patient's postoperative discomfort.<sup>103</sup> General anesthesia or sedoanalgesia should be performed only by an anesthesiologist, who can stabilize the patient or help to medically reduce the intraocular pressure. Nitrous-containing agents should be terminated before an intraocular gas bubble is injected.<sup>87,103</sup>

## Preoperative Preparation

To provide adequate intraocular visualization, wide pupillary dilatation is necessary. A combination of different mydriatic, sympathomimetic, and cycloplegic drops should be instilled repeatedly before surgery to allow for a maximal pupillary dilatation.<sup>87</sup> Additional topical medications, as antibiotic or antiphlogistic drops, may be added, as well as systemic sedative or diuretic medications for optimal preparation of the patient. If general anesthesia is scheduled, additional preoperative medication or modification of the patient's medications should be discussed with the anesthesiologist.

In the operating room, a 5% povidone iodine solution must be applied on the eyelids and a 5% solution in the conjunctival sac, respectively, and should dry out for at least 3 minutes to guarantee adequate disinfection.<sup>104</sup> The eye is then covered with a sterile plastic sheet, equipped with 1–2 side bags, and a lid speculum is inserted (Fig. 115.11).

**FIG. 115.11** Preoperative situs before vitrectomy. The eye was covered with a blue plastic sheet, equipped with two side bags, and a lid speculum was inserted. Sterile hand grips were attached on the binocular microscope and all necessary instruments, as well as a modern phacovitrectomy unit, prepared.

## Surgical Equipment

### Microscope and Lenses

As prerequisite, a modern binocular surgical (stereo-) microscope is required with coaxial illumination that should allow a magnification of 10–30-fold. It should be equipped with a motorized power zoom, power focusing, and X–Y-positioning via foot pedals. The microscope must be fitted with the corresponding laser filters to permit photocoagulation. A light-splitter is necessary for covisualization of the operating personnel and for the integration of a video system or other imaging features, as intraoperative OCT.<sup>105</sup>

For fundus visualization, different lens systems are available to neutralize the cornea's refractive power. The initial visualization of the central retina was performed using hand-held, planoconcave lenses or various contact lenses centered by the assistant or a sclera-fixed metal ring. For a better visualization of the fundus periphery, especially in gas-filled phakic eyes, biconcave lenses with 20–35° angle were developed.<sup>106,107</sup>

Today, 130° wide-angle viewing systems are available, and the inverted image is corrected through a stereoscopic diagonal inverter. Non-contact wide-angle systems (BIOM, EIBOS) are widely in use and can be managed by the surgeon alone.<sup>105,108</sup> They offer a greater depth of field and better visualization through media opacities. Also, a lower incidence of postoperative epithelial defects or retinal detachments has been reported.<sup>109,110</sup> To protect the corneal epithelium and guarantee for optimal fundus visualization, a corneal tear film must be maintained. The adjunctive use of carboxymethylcellulose gel or similar substances at surgery will promote corneal clarity.

## **Microinstruments and Illumination**

Various types of surgical instruments have been developed and modified over the years. The instruments vary in the number of functions provided. Currently, a trend is towards single-use instruments or parts of them, providing maximal aseptic conditions. Twenty-gauge systems had become the long-time standard and are still used in rare situations, offering the greatest number of supplementary instruments with minimal flex.<sup>87,111</sup>

### **Small-Gauge Systems.**

In more recent years, 23-, 25-, and 27-gauge instruments have been developed to provide nonsuturing vitrectomy, thereby minimizing inflammation and postoperative discomfort to the patient (Fig. 115.12).<sup>112-115</sup> However, their efficiency in complex cases, such as advanced diabetic retinopathy, is still a matter of debate, as a higher rate of postoperative hypotony has been reported.<sup>116</sup> In the recent literature, 23- and 25-gauge systems showed more stable and reproducible results even in severe proliferative diabetic retinopathy, compared with 27-gauge.<sup>112,117,118</sup>

**FIG. 115.12** Comparison of 20-, 23-, 25- and 27-gauge vitrectomy cutter handpieces. Notably, the ports of the thinner handpieces are closer to the probe tip.

### **Basic Equipment.**

The standard equipment for vitrectomy consists of a vitrectomy cutter, combined with a suction unit, a fiberoptic light pipe, an infusion of balanced salt solution (BSS), and an air pump. A modern vitrectomy unit provides all those base functions, in different combinations with diathermy, endolaser coagulation, gas filling, or phacoemulsification modules (Fig. 115.13).

**FIG. 115.13** Front view of a new Constellation© vitrectomy unit, providing phacoemulsification, vitrectomy, photocoagulation, diathermy, and air/gas/silicone tamponades in one machine.

### **Vitrectomy Cutter.**

The vitrectomy probe serves to cut and dissect membranes or fibrovascular proliferations in addition to vitreous gel. Shaving of peripheral vitreous or membranous fibrovascular proliferations has become significantly safer with the newer probes, in which the port is closer to the probe tip.

### **Illumination.**

Handheld illuminators range from single-function illumination probes to multipurpose illuminated scissors, forceps, or vitrectomy probes. The use of “chandelier” light illuminators inserted manually or through additional sclerotomies allows for bimanual dissection.<sup>119-121</sup>

### **Membrane Dissecting Instruments.**

A wide variety of tissue scissors, forceps, spatulas, picks, or cannulas are available to peel or remove epiretinal membranes;

similarly, the vitrectomy probe can be used with lower suction rates at the decision of the surgeon. Vertical scissors may be used for segmentation of tissues in complex fibrovascular proliferations, whereas horizontal scissors are beneficial to delaminate the vitreous cortex from the retina.<sup>122,123</sup>

### **Retinopexy Instrumentation.**

Different endolaser probes for all incision sizes are available to perform panretinal photocoagulation or retinopexy. Scleral depression with an indentator may be used for peripheral treatment. Endodiathermy is useful for stopping bleeding during surgery or for preparing retinotomy sites.

### **Dyes and Tamponades**

Various dyes are used to identify vitreous and epiretinal structures. Corticosteroid crystals may be used for easier identification of the vitreous cortex, especially in retinal detachment surgery; e.g., triamcinolone acetonide marks otherwise invisible remnants or patches of vitreous on the retina.<sup>104,124–126</sup> In addition, it may help to prevent fibrin exudation in proliferative diabetic retinopathy due to its antiinflammatory potential. No retinal toxicity was described for intravitreal doses of 2–4 mg of triamcinolone acetonide.<sup>105,127</sup>

Epiretinal membranes or fibrovascular proliferations must be carefully removed to prevent recurrent proliferative vitreoretinopathy or tractional detachment. Dyes as trypan blue are helpful to stain epiretinal membranes; indocyanine green, infracyanine green, and brilliant blue are more specific for internal limiting membrane identification; epiretinal structures appear in negative contrast with those substances.<sup>128–131</sup> There is divided opinion on whether infracyanine or indocyanine green might have toxic retinal effects, provoking (peripheral) visual field defects. However, this effect could be time- and dose-dependent.<sup>131,132</sup>

For internal tamponade of the vitreous cavity, various gases and liquids are in use. As a short-term intraoperative instrument, perfluorocarbon liquid is most commonly employed. It is helpful to reattach the retina or to protect the retina against damage from endophacoemulsification, intraocular foreign bodies, or lens fragments.<sup>133–136</sup> Filtered air may serve as a short-term, nontoxic

tamponade; for a more prolonged tamponade in cases of retinal detachment or proliferative diabetic retinopathy, different gases such as SF<sub>6</sub>, C<sub>2</sub>F<sub>6</sub>, or C<sub>3</sub>F<sub>8</sub> are in use, providing tamponade times from 2 to 8 weeks. Gases are preferred for superior or posterior pathologies, in patients where positioning is possible, or when surgical removal would not be possible.<sup>137-139</sup>

Silicone oil is still the instrument of choice for longer tamponades in most severe cases. Different silicone oil types from 1000 to 10,000 centistokes are available. They can also serve as protective shield to inhibit neovascular growth factors and cytokines from dissolving in ocular tissues. Silicone oils usually should be removed after a short time, usually 3–6 months, to avoid silicone-related complications.<sup>140-144</sup>

## **Additional Equipment**

To improve the efficacy and outcome of surgery in proliferative diabetic retinopathy, different helpful adjuncts have been developed in the past years. A peri- or intraoperative injection of antiangiogenic drugs might decrease the risk of recurrent intravitreal hemorrhage or neovascular glaucoma with rubeosis iridis. Preoperative injections 7 days prior to surgery have shown to improve the outcome and facilitate surgical manipulations in diabetic tractional detachment.<sup>145,146</sup> To facilitate posterior vitreous detachment and to shorten operating time, pharmacologic vitreolysis with plasmin, microplasmin, and/or hyaluronidase was developed. Such agents may reduce intraoperative complications, such as retinal tears.<sup>147,148</sup> When there is a need for visualization of the ciliary body in cases of severe anterior hyaloidal fibrovascular proliferation or extreme corneal opacification or capsule fibrosis, endoscopy provides a novel, elegant approach. The endoscope is inserted through the pars plana, providing a direct visualization of the entire vitreoretinal anatomy.<sup>149,150</sup>

## **Surgical Procedure**

### **Cataract Surgery**

Patients undergoing vitrectomy surgery for proliferative diabetic

retinopathy may have concomitant cataract. Surgical management options include cataract surgery followed by vitrectomy surgery later, or combined operations in a single procedure.<sup>151</sup> Further variations include cataract extraction, followed by vitrectomy and lens implantation at the end of surgery, or alternatively, cataract extraction with primary lens implantation, followed by vitrectomy. Cataract and vitrectomy surgery may be both performed by one surgeon or two different surgeons, depending on geographic and cultural differences.<sup>151</sup>

As cataract surgery has become safer over the years and small incision phacoemulsification is now available, combined phacoemulsification with simultaneous implantation of a posterior chamber lens is performed by our group in patients over 60 years and with signs of cataract. Performing a capsulorhexis without red reflex in an eye with vitreous hemorrhage can be challenging. Here, the vitreous surgeon also has to be an experienced cataract surgeon, or this part of the surgery is provided by an anterior segment surgeon. In any case, the dying of the anterior capsule is recommended. In 20-gauge vitrectomy, the infusion line is preplaced but not connected before the lens surgery to avoid pressure created during infusion placement and sutures. In small incision vitrectomy, all three sclerotomies are performed and trocars inserted before cataract surgery for the same reason.

The advantage of any cataract extraction procedure is a much better intraoperative access to the vitreous base, which is of utmost importance in cases of fibrovascular proliferations in diabetic retinopathy or proliferative vitreoretinopathy; there is also evidence that reoperation rates seem to decrease when the lens has been removed during vitrectomy.<sup>24</sup>

Progression of coexisting diabetic macular edema may be lower when grid/focal laser is applied before cataract surgery, or when panretinal photocoagulation is applied after lens extraction instead of before.<sup>20</sup> All cases with proliferative diabetic retinopathy should be treated with panretinal photocoagulation, if possible, and/or anti-VEGF injections before cataract surgery, to avoid a higher incidence of postoperative iris neovascularizations; panretinal photocoagulation may also be applied at time of surgery or shortly thereafter.<sup>21,24</sup> In younger patients with less cataract formation, the

loss of accommodation after cataract extraction has to be weighed against possible serious intra- and postoperative complications when the lens was not removed. The patient should be informed that an earlier cataract formation is common after vitrectomy.<sup>17,24</sup> Likewise, it has been reported that in eyes without a crystalline lens, a more complete panretinal photocoagulation and resection of proliferations was possible.<sup>24</sup>

## Glaucoma Surgery

### Aqueous Shunt Procedures

Diabetic patients with refractory advanced open angle glaucoma or neovascular glaucoma with different stages of angle closure almost always need glaucoma surgery, depending on the prognosis for visual function.

Nonpenetrating procedures, as canaloplasty or viscocanalostomy, are usually not indicated, especially when the chamber angle is closed.<sup>152</sup> Similarly, filtering surgery such as trabeculectomy in neovascular glaucoma has significantly lower success rates than surgery for primary or secondary open angle glaucoma.<sup>78</sup> The reason is an excessive risk for inflammation and hemorrhage in these eyes. To improve the outcome, it is advisable to use intraoperative antimetabolites, such as 5-fluorouracil and mitomycin C, as well as perioperative anti-VEGF injections and panretinal photocoagulation.<sup>71,79</sup>

It has recently been shown that an intravitreal injection of bevacizumab, followed by panretinal photocoagulation and glaucoma surgery 1–2 weeks later, may produce a much better pressure control.<sup>153</sup> Alternatively, glaucoma-drainage tubes, as Molteno, Baerveldt, or Ahmed implants, may be implanted. They can be used either after or at the same time as vitrectomy with endophotocoagulation. The tube may be placed in the anterior chamber or in the sulcus ciliaris or through the pars plana, if the chamber angle is closed.<sup>152</sup>

Postoperative results are inferior to standard trabeculectomy procedures in nondiabetic patients, as the drainage capacity can be compromised by scarring of epibulbar tissue, bleb formation, or recurrent intracameral or intravitreal hemorrhages.<sup>80,81</sup>

Furthermore, other long-term complications, such as exposure of tube material or decompensation of the corneal endothelium, have been described.<sup>153–155</sup> Bevacizumab has been reported to improve the outcome after glaucoma implant surgery as well; however, more trials are needed to clarify the role of anti-VEGF medications in surgery for diabetic glaucoma.

In addition, vitrectomy surgery may be considered even at earlier stages of glaucoma in proliferative diabetic retinopathy, as it can be easily combined with full scatter panretinal photocoagulation ab interno.<sup>74,75,82</sup> Furthermore, a pars plana glaucoma drainage implant may be considered to stabilize the intraocular pressure.<sup>80</sup>

## Cyclodestructive Therapy

In eyes with extensive retinal ischemia or optic nerve damage in advanced neovascular glaucoma, in which visual outcome is expected to be very poor, the efforts and risks of incisional trabeculectomy or glaucoma implant surgery may not be accepted.<sup>152</sup> In those eyes, cyclodestruction procedures, such as transscleral cryo- or diode-laser cyclocoagulation, can be helpful methods, depending on the grade of angle closure.<sup>83,84</sup> In the right indication, it has proven as effectively as trabeculectomy or drainage implant surgery.<sup>156,157</sup>

Before transscleral cyclophotocoagulation, a retrobulbar injection with lidocaine 2% is usually given and a lid speculum should be used. The handpiece of the diode laser features a footplate designed for this procedure.<sup>152</sup> The footplate is placed along the limbus so that the fiberoptic tip sits on the surface directly over the ciliary body to concentrate the laser energy in the target tissue. Power settings of between 1500 and 2500 mW with a pulse delivering time between 1.5 and 2.0 seconds are commonly used. A total of 15–30 applications of the laser are applied to the full circumference; only the horizontal meridians should be spared.<sup>152,158</sup> After surgery, topical prednisolone, diclofenac, and atropine, eventually subconjunctival prednisolone–hydrogen succinate, are given. The intraocular pressure will be reduced postoperatively for 6–8 weeks on average, providing effective pressure control in about 67% of patients.<sup>152,158</sup> The treatment may be repeated after several months. Cyclocryocoagulation of the ciliary body in a similar fashion or

cryocoagulation of the peripheral retina by indirect ophthalmoscopy may be an alternative; however, “blind” cryocoagulation bears the risk of overtreatment and induction of choroidal neovascularization.<sup>73,159</sup>

Blind, refractory, painful eyes may be treated with retrobulbar alcohol injections or finally by evisceration or enucleation.<sup>85</sup>

## Pars Plana Vitrectomy

### Preparation of Entry Sites

Three-port vitrectomy remains the most used technique, in which two sclerotomies are prepared superotemporally and superonasally, and a third inferotemporal pars plana incision permits intraocular infusion. Incisions are chosen in 3.5–4.0-mm distances from the limbus. Transconjunctival trocar-guided systems are used with increasing frequency in diabetes-related indications in smaller gauges (23-, 25- and 27-gauge) to provide higher comfort for the patients and reduce surgical trauma.<sup>112</sup>

To avoid intra- or postoperative wound dehiscence, sclerotomy blades should be oriented parallel to the limbus and trocars should be inserted 20–30° oblique to the scleral surface (Fig. 115.14).

**FIG. 115.14** The blade or trocar is directed toward the center of the vitreous cavity to avoid contact with the

lens or retina.

However, 27- and 25-gauge systems might be more preferred in easier diabetic cases such as nonclearing vitreous hemorrhage or macular edema.<sup>111,118</sup> In eyes with complex pathologies where silicone oil injection is likely, 23- or even 20-gauge incisions provide the surgeon with a higher range of instrumentation and an easier silicone oil tamponade.<sup>111,116,118</sup> Suturing of sclerotomies is recommended in silicone oil use because silicone oil can evade through unsutured wounds subconjunctivally. Precise infusion cannula placement is critical to avoid suprachoroidal infusion and choroidal detachment (Fig. 115.15).

**FIG. 115.15** The infusion cannula is inserted and secured with a suture in the inferotemporal pars plana sclerotomy. Indentation of the infusion cannula allows visualization of the unobstructed tip in the vitreous cavity behind the pupil.

A 6-mm cannula can be used instead of the routinely used 4-mm infusion cannula in eyes with anterior displacement of the retina or fibrotic tissue strongly connected with the retina. Sometimes both

hands are needed for dissection of epiretinal tissue with forceps and scissors. Then, a four-port vitrectomy is needed in which a (chandelier-) light probe is fixed either in the nasal inferior quadrant or at 12 o'clock between the two superior sclerotomies.

## Vitrectomy

Light probe and vitrector are inserted through the trocars/sclerotomies, and vitreous removal is started behind the crystalline or intraocular lens (Fig. 115.16). The infusion is turned on only when the cutter is in the eye and vitreous removal can be started simultaneously. Otherwise, the infusion pressure will move the lens implant anteriorly and iris incarceration into the wound can occur. The anterior part of the vitreous is removed under microscopic view, then a wide-angle viewing system (e.g., BIOM) is inserted and central vitreous removal performed.

**FIG. 115.16** The vitreous cutter and fiberoptic illuminator are positioned in the anterior vitreous cavity and visualized through the pupil.

To facilitate identification of the vitreous cortex, triamcinolone acetonide may mark otherwise invisible remnants or patches of vitreous on the retina.<sup>125,126</sup> Due to its antiinflammatory potential it

may also help to prevent fibrin exudation in proliferative diabetic retinopathy. Intravitreal doses of 2–4 mg of triamcinolone acetonide will offer sufficient staining with no retinal toxicity.<sup>105,127</sup>

### **Eyes With Complete Posterior Hyaloid Separation.**

If a nearly complete separation of the posterior hyaloid is present after anterior and central vitreous removal, the posterior hyaloid membrane is incised and the opening enlarged circumferentially to allow adequate visualization of the retinal area (Fig. 115.17).<sup>12</sup> While cutting rate is usually highest (3000–7000 cuts/min), aspiration might be increased in the midportion of the vitreous, but should be decreased again during posterior hyaloid removal to avoid unnecessary traction. Blood might be pooled at the posterior pole, usually unclotted, and it can be aspirated with a soft-tipped fluid needle (Fig. 115.18). As precise visualization of the retina is achieved, areas of neovascularizations or small bleeding sources can be identified. Diathermy should be used for bleeding sources, and then the vitreous is removed out to the periphery. Indentation is used to remove all anteriorly located blood and vitreous. Otherwise this can be a source for rebleeding, tissue contraction, and rubeosis iridis. Full-scatter endophotocoagulation is now performed up to the peripheral retina for the same reason.

**FIG. 115.17** The vitreous cutter easily incises the posterior hyaloid face since a complete posterior vitreous detachment is present.

**FIG. 115.18** Removal of layered hemorrhage using a soft-tipped cannula.

If a glistening reflex over the fovea is visible, dyes or an intraoperative OCT system (Fig. 115.19) can be used to look for residual preretinal membranes; as well, the internal limiting membrane can be removed. However, it remains uncertain if removal of the internal limiting membrane improves the final visual outcome.

**FIG. 115.19** Intraoperative optical coherence

tomography to visualize epiretinal membrane formation and removal.

In contrast, it was reported from a pilot study that peeling of the internal limiting membrane in proliferative diabetic retinopathy with fibrovascular proliferations might reduce postoperative epiretinal membrane formation; similarly, this was reported for primary retinal detachment (RD) repair surgery<sup>51,160</sup>

Finally, an air tamponade can be used to avoid both hypotony and hemorrhage in small incision vitrectomy. In phakic eyes, anterior vitrectomy can be performed using indentation, but usually more residual vitreous will remain than in pseudophakic eyes.

### **Eyes With Incomplete Posterior Hyaloid Separation.**

If incomplete separation of the posterior hyaloid is present, which is usually the case in these eyes, surgery can be difficult and should remain in experienced hands. Usually a core vitrectomy is performed at the beginning to gain sufficient view over the areas of adhesion and the connections between them. If there is a wide separation between the formed vitreous and the retina, circumferential release of anterior–posterior traction can be achieved with the vitreous cutter. However, if the posterior vitreous is closely overlying the retina in certain areas, care must be taken not to injure the retina (Fig. 115.20). If the retina is attached, gentle suction with the vitrector might be sufficient to further separate the vitreous from the retina to provide safe dissection. If the retina is detached or holes do exist, separation of tissue might be achieved with the use of some viscoelastic to provide higher safety.<sup>161–163</sup> In any case, careful separation, usually with scissors, has to be done. Several surgical techniques for membrane removal have been developed. The first were delamination and segmentation.<sup>164</sup> In segmentation, tractions between centers of adhesions are removed (Figs. 115.21 and 115.22),<sup>12,55,165</sup> while in delamination, the connections between the posterior hyaloid and/or fibrovascular tissue and the internal limiting membrane are cut (Fig. 115.23).<sup>165–167</sup> The later developed “en bloc” technique includes removal of the vitreous and associated vitreoretinal membranes as a single unit

(Fig. 115.24).<sup>168</sup> If only one or few focal adhesions do exist, vitrectomy might be started with a core vitrectomy, followed by excision of the posterior hyaloid over 360° in order to separate small islands of adhesions. If extensive, firm adhesions are present, the “en bloc” technique might facilitate surgery: a core vitrectomy is performed and the posterior hyaloid opened in an area close to or over the optic nerve. The fibrovascular tissue is now grasped with an end-gripping forceps and the tissue separated. Gentle traction is exercised to avoid bleeding or hole formation. If it is possible to loosen the connected tissue over the posterior pole in one piece, then the remaining hyaloid of the peripheral vitreous will lift the residual vitreous and membranes into the midvitreal cavity, where it can be removed safely (Fig. 115.25). As tempting as it might sound to remove everything in one big piece, two things need to be mentioned: first, complete removal of membranes and vitreous together in cases with adhesions of different strength is rarely possible. Second, bleeding from several sources might create a less controllable situation. If confronted with a firm adhesion during the “en bloc” technique, a change to delamination or segmentation is advisable. The newer cutters of the 23- and 25-gauge systems have an opening nearer to the end tip and do allow segmentation of tissue without additional scissors or picks (Fig. 115.26). The use of some perfluorocarbon to prevent bleeding into the foveal area can be helpful if a bridging membrane has been removed, but further dissection needs to be done in the midperipheral retina. If the retina is cleaned from all fibrovascular tissue up to the periphery and bleeding sources are cauterized, circular photocoagulation treatment is performed up to the ora serrata under indentation.

**FIG. 115.20** Incomplete posterior vitreous detachment with multiple focal vitreoretinal adhesions. An opening is made in the outer cortical vitreous into the subhyaloid space in an area of vitreoretinal separation. The cutting port is against the cortical vitreous and away from the retina.

**FIG. 115.21** Tangential traction is released with the vitreous cutter by excising the remaining posterior hyaloid and fibrovascular tissue between areas of vitreoretinal adhesions.

**FIG. 115.22** When posterior vitreous separation is inadequate to accommodate the vitreous cutter, a plane between the posterior hyaloid and retina can be created with vertical membrane peeler–cutter scissors.

**FIG. 115.23** In delamination, fibrovascular adhesions to the posterior hyaloid are excised parallel to the retinal surface with horizontal scissors.

**FIG. 115.24** En bloc vitrectomy. After an opening is made in the posterior hyaloid adjacent to vascular epicenters, membrane peeler–cutter scissors enter the subhyaloidal space. The unremoved formed vitreous provides anterior traction that helps separate the vitreous and fibrovascular tissue from the retina and helps identify sites of adhesion.

**FIG. 115.25** After all posterior adhesions have been released, the vitreous cutter is used to excise the detached formed vitreous and associated fibrovascular membranes en bloc.

**FIG. 115.26** Fibrovascular tissue that is firmly attached to the disc is reduced with the vitreous cutter.

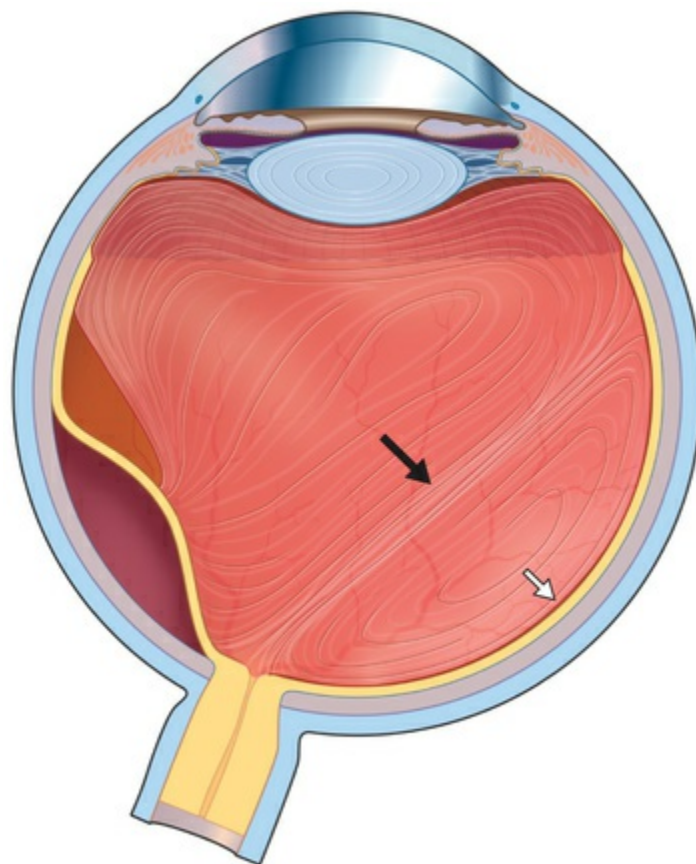

### **Eyes With Subtotal Posterior Vitreous Adhesion.**

If the posterior hyaloid is almost completely attached to the retina, access to the subhyaloidal space is difficult. After a core vitrectomy is performed, gentle suction can be used to find areas where the vitreous is less adherent. Usually, these are areas of subhyaloidal hemorrhage. As it is not possible to incise this tissue with the vitrector, a sharp blade or subretinal pick is used to create an opening into the subhyaloidal space. The safest areas for such maneuvers are around the optic disc. Once part of the hyaloid is lifted, a patient separation of the fibrovascular tissue is needed.

Usually, dissection is performed centripetally. Again, bleeding sources need to be cauterized immediately, and it is mandatory to maintain a controlled situation. If retinal holes are detected under proliferating tissue or created during preparation, the surrounding tissue must be excised without residual traction. Also here, some perfluorocarbon might be helpful to flatten out a localized retinal

detachment and facilitate sufficient laser treatment of the holes. As already mentioned above, careful panretinal laser treatment is performed once the retina is cleaned. The tamponade of choice can be either a longer-acting gas tamponade or silicone oil.

When identifying the posterior vitreous cortex in diabetic patients, surgeons should be aware of posterior vitreoschisis, simulating posterior vitreous separation (Fig. 115.27).<sup>94,169</sup> If this phenomenon is unrecognized, only the inner wall of the vitreoschisis will be removed, leaving much traction unrelieved.<sup>12</sup>

**FIG. 115.27** Posterior vitreoschisis. Split hyaloid with partial vitreous separation. Although there is unseparated posterior hyaloid (*white arrow*), there is a pseudohyaloidal membrane (*black arrow*), giving the illusion of vitreous separation. The pseudohyaloidal membrane may be the result of condensed vitreous collagen that is often found after a hemorrhage in formed vitreous.

## Eyes With Combined Tractional and Rhegmatogenous Detachment.

In eyes in which rhegmatogenous retinal detachment is present in addition to tractional detachment, great care has to be taken to avoid aspiration and inadvertent cutting of the retina. Core vitrectomy is performed with lesser suction than usual, and the tissue is carefully inspected before cutting. Once a clear overview of the retinal situation is created, dissection of tissue is started usually in an area distant from the detached retina. Still, preparation of tissue from the center to the periphery is advisable. Perfluorocarbon can be used to stabilize the posterior retina, while further tissue removal in the periphery is performed. However, if an atrophic retinal detachment is present, the use of perfluorocarbon can be dangerous because the retina is inelastic and shortened. A primarily small retinal hole can turn into a large retinal hole, and perfluorocarbon may glide in the subretinal space. A similar situation can occur when silicone oil tamponade is used too early and the retina is still under traction. Careful inspection of the periphery under indentation is needed, and anteriorly dislocated retina is either freed from fibrotic tissue or cut. Retinectomies and retinotomies should be used only in selected cases and performed as a last resort (see also [Chapter 112, Retinotomies and retinectomies](#)). They cannot replace careful membrane dissection. Usually peripheral retinectomies are needed in eyes where reoperations become necessary and severe anterior hyaloid fibrovascular proliferation has developed. Before the retina is cut, diathermy is applied to the anterior and posterior margin of the retina and the vessels to be excised. The extension of the retinotomy should reach normal retinal area around the area of traction. The retina can be cut either with the cutter or scissors. If not already detached, a shallow detachment must be created in order to cut without traumatizing the choroid or creating hemorrhage. It is mandatory in diabetic vitrectomy to release all tractions around retinal holes before tamponades can be used. The anterior part of the retina is also trimmed and cauterized in retinectomies to avoid secondary fibrosis of residual anterior retina and traction on surrounding tissue and/or the ciliary body. Smaller posterior retinotomies can also become necessary if persistent traction

around an old tear exists. Silicone oil is the tamponade of choice for diabetic eyes requiring retinectomies. Eyes requiring retinectomies have a poorer outcome and visual prognosis than those not requiring them.<sup>170</sup> Placement of a scleral buckle can be added to complex surgery in diabetic vitrectomy. It is usually performed in reoperations or as a primary surgery in younger diabetic patients where massive activity and fibrovascular proliferation and detachment exist, but visual acuity is still useful.

In primary procedures, the retina is usually more elastic and an additional encircling band might make a large retinectomy unnecessary. Usually, the surgery is started with episcleral surgery. The conjunctiva is dissected over 360° at 1–2 mm distance from the limbus, and Tenon capsule peritomy performed. Four-0 sutures are placed under each rectus muscle and four 5-0 nylon mattress sutures prepared in each quadrant to secure the band. The anterior suture is placed 2–4 mm behind the insertion of the rectus muscles; the posterior suture depends on the size of the band. For a 4-mm band, at least a 6-mm distance between sutures has to be chosen in order to create indentation. Alternatively, scleral tunnels can be created for this purpose. When the silicone band is placed under the muscles and the sutures (or tunnels), sutures are fixed and the ends of the band secured with a variety of choices.

The buckle should be relatively shallow and mainly support the vitreous base. A paracentesis can be performed to reduce pressure during buckle placement. Certainly fixation of the cerclage can be postponed until after vitrectomy, but this makes a change from internal surgery to external surgery necessary. In eyes where lens surgery is planned, an inferior sclerotomy is placed to allow some liquefied vitreous to escape. Then the infusion line is prepared but not turned on. If the eye pressure is too high, a second or third paracentesis is performed. If the anterior chamber is deep enough to allow cataract surgery, a small limbal incision is performed and the anterior chamber filled with viscoelastic. Routine phacoemulsification and IOL implantation follows as the next surgical step. A permanent or transient 10-0 nylon suture to seal the cataract wound is advisable in complex diabetic vitrectomy, where changes in intraocular pressure can be expected during and after surgery.

## Photocoagulation

Panretinal photocoagulation with an endophotocoagulation probe is always performed during diabetic vitrectomy to achieve regression of neovascularizations and to create adhesions around retinal breaks, retinotomies, and retinectomies.<sup>6,43,163,171</sup> Although preexisting panretinal photocoagulation might be present, additional photocoagulation is usually applied, especially to the retinal periphery, and in areas around neovascularizations.

The adequate coagulation effect requires apposition of the retina to the retinal pigment epithelium, which eventually requires the use of intraoperative internal tamponades, as gas or perfluorocarbon liquids.<sup>172</sup> The power of the laser beam is continuously adjusted, depending on the clarity of media, the density of subretinal pigmentation, and the distance to the retina. The angle of the instrument in relation to the retinal plane will also influence intensity of the coagulates. Whitish laser effects should be visible; however, hard hyperintense treatment should be avoided.<sup>43,173</sup>

Endocryocoagulation is rarely applied to the retinal periphery today because endophotocoagulation with flexible probes is available, which makes a treatment up to the ora serrata possible, eventually with the help of scleral depression.<sup>174</sup> Moreover, cryocoagulation usually causes more inflammation than standard panretinal photocoagulation, and the effect is less predictable.<sup>43</sup>

## Tamponades

Various gases and liquids are in use to provide internal tamponade of the vitreous cavity. As a short-term intraoperative instrument, heavy perfluorocarbon liquid is most commonly used. It is helpful to reattach the retina, permitting panretinal photocoagulation or membrane dissection. Perfluorocarbon must be completely removed before the end of surgery due to retinotoxic effects.<sup>133–136</sup>

Filtered air serves as short-term tamponade for a few days. For a fluid–air exchange, infusion is turned off and air is supplied through the infusion port with a continuous air pump. A silicone-tipped fluid needle or cannula is then used to aspirate the fluid from the vitreous cavity. If subretinal fluid is present, it can be aspirated through a preexisting or iatrogenic retinal break.<sup>12</sup>

For a more prolonged tamponade in cases of retinal breaks with

traction, retinal detachments, or diffuse hemorrhage, different gases such as SF<sub>6</sub>, C<sub>2</sub>F<sub>6</sub>, or C<sub>3</sub>F<sub>8</sub> are in use, providing tamponade times from 2 to 8 weeks. Gases are preferred tamponades for superior or posterior pathologies or in patients where positioning is possible.<sup>137-139</sup> After fluid-air exchange, the intraocular air is usually exchanged for long-acting gases. The eye is flushed with gases in the desired nonexpansive concentration, usually 18% for SF<sub>6</sub>, 16% for C<sub>2</sub>F<sub>6</sub>, and 14% for C<sub>3</sub>F<sub>8</sub>, to guarantee for a maximal duration with no risk of pressure elevation. If nitrous oxide is used in general anesthesia, it must be discontinued 20 minutes before gas injection to prevent high nitrogen in the gas bubble, resulting in an undesirably small postoperative gas bubble.<sup>12</sup>

Finally, silicone oil is the instrument of choice in reoperations or severe cases, if a longer tamponade is required, if positioning is difficult, or if air travel is necessary. Silicone oil may be instilled directly or after fluid-air exchange. In aphakic eyes, an inferior ("Ando"-) iridectomy should be created to prevent silicone oil from entering the anterior chamber. If possible, silicone oils should be removed after several (3-6) months to avoid late silicone-related complications, as cataract, secondary glaucoma, keratopathy, or optic disc atrophy.<sup>134,140,141,143,144</sup>

## Wound Closure

Sclerotomy closure prevents leakage of vitreous cavity fluid, gas, or silicone oil and helps to maintain a normal intraocular pressure. During closure of the superior sclerotomies, the infusion maintains a stable intraocular pressure; if self-sealing incisions were used, the intraocular pressure should be slightly lowered before removal of the cannulas. In 20-gauge vitrectomy, sclerotomies are sutured carefully with partial-thickness 7-0 or 8-0 Vicryl sutures. In 25- or 23-gauge transconjunctival small incision vitrectomy, wounds can remain unsutured. Here, the trocar cannulas will be removed and the eye may be pressurized with a gas bubble. If silicone oil is used, careful wound closure is recommended to avoid subconjunctival silicone escape. In addition, one should keep in mind that delayed wound healing is present in diabetic patients, simultaneously with a higher likelihood of infections, and therefore decide on the

necessity of suturing even smaller incisions. Injections of antibiotics and/or steroids in the Tenon capsule or the bulbar conjunctiva may prevent infection and postoperative inflammation. At the end of surgery a paracentesis may be necessary to normalize an increased intraocular pressure. Topical antibiotics, cycloplegics, and steroids are applied together with a sterile dressing and/or a protective shield.

## Postoperative Care

### Examinations

Regular ophthalmic examinations are scheduled according to the individual case; however, they should usually be performed on a daily basis in the first postoperative days. Additional unscheduled examinations are necessary when the patient complains of abnormal or increasing pain, especially in cases with a history of glaucoma or when expanding gas bubbles were used. It is reasonable to perform further evaluations on a weekly basis in the first month and on a monthly basis until the eye has stabilized and/or local or systemic medications are stopped.<sup>87</sup> Finally, periodical routine examinations every 3–6 months are recommended, according to the severity of diabetic retinopathy. In the routine evaluation, the anterior segment must be checked for unexpected inflammation, media opacities, or signs for neovascular glaucoma, such as rubeosis iridis. Intraocular pressure is monitored and normalized to prevent pain or eventual visual field loss. The posterior segment must always be carefully examined to observe the healing process and identify possible complications. Macular edema or tractional detachment may take time to resolve and can be monitored by optical coherence tomography. Written instructions, such as medical prescriptions or visits, are always preferred.<sup>43,87,175</sup>

### Hospitalization and Convalescence

The length of any hospitalization is determined by the rules for admission, extent of surgery, and the condition of the patient.

Cataract surgery is usually performed on an outpatient basis, whereas after vitrectomy or complicated surgery, hospitalization is routine in many countries. The management of patients with pain or elevated intraocular pressure, who need more frequent examinations and adaptations of their medication, is always more efficient in hospital.<sup>87</sup> Furthermore, good diabetic and general medical control is necessary (see below).

When surgery on outpatient basis is performed, it is important to carefully instruct the patient for further behavior, medications, and visits. For confused or disoriented patients, it is important that responsible persons always accompany them. Postoperative positioning is of great importance when intraocular gases were used, depending on the location of retinal breaks, and this may be facilitated with pillows and tables.<sup>43</sup> Normally, adhesion of the retina to the retinal pigment epithelium occurs in 1–4 days after laser retinopexy.<sup>176,177</sup> Face-up positioning might accelerate cataract formation in phakic eyes, iris capture in pseudophakia, or loss of anterior chamber in aphakia.<sup>178,179</sup> If additional laser treatment is needed when a gas bubble is in the eye, the surgeon should be aware of unintentional retinal damage from laser beam reflection at the fluid/gas interface.<sup>180</sup> In cases with intraocular silicone oil tamponade, positioning is less critical. However, silicone oil changes the refractive power of the eye and interferes with diagnostic ultrasound, possibly hampering follow-up examinations or axial length measurements.<sup>181,182</sup> Despite the need for early silicone oil removal due to complications, silicone oil is usually removed after 3–4 months at the decision of the surgeon. Recurrent retinal detachment is unusual after silicone oil removal and appears to be independent of the duration of silicone oil tamponade.<sup>183,184</sup> In most severe cases, silicone oil might be also used as long-term tamponade to prevent phthisis of the eye.<sup>144,185</sup>

## Medications

The common preference for few topical medications in ophthalmology might differ after surgery for proliferative diabetic retinopathy, especially in more complex cases. Patients will rarely feel heavy pain after vitrectomy, but it can happen more frequently

after additional buckling surgery.<sup>87</sup> Oral analgesics are usually sufficient, but sometimes additional intravenous analgesics are needed. The use of patches did not appear to be helpful in controlling pain from corneal abrasions; however, pain from corneal epithelial defects might be more common due to diabetic neuropathy.<sup>186,187</sup> An increase of intraocular pressure needs topical or systemic pressure lowering medications. Topical cycloplegic drops provide pupillary dilatation, immobilization of the ciliary body, reduction of inflammation, and the risk of synechia formation.<sup>87</sup> In addition, topical antibiotics, steroids, and antiinflammatory drops are prescribed in the first postoperative days or weeks to minimize inflammation and prevent infection. Steroids may be administered periorbitally during or after surgery. In severe cases, systemic antiinflammatory drugs or corticosteroids might be added, but they can interfere with the patient's antidiabetic medication. A sudden, increasing inflammation raises suspicion of endophthalmitis and needs urgent intravitreal antibiotic injection, vitreous culture, and vitrectomy.

## Further Surgery

After cataract surgery, proliferative diabetic retinopathy must be sufficiently treated or re-treated with panretinal photocoagulation if it was not performed at time of cataract surgery.<sup>21</sup> Similarly, diabetic macular edema progression may be slightly lower when grid/focal laser and/or anti-VEGF medications are applied after lens extraction instead of before.<sup>20</sup> In patients who had vitrectomy surgery with silicone oil instillation, recurrent retinal detachment after silicone oil removal is unusual and seems not to be related to the duration of silicone oil tamponade.<sup>183,184</sup> In most severe cases, silicone oil might be used as a long-term tamponade to prevent phthisis.<sup>144,185</sup> In cases of secondary or neovascular glaucoma in the absence of preoperative panretinal photocoagulation, adjunctive treatments with panretinal photocoagulation, anti-VEGF injections, or glaucoma filtering surgery might be useful.<sup>24,152,188</sup>

## Diabetes Control

The challenge for the primary care physician and the diabetologist

in managing all patients with diabetic retinopathy is to attain excellent glycemic control, aggressive control of blood pressure, and normalization of lipids.<sup>189</sup> After surgery for proliferative diabetic retinopathy, diabetic patients are at increased risk for adverse outcomes, which are related to preexisting complications of diabetes, especially atherosclerotic disease, nephropathy, and peripheral and autonomic neuropathy; similarly, hyperglycemia is associated with a higher risk for poorer wound healing or infections,<sup>190</sup> and a possible loss of nutrients through glycosuria.<sup>191</sup> The use of insulin offers great flexibility of timing and dose in the postoperative management of most diabetic patients. Short-acting insulin analogs have been shown to work well as premeal medication or as rapid counteraction against pronounced hyperglycemia for outpatients as well as hospitalized patients.<sup>191</sup>

On the other hand, rapid-acting insulin analogs may be associated with an increased risk for hypoglycemia, especially if the delay to the next meal is too long.<sup>192</sup> Accordingly, oral sulfonylurea and other insulin secretagogues lower blood glucose levels acutely; however, the risk for hypoglycemia is smaller with nonsulfonylurea agents.<sup>191</sup> In general, hospitalization provides a chance to organize long-term diabetes management issues: advice and information on optimum nutrition, exact glycemic control, management of hypertension or dyslipidemia, as well as basic guidelines for foot care should be given during this time. Finally, an appropriate diabetes education for newly diagnosed or poorly controlled diabetic patients, arrangements for medical nutrition, and regular medical follow-up visits are important to attain the best possible long-term surgical and medical outcomes.<sup>191,192</sup>

## Complications

### Intraoperative Complications

New technologies and improved understanding of the disease process have reduced both numbers and severity of complications in diabetic vitrectomy. Nevertheless, complications do occur and proper management is essential to achieve a successful completion of the surgery.

## Cornea, Anterior Chamber, Lens

### Reduced Visualization.

Corneal edema, a narrow pupil, and lens opacification are the main reasons for reduced intraocular visualization during vitrectomy in diabetic patients.<sup>12</sup> From these three, corneal edema still remains the most problematic.

### Corneal Edema.

Reduced epithelial adherence and epithelial basement membrane abnormalities in diabetic patients predispose these eyes to develop corneal edema during surgery.<sup>12,193,194</sup> Clear visualization of details is hindered because of the edema, and this might occur during the most important steps during surgery. The occurrence of corneal edema might be related to intraocular pressure, dryness, duration of surgery, or trauma to the epithelium or endothelium.<sup>194,195</sup>

Mechanical abrasion of the epithelium, performed almost routinely in diabetic patients in earlier years, should be avoided if possible.

Gently wiping the cornea with a cotton-tip to reduce the water content might help for a short period. In addition, viscoelastic placed in the anterior chamber can improve visualization. The use of corneal lubricants as methylcellulose in different compositions maintains a longer corneal integrity and clarity during vitrectomy surgery, reducing the need for intraoperative debridement.<sup>196</sup> If an epithelial debridement is unavoidable, the patient should be provided with a medical contact lens at the end of surgery to provide painless and quick healing of the epithelial defect. It has been shown that the debridement rate for infusion lenses was 23.8% compared with 13.0% for sew-on lenses and 15.6% for non-contact wide-angle (e.g., BIOM) lenses.<sup>197</sup> Folds in Descemet's membrane may develop during fluid–air exchange, resulting in distortion of intraocular structures. This issue can be improved by viscoelastic, placed under the corneal endothelium.<sup>12</sup>

### Pupillary Constriction.

Intraoperative miosis reduces peripheral fundus visualization. It usually occurs after prolonged surgery, ocular hypotony, or direct surgical trauma during cataract extraction. As wide-angle systems

are now used in almost all vitrectomies, better visualization is provided also if the pupil becomes medium-sized during surgery. Dilating medications, such as mydriatic agents or viscoelastic substances, might be used either topically or injected into the anterior chamber via a paracentesis. Alternatively, flexible iris hooks can be used temporarily to achieve better visualization of the periphery.<sup>198,199</sup>

### **Lens Touch, Cataract Formation.**

Lens opacities may develop from direct instrument contact during surgery, after prolonged surgery in phakic patients, or, less frequently, if the patient's serum glucose is much higher than in the infusion fluid.<sup>12,200</sup> The overall incidence of postoperative cataract formation after vitrectomy in diabetic eyes was reported to occur in 17–37%.<sup>17</sup> Touching a clear lens with instrumentation must be avoided. As diabetic vitrectomies combined with lens surgery and IOL implantations are increasing in numbers, this problem has become rare. However, if lens opacification does occur during vitrectomy, immediate lens removal is advisable if the surgery would be otherwise incomplete. If lens opacification is so discrete that vitrectomy can be finalized, proper cataract surgery can be delayed. A careful dissection, especially in the horizontal meridian, may protect from lens touch; alternatively, a small amount of vitreous gel can be left behind the lens capsule to protect the lens from infusion fluid or mechanical damage.<sup>194,200</sup>

### **Intraocular Hemorrhage**

Intraocular hemorrhage is frequently observed in proliferative diabetic retinopathy, representing a potential serious complication. Bleeding during surgery mainly occurs from inadvertent cutting of vessels. If not controlled immediately, it can prevent successful completion of surgery, with untimely silicone tamponade in an uncontrolled situation. As a general rule, even if a small hemorrhage occurs, the source needs to be identified and controlled. Systemic blood pressure should be immediately evaluated and treated aggressively if it is too high. Sometimes transient intraocular pressure elevation might be sufficient to control bleeding, but mainly diathermy should be used to cauterize

sclerotomy sites, iris vessels, choroid, or retina. Modern vitrectomy machines allow an automatic pressurization of the infusion system so that the intraocular pressure can be controlled faster and more exactly. The elevated pressure should then be normalized as soon as possible to prevent ischemic damage to ocular structures.<sup>12</sup> Combined instruments providing infusion and cauterization are useful because they eliminate the need to exchange instruments. For small hemorrhage, viscoelastic or perfluorocarbon can be used to prevent pooling of blood over the posterior pole; for a larger hemorrhage, thrombin was reported to control bleeding.<sup>201,202</sup> Pre- or intraoperative intravitreal application of anti-VEGF medication might reduce intraoperative complications and improve the surgical outcome in severe proliferative diabetic retinopathy.<sup>203,204</sup> Finally, blood clots should be carefully removed from the eye without provoking new hemorrhage. It is advisable to let a small plug of fibrin on the site that has bled to support hemostasis.<sup>121</sup> Reducing the intraocular pressure at the end of surgery may identify potential bleeding sites that can be treated before closing the eye.<sup>12</sup>

## **Retinal Breaks and Detachment**

Retinal breaks are a typical, severe complication during or after any vitrectomy; however, in proliferative diabetic retinopathy they are observed more frequently.<sup>161,205</sup> Occult preexisting retinal breaks may be sometimes detected under fibrovascular tissue, or may occur during tissue manipulation. Usually they are located in the posterior pole and can be treated once all traction around the breaks is relieved. They mainly occur in eyes with long-standing tractional retinal detachment where the retina is atrophic and vulnerable. Although creation of holes should be avoided, small iatrogenic breaks are preferable to an unclean separation of the posterior hyaloid, resulting in persistent or recurrent traction. If a localized retinal detachment develops, perfluorocarbon is usually used to flatten the retina and to facilitate photocoagulation of the tear. A gas tamponade might also be sufficient to seal tears and retinal detachment.<sup>161</sup> Because fluid dynamics are now better controlled with newer vitreous machines, incarceration of the retina and tear formation at the entry sites have become rare. Trocar systems for

small-gauge vitrectomy can prevent excessive incarceration of tissue. However, entry site retinal detachments, related to postoperative shrinking of residual fibrovascular tissue around the sclerotomies, may still occur postoperatively. Posterior or central retinal breaks most frequently occur in eyes with chronic tractional detachments, massive vitreoretinal adhesions, or tractional fibrovascular proliferations.<sup>205,206</sup> For posterior breaks, diathermy can be used to recognize the breaks when performing laser coagulation under air or gas.

### **Subretinal Perfluorocarbon or Silicone Oil**

As mentioned above, perfluorocarbon and silicone oil can glide under the retina if the retina is atrophic and under tension. In any case, removal is necessary. With subretinal perfluorocarbon, a more posteriorly located retinotomy can be created if the primary retinal defect is in the periphery and aspiration via a fluid needle or with an active aspiration cannula cannot be achieved. For subretinal silicone oil, aspiration via a fluid needle is rarely possible. A retinectomy might be the last resort to remove the subretinal substances. If perfluorocarbon or silicone oil can be removed successfully, further preparation of tissue is mandatory to relax the retina even if this means to enlarge a retinectomy. While maintaining a rather low intraocular pressure, perfluorocarbon is injected again slowly over the optic disc and additional photocoagulation is performed around the retinotomies and retinectomies. Carefully, perfluorocarbon is then exchanged with silicone oil.

## **Postoperative Complications**

The most frequent postoperative complications after vitrectomy for diabetic retinopathy are elevated intraocular pressure, corneal erosion, fibrin formation, bleeding, and retinal detachment.

### **Anterior Segment**

#### **Conjunctival Complications.**

Wound dehiscence and stitch abscess may eventually progress to

conjunctivitis, scleritis, or endophthalmitis. It is commonly treated by local or systemic antibiotic therapy after taking a swab from the infectious site; treatment should be continued until resorption of all sutures. Careful stitching or buried knots may prevent incision sites or scleral implants from exposure. Subconjunctival silicone oil granuloma is prevented by exact closure of sclerotomies.<sup>193</sup>

### **Corneal Complications.**

Corneal epithelial defects after vitrectomy in diabetic patients are common. They may be caused by prolonged operating time or iatrogenic debridement, and are often the consequence of diabetic neuropathy and a pathologic basement membrane. Large corneal erosions heal slowly in diabetic patients and need immediate treatment to prevent scarring and additional visual loss. A curative contact lens might prevent pain and can be supplemented with a combination of liquefying drops as well as antibiotics.<sup>194–196,207</sup>

### **Uveitis.**

Postoperative iritis and uveitis are usually mild following diabetic vitrectomy. Pronounced inflammation or fibrin deposition combined with pain is uncommon and should raise suspicion of beginning endophthalmitis. White deposits of triamcinolone after an intravitreal injection can simulate inflammation or hypopyon (“pseudoendophthalmitis”) but are recognized by the chalk-white appearance of multiple crystals.<sup>43,208</sup>

### **Iris Neovascularization and Neovascular Glaucoma.**

See below, Results of surgery by evidence-based trials.

### **Cataract Formation.**

See below, Results of surgery by evidence-based trials.

### **Intraocular Pressure Elevation**

Elevated intraocular pressure represents one of the most common issues in the early postoperative period after vitrectomy for proliferative diabetic retinopathy.<sup>209–212</sup> Moreover, diabetic eyes are especially vulnerable to pressure rise due to long-standing retinal

ischemia. In the literature, the incidence of significant pressure elevation of  $\geq 30$  mmHg is about 36% in the first 48 hours after surgery.<sup>210</sup> Elevation of intraocular pressure can occur as a result of inflammation after surgery, bleeding, or be related to tamponade use. In addition to antiinflammatory medication and mydriatics, topical antiglaucomatous treatment is primarily used. This can be supplemented with oral acetazolamide for the first postoperative days or weeks. If the pressure remains high but inflammation or blood have resolved, transscleral laser treatment might be indicated. In some cases, filtering surgery becomes necessary. For eyes with intraocular gas tamponade, the gas bubble may provoke angle closure from anterior displacement of the iris diaphragm.<sup>213,214</sup>

Face-down positioning may allow an accumulation of intraocular fluid in the anterior chamber; an additional paracentesis of the chamber can relieve excessive fluid. An expanding large intraocular gas bubble might as well be removed by fluid needle through the pars plana or through the limbus in aphakic eyes. For eyes with an additional scleral buckle, angle closure may result from choroidal detachment or swelling that can be treated by topical cycloplegics and corticosteroids.<sup>12</sup>

## **Fibrinoid Syndrome**

As vitrectomy surgery in diabetic patients may lead to the breakdown of the blood–retina barrier, this can result in intraocular fibrin deposition.<sup>12</sup> In some patients, fibrin in the anterior chamber will provoke a pupillary block. In young patients with massive retinal ischemia, massive fibrin formation in the vitreous cavity (the fibrinoid syndrome) may cause tractional retinal detachment, a pupillary block, ciliary body detachment, hypotony, or finally rubeosis iridis with neovascular glaucoma.<sup>215,216</sup> Other risk factors include lensectomy, extensive dissection, intensive panretinal photocoagulation, or scleral buckle surgery. The incidence of the fibrinoid syndrome associated with retinal detachment was reported to be 5%.<sup>215</sup> Those eyes have a bad prognosis with recurrent fibrin deposition, intraocular hemorrhage, and tractional detachment.<sup>217</sup> Prophylactic treatment consists of a subconjunctival dexamethasone injection at the end of surgery. Postoperative fibrin formation is primarily treated with topical corticosteroids, applied

frequently during the day. If there is massive fibrin also in the vitreous, recombinant tissue plasminogen activator (r-tPA) can be injected into the anterior chamber.<sup>218,219</sup> In eyes in which a corneal erosion is present, peribulbar or subconjunctival injection of a corticosteroid might be preferable to topical treatment, to avoid delay of wound healing. When substantial fibrin deposition occurs, eyes are best managed with repeated vitrectomy, fibrin removal, and silicone oil injection.<sup>12</sup>

## **Vitreous Hemorrhage**

Postoperative vitreous hemorrhage after vitrectomy is common. A single postoperative vitreous hemorrhage occurs in about 65% of patients, whereas 35% will suffer two or more recurrences of vitreous hemorrhage.<sup>64,175,209,220</sup> However, the vast majority of immediate postoperative vitreous hemorrhages are mild and do not impair fundus visualization; 80% of them will occur in the first postoperative year.<sup>220</sup> Vitreous hemorrhages may also occur in association with iris or angle neovascularizations, retinal fibrovascular proliferations, or an anterior hyaloidal fibrovascular proliferation (AHFVP).<sup>12</sup> A careful control of intraoperative hemorrhages may prevent or reduce postoperative vitreous hemorrhage (see above). The management of postoperative vitreous hemorrhage includes observation, vitreous cavity lavage, or repeated vitrectomy. A slight hemorrhage might occur in eyes where silicone oil has not been used. If it clears within 1–3 weeks, no further treatment is necessary. If the hemorrhage is massive, a washout procedure might be indicated after 3 weeks in eyes where the retina is attached. Serial ultrasound tests are mandatory in eyes without fundus visualization. If the retinal situation is unclear, repeated vitrectomy is necessary. Only 4–10% of cases will require another vitrectomy, which includes removal of blood and probable residual fibrovascular tissue, additional photocoagulation treatment, and most likely silicone oil tamponade.<sup>25,32,167,221,222</sup>

## **Anterior Hyaloidal Fibrovascular Proliferation**

AHFVP is a most severe complication following diabetic vitrectomy, occurring in up to 13% of cases with severe proliferative diabetic retinopathy (Figs. 115.28 and 115.29).<sup>43,223</sup> The presentation

of AHFVP includes the growth of neovascular tissue onto the vitreous base, the anterior retina, ciliary body, lens capsule, and iris. Therefore patients may present with rubeosis iridis, vitreous hemorrhage, peripheral tractional retinal detachment, or hypotony.<sup>43</sup> Risk factors for AHFVP include male gender, type I diabetes, phakic patients, insufficient panretinal photocoagulation, severe ischemia with recurrent neovascularizations, and previous surgery with placement of a scleral buckle.<sup>223</sup> The origin of the disease may be at the sclerotomy sites or at the peripheral retina.<sup>43,100</sup> For treatment, cataract extraction, lensectomy, scleral buckling, extensive laser or cryopexy, and anterior dissection with eventual retinectomy might become necessary.<sup>223</sup> As membranes are highly vascularized, preoperative injections of bevacizumab can be helpful for short-term regression during vitrectomy.<sup>224</sup> The functional prognosis is always poor; therefore, all efforts for prevention and early detection of AHFVP should be made.<sup>43</sup>

**FIG. 115.28** Anterior hyaloid fibrovascular proliferation. Peripheral retinal fibrovascular proliferation is seen extending on the posterior lens capsule.

**FIG. 115.29** Microscopic features of anterior hyaloid fibrovascular proliferation. The peripheral retina is detached and displaced anteriorly by fibrovascular tissue originating in the retina and extending along the anterior hyaloid towards the posterior lens capsule (hematoxylin and eosin,  $\times 30$ ).

## Results of Surgery as Indicated by Evidence-Based Trials

### Cataract

There is a frequent coexistence of cataract and proliferative diabetic retinopathy.<sup>225,226</sup> Improvement in acuity after cataract surgery may be achieved in  $>55\%$  of patients,<sup>227,228</sup> but long-term results are generally inferior to patients without diabetes.<sup>229,230</sup> The Early Treatment for Diabetic Retinopathy Study (ETDRS) reported a gain of  $\geq 2$  lines in 64.5% of eyes with early and 59.3% of eyes with delayed panretinal photocoagulation one year after cataract surgery.<sup>189,231</sup> However, the literature regarding optimal timing of cataract surgery and panretinal photocoagulation, with respect to maximal visual gain and minimal risk of diabetic macular edema, is scarce.<sup>73</sup> There were reports about progression of untreated proliferative diabetic retinopathy after extracapsular cataract surgery or development of vitreous hemorrhage in 20% of patients after intracapsular surgery.<sup>19,20,232</sup> Another randomized study

reported that panretinal photocoagulation treatment shortly after cataract surgery was associated with less macular edema and less acuity loss than with panretinal photocoagulation right before cataract surgery.<sup>73</sup> As levels of intraocular VEGF and other cytokines are elevated after cataract surgery, intraocular injections of triamcinolone acetonide or anti-VEGF agents are indicated to stabilize the eye if panretinal photocoagulation cannot be adequately applied before cataract surgery.<sup>233–237</sup>

Similarly, those agents may be helpful in cases of diabetic macular edema with the risk of deterioration after cataract extraction.<sup>238</sup> Cataract surgery before or during vitrectomy was reported to produce faster visual recovery and less vitrectomy reoperations.<sup>239–243</sup> Disadvantages are a poor red reflex in eyes with vitreous hemorrhage and a higher rate of postoperative inflammation or synechia formation.<sup>244–247</sup> Inflammation has shown to be lower in two separate procedures or in combined vitrectomy with pars plana lensectomy procedures, especially in complicated tractional detachment cases requiring silicone oil tamponade.<sup>22,245,248–252</sup>

In all cases with combined surgery, independent of timing, additional complications may occur: capsular tears, zonulolysis (10%), anterior capsule opacification and traction, hypotony, or ciliary body effusion.<sup>245,253–255</sup> The risk of rubeosis iridis and neovascular glaucoma, on the other hand, is diminished to <1% with appropriate application of panretinal photocoagulation.<sup>6,243,256</sup> Visual outcome is related to the severity of diabetic retinopathy, according to the ETDRS.<sup>256</sup> Therefore, patients with proliferative diabetic retinopathy are far less likely to achieve a 20/40 or better acuity than patients with nonproliferative diabetic retinopathy.<sup>227,256</sup> In summary, the general effect of cataract surgery on the progression of diabetic retinopathy, diabetic macular edema, or proliferative diabetic retinopathy is still a matter of debate. Although literature is insufficient, it seems that if diabetic macular edema or proliferative diabetic retinopathy is sufficiently treated with laser and/or anti-VEGF medications before cataract surgery, no significant progression of diabetic retinopathy should occur.<sup>256–258</sup>

## Vitreous Hemorrhage

In diabetic eyes with nonclearing vitreous hemorrhage, the benefit of early vitrectomy, defined as 1–4 months from onset, was clearly demonstrated by the DRVS.<sup>27</sup> Patients with visual acuity <5/200 and vitreous hemorrhage for 1–6 months were enrolled and randomized into an early and late surgery group, where vitrectomy was delayed for 12 months. Recovery of vision was significantly better for early surgery, compared to late surgery, at 3 months (50% vs. 17%) and 2 years (25% vs. 15%). Slightly better results for the early surgery group were reported at the 4 years-visit as well. Benefits were much higher for patients with type 1 (36% vs. 12%) than for those with type 2 diabetes mellitus (16% vs. 18%), probably because of the more severe course of proliferative diabetic retinopathy in type 1 diabetic patients.<sup>27</sup> Also, the poorer results for type 2 diabetics could be a consequence of a higher rate of maculopathy or posterior vitreous detachment in those cases. In addition, it should be noted that the DRVS preceded the use of the most contemporary equipment, including intraocular and indirect laser systems. Other retrospective studies for diabetic vitreous hemorrhage reported an improvement of acuity in >80% of operated cases, with a final vision of 20/200 or better in 48–72% of eyes, with a proportion of 20/40 or better in up to 38%.<sup>32,221</sup> Good prognostic factors are a preoperative vision >5/200, no neovascular glaucoma or rubeosis, no or minimal cataract, and preexisting panretinal photocoagulation in at least one quadrant.<sup>32,221</sup> Cases of associated anterior segment neovascularization (rubeosis iridis or manifest neovascular glaucoma) and/or severe progressive proliferation of the fellow eye are indications for an early vitrectomy.<sup>25,27</sup> Postoperative vitreous hemorrhage after vitrectomy is common; however, only 4–10% of cases will require another vitrectomy, according to the literature.<sup>25,32,167,221,222,259,260</sup>

## Diabetic Maculopathy and Macular Traction

The benefits of early vitrectomy in cases with advanced proliferative diabetic retinopathy and macular traction, despite hemorrhage or retinal detachment, have been known since the DRVS.<sup>7,261</sup> In eyes after early vitrectomy, a final acuity of 10/20 or

better after 4 years could be reached in 44% compared with 28% of the nonoperated eyes ( $p < 0.005$ ).<sup>7,73,261</sup> Other authors reported improved vision after vitrectomy for macular traction detachments in 59–80% of cases, with a postoperative acuity of  $\geq 20/200$  in 21–58% of cases.<sup>66,262–264</sup> Starting in the 1990s, several authors reported good anatomic and functional effects of vitrectomy in persistent diabetic macular edema;<sup>265–270</sup> the procedure of surgically induced vitreomacular separation based on the finding that a posterior vitreous detachment was less frequent in patients with diffuse diabetic macular edema than in diabetic controls without edema.<sup>271–274</sup> Similarly, one trial reported about a resorption of diabetic macular edema in 55% of patients with posterior vitreous detachment, in contrast to only 25% of patients without.<sup>274</sup> Consequently, a large number of mostly retrospective case series and trials have been conducted, performing vitrectomy for diabetic macular edema in eyes with taut hyaloid adherent to the macula;<sup>266–268,275,276</sup> in eyes with attached, but nonthickened hyaloid;<sup>277–280</sup> in eyes with persistent diabetic macular edema despite previous laser or anti-VEGF therapy;<sup>281–283</sup> or as primary therapy in eyes with severe diabetic macular edema irrespective of posterior vitreous detachment.<sup>284–288</sup> One trial in eyes with diabetic macular edema unresponsive to laser therapy and a taut, adherent hyaloid reported a functional improvement of two lines in 49% and a reduction in diabetic macular edema in 94.5% of patients.<sup>73,268</sup>

However, the majority of those trials lack homogenous inclusion criteria or even an accurate definition of such criteria (as “taut hyaloid” or “macular thickening”).<sup>288</sup> Similarly, the effect of internal limiting membrane peeling is still controversially discussed; potential benefits in releasing traction have to be weighed against surgical complications, such as possible toxic effects of indocyanine green staining.<sup>289–291</sup> Other open questions include different intraoperative steps that could affect diabetic macular edema: enzymatic adjuncts, panretinal photocoagulation or focal laser treatment, cataract extraction, or concomitant injection of anti-VEGF medications.<sup>286,287,289,292–294</sup> Interestingly, the effect of vitrectomy was found to be independent of preexisting posterior vitreous detachment in one case series, indicating other causative factors for diabetic macular edema, as different cytokines.<sup>287,295</sup>

Finally, results show a large variety of outcomes following vitrectomy. Even in those trials reporting both morphologic and functional improvements, the effects on morphology have been always more pronounced than the acuity gain. This could be the consequence of ischemia, more subretinal exudates, longer duration of diabetic macular edema, or damage of previous therapies.<sup>296–299</sup> Therefore, at least some agreement exists about which conditions may negatively affect the outcome after vitrectomy for diabetic macular edema: previous focal/grid laser therapy, presence of submacular fluid, longer duration of diabetic macular edema, significant ischemia, or subretinal fibrosis.<sup>298,300–303</sup> In sum, for best ophthalmic treatment, it is not only necessary to know the different techniques, risks, and benefits of vitrectomy in diabetic maculopathy; the most important clinical issue is whether to attempt focal/grid laser therapy or intravitreal antiangiogenic injections prior to surgery to treat the nontractional component of diabetic macular edema.<sup>288,304</sup>

For the future, large controlled, randomized, multicenter studies will hopefully provide a better definition of the role and efficacy of vitrectomy in diabetic macular edema, e.g., pharmacologic vitreolysis may be used adjunctively with small-gauge vitrectomy surgery, and precise nearly tractionless cutting of membranes seems possible with a new pulsed electron knife.<sup>305,306</sup>

## Retinal Detachment, Tractional Detachment, and Proliferative Vitreoretinopathy

Outcomes of vitrectomy for retinal detachment in proliferative diabetic retinopathy are worse than for diabetic vitreous hemorrhage alone.<sup>6,307</sup> For diabetic tractional detachment, visual improvements of  $\geq 2$  lines have been reported in 60–75% of cases, with a mean postoperative acuity of  $\geq 20/200$  in 47–57% of patients, or  $\geq 5/200$  in 69–77% (Table 115.1).<sup>57,58,168,309–312</sup> An overall persistent reattachment rate of 82% was reported within 6 months,<sup>304,313</sup> with successful anatomic reattachment of the macula in 80–100%.<sup>57,59,312,314,315</sup> In contrast, for cases with complete tractional detachment, average reattachment rates were approximately 56%.<sup>58</sup> Results for combined rhegmatogenous and tractional detachments

or long detachments including the macula were even worse than for cases with tractional detachment alone. These subgroups reach visual improvements in 20–53%, a final acuity of  $\geq 20/200$  in 25–36%, and a final acuity of  $\geq 5/200$  in 55–68% of all eyes, on average.<sup>61,262,307,313</sup> Retinal reattachment was reached in 47–82%. With the use of encircling bands and silicone oil, attachment rates of 73–93% could be reached.<sup>43</sup> Improvement in vision increased to 64–81%, with a final acuity of  $\geq 5/200$  in 55–68% of eyes.<sup>43,66,307,316–318</sup> In a parallel fashion, the incidence of phthisis decreased from 10% to nearly 0%.

Functional results are often disappointing, although a good anatomic success is achieved; this may be the consequence of (long-standing) retinal or macular ischemia, optic disc atrophy, or retinal thinning. Other conditions that negatively influence the outcome

are preoperative rubeosis iridis, neovascular glaucoma, age >50 years, visual acuity <5/200, ischemic maculopathy, vitreopapillary traction, lack of panretinal photocoagulation, vitreous hemorrhage, fibrinoid syndrome, or AHFVP.<sup>6,55,58,61,73,248</sup> As anatomic and functional results after vitrectomy have substantially improved, so too has the management of peripheral retinal tractional detachment in recent times.<sup>318</sup> Generally, there is a better prognosis, with a risk of only approximately 14% of severe visual loss per year.<sup>55,73,319</sup> Nevertheless, an earlier surgical approach in those cases seems reasonable to avoid the risk of macular involvement with poorer prognosis.<sup>56–58,244</sup> The need for vitrectomy reoperation generally ranges from 24% to 47% after diabetic tractional detachment, and from 29–90% after combined rhegmatogenous and tractional detachment, excluding laser treatment.<sup>57,59,61,66,185,288,307</sup>

## Secondary Glaucoma (Neovascular Glaucoma)

At earlier stages of neovascular glaucoma with rubeosis and normal or moderately elevated intraocular pressure, panretinal photocoagulation alone can normalize pressure in 33–88% of patients.<sup>320</sup> Regression of rubeosis can be achieved in 33–94% of patients, depending on how many quadrants of anterior synechia are present.<sup>152,321</sup> In more advanced, refractory neovascular glaucoma, glaucoma filtering surgery is still the most promising approach; however, long-term success rates have been relatively poor, with an effective 5-year-control of intraocular pressure in only 25–30% of operated eyes. Similar results are reported for glaucoma implants, using Ahmed, Molteno, or Baerveldt valves.<sup>152,322–324</sup> A better control of intraocular pressure has recently been shown by panretinal photocoagulation and glaucoma implant surgery 1–2 weeks after an intravitreal injection of bevacizumab.<sup>153,325</sup> Success rates were 85% for patients who received adjunctive bevacizumab plus panretinal photocoagulation, compared with 70% for those who were given photocoagulation alone.<sup>152,326,327</sup> As an alternative treatment option, vitrectomy with photocoagulation may help to treat or prevent rubeosis iridis.<sup>74,75</sup> In earlier reports, a substantial risk of development or progression of iris neovascularizations after

vitrectomy in 8–26% of phakic and 31–55% of aphakic eyes was described,<sup>15,328</sup> however, recent series do not support this hypothesis any-more, quantifying the risk to <5%.<sup>152,308</sup> The risk may be somewhat higher (OR = 1.7) in the absence of preoperative panretinal photocoagulation.<sup>64</sup> In eyes with advanced neovascular glaucoma and low visual function, transscleral cryo- or diode-laser cyclocoagulation have proven as effective as trabeculectomy or drainage implant surgery.<sup>156,157</sup>

## Conclusion

Modern vitrectomy techniques have significantly reduced the rate of severe visual loss in diabetic patients. The main surgical principles are removal of intravitreal hemorrhages, relief of vitreoretinal tractions by excising the posterior cortical vitreous surface, laser treatment of ischemic retinal areas, and application of tamponades or antiangiogenic substances. Prerequisites are complete, up-to-date technical equipment; refined skills; and, last but by no means least, well-trained and experienced surgeons.

**Conclusion**

## Introduction

Retinal detachments (RD) are infrequent in the setting of intraocular inflammation but present a particular challenge both to the vitreoretinal surgeon and to the uveitis specialist. They occur most frequently during or following an episode of intraocular infection and are most commonly seen in eyes having suffered from a viral retinitis. Whether not related to ocular infection, the diagnostic and therapeutic approach may be difficult since different forms of retinal involvement suppose different treatments and prognosis. Serous retinal detachments (SRD) are the form most commonly associated with active, purely inflammatory conditions and, often, their presence helps to establish the diagnosis, as in the case of Vogt–Koyanagi–Harada disease (see [Chapter 78](#), Vogt–Koyanagi–Harada disease). At times, it may be misdiagnosed for a rhegmatogenous retinal detachment (RRD), but the management of SRD is pharmacologic, aimed at controlling the intraocular inflammation, though on a rare occasion, surgery may be needed to drain the subretinal fluid.<sup>1</sup> Visual prognosis in most cases of SRD is excellent provided that the immunosuppressive agents have been introduced at a sufficient dose to lead to rapid resolution, and tapering is done slowly.

Rhegmatogenous retinal detachment (RRD) is fortunately rare in active uveitis, but when present, the visual prognosis is guarded even with modern vitreoretinal surgical techniques. Tractional retinal detachments (TRD) are observed in both infectious and noninfectious uveitis, whenever vitreous organization develops in an eye without posterior vitreous detachment (PVD), or when proliferative vitreoretinopathy (PVR) complicates the course of

intraocular inflammation. Combined forms of RD are also possible. Establishing the exact cause, and the mechanisms involved in each individual case, is needed to ascertain the appropriate therapeutic approach and ensure visual recovery.

## Epidemiology

A systematic review of population-based studies on RRD published between 1970 and 2009 found a reported incidence between 6.3 and 17.9 for 100,000 people/year, with significant geographic variations.<sup>2</sup> It is widely accepted that RRD occurrence varies with ethnicity and is strongly associated with aging, myopia, vitreoretinal degeneration, and pseudophakia.<sup>3,4</sup> Uveitis itself is not considered a predisposing factor for developing RRD. However, a retrospective study conducted in The Netherlands found a prevalence of RRD of 3.1% among 1387 uveitic patients, suggesting inflammation as an independent risk factor for its development.<sup>5</sup>

Not all types of uveitis carry the same risk of RRD; this complication is most commonly seen in posterior uveitis from infectious etiology, with the highest risk in viral retinitis cases. Acute retinal necrosis (ARN) (see [Chapter 91](#), Acute retinal necrosis syndrome) evolves to RRD in more than 50% of cases, in a median time of 53 days after presentation.<sup>6</sup> This risk is even higher for progressive outer retinal necrosis (PORN), in which almost 70% of affected eyes will develop RRD soon after presentation.<sup>7</sup> For cytomegalovirus (CMV) retinitis (see [Chapter 84](#), HIV-associated infections), even though the course of the disease has positively changed with the introduction of highly active antiretroviral therapy (HAART), the rate of RRD remains as high as 2.3/100 eye-years.<sup>8</sup>

Parasitic infections can lead to RD when a choroidal process extends to the retina and vitreous or when a retinal process causes overlying vitreous to condense and contract. Toxoplasmic retinochoroiditis (see [Chapter 88](#), Ocular toxoplasmosis) presents a risk of RRD of 3.5–6%.<sup>9–11</sup> In a subset of toxoplasmosis patients addressed for vitreoretinal surgery, Adan et al. found 53.3% of cases of RD, most of which had pure RRD, with a few cases having combined tractional and RRD.<sup>12</sup> Exudative detachments are rarely

associated with ocular toxoplasmosis but have been described in the literature.<sup>13,14</sup> Vision-threatening features in ocular toxocariasis (OT) (see [Chapter 89](#), Helminthic disease) are mainly severe vitritis, cystoid macular edema, and tractional detachment of the macula. A retrospective series on OT found a prevalence of macular traction of about 30% regardless of the site where the choroidal granuloma was located. In peripheral lesions with retinal traction, TRD occurs in about 40% of cases.<sup>5,15</sup>

Acute syphilitic panuveitis may be complicated by retinal detachment: while SRD are well known to occur in these cases, RRD have been recently reported in 11 patients following a literature review. Seventy-five percent of these were HIV-positive. The detachment occurred in the convalescent period following a severe vitreous inflammatory response.<sup>16</sup>

Among noninfectious uveitis, the risk of RRD is less than 1%. Most patients developing retinal tears and detachments appear to do so as a result of concomitant retinal pathology, often in areas unrelated to sites of inflammation. However, inflammatory processes affecting the vitreous base may present an exception to this rule. In the healing phase, following severe inflammation, vitreous contraction can lead to important tractional forces on the retina. Hence, pars planitis, when untreated for a prolonged period of time or if severe, is known to develop TRD<sup>17</sup> and retinoschisis.<sup>18</sup> The differentiation between true retinoschisis and TRD may sometimes be difficult, especially for those lesions situated in the far periphery.<sup>19</sup> Sarcoidosis is also known to develop various forms of RD (see [Chapter 81](#), Sarcoidosis), though this complication is rare. Serous RD,<sup>20</sup> RRD,<sup>21</sup> retinal pigment epithelium (RPE) detachments,<sup>22</sup> and even a rare case of necrotizing retinitis with subsequent RRD<sup>23</sup> were described in the context of ocular sarcoidosis, but mostly as isolated cases. RRD may be also part of the spectrum of posterior segment complications of Behçet's disease, both in the active stage or in the convalescent period. Detailed funduscopy should be performed periodically in these patients, particularly in cases with healed retinitis or in the presence of vitreous shrinkage.<sup>24</sup> A case of RRD secondary to a macular hole in a young patient with Behçet uveitis has also been reported, stressing the role of recurrent vitritis and vitreous traction in the

pathogenesis of this severe complication (see [Chapter 80](#), Autoimmune retinopathies).<sup>25</sup>

## Pathophysiology

The nature of the inflammatory or infectious process determines the mechanism by which the detachment occurs and provides an indication as to the means by which it can be resolved. SRD is usually the result of an immune-mediated assault on the choroid, RPE, and retinal vasculature. It follows from loss of the tight junctions between retinal endothelial cells, leading to increased outward flow of fluid from the retinal vasculature, loss of tight junctions between RPE cells, and a failure of the compensatory pump function of RPE cells. Disruption of the normal oncotic gradient between the vitreous cavity and the choroid may also compromise passive transfer mechanisms responsible for a good portion of normal fluid flow to the choroid. Inflammatory mediators modulate vascular permeability and modulate the type and expression of aquaporins within the retina (mainly Müller cells) and the RPE, as well as of chloride receptors such as CLIC4 necessary for retinal attachment.<sup>26-28</sup> Resolution of a serous detachment requires one to reestablish the status quo by inhibiting both humoral and cellular inflammatory mechanisms through appropriate systemic or local immunosuppression ([Fig. 116.1](#)).

**FIG. 116.1** Serous retinal detachment in a patient with Vogt–Koyanagi–Harada disease. Detachments are usually bullous, with shifting fluid but without undulating retinal surface. Hyperemia of the optic nerve head is often present.

In the case of both RRD and TRD, vitreous body traction plays a predominant role. In RRD associated with toxoplasmosis, active toxoplasmic retinochoroiditis often precedes or is concurrent with the development of the RRD.<sup>9</sup> Inflammation not only enhances vitreous liquefaction but also leads to crosslinking between collagen fibrils, particularly those close to the retinal interface, leading to the formation of an anomalous PVD and retinal tears<sup>29–31</sup> Vitreal strands between the optic disc and the ocular toxocariasis granuloma are present in nearly 50% of patients (Fig. 116.2). These strands are often the source of retinal traction and detachment. Contraction of the vitreous base, particularly seen in chronic longstanding uveitis, leads to the development of fibrous or fibrovascular bands, which can be very adherent to the underlying retina.<sup>30,32</sup> Their removal can be quite challenging at the time of surgery (Fig. 116.3).

**FIG. 116.2** Fundus photograph from an ocular toxocariasis case. A peripheral granuloma causes a tractional retinal detachment in the central retina.

This tissue may be particularly difficult to remove surgically (hematoxylin and eosin,  $\times 110$ ). (B) Artist rendition of the pars plana exudation leading to vitreous base fibrosis and traction on the peripheral retina. (Panel A courtesy of Dr. Chi-Chao Chan, National Eye Institute, Bethesda, United States.)

High levels of s-ICAM1 (type 1 soluble intercellular adhesion molecule) are found in vitreous from uveitic eyes complicated by RD similar to what has been observed in cases of proliferative

vitreoretinopathy (PVR) where it is felt to perpetuate a cytokine-mediated vascular reaction that may contribute to PVR formation.<sup>33-35</sup> It correlates positively with vitreous levels of tumor necrosis factor-alpha (TNF- $\alpha$ ), a cytokine with a key role in the initiation of the inflammatory cascade and the pathogenesis of uveitis.<sup>36</sup> Though the exact role is not known in this context, it is probably a marker of disease severity, an important predisposition to the development of any RD.

The cause of RD following viral retinitis is somewhat different. Herpetic retinal infections (CMV, HSV, VZV) are characterized by retinal necrosis leaving in its wake a diaphanous glial membrane (Fig. 116.4). Any traction on these areas can easily lead to retinal tears and a detachment. Depending on the interplay between the virus and the host immune system, it is associated with moderate to severe vitreous inflammation. Cytomegalovirus retinitis is quintessentially seen in the context of AIDS or severe immunosuppression. It still today remains an AIDS-defining infection but is also seen in patients who fail to respond, become intolerant of, or stop responding to HAART. Traditionally, it was not associated with vitreous inflammation, and therefore detachments were rarely complicated by proliferative vitreoretinopathy. In the HAART era the frequency of an inflammatory response, late detachments, and PVR has increased, with some series reporting up to 30% of CMV retinitis cases complicated by PVR.<sup>37</sup> The incidence of RD is highest among newly diagnosed patients (within 45 days of diagnosing a CMV retinitis) at 4.9/100 eye-years, while the overall rate among AIDS patients with CMV retinitis is 2.3/100 eye-years.<sup>8</sup> Additional risk factors for RD include large lesion size, anterior lesion location, associated retinal pathology (e.g., myopia), and older age.<sup>38,39</sup> Local and systemic therapy might reduce slightly the risk of RD, possibly due to a more rapid resolution of retinitis.<sup>40</sup> Most detachments occur once the initial infection has subsided. The healed retinitis leaves a thin glial sheet above which an epiretinal membrane, possibly containing condensed vitreous, can be found (Fig. 116.5).<sup>41</sup> Vitreoretinal gliosis is often present at the interface between normal and abnormal retina on optical coherence tomography (OCT) images but is difficult to visualize clinically. It is possible that the

gliosis contributes to the formation of retinal detachments in these patients.

**FIG. 116.4** (A) Histopathologic section of the retina in acute retinal necrosis showing a sharp border between healed and affected tissue. (B) Histopathologic section of the retina in cytomegalovirus retinitis, showing also a sharp border in the healed phase.

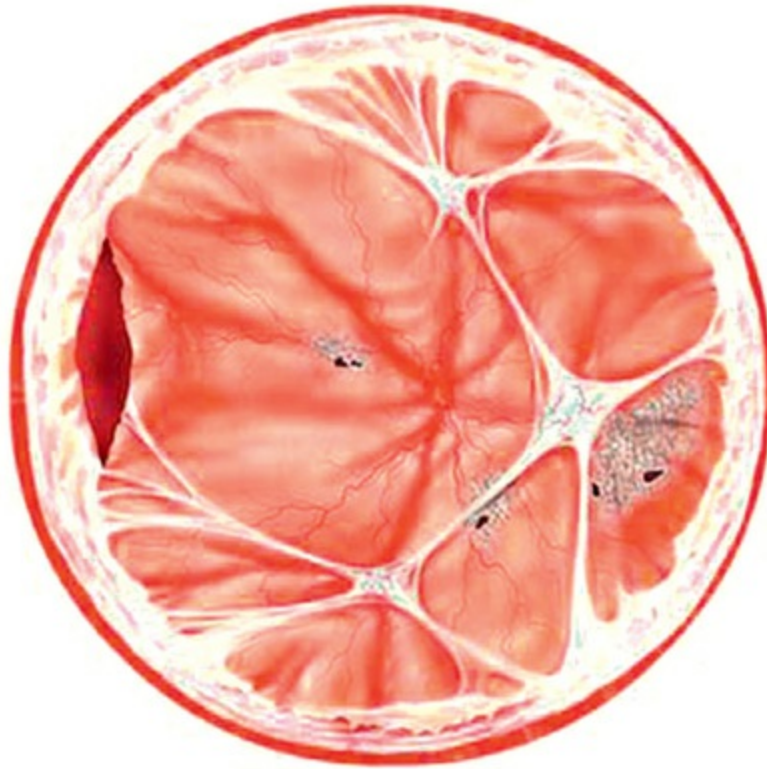

**FIG. 116.5** Artist's rendition of a retinal detachment following cytomegalovirus retinitis. Atrophic scars of healed retinitis often harbor retinal breaks.

Acute retinal necrosis (Fig. 116.6A) is characterized by large, peripheral, often confluent zones of retinitis.<sup>42-44</sup> Pathologically, it is characterized by full-thickness retinal necrosis and occlusive vasculitis (Fig. 116.4B).<sup>45</sup> Vitreous involvement, often not present initially, develops within days and can obliterate the view of the posterior pole. A more aggressive form starting at the posterior pole, called progressive outer retinal necrosis (PORN, Fig. 116.6B), also affects all retinal layers and represents an ophthalmic emergency since it may lead to complete blindness within hours if not treated aggressively.<sup>46-48</sup> In both cases, detachments occur due to vitreous traction on the atrophic retina, often as a PVD develops. When severe inflammation is present, they may occur even before resolution of the active retinitis. Retinal detachments in ARN are frequently complicated by an anterior vitreous contraction along the vitreous base. Retinal breaks are usually multiple and located at the juncture between normal and gliotic retina. Vitreoretinal adhesions are common, and the retinal detachment has both tractional and rhegmatogenous components (Fig. 116.7).

**FIG. 116.6** (A,B) Fundus picture of retinal involvement in viral posterior uveitis. (A) A large peripheral area of retinal whitening with diffuse borders and hazy view, due to important vitritis, in a case of herpes simplex-associated acute retinal necrosis. (B) Several areas of retinal whitening surrounding the optic nerve head, clearly viewed through a noninflammatory vitreous, in an immunosuppressed patient suffering from varicella-zoster-associated progressive outer retinal necrosis.

**FIG. 116.7** Artist's rendition of a retinal detachment associated with acute retinal necrosis showing vitreous strands, vitreous base fibrosis, and retinal thinning, tears, and preretinal fibrosis. Large tears form in areas of retinal gliosis. The more extensive the area of gliosis, the more probable is the development of a detachment.

## Clinical Examination and Findings

As stated above, RDs in uveitis can arise in a number of ways. Not infrequently, TRD, even schisis cavities, can be misdiagnosed as RRD ([Fig. 116.8](#)).<sup>18</sup> As part of the initial workup, it is important to establish the nature of the detachment, the etiology, severity, and stage of ocular inflammation or infection, and the status of the

retina and vitreous. In particular, it is important to determine the relationship between the detached retina and the area of retinal inflammation or infection, the presence or absence of a PVD, and the presence of peripheral vitreous base fibrosis and foreshortening. These observations and workup are often hampered by poor visualization resulting from posterior synechiae, cataract, vitreous haze, or cellular infiltration. In infectious cases, particularly ARN, vitreous inflammation may increase shortly after initiating treatment to the point where it is impossible to visualize the fundus. Analogous to trauma cases, it is important in these cases to document, as early as possible, findings in the vitreous and retina.

**FIG. 116.8** Peripheral traction due to vitreous bands and contraction in a patient with pars planitis and neovascularization of the vitreous base causing exudation into the subretinal space. One of the vitreous bands is visible on the retina surface.

When visualization becomes inadequate, ancillary tests may be required. To evaluate the macular area through a small pupil, a nonmydriatic camera, SLO (scanning laser ophthalmoscopy), or OCT may be useful. Unfortunately, they do not give any information on the condition of the peripheral retina. B-scan ultrasonography (both 10 and 50 MHz) is probably the most useful tool to evaluate the peripheral fundus. Uveitis-related RD often has

a highly reflective posterior hyaloid when detached (which can even mimic a RD).<sup>49</sup> Occasionally, during active inflammation, fine echoes within the retrohyaloid space are visible, corresponding to inflammatory cells within the vitreous. If visualization of the vitreoretinal interface becomes difficult and therapy with intravitreal steroids is envisaged, triamcinolone will improve the ultrasound signal and facilitate visualization of posterior structures.<sup>50</sup> The presence of a thickened choroid ( $\geq 2$  mm thickness) and the asymmetry between the two eyes can help confirm the diagnosis of a choroidal inflammation in the involved eye.<sup>49</sup> Choroidal detachments are not infrequent, and their anterior extent needs to be defined.

Ciliary body detachments may develop as a result of uveitis, causing or predisposing to hypotony. Ultrabiomicroscopy (UBM) is the preferred tool to visualize the ciliary body. It is also possible to assess the state of the peripheral vitreous, in particular, if it has become adherent to the posterior iris surface causing posterior displacement of the iris plane (an indirect sign of vitreous base fibrosis and likely foreshortening of the retina) (Fig. 116.9).<sup>51,52</sup>

**FIG. 116.9** Ultrasound biomicroscopy of the pars plana region of a patient with sarcoidosis. Vitreous condensation and contraction onto the posterior iris surface has also led to traction and detachment on the ciliary processes.

Tears in inflammatory retinal detachments are usually found and localized using the same rules as for standard detachments. In posttherpetic detachments, tears are often located at the margin of the atrophic scar or at the insertion of the posterior hyaloid onto the retinal surface.

## Management

As in all retinal detachment repairs, the decision and mode of intervention is based on an analysis of the potential risks contrasted with the probability of anatomic success and vision improvement. In the absence of active inflammation, most cases respond as if they were uncomplicated retinal detachments, and thus the benefit outweighs the surgical risk. With active inflammation, or in AIDS patients, vision recovery is likely to be more limited, and there is a higher risk of recurrence or PVR. Here, timing may need to be modified and a more aggressive approach adopted.

As in every case of intraocular surgery on uveitis patients, results are best if inflammation is absent. It should be under control and as low as possible prior to the intervention. Preoperative, intraoperative, and postoperative systemic and local medications (corticosteroids, antivirals, and antibiotics) should be adapted for each particular case.

## Rhegmatogenous Retinal Detachment With Active Inflammation

Results of surgery performed on retinal detachments during active inflammation have generally been poor.<sup>5,53,54</sup> Inflammation leads to poor postoperative visualization and development of fresh membranes on the retinal surface and in the retrolenticular space. It is crucial to adequately and aggressively manage the inflammatory component with a combination of systemic and local therapy. Systemic therapy should be initiated prior to surgery. The choice will depend on the nature of inflammation and previous response to treatment. If the iris requires manipulation during surgery, prostaglandin inhibitors should be added topically as well as systemically starting the day prior to surgery. This is commonly

done in uveitis patients undergoing cataract surgery as it can significantly reduce postoperative anterior segment inflammation.<sup>55</sup> At the end of surgery, periocular and intraocular steroids should be considered. The use of a long-acting (or slow release) steroid preparation will reduce the severity of any recurrence developing in the postoperative period.

In general, better surgical success is obtained when a more aggressive approach is taken. The lens, if present, is removed, the decision whether to implant an intraocular lens (IOL) or not will depend on the degree of inflammation and the underlying diagnosis. In case implantation is chosen, in-the-bag fixation with a hydrophobic acrylic or polymethyl methacrylate IOL is preferred (since the use of silicone oil tamponade in these cases is almost the rule, as will be further discussed). Lens extraction should be considered, even in the presence of a clear lens, in all cases requiring vitreous base shaving or when a significant postoperative fibrinous response is expected. It is very difficult to achieve an adequate ablation of anterior vitreous over 360° without removal of the lens. Anterior displacement of the lens by draining the anterior chamber is frequently not sufficient.

Following a core pars plana vitrectomy, which preferably is performed with small-gauge instruments, a posterior vitreous detachment is induced and carried out to the vitreous base (Fig. 116.10A). This can be facilitated by the use of intravitreal triamcinolone or a coloring agent. If it is not possible to remove the posterior hyaloid completely, the vitreous is shaven down to the retinal surface (Fig. 116.10B). This is particularly important at the vitreous base (Fig. 116.10C), as there will be a tendency for any remaining scaffold to contract and pull on the ciliary body and peripheral retina potentially leading to hypotony and/or recurrent detachments (Fig. 116.9). Membranes present on the retinal surface are peeled; given their tenacity, this is often best done using a bimanual technique with a pic and a forceps (Fig. 116.10D).

**FIG. 116.10** Vitrectomy for retinal detachment in patients with active uveitis. (A) A standard pars plana vitrectomy is carried out, followed by the induction of a posterior vitreous detachment. The vitrectomy is usually initiated after removal of the crystalline lens and its replacement with an intraocular lens. (B) When the posterior hyaloid cannot be easily detached even with the use of a coloring agent, the vitreous is resected up to the surface of the retina. (C) Resection of the vitreous is carried out over the vitreous base, where the vitreous remnants are shaven down to the retina surface. (D) Dissection of membranes present on the retinal surface is best achieved using a bimanual technique, the use of perfluorocarbon, and a

chandelier lighting system.

Illumination is provided by a chandelier or transscleral illumination system. Peeling is facilitated by using perfluorocarbon, which acts as a “third” hand, providing posterior stabilization to the membranes being peeled. Once the retina is fully reattached under perfluorocarbon, the edges of the tears are treated by photocoagulation. Cryotherapy should be avoided, as it enhances breakdown of the blood–ocular barrier and can increase postoperative inflammation.<sup>56</sup> Silicone oil is the preferred tamponading agent, as it will allow continued visualization of the retinal structures while the inflammation is brought under control (Fig. 116.11). It is also thought to limit the accumulation of proinflammatory cytokines in the vitreous cavity.<sup>57</sup> The oil can be removed when the retina has completely healed, and the inflammation is brought fully under control. This may take 6 or more months to occur.

**FIG. 116.11** Once the retina is mobilized, an air–fluid exchange is performed to reattach the retina. Retinotomies are done if traction is not fully relieved. Alternatively, silicone oil–perfluorocarbon exchange can be undergone.

## Persistent Inflammatory Serous Retinal Detachment

When inflammation has already been controlled and SRD persists after at least 3 months of corticosteroid and/or immunosuppressive treatment, surgical drainage may be considered to hasten recovery in cases with macular involvement and decreased vision. Galor et al.<sup>1</sup> reported on five cases of persistent SRD surgically drained through a technique involving a complete vitrectomy, a

peripherally and superior drainage retinotomy, use of perfluorocarbon to assist drainage followed by endolaser, and a gas tamponade. In all cases a scleral buckle was used to provide peripheral support in the area of drainage. In our own experience the buckle is not required, provided tamponade can be achieved until the laser forms a firm adhesion between the retina and choroid. As indicated by the authors, this approach is meant to drain persistent subretinal fluid in patients with quiescent inflammation. If inflammation persists, the subretinal fluid will reaccumulate.

## Retinal Detachment With Retinal Necrosis

### Cytomegalovirus Retinitis

In selected cases of CMV-associated retinal detachments, photocoagulation may be effective in delimiting or demarcating the affected area.<sup>58-60</sup> This approach can lead to a significant delay in macular detachment. Delaying intraocular surgery in these patients is a valid strategy, since successful surgical reattachment, as several studies have suggested, is often associated with some degree of central loss of vision, possibly related to microangiopathy, optic neuropathy, or silicone-oil-related toxicity.<sup>61-65</sup> Once a surgical option is chosen, retinal detachments due to CMV, whether or not associated with PVR, should be approached in a standardized fashion. The risk of recurrence or progression of CMV should be assessed in conjunction with the treating internist, as it will determine the choice of tamponade and the need for concurrent cataract extraction.

The surgery begins with a standard three-port vitrectomy (Fig. 116.10). When preexisting vitreous separation is present, the posterior hyaloid is identified and resected up to the posterior margin of the vitreous base. In some cases, however, the vitreous has not detached posteriorly. If it can be mechanically engaged and easily elevated from the retina, this is done to create a posterior vitreous separation. In some cases, this technical separation cannot be safely accomplished. An attempt should be made to resect the vitreous as close to the surface of the retina as possible, without inducing a vitreous detachment. In cases in which CMV has caused

necrosis of a large area of retina, an en bloc dissection of diaphanous retina and vitreous is possible but should in most cases follow separation of the vitreous from surrounding healthy retina, or at least after it has been shaven off the retinal surface. The edges of retinal breaks or the area of resection are marked with intraocular diathermy (Fig. 116.12). This makes later identification easier. Internal drainage of subretinal fluid in conjunction with air–fluid or fluid–silicone exchange is performed to flatten the retina (Fig. 116.11). The retinal breaks are surrounded with endophotocoagulation (Fig. 116.13).

**FIG. 116.12** The retinal breaks are identified and marked with diathermy, particularly if a gas exchange is chosen to flatten the retina.

**FIG. 116.13** Once attached under air, perfluorocarbon, or silicone oil, the edges of all tears and retinotomies are treated with endolaser.

Many surgeons advocate demarcating the atrophic areas with laser, as well as those regions that are likely to harbor retinal breaks. In certain circumstances, scatter photocoagulation applied to the lower hemisphere up to the edge of the inferior vascular arcade can help mitigate the appearance of a later detachment, particularly if CMV progression in this area is expected in the following months. A silicone–air exchange or air–gas exchange is performed at this point. The choice will depend on the configuration of the detachment and the likelihood of recurrent activity. If progression is likely, silicone oil is a better and more permanent choice. Postoperatively, the patient is kept face down for 12 hours, after which time special positioning is not necessary. Postoperative follow-up is aimed at identifying evidence of silicone oil toxicity, reactivation of the viral infection, and to detect

recurrent retinal detachment.<sup>39,61,62,64–69</sup>

Redetachment of the retina may occur at any time postoperatively and may be caused by new retinal breaks or reopening of previously treated breaks. Typically, the recurrent retinal detachment is shallow and located inferiorly, where the silicone bubble may not be entirely in contact with the retina. If the redetachment is localized and extramacular, observation is usually the best strategy. If the macula is threatened or detached in an eye with previously good vision, then reoperation may be warranted. Often, drainage of subretinal fluid combined with injection of more silicone with additional photocoagulation is the treatment of choice. If visualization is poor, the oil must be removed and the retina reattached, as described above, before the oil is reinjected.

Lensectomy may be necessary, preferably with the implantation of an intraocular lens, maintaining the posterior capsule. Later capsular opacification is common, however, and one should consider primary capsulotomy in selected cases.<sup>70</sup> An inferior iridectomy must be performed in aphakic eyes and should be considered in pseudophakic eyes to prevent pupillary block.

If the lens is extracted, a planoconvex polymethylmethacrylate (PMMA) or hydrophobic acrylic intraocular lens provides the ideal optical correction.<sup>71,72</sup> Engstrom et al. reported satisfactory results with simultaneous lensectomy and intraocular lens implantation at the time of vitrectomy and silicone oil injection.<sup>71</sup> This strategy is used to avoid silicone-oil-induced anisometropia and to obviate the need for later cataract removal, as silicone oil almost always induces cataract formation.<sup>70</sup>

## Acute Retinal Necrosis

The operation should be tailored to the severity of the disease. In most cases, traction from a partially detached vitreous on the vascular scaffold remaining in the friable retinal tissue after the infection subsides and leads to the presence of multiple holes, low-lying detachments, and PVR, both anterior and posterior.

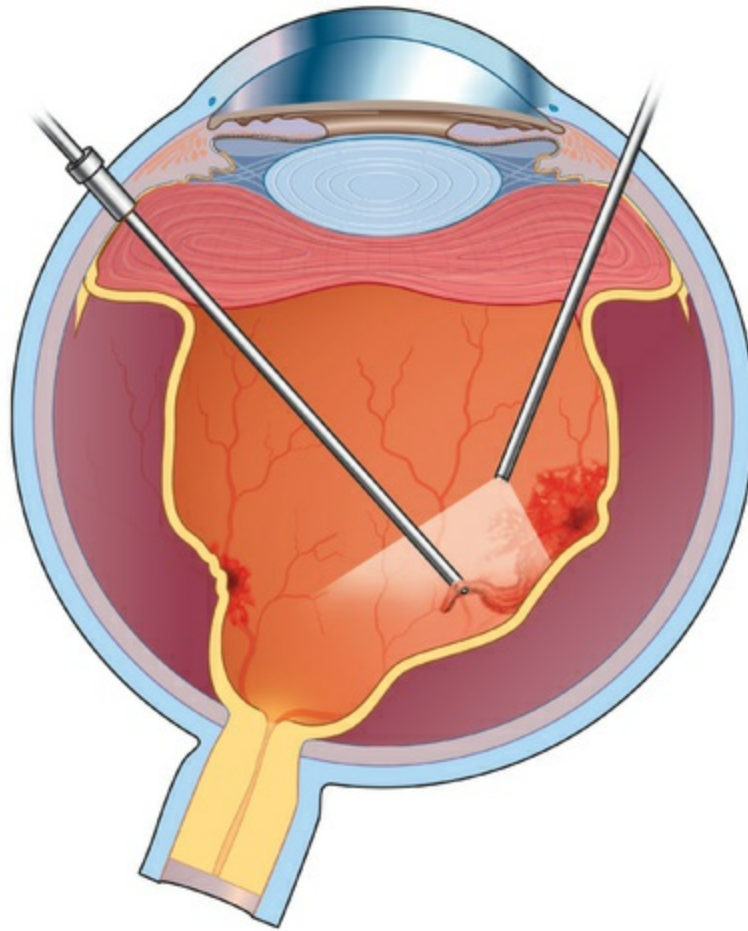

A standard three-port vitrectomy is performed (Fig. 116.10). As in CMV cases, the infusion pressure should be kept low since the ischemic optic nerve in these patients does not tolerate standard

infusion pressures. Looking at the nerve to avoid a pulsatile perfusion at the onset of surgery, and periodically during surgery, can avoid further loss of vision from prolonged retina anoxia. A lens extraction is required in nearly all cases to expose the full extent of the vitreous base so that all condensed vitreous and vitreous traction can be eliminated.

In the presence of a RRD, a spontaneous posterior vitreous detachment is present. The vitreous gel must be resected out to the margin between healthy and atrophic retina or to the posterior margin of the vitreous base (Fig. 116.14). Posterior epiretinal membranes overlying healthy retina are identified and removed with pick and forceps. A chandelier lighting system may facilitate this maneuver (Fig. 116.15).

**FIG. 116.14** In acute retinal necrosis syndrome, a posterior vitreous detachment is usually present. It is carried out to the vitreous base.

**FIG. 116.15** In acute retinal necrosis syndrome, posterior epiretinal membranes are identified and removed with pic and forceps.

Once the posterior healthy retina is free of membranes, perfluorocarbon is used to tamponade this retina out to the edge of atrophic retina. If detached, atrophic retina should be removed en bloc. Its diaphanous nature makes it difficult to peel off membranes, and it does not coagulate well with laser. As this is nonfunctional retinal tissue, it has no physiologic function and can best be removed. Larger vessels, even though these are attenuated, should be treated with diathermy as they may bleed. To facilitate removal, deep scleral depression can be used. This may lead to a 360° retinotomy leaving a fairly central area of viable, healthy retina.

Once the vitreous, preretinal membranes, and detached atrophic

retina have been removed, remaining retinal breaks are identified and marked with endodiathermy. Under perfluorocarbon the edge between healthy and any remaining atrophic retina, as well as the free edge that was created earlier, are treated by endophotocoagulation, placing several rows of laser along the edge of healthy retina.

If peripheral support is necessary, particularly inferiorly, an encircling band or a complete scleral buckle can be placed. However, in many cases it is not needed, and best avoided, as it can lead to choroidal ischemia and compromise residual retinal function.

In most cases silicone oil is used to tamponade the retina. The oil should be ideally removed in 3–6 months to avoid long-term complications related to its presence. Removal should be considered only if the risk of redetachment is believed to be minimal.

In managing PORN-related retinal detachments, the surgical principles are identical to those for ARN. The extent of the necrosis, however, is almost always greater than in patients with ARN-related retinal detachments, so extra care must be taken with vitreous manipulation, and the amount of photocoagulation required is often much more extensive in an effort to surround and preserve the macular region.<sup>46,73</sup>

## Prognosis

Visual restoration after SRD is usually good, with most eyes achieving >20/40 after adequate treatment. Visual function after uveitis-associated RRD is frequently guarded, with almost 70% of eyes remaining under 20/200 if the RD was repaired during active inflammation. This poor visual prognosis is related both to the ocular inflammation itself and to the high frequency of proliferative vitreoretinopathy (PVR) appearing after surgery. In order to mitigate the effects of inflammation, it is necessary to anticipate its consequences and hence use silicone oil, even though there may be little evidence of PVR at the time of surgery, or remove a perfectly clear crystalline lens in order to complete the vitreous resection up and over the vitreous base. In viral retinitis, a similar approach is

often required. In addition in these conditions, the surgery should be carried out as much as possible with a low intraocular pressure, as the circulation through the optic nerve may be occluded at even standard infusion pressures. Proliferative retinopathy (PVR) is enhanced by inflammatory cytokines, and chemokines normally present in the anterior chamber and vitreous body of eyes with uveitis. Reducing these molecules can improve the prognosis and implies a concerted local and systemic effort to minimize intraocular inflammation. It is best achieved as a team effort between the vitreoretinal surgeon and the uveitis specialist.

## Conclusion

Management of retinal detachments in patients with inflammation or infection demands not only knowledge of surgical options, but also a good grasp of the underlying disease, an estimate of the probable postoperative course as well as the likelihood of recurrence. A multidisciplinary approach is most likely to provide the optimal outcome in most settings. While in the past, visual results after surgery were relatively poor, the advent of better equipment, less traumatic surgical approaches, and a better understanding of the pathophysiologic processes at hand have improved both short-term and long-term outcomes. Both timing and extent of surgery are critical issues, which vary depending on the etiology. Larger series obtained by combining results from several different centers will help to define more precisely these parameters in years to come.

## Introduction

The incidence of high myopia varies among ethnic groups, races, and countries, but there is a higher incidence in Asian countries. Some of the incidence rates worldwide range from 1% in Black Americans,<sup>1</sup> 2% in Caucasian Americans,<sup>1</sup> 2.6% in Chinese individuals,<sup>2</sup> to 5.5% in Japanese individuals.<sup>3</sup> The prevalence of myopia seems to be increasing,<sup>4</sup> and it is one of the major causes of visual impairment, especially in Europe and East Asia.<sup>5,6</sup>

The definitions of high myopia vary slightly; however, there is agreement that the spherical equivalent refractive error exceeds  $-6$  diopters (D) and/or the axial length is longer than 26.5 mm. Pathologic myopia is defined as high myopia with any posterior myopia-specific pathology from excess axial elongation. Pathologic myopia is characterized by posterior staphyloma formation and also is associated with specific macular complications such as choroidal neovascularization and chorioretinal atrophy. Myopic foveoschisis and macular holes with or without retinal detachment are also specific to myopia and major indications for surgical

intervention.

Observation of a myopic macular area using a contact or non-contact lens has been challenging because the atrophy lowers the contrast. This has hindered detailed observation and consequent understanding of the pathophysiology, although myopia-specific macular diseases have been well known for a long time. Technologies such as optical coherence tomography (OCT) have facilitated both visualization of the retinal microstructures in pathologic conditions and an understanding of the pathogenesis, interaction, and disease progression. For instance, a recent OCT study showed a more detailed interaction between the vitreous and retina using swept source OCT (Fig. 117.1) and described that even after a Weiss ring was visible, vitreous cortex still remained on the macula,<sup>7</sup> which may play an important role in development of such myopic pathologies as macular holes and retinoschisis. This information has led to revolutionary changes in the disease concept of myopia-specific macular diseases. Pathologic myopia is now a much more accessible disease than it was 20 years ago.

**FIG. 117.1** The status of posterior vitreous in normal highly myopic eyes. Swept-source optical coherence tomography (SS-OCT) can visualize vitreous gel and thus shows an interaction between the vitreous and retina. This OCT image clearly shows a cortical vitreous pocket (*asterisk*).

Examiners often have difficulties obtaining clear and high-contrast OCT images in highly myopic eyes. The characteristics of the OCT image in these eyes are (1) a relatively low signal to noise ratio; (2) deep posterior staphyloma in the presence of which the peripheral tissue often drops off from the top edge of the image; (3) poor fixation due to a large central scotoma from chorioretinal atrophy; and (4) critical signs that are mostly outside the fovea. The pearls for the OCT examination are as follows. First, it is much better to use spectral domain (SD-) OCT, which provides much higher sensitivity and scanning speed than time domain (TD-) OCT. Second, the pathology of interest must be located near the top of the OCT image. SD-OCT has the strongest signal at the top and the weakest at the bottom because of the so-called signal decay. This procedure maximizes the signal and enhances the contrast of the pathology being targeted. Third, large internal fixation or external fixation must be used to avoid unnecessary ocular movement in cases with a large central scotoma. Finally, attention must be paid to pathologies outside the fovea. For instance, a small macular hole is sometimes outside the fovea, and other micropathologies such as retinal vascular microfolds, internal limiting membrane detachments, and paravascular microholes are far outside the macula. The use of the 5-lines or grid scan has a significantly higher rate of detection of these pathologies than the use of a single B-scan alone.

Imaging technologies have identified myopic foveoschisis, which is a relatively new pathology that was recognized about 15 years ago.<sup>8</sup> It is now generally agreed that this pathology is common in highly myopic eyes, and myopic foveoschisis is regarded as a precondition for development of a macular hole and retinal detachment. OCT studies of myopic foveoschisis have revealed many preclinical and pathologic conditions underlying the myopic macular diseases, as discussed below. This information is also helpful for understanding the process and pathophysiology of macular holes and retinal detachments, which are the most problematic complications for vitreoretinal surgeons. In this chapter, we review the recent studies and shed light on the vitreoretinal complications of high myopia.

## Retinal Detachment From Peripheral Breaks

Retinal detachments from peripheral retinal breaks are common in high myopia. The prevalence of any type of retinal detachment increases in association with the degree of negative refractive error.<sup>9</sup> The distribution of high myopia exceeding  $-6.0$  D is about 16% in overall cases, and the lifetime risk is more than 20-fold compared with emmetropia.<sup>9</sup> In addition, the onset of retinal detachment is at a younger age, based on the degree of myopia.<sup>10</sup> The frequency of retinal peripheral degeneration increases along with the axial length.<sup>11</sup> The development of posterior vitreous detachment (PVD) according to the higher liquefaction of the vitreous body occurs at a younger age in eyes with severe high myopia.<sup>12</sup> These facts seem to account for the increased prevalence of retinal detachment.

A rhegmatogenous retinal detachment (RRD) must be treated with a scleral buckling procedure or vitrectomy combined with gas or silicone oil tamponade, as for non-highly myopic retinal detachment. Scleral buckling is the first choice for retinal breaks with non- or minimal vitreous traction and vitrectomy for significant traction from the vitreous. We normally use a 25-gauge system for vitrectomy, and a small-gauge system works well in cases of high myopia.

## Epidemiology of Surgical Macular Complications

The incidence rates of myopia-specific macular complications such as myopic foveoschisis and macular holes with or without retinal detachments have not been well documented because these complications are rare. Myopic foveoschisis was identified in 9% of patients with posterior staphyloma.<sup>13</sup> In patients with a macular hole and retinal detachment, 8.5% develop the same pathology in the fellow eye within 4 years.<sup>14</sup>

## Rhegmatogenous Retinal Detachment After

## Refractive Surgeries

Rhegmatogenous retinal detachment is a major complication after refractive surgeries. The incidence is not as high after laser in situ keratomileusis (LASIK) and was reported to be 0.25%,<sup>15</sup> however, it is much higher after refractive lens exchange, reportedly 7.3% within 3 years.<sup>16</sup> Retinal detachment is a rare but general complication after cataract surgery, with incidence rates of 0.9% in the general population<sup>17</sup> and 1.5–2.2% after phacoemulsification in highly myopic eyes.<sup>18,19</sup> A high likelihood of PVD occurring within 5 years after surgery<sup>20</sup> seems to be associated with a higher incidence.

## Etiology and Pathophysiology

### Myopic Foveoschisis

Myopic foveoschisis is characterized by retinoschisis with or without localized retinal detachment and is specific to high myopia. OCT can depict the pathology very clearly ([Fig. 117.2](#)). Myopic foveoschisis is also referred to as a posterior retinal detachment without a macular hole in highly myopic eyes, described by Phillips in 1958, who reported a case with a retinal detachment within posterior staphyloma but no apparent macular hole.<sup>21</sup> The detailed pathology and its mechanism awaited the development of OCT for decades. Takano and Kishi examined 32 highly myopic eyes with OCT and found retinoschisis in nine eyes and a foveal detachment in one eye, suggesting that retinoschisis and foveal detachment are common in highly myopic eyes.<sup>8</sup> It has been reported that myopic foveoschisis is characterized by variations in the foveal architecture, including a foveal cyst in 47%, a lamellar hole in 29%, and a foveal detachment in 29%.<sup>22</sup>

**FIG. 117.2** Typical appearance of myopic foveoschisis. The fundus photograph (inset) shows a slightly elevated retina at the posterior pole, although it is not visually apparent. A horizontal optical coherence tomography scan involving the macula shows retinoschisis in multiple retinal layers and a retinal detachment at the fovea (*asterisk*). There is glial tissue bridging the inner and outer layers of the retinoschisis (a so-called column, *arrow*).

The pathogenesis of myopic foveoschisis has been disclosed recently. Various OCT images from these myopic eyes have led to the hypothesis that the inner retina is less flexible than the outer retina.<sup>23</sup> Factors limiting the inner retinal flexibility include the vitreous cortex adhering to the retina, epiretinal membranes (ERMs), internal limiting membrane (ILM), and retinal vessels. Preretinal membranes, which can be hard to recognize clinically and are found only at the microscopic level in highly myopic eyes,<sup>24</sup> cause deterioration in the retinal flexibility.

Histologic studies have shown retinoschisis at multiple levels in the outer plexiform layer, inner plexiform layer, ganglion cell layer, and nerve fiber layer.<sup>25</sup> There also is a preretinal fibrous membrane. An electron microscopic study on excised ILM samples during vitrectomy has shown that collagen fibers and cell debris were present on the inner surface of the ILM in 70% of the myopic foveoschisis, substantially more than that found in idiopathic nonmyopic macular holes (0%).<sup>24</sup> Another study has shown a much higher incidence (61.8%) of preretinal membrane recognized during vitrectomy in high myopia than controls (7.0%).<sup>26</sup>

ILM detachments, sometimes recognized as “inner retinoschisis,” are often seen in highly myopic eyes, which explains the underlying traction from the ILM on the other retinal layers (Fig. 117.3).<sup>27</sup> Inner

retinal elevations along with retinal vessels recognized as tent-like lesions on OCT images, so-called retinal vascular microfolds, are observed especially in vertical sections (Fig. 117.4).<sup>28</sup> This finding represents traction from the vessels on the retinal surface. A large OCT study of 200 highly myopic eyes reported a 6% incidence of ILM detachments, a 13.5% incidence of retinoschisis, and a 20% incidence of retinal vascular microfolds.<sup>29</sup> These components generate inward tractional force on the inner retina, which potentially splits the retina, causing retinoschisis, and finally leads to a retinal detachment at the fovea.

**FIG. 117.3** Representative optical coherence tomography appearance of an internal limiting membrane (ILM) detachment (*arrows*) in highly myopic eyes. The ILM layer is detached from the other retinal layers.

**FIG. 117.4** Representative optical coherence tomography appearance of retinal microfolds (*arrow*) in highly myopic eyes. This microfold is associated with the retinal vessels and warrants microvascular traction

on the retina.

## Macular Hole With or Without Retinal Detachment

Retinal detachments from a macular hole are a typical complication in highly myopic eyes. The vitreous cortex adhering to the retinal surface around the hole causes tangential traction that generates an inward vector component in deep staphyloma in highly myopic eyes, resulting in a retinal detachment.<sup>30</sup> Releasing the retinal traction is critical to successful reattachment; thus, vitrectomy with vitreous cortex and membrane removal is effective. An OCT study reported that persistent traction at the macular hole edge after opening is critical for initiating a retinal detachment.<sup>31</sup> A macular hole with retinoschisis has a higher likelihood of progressing to a retinal detachment than those with a retinal cyst, resembling idiopathic nonmyopic macular holes (Fig. 117.5).

**FIG. 117.5** Optical coherence tomography appearance of two distinct subtypes in highly myopic macular holes. (A) A macular hole with surrounding retinoschisis usually presents a higher likelihood of consequent retinal detachment, while (B) a macular hole without retinoschisis has only retinal cysts and is

normally stable.

A macular hole with retinoschisis typically presents with deeper posterior staphyloma, which explains the lower anatomic success rate in this subtype.<sup>31,32</sup> Deep posterior staphyloma generates a larger vector component from the tangential traction exerted by the ERM or the ILM, which acts on the retina as an inward tractional force. In addition, with deep staphyloma it is more difficult to close the macular hole because of excess stretching in the retina. While shallower, posterior staphyloma generates less tractional force and the retina is flat as seen in nonmyopic eyes. This flat configuration exerts less stretching in the retina, and, thus, the macular hole is more likely to close. The type of macular hole is highly dependent on the depth of the posterior staphyloma and underlying tractional force, which affect the anatomic success rate. Thus, preoperative OCT observation of the macular hole edge provides one clue to the prognosis.

In highly myopic eyes, multiple components adhere to the retinal surface in most cases and are often recognized during vitreous surgery. Electron microscopic studies have shown that they are the vitreous cortex, cellular ERMs, and ILMs,<sup>33</sup> suggesting that complete removal of these tractional forces is essential in reattachment surgery.

## Posterior Retinal Detachments From Paravascular Microholes

Retinal detachment from a paravascular microhole is also specific to highly myopic eyes (Fig. 117.6). Microholes are typically small, round or oval retinal holes associated with posterior major vessels.<sup>34</sup> There are sometimes multiple holes that are adjacent to the major vessels. An OCT study of highly myopic eyes reported that the incidence rates of retinal cysts and paravascular holes were 50% and 27%, respectively.<sup>35</sup> The vitreoretinal adhesion is often strong at the paravascular region, and traction from the vitreous at the site is believed to be a main cause of retinal rarefaction, resulting in retinal cysts and breaks.<sup>36</sup> Paravascular microholes often colocalize with vascular microfolds and retinoschisis,<sup>28</sup> suggesting a close

relationship with the retinal vascular traction.

**FIG. 117.6** Intraoperative view of paravascular microholes in a highly myopic retinal detachment. Multiple, small and round retinal holes are located along the retinal vessels of the temporal arcade (arrows). A, Retinal superotemporal artery; V, retinal vein.

## Symptoms of Myopic Foveoschisis and Macular Holes With or Without Retinal Detachments

Myopic foveoschisis and macular holes with or without retinal detachments typically occur in highly myopic, middle-aged to older women. In the authors' clinic, 44 of 52 patients referred for this disease during the period from 2000 to 2005 were women.<sup>37</sup> Patients are normally aware of central visual distortion if they have only retinoschisis and a relative central scotoma corresponding to the involved area when the retinal detachment starts. Patients may be aware of an absolute scotoma at the center of the relative scotoma when a macular hole opens. Patients also report visual loss at the involved area if an extensive retinal detachment is complicated. Even if patients present with a macular hole, the Watzke–Allen test is usually negative.

## Clinical Findings

Myopic foveoschisis can be recognized as a slight elevation of the posterior retina in highly myopic eyes; however, it is difficult to accurately diagnose without OCT, especially in an atrophic fundus. OCT and other imaging tools are essential for complete assessment of the retinal status for surgical decision-making, for example, to determine the presence/absence of retinoschisis and the area of retinoschisis or retinal detachment. This information is essential for surgical planning. For instance, if there is a foveal detachment found on OCT images, macular hole formation is likely to start in the near future, and surgery must be planned soon (normally within 1 or 2 months). However, if the patient presents with only retinoschisis but not a foveal retinal detachment, the surgery is not as urgent. Evolution of macular hole and its diagnosis are difficult in high myopia.<sup>38</sup> OCT also facilitates assessment of the presence/absence of the hole and its size.

## Optical Coherence Tomography Features

Myopic foveoschisis presents with retinoschisis in multiple retinal layers. The split retinal layers normally have a bridge between them, the so-called column, which is presumed to be residual Müller cells (Fig. 117.2). In cases with a very atrophic retina, it can be difficult to distinguish retinoschisis from a retinal detachment, and the presence of the column is an important clue for diagnosing retinoschisis but not a detachment. Tracing the junction of the inner/outer-segment (IS/OS) line of the photoreceptors is also useful for differentiating a retinal detachment from retinoschisis as shown in an early OCT study.<sup>39</sup> ILM separation from the other retinal layers also is observed, i.e., a so-called ILM detachment, and is an indicator of the tractional force from the ILM.<sup>27</sup> The tent-like peak of the inner retina is observed on the OCT image. This is coincident with retinal vessels and the so-called retinal microvascular traction.<sup>28</sup> Because the retinal vessels normally run horizontally around the macular area, there is a higher chance of finding this in a vertical than a horizontal section because of the higher chance of observing a cross-section of the retinal vessels. The IS/OS junction

line of the photoreceptors sometimes disappears in the area of the retinal detachment;<sup>40</sup> however, the IS/OS junction line is typically well preserved in the area of retinoschisis, suggesting that the photoreceptor function is well preserved in this subtype.

There are two stages before macular hole formation associated with retinoschisis (Fig. 117.7). The first stage is the development of the so-called retinoschisis type, in which only retinoschisis is present and not a retinal detachment. Several months (sometimes several years) later a retinal detachment begins around the fovea. This stage is the so-called foveal detachment type, and a retinal detachment involving the fovea and retinoschisis around the macula are present. After a while, the inner retina above the detachment is stretched and torn. This is how a macular hole appears as a consequence of retinoschisis with a retinal detachment. Small macular holes are often difficult to visualize in a B-scan image because the fixation point has shifted.

**FIG. 117.7** Two distinct subtypes of myopic foveoschisis. (A) The retinoschisis type is characterized by only retinoschisis without a retinal detachment. (B) The foveal detachment type is characterized by a small localized retinal detachment, and the inner/outer segment line is separated from the retinal pigment epithelium. The retinoschisis type

develops before the foveal detachment type.

The edge of a macular hole provides valuable information. As discussed previously, there are two types of macular holes in highly myopic eyes.<sup>31,32</sup> One is similar to an idiopathic macular hole, as normally seen in nonmyopic eyes (Fig. 117.5B). In these, the edge of the hole is thickened with retinal cysts. There is no retinal detachment around the hole clinically, and this type usually does not progress for months or years. The other type has surrounding retinoschisis instead of retinal cysts around the hole (Fig. 117.5A). This type of macular hole results from myopic foveoschisis and can be considered a transition from foveoschisis to a macular hole with a retinal detachment. This type of macular hole typically progresses rapidly and is likely to complicate the retinal detachment because of underlying traction (see [Etiology and pathophysiology](#), above). The typical OCT appearance of this type is characterized by a relatively high and rectilinear wall of the macular hole edge with an acute angle to the RPE line, and a sharp-angled edge of the top of the macular hole.<sup>31</sup> Therefore, observing the macular hole edge is essential for exact diagnosis, which is critical for decision-making and planning of the vitreous surgery.

## Fundus Autofluorescence

Fundus autofluorescence (FAF) stimulates emission of light from the lipofuscin accumulated in the RPE and is an indicator of the oxidative stress level<sup>41</sup> and the functioning of the RPE. In the atrophic fundus in myopic eyes, FAF helps distinguish the retinal detachment from the retinoschisis, because loss of the contact between the photoreceptors and the RPE results in hypoautofluorescence.<sup>42</sup> The hypofluorescent area indicates the area of the retinal detachment and is a good indicator for monitoring its progression and the level of RPE damage and consequent visual outcome.<sup>43</sup>

## Treatment of Foveoschisis

The natural course of myopic foveoschisis is unfavorable.

Investigators have reported that the vision decreased in 69% of patients, a macular hole developed in 31% after 3 years of follow-up,<sup>44</sup> and in 50% of patients with retinoschisis a macular hole or retinal detachment developed after 2 years.<sup>45</sup> These observations encourage surgery to treat myopic foveoschisis as prophylaxis to prevent macular holes with consequent development of a retinal detachment.

## Surgical Indications

Myopic foveoschisis is sometimes asymptomatic, especially in cases with simple retinoschisis and no retinal detachment. Those cases are not good indications for vitreous surgeries. Even though patients are aware of a visual disturbance, turbulence, or visual loss, surgery can be postponed until the vision decreases to about 20/40 because there is still a chance of visual worsening after vitrectomy. The chance of visual improvement after surgery is about 80% in cases with a foveal detachment and 50% with retinoschisis alone.<sup>46</sup> Another study reported a similar trend and showed that 70% of eyes with a foveal detachment had significant visual improvement compared with 42% in the retinoschisis group.<sup>47</sup> The chance of visual improvement is substantially smaller if a macular hole is present before surgery,<sup>46,48</sup> which is partly because macular holes have a poor closure rate after surgery. Appearance of subretinal fluid after macular hole formation indicates a worse prognosis.<sup>49</sup> Hence, surgical intervention before macular hole formation is considered beneficial, although there is not yet strong evidence for this.

A localized retinal detachment in the posterior staphyloma from the macular hole often develops; however, there may be surgical benefits only in selected cases. This type of detachment is sometimes stable and does not progress. The retina is detached from the RPE and follows the minimal distance bridging the posterior staphyloma edge on the opposite site, which maintains balance and compensates for the retinal traction. Surgery can be postponed if the retinal detachment does not extend beyond the border of the staphyloma, and its progress should be monitored with OCT and/or FAF (see [Fundus autofluorescence](#), above). The

surgery should be performed as soon as possible if the situation progresses, because patients are at risk of total visual loss.

A macular hole with an extensive retinal detachment is a good indication for surgery. The surgical goal is to remove the entire component that is generating the tractional force on the retina and causing a detachment, including the vitreous cortex, ERMs, and the ILM. However, sometimes the traction persists from the retinal vessels even after a complete vitrectomy, leading to recurrence of the retinal detachment. Treating the posterior staphyloma is theoretically required for these cases, and placing a macular buckle might be considered. Simple gas injection was attempted in an early case series especially for eyes with a PVD; however, this procedure cannot relieve the traction exerted by ERMs, for instance. Therefore, the expectation for anatomic success is not as high as that associated with vitrectomy with complete removal of any traction.<sup>50</sup>

## Surgical Prognosis

The retina usually reattaches to the retinal pigment epithelium (RPE) slowly after the surgery (Fig. 117.8). The visual outcome associated with myopic foveoschisis is favorable if no macular hole develops. We reported that a substantial visual gain was achieved after vitrectomy in either group and that the final vision was similar between the foveal detachment type and the retinoschisis type; however, the visual change was significantly greater in the foveal detachment group than in the retinoschisis group.<sup>46,47</sup> Postoperative macular hole formation is a great concern in myopic foveoschisis. We investigated the incidence of postoperative macular hole formation and explored the risk factors. The incidence of macular holes was 19.8%, and eyes with preoperative discontinuity of the IS/OS line (IS/OS defect) seen on OCT was a predictor of macular hole development. Other factors, such as age, gender, and visual acuity, did not affect the rate of macular hole formation (Fig. 117.9).<sup>51</sup>

**FIG. 117.8** Optical coherence tomography (OCT) appearance of a patient who underwent vitrectomy with internal limiting membrane peeling and gas tamponade for myopic foveoschisis in [Fig. 117.7](#) (lower panel, foveal detachment type). (A) OCT image 2 months after surgery shows flattening of the retina. (B) An OCT image at the same position, 6 months after surgery shows that the retinoschisis has resolved; however, there is still substantial subretinal fluid. (C) An OCT image 12 months after surgery shows complete resolution of the retinal detachment.

**FIG. 117.9** A preoperative photoreceptor inner/outer segment (IS/OS) defect and postoperative macular hole formation after vitrectomy for myopic foveoschisis. (A) A 66-year-old woman had an IS/OS defect at the fovea (*arrow*) and surrounding retinoschisis preoperatively. (B) One month after vitrectomy, including internal limiting membrane peeling, the macular hole was open (*arrow*).

Once a macular hole develops, the hole is hard to close after vitrectomy in highly myopic eyes.<sup>52</sup> Also the visual outcome is not so favorable as nonmyopic eyes.<sup>53</sup> The macular hole closure rate with retinoschisis or retinal detachment is about 40–50% based on OCT images.<sup>54,55</sup> The mean visual acuity after vitrectomy for macular hole with retinal detachment was below 20/200, and the initial reattachment rate was about 50–70% after vitrectomy.<sup>56</sup> A longer axial length is generally a poor prognostic factor.<sup>57,58</sup> Usage of long-term gas tamponade seems to improve the visual outcome.<sup>59</sup> Macular buckling can compensate for any tractional force and showed a slightly higher initial reattachment rate than vitrectomy in macular hole with retinal detachment.<sup>60,61</sup>

## Surgical Procedures

### Vitreous Separation

A 25-gauge vitrectomy system is the first-line treatment for highly myopic eyes. The vitreous plays an important role; therefore, creating a PVD is critical for reattaching the retina. The vitreous tightly and extensively adheres to the retinal surface in highly myopic eyes. Use of triamcinolone acetonide is essential for visualization and to identify residual cortex. To create posterior vitreous separation, a vitreous cutter and silicone-tipped backflush needle with active suction are normally used. A diamond-dusted membrane scraper<sup>62</sup> is another option for an extremely thin vitreous cortex. The vitreoretinal adhesion is normally tight around the optic nerve disc, and, therefore, the surgeon might consider starting temporally where the adhesion is normally the weakest. Importantly, great care is needed to separate the vitreous at the macula because the macula is tightly adhered to the vitreous; placing stress on the macula may lead to macular hole formation. This procedure is difficult to perform in the detached retina, and a bimanual technique can be considered for a safe separation.

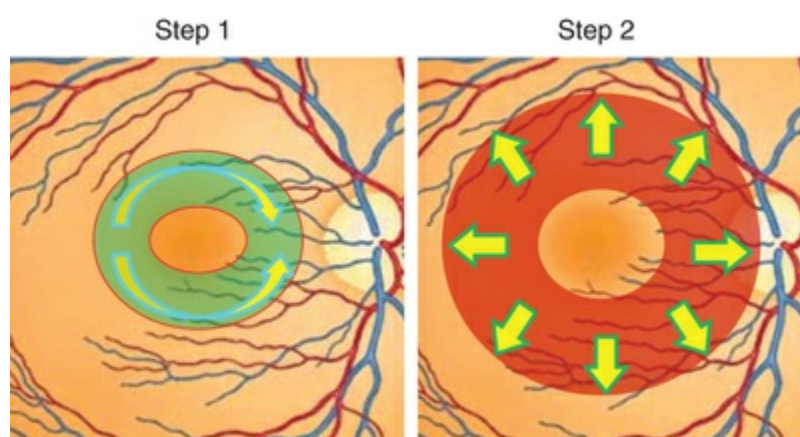

### **Internal Limiting Membrane Peeling**

The necessity for ILM peeling remains controversial in myopic foveoschisis, and one group reported a high success rate even without this procedure.<sup>63</sup> However, the ILM is separated from the other retinal layers on OCT images in most eyes,<sup>27</sup> suggesting that rigidity of the ILM plays a major role in this pathology. Also, a higher recurrence rate of macular detachment was reported in eyes without ILM peeling in the initial surgery.<sup>64</sup> This fact warrants the necessity of ILM peeling for myopic foveoschisis at least in selected cases.

ILM peeling also can enhance macular hole closure and remove any traction on the retina in myopic macular holes with a retinal detachment,<sup>65</sup> and this raises the initial success rate.<sup>66</sup> Indocyanine green was used to stain the ILM in the initial case series; however, it remains in the eye for longer than 6 months postoperatively.<sup>67</sup> Brilliant blue G (BBG) can selectively stain the ILM and is less toxic.<sup>68</sup> However, a recent OCT study of retinal surface has shown an increasing number of dimples within the area of ILM peeling after surgery.<sup>69</sup>

It is hypothesized that traumatic damage at the fovea induced by

ILM peeling may cause full-thickness tissue loss at the fovea in myopic foveoschisis. This idea led us to attempt to leave the foveal ILM. Recently, a nonfoveal ILM peeling technique was introduced in an attempt to avoid macular holes (Fig. 117.10).<sup>70</sup> One study reported a significant reduction of the incidence of postoperative macular holes; however, the visual acuity level was similar even with a higher anatomic success rate.<sup>71</sup>

**FIG. 117.10** The two-step technique of nonfoveal internal limiting membrane (ILM) peeling for myopic foveoschisis. Step 1: After vitreous separation from the retina, the peeling of the ILM is started at a distance from the fovea. The ILM is peeled in a donut-fashion, and a round strip of ILM remains around the fovea. Step 2: The ILM peeling then is extended toward the periphery to leave the fovea unpeeled.

Macular holes in eyes with high myopia are much less likely to close. This is partly because of higher mechanical tension of the posterior eye wall inside the posterior staphyloma. The inverted ILM flap technique, introduced for idiopathic macular hole cases, was applied for highly myopic cases. The visual benefit has not been proven, especially in cases with retinal detachment;<sup>72</sup> however, the macular hole closure rate seems to be higher than with the conventional ILM peeling technique (Fig. 117.11).<sup>73</sup> Most recently, this technique was modified by use of an autologous blood clot, resulting in a high anatomic success rate of 96%.<sup>74</sup> We also reported in a case series that temporal scleral shortening facilitates retinal reattachment (100%) and macular hole closure (75%).<sup>75</sup>

**FIG. 117.11** The schema and intraoperative view of the inverted internal limiting membrane (ILM) peeling technique for a retinal detachment that developed from a macular hole in highly myopic eyes. (A) The ILM is peeled in the usual manner; however, the ILM remains attached at the edge of the macular hole. The peeled ILM then is inverted and placed inside the hole. (B) The ILM flap is held with forceps and pushed into the hole during the surgery. After this, vitreous fluid is exchanged with air, and gas tamponade is performed. *ILM*, internal limiting membrane; *MH*, macular hole; *RPE*, retinal pigment epithelium; *BBG*, brilliant blue G.

## Tamponade

In cases of macular holes with or without a retinal detachment, gas tamponade must be performed at the end of surgery. Long-acting gas tamponade (i.e., perfluoropropane) must be used because it has a higher anatomic success rate.<sup>59,76</sup> Because there is no coagulation maneuver around the macula, it is critical to support the retina for a long time to recover the integrity between the RPE and photoreceptors in atrophic eyes. Silicone oil tamponade is also an effective option.<sup>55,77</sup>

## Macular Buckling

In cases of recurrent retinal detachments, placing a buckle can be considered to fix the dimensional abnormality of the posterior staphyloma. Several case series have been reported with better surgical outcome in eyes with a macular hole and retinal detachment.<sup>60,61</sup> Vitrectomy is more commonly used to treat myopic foveoschisis;<sup>78</sup> however, macular buckling is also considered as

another option.<sup>79,80</sup> Direct macular buckling was attempted in the initial cases, and the modified silver clip<sup>81</sup> method was then developed. Most recently use of silicone sponges with bendable metallic wire inside the sponge has been reported.<sup>82</sup> The superotemporal conjunctiva is cut down and a mattress suture placed to fixate the top of the buckle. The indented part is on the other side. The arm is adjusted to fit the scleral curve so that the tip of the buckle reaches the macula.

Macular buckling reportedly has a higher success rate for retinal reattachment than vitrectomy,<sup>60,61</sup> likely because of the change in the vector force. Tangential traction generates the inward vector force in the posterior staphyloma, which is concave in shape. Macular buckling changes the macular area to a convex shape, and the vector force changes in direction to reattach the retina. Therefore, macular buckling is supposed to provide stronger contact between the neural retina and the RPE.

However, metamorphopsia and disruption of the choroidal circulation with protrusion of the posterior pole are the major concerns after macular buckling surgery. This maneuver is associated with a learning curve for placing the tip at the macula because it is a blinded procedure.

The authors normally perform vitrectomy as the first-line treatment for macular holes and retinal detachments and attempt to remove all tractional force from the vitreous cortex, ERMs, and ILMs, and long-acting gas or silicone tamponade. This technique is associated with a success rate of approximately 70–90%. However, if the retina detaches again because of macular hole reopening, macular buckling is performed, since another vitrectomy would not work well. Thus, the authors regard this procedure as rescue surgery for redetachment cases.

## Postoperative Complications

Opening of a macular hole occurs from 10% to 20% of patients who undergo vitrectomy for myopic foveoschisis.<sup>46,47,51</sup> Cases in which ILM peeling was performed in the presence of an extremely thin, stretched fovea are at risk of developing this complication.

Attention must be paid to detecting any small macular holes before

vitrectomy because the holes are normally stretched and enlarged postoperatively. Simply using a long-acting gas injection is not well accepted for postoperative macular holes, because this complication results from a shortage of retinal redundancy. Reoperation and removing any residual traction might be useful.

Recurrence of a retinal detachment is a major postoperative complication after vitrectomy performed to treat a macular hole with a retinal detachment. Removing residual vitreous cortex and ERMs is critical during a reoperation. However, it is sometimes difficult to identify the apparent cause of a redetachment. In those cases, persistent traction, such as microvascular traction, is responsible. Macular buckling is essential in those cases.

## Conclusion

Thanks to the development of ocular imaging technologies, the pathophysiology of myopic macular diseases has become more understandable. Numerous interesting findings have suggested the presence of underlying traction in highly myopic eyes. We must evaluate the preoperative features of these pathologies carefully. This is useful in deciding upon the most minimally invasive and effective procedures for vitrectomy in patients with myopic macular complications.

Techniques for Closed Lensectomy Pars Plicata Vitrectomy

## **Introduction**

Retinopathy of prematurity (ROP) affects thousands of children each year. Fortunately, ROP causes blindness in only a small percentage. ROP was previously called “retrolental fibroplasia.” The original work in the 1950s of Kinsey et al.<sup>1</sup> and Patz and Kinsey<sup>2</sup> showed that oxygen contributes to the tissue change described as ROP. It was believed that if the arterial oxygen was

kept within prescribed guidelines, ROP might be eliminated. However, with the ability of neonatologists to keep alive newborns of very low birthweight and very young gestational age, there has been a resurgence of ROP despite tight control of the partial pressure of oxygen.

Oxygen's role in ROP has come under extensive investigation. Many workers have shown in animal models that immature vessels characteristic of ROP can be produced but not retinal detachment.<sup>3-6</sup> Clinical observations by many investigators have shown that ROP can be seen in 85–90% of children of low birthweight when exposed to oxygen.<sup>7</sup> Similar clinical pictures have been seen in full-term infants, in familial exudative vitreoretinopathy, and in infants of mothers who are cocaine users.<sup>8,9</sup>

The role of vascular endothelial growth factor (VEGF) in ROP has been well established. VEGF under control of oxygen concentration or retinal ischemia can overcome the genetic mandate to form normal retinal vasculature and instead contribute to neovascularization or development of abnormal intraretinal vascular patterns in the retinal periphery.<sup>10</sup>

The lesser stages of ROP are so common in the closely observed low birthweight (<1500 g) infants as to suggest that these early changes are a physiologic response of the immature eye to oxygen. Endogenous transforming growth factor-beta (TGF- $\beta$ ) produced at the due date causes the process to regress in a large percentage of eyes but continue to progress to retinal detachment in only a small percentage of cases.

## Classification System

In the past, there were several classifications of ROP, which led to much confusion between ophthalmologists, neonatologists, and pediatricians. However, an International Classification of Retinopathy of Prematurity (ICROP) was subsequently adopted.<sup>11</sup> It describes three zones of the eye. Zone I uses the optic nerve as the center of a circle, and the radius is defined as twice the distance between the foveola and the optic nerve. Zone II uses as a radius the distance between the nasal ora serrata in the horizontal meridian and the center of the optic nerve. All of the remaining

retina is zone III (Fig. 118.1); that is, zone III is present in all meridians except at the nasal horizontal meridian.

**FIG. 118.1** Zones of the retina with the threshold criteria used in the Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) study.

Children who have vessels only in zone I at their first examination tend to have a worse prognosis and may have “aggressive posterior ROP” (AP-ROP), in which the eye has a high risk of progression to retinal detachment. It seems that retinal ischemia may be at least one of the mechanisms of VEGF that support the neovascular process. It makes sense therefore that an eye with zone I vasculature at only 32 weeks postmenstrual age (PMA) and a very large avascular (ischemic) zone concentrically would have the worst prognosis.

The ICROP defines five stages of ROP. The process of ROP begins at the junction between the vascular and avascular retina. ROP is described as stage 1 if a narrow white line is present at the junction. Stage 2 is a ridge of activity that shows thickening of this line (Fig. 118.2). In addition to this thickening, there is sometimes a ruddy appearance due to a vascular shunt within this ridge. Stage 3

involves the growth of vessels from the retina toward the vitreous cavity immediately posterior to and contiguous with the ridge (Fig. 118.3). Stage 4 is a partial retinal detachment and is subclassified as 4A, with the macula attached, and 4B, with the macula detached. Stage 5 implies a total detachment of the vascularized retina (Fig. 118.4) and can be classified further depending on the opening or closure of the anterior and posterior aspects. Even with significant retinal detachment causing a white retrolenticular appearance, the very far peripheral avascular retina often remains attached (Fig. 118.5). The avascular peripheral retina, however, if functioning, can yield only low vision.

**FIG. 118.2** Widened line of stage 2 retinopathy of prematurity at the junction of the vascularized and avascular retina.

**FIG. 118.3** Extraretinal neovascularization immediately posterior to the ridge. Several clock-hours of neovascularization are visible.

**FIG. 118.4** Leukocoric pupil of advanced retinopathy of prematurity.

**FIG. 118.5** Cross-sectional drawing of a rare configuration of stage 5 retinopathy of prematurity with large areas of attached peripheral retina despite total detachment of the vascularized retina as seen in very posterior zone I disease.

The ICROP also addressed the problem of “plus disease.” It is not a disease different from ROP but is a descriptive term for dilated and tortuous vessels of the posterior pole. In addition, the anterior segment in plus disease often shows dilated iris vessels (Fig. 118.6). These iris vessels may not be true neovascularization of the anterior segment but may represent dilation of an existing tunica vasculosa lentis.<sup>11</sup> This anterior segment vessel dilation appears to be a manifestation of a generalized intraocular increased VEGF concentration.

**FIG. 118.6** Rubeotic iris vessels. These make the iris appear red and may represent a persistent dilated tunica vasculosa lentis. “Plus disease” refers to the dilated tortuous vessels of the posterior pole and can be seen with or without this anterior segment change.

The ICROP was updated in 2005.<sup>12</sup> As neonatology has progressed, smaller babies are being kept alive, and these babies present with more posterior disease. Three features are worthy of discussion:

- First, ROP presenting completely in zone I or posterior zone II as mentioned above usually has a more aggressive course, and this type of ROP (AP-ROP) may require more aggressive ablative treatment.
- Second, the stage 3 neovascularization of ROP may appear differently depending on the zone of involvement: (1) mid and anterior zone II and zone III neovascularization is always posterior to the ridge tissue and growing into the vitreous cavity; and (2) zone I and posterior zone II can be flat, lying along the retinal surface, without the typical ridge tissue features.
- Third, “plus disease” is a function of an open shunt vessel contained deep within the ridge tissue. As this arteriovenous shunt is established, the vessels become dilated in the periphery. With the advent of wide-angle photography, this image can be easily appreciated. Although plus disease is a posterior pole finding and should remain so, the dilated peripheral vessels have

been referred to as “pre-plus” and suggests that the eye is at higher risk of developing frank “plus disease.”

Of these three findings, the aggressive posterior form seems to encompass many features of a very “vascularly active” eye, namely posterior disease, severe plus disease, and absence of ridge tissue, but also marked circumferential shunt vessels and areas of flat neovascularization that can be very large. Eyes such as this suggest eyes with a high degree of vascular activity and a high risk of progression to retinal detachment. These eyes merit consideration for earlier laser treatment. Later in the chapter, the Early Treatment for Retinopathy of Prematurity Study will be discussed.

In order to try to identify eyes at high risk of progression, the authors have adopted a modification of the ICROP system. Namely, we designate the number of clock-hours of vessels that are entirely in zone I by a subscript. For example, if all 12 clock-hours are in zone I, that would be written zone I<sub>12</sub>. Additionally, if flat neovascularization is present, we use another subscript, “F.” Stage 3<sub>F</sub> denotes flat neovascularization is present. Since these vessels lie flat on the retina and appear anterior to the shunt vessels, the drawing of the findings show the extent of the clock-hours of the flat stage 3 (Fig. 118.7). This designation is best done by photographic screening, which allows the images to be studied carefully.<sup>13-15</sup>

**FIG. 118.7** Flat neovascularization.

In our experience, an eye with one clock-hour of vessels in zone I and no flat neovascularization (zone I<sub>1</sub> stage 3) behaves better than an eye with 12 clock-hours of vessels in zone I and flat neovascularization (zone I<sub>12</sub> stage 3<sub>F</sub>). Both of these eyes are less at risk if they do not have plus disease. It is rare that an eye with 12 clock-hours in zone I does not have plus disease. We have found that plus disease is the clinical finding that exemplifies a vascularly active eye (excessive VEGF) and requires treatment. This is particularly true in a child who presents with these findings prior to the due date (40 weeks' postmenstrual age).

## **Histopathologic Features, Clinically Relevant Cell Biology, and Pathophysiology**

### **Stages 1 and 2**

Much work has been done to promote the understanding of the early changes at the junction of the vascular and avascular retina. Foos<sup>8</sup> speaks of a vanguard and rearguard of cells that contribute to the tissue changes.<sup>3,11</sup> These cells have been infrequently studied in their active form because most of these neonates survive and the eyes do not become available for study. Other authors<sup>16</sup> have described the cells in this region as “spindle shaped.” These spindle-shaped cells are found in many proliferative processes, and this descriptive term does not help define the cell biology. Histologic features of the avascular and vascularized retina reveal a difference in the retina's thickness, with the posterior vascular retina being somewhat thicker than the more peripheral avascular retina.

Terry<sup>17</sup> was perhaps the first to note vitreous abnormalities in children with ROP. The vitreous, which is normally firm and dense in the newborn, is synergetic and organized into fluid lacuna and sheets of collagen in ROP. This vitreous abnormality seems to be present in children with lesser stages of ROP and certainly is present in children with more advanced stages. The significance of these vitreous abnormalities may relate to both development of

exudative and tractional detachments and to development of late rhegmatogenous retinal detachments. ROP should properly be thought of as a vascular *vitreo*retinopathy. Stage 1 ROP is the visible white line that separates the vascular from the avascular retina. In stage 2 that line widens and may become a salmon color as the shunt vessel opens.

### Stage 3

The classical concept of neovascularization in ROP is that a retinal vasoconstriction secondary to oxygen administration or an increase in oxygen concentration as seen with birth alone is followed by vasodilation and associated vascular budding after oxygen withdrawal. However, some infants show significant vasodilation or plus disease even while receiving supplemental oxygen. No matter what the mechanism, the neovascularization that develops in stage 3 ROP has interesting features. One is that the active vessels are usually present at the posterior ridge of tissue. Also, there is often a directional orientation of the vessels toward the posterior apex of the lens in zones II and III. One of the most curious findings of the more posterior ROP is the lack of ridge tissue seen in eyes with extensive shunts and plus disease. The concept of Foos and spindle cells is based on eyes with changes in mid-zone II, and the absence of ridge tissue is a posterior finding. One suggestion is that angioblasts and astrocytes do not meet until the progenitor cells have progressed from the area of the disc into mid-zone II in the animal models of ROP.<sup>18</sup> This still leaves the difference in appearance of the flat stage 3 neovascularization in zone I. It may be that the secondary vitreous formed by vascularized retina may dictate at least in part the position of the neovascular fronds. The more posterior smaller-volume vitreous cavity may produce enough secondary vitreous to press the frond along the retinal surface. As is known from diabetic retinopathy, these fronds tend to grow on the posterior hyaloid surface. As the vascularized retina expands, the volume of secondary vitreous needed to fill the hemisphere of the vitreous cavity may not keep pace and allow vessels to grow along the anterior surface of the developing secondary vitreous toward the center of the vitreous

cavity or toward the lens. This organization of vitreous collagen or hypocellular gel contraction requires few cells to organize large amounts of collagen, as seen in eye tissue samples with stage 5 ROP (Fig. 118.8). In tissue culture, cells have been identified that have the ability to organize large amounts of collagen (Fig. 118.9). It is believed these cells organize anterior vitreous collagen into a plane that allows the vessels to grow on a surface anteriorly toward the posterior aspect of the lens.

**FIG. 118.8** Scanning electron micrograph of the dense core of vitreous collagen removed from an eye with stage 5 retinopathy of prematurity. It is organized into a tight central core with only a few cells and cell processes, as seen on its surface. (Final magnification  $\times 1000$ ; higher magnification of inset  $\times 2500$ .)

**FIG. 118.9** A phase-contrast micrograph of cells with long processes that reach out from their cell body. Antisera immunofluorescent technique determined that these cells were neuroglial in origin.

## **Distortion of Retinal Vascular Architecture**

Machemer<sup>19</sup> suggested that avascular retina is more elastic because it lacks retinal vessels and that this helps explain why the peripheral avascular retina can stretch over large areas of retinal pigment epithelium (RPE). In contrast, we believe that the organization of the cortical vitreous collagen, which is formed by and intimately attached to the vascularized retina, makes this stretching of the vascularized retina difficult. This inelastic cortical vitreous collagen and retinal ridge inhibits stretching of the vascularized retina. It is the absence of the cortical collagen over areas of avascular retina that allows the avascular retina to be stretched over large areas of RPE. Circumferential stretching of the retina is often recognized because of distortion of retinal vessels and is associated with an incomplete retinal ridge.

## **Stages 4 and 5**

ROP has both exudative retinal detachments and traction retinal detachments. In the evolution of retinal detachments of ROP, at least three factors are involved. The first is the existence of permeable, leaky blood vessels, as seen in stage 3 ROP. These

vessels, within the shunt and posterior to the ridge, are capable of supplying large amounts of proteinaceous fluid to both the vitreous cavity and subretinal space. Second, as shown by Ashton and Cook,<sup>20</sup> the neovascularization that is commonly thought of as growing only into the vitreous cavity also can be seen growing into the subretinal space (Hirose, pers. comm.). Third, these blood vessels can bleed into both the vitreous cavity and subretinal space. Foos<sup>21</sup> showed that eyes with vitreous hemorrhage are susceptible to retinal detachment and seem to have a worse prognosis for total retinal detachment.

Okamoto et al.<sup>22</sup> developed a murine model showing that neovascularization into the subretinal space from the retina can occur with increased VEGF expression. Cells from the retinal ridge or regressing hyaloid and tunica vasculosa lentis organize vitreous collagen that is tightly attached to the retina. This creates traction on these permeable vessels and results in additional leakage of fluid or blood from these vessels. In children who develop stage 4 ROP, the retinal ridge is the most common location for retinal detachment to begin. Detachments without traction in the area of the ridge often settle spontaneously.<sup>23</sup>

Most retinal detachments in ROP have a tractional and an exudative component. By attempting to determine the predominate component, one can better select clinical therapy. We suggest that the exudative detachment is caused by leaking vessels and traction on these vessels. The tractional forces aggravate the exudative component. Resolution occurs when the vessels spontaneously involute before significant traction (vitreous organization) has occurred. However, if enough cells have migrated into the vitreous cortex, even if the leaking vessels involute, cell-mediated organization of the vitreous can continue to cause complicated, predominantly traction retinal detachments.

In eyes with ROP, cells that organize the vitreous appear to migrate into the vitreous cortex from the ridge of retina between avascular and vascular retina and from the area of the optic disc. This means that manipulation of these two areas is important to resolve the tractional component of retinal detachment. It also may be that the cells of the primary vitreous or tunica vasculosa lentis, or both, now called "ocular fetal vasculature," may contribute cells

to this hypocellular gel contraction. The genetically determined apoptosis of the cellular elements of the primary vitreous and tunica vasculosa lentis may be clinically slowed or reversed under the influence of increased VEGF. The higher the concentration of VEGF, the less the apoptosis proceeds, and the more cells are available to organize vitreous collagen and contribute to retinal traction.<sup>24</sup>

We, and colleagues, have grown cells in tissue culture from the retrolenticular membrane of stage 5 ROP eyes. These cells have been studied by immunofluorescent techniques and appear to be predominantly neuroglial in origin. Some cells seemed very immature, perhaps representing multipotent cells that have migrated from the retina into the vitreous cavity. These cells show the ability to organize large amounts of collagen in vitro, as well as the ability to produce collagen. When these cells are tested for collagen organization against cells from both proliferative vitreoretinopathy and tractional diabetic retinal detachment, the cells of ROP are able to organize much more collagen than the proliferative vitreoretinopathy cells.<sup>25,26</sup> This organization of vitreous collagen into sheets is supported by the original observations of Terry<sup>17</sup> in eyes with ROP.

## **Development of Stage 4A ROP Retinal Detachments**

In stage 4A ROP, the detachment begins at the ridge of the retina. Fluid can leak posteriorly under the retina and cause the posterior retina to detach as well. When a primarily exudative retinal detachment develops, the retinal surface is smooth and shows no evidence of epiretinal proliferation or peaked folds. This is a significant observation in our clinical experience. Eyes with smooth anterior retinal surfaces, despite large areas (four disc areas) of retinal detachment, sometimes flatten spontaneously over several months. When the retina flattens, however, the RPE is often disrupted, and many eyes do not have useful vision. As cells migrate into the vitreous cortex along the surface of the vascularized retina, both anteriorly from the ridge and posteriorly from the disc, they can form folds in the retina. These cells can convert a predominantly exudative retinal detachment to a predominantly tractional detachment. Machemer,<sup>19</sup> Charles,<sup>27</sup> and

others often discussed the peripheral retinal “trough,” or anterior loop traction, associated with ROP. The vitreous is organized in a fashion that allows the retina to form a trough in the far periphery. As retinal detachment in ROP evolves, its configuration depends partly on the symmetry of the retinal ridge. A ridge that contracts evenly and is located an equal distance from the disc in all meridians results in a detachment that closes centrally.

Subretinal fluid can have several clinical manifestations. It can be opalescent or red, being either serum or blood in the subretinal space. This fluid may have a toxic effect on the neurosensory retina and RPE, in addition to the expected degenerative effect on the photoreceptors from retinal detachment itself. This subretinal fluid has been found to have high concentrations of hemoglobin and iron, both bound and unbound.<sup>28,29</sup> In addition, cholesterol is often found in the subretinal space, either crystallized or in solution. Opaque subretinal fluid, after even spontaneous reattachment, appears to leave the eye with disrupted RPE and presumably a poor visual result.

## Clinical Considerations

Many years ago, examination of an infant's eye for ROP in a teaching institution was often assigned to a resident with limited indirect ophthalmoscopy experience. Now with new information regarding ROP, it is necessary for an experienced physician to examine carefully infants who are at risk photographically and with confirmatory bedside exams.

In the results of the Cryotherapy for Retinopathy of Prematurity Study<sup>30</sup> and the Early Treatment for Retinopathy of Prematurity Study,<sup>31</sup> a positive treatment effect was reported, and it was suggested that infants be examined at the later of either 4 weeks after birth or at 31 weeks PMA, if they are less than 1500 g birth weight or 30 weeks or less gestational age. These infants need to be examined meticulously, including indirect ophthalmoscopy, for vascularization of the anterior segment, pupillary dilation, plus disease, zone of eye involvement, and stage of the disease process. The authors have found that the Alfonso lid speculum (Fig. 118.10A) and Kelge swab (Fig. 118.10B), accompanied by the

indirect small pupil ophthalmoscope and 28 diopter lens, are the best instruments to examine the peripheral retina in the neonate. When bedside examination is needed, we do not use topical anesthesia because this can cause clouding of the cornea.

**FIG. 118.10** (A) Alfonso lid speculum. (B) Kelce swab used for scleral depression.

This examination is generally well tolerated, even by the intubated neonate. It is important to know that scleral depression can obscure the minimal demarcation line or ridge. Therefore minimal force should be used with scleral depression. It occasionally may cause some hemorrhage along the ridge or sometimes even into the vitreous cavity, but this generally resolves without incident.

## Photographic Imaging

The Photo-ROP (Photographic Screening for Retinopathy of Prematurity) study and that of Ells et al. evaluated and confirmed the utility of photographic imaging in ROP screening.<sup>32,33</sup> This photographic imaging allows a very good representation of the posterior pole and the midperiphery of the eyes of premature

infants. Photographic documentation in diabetes, age-related macular degeneration, and other retinal vascular disease is well known,<sup>34-36</sup> and photographic documentation of ROP has been available for several years and is equally valuable. Treatment in ROP in large part is driven by zone I and zone II findings, which are well seen with photography.<sup>32</sup>

The interpretation of these pictures requires they be obtained and managed in a timely fashion and read by a qualified reader. Retinopathy of prematurity is a time-dependent disease, allowing development of stage 1 to stage 5 to occur in as little as 2 weeks.<sup>37-39</sup> FocusROP (FocusROP, LLC, Troy, MI), an internet-based, HIPAA-compliant, secure website using certified and expert readers, has been developed to handle these images. This website ([www.FocusROP.com](http://www.FocusROP.com)), receives the uploaded digital information obtained by trained individuals in the neonatal care centers and immediately notifies a previously certified local ophthalmologist to read these images. The follow-up algorithm contained in the software program allows an unchangeable examination schedule, which reduces the risk of late treatment.

Though bedside examinations allow a more extensive examination of the periphery, photographic screening has its advantages. Such advantages include an excellent view of the most severe aggressive posterior ROP and the ability to compare, side by side, the current exam with the previous one. The coupling of this remote management by photographic images as well as bedside examinations gives perhaps the ideal screening mechanism for the early stages of retinopathy of prematurity. Implementation of a longitudinal digital-imaging paradigm with remote image interpretation (i.e., a reading center) has the potential to maximize utilization of the physician's time, broaden the availability of high-level ROP diagnostic expertise, and provide excellent patient care. Photographic screening does not replace the bedside examination but can be sufficient for screening to provide care for the patient and protect the hospital and doctor in malpractice cases. In addition, the ROptool, which gives a numeric value to tortuosity, can aid the examiner as to the development of plus disease.<sup>40</sup>

## Cryotherapy

The Cryotherapy for Retinopathy of Prematurity study defined eyes with plus disease showing five contiguous or eight discontinuous clock-hours of stage 3 ROP (Fig. 118.1) as reaching a threshold for cryotherapy. Cryotherapy was defined as use of a cryoprobe to treat the avascular retina but not the ridge.<sup>41</sup> This technique was found to be effective in reducing by 50% the unfavorable outcome of retinal fold and retinal detachment.

As mentioned earlier, eyes with zone I disease tend to have the worst prognosis, and eyes with zone I involvement and extensive plus disease are said to have Rush disease. Rush disease refers to the tempo of ROP, which can go from stage 1 to stage 5 in only 2 weeks.<sup>37-39</sup> Zone I cryotherapy, however, requires extensive treatment and risks occlusion of the central retinal artery for a significant time.

Cryotherapy has the potential to induce future retinal problems in these patients, who have an increased risk for rhegmatogenous retinal detachment as adults, with or without treatment.<sup>30</sup> There has been several eyes that developed cataract, hypotony, and iris depigmentation.<sup>29</sup> These changes were seemingly caused by anterior segment ischemia following peripheral cryotherapy treatment. Cryotherapy is no longer considered the treatment of choice with the advent of the indirect laser.

## Indirect Laser Photocoagulation

Numerous reports have shown peripheral ablation by laser (argon blue-green and diode) to be effective in the treatment of ROP. This is not surprising in that peripheral ablation, no matter how performed, should have a similar effect on the course of the disease. Iverson et al.,<sup>42</sup> Landers et al.,<sup>43</sup> and McNamara et al.<sup>44</sup> have shown a positive treatment effect for the use of peripheral laser ablation. This type of treatment can be performed using topical anesthesia and may be performed in the nursery, eliminating the need for the infant to be transported to the operating room. The diode laser has significant physical advantages because of its portable nature.<sup>45</sup> We prefer using the red diode laser because it theoretically causes less lens damage from tunica vasculosa lentis laser uptake.

Most physicians who treat ROP today prefer using indirect laser

to ablate the retinal periphery. It should be noted that cataracts, as well as anterior segment ischemia, can be observed after laser treatment with either argon or diode energy. It is important to recall that the nursery personnel require education regarding laser safety before such treatment is instituted in the nursery area.

## The Early Treatment for Retinopathy of Prematurity Study (ETROP)

The ETROP<sup>31</sup> used a risk management program RM-ROP2 to evaluate each eye. If the risk generated by the program exceeded 0.15, the eye was randomized to treatment. The eyes eventually were analyzed, and using an ICROP-based classification system, they were grouped into type 1 and type 2:

Type 1 prethreshold

- Zone I any stage ROP with plus disease
- Zone I stage 3 with or without plus disease
- Zone II stage 2 or 3 with plus disease.

Type 2 prethreshold

- Zone I stage 1 or 2 without plus disease
- Zone II stage 2 or 3 without plus disease.

The ETROP treatment systems yields 9.6% failure rate, which is better than the CRYO-ROP study results.<sup>46</sup>

As with all clinical trials, the results of the CRYO-ROP study and the ETROP study should be considered when the treatment of a child is considered, but physicians should choose the treatment plan in a fashion that best suits the patient's circumstance in their best medical judgment. The results of the ETROP study describe times when treatment should be considered. There may be

circumstances where, with close monitoring of the patient, treatment can be avoided or treatment should be performed earlier. The physician needs to realize what is in the balance. The ETROP study, as did the CRYO-ROP study, shows that plus disease is very important in determining the need for treatment. The eye that is vascularly active is an eye that may need treatment. The ETROP study also points out that eyes with zone I disease are worthy of evaluation for treatment. These eyes again have a very large area of avascular retina and therefore are vascularly active eyes with a high likelihood of progression. As the physician becomes more comfortable with the progression of the disease and its potential tempo, the timing of evaluation and treatment can be adapted to the clinical situation.

Examination is probably the most difficult part of ROP care. The best plan is to have weekly examination coverage done at the same time and scheduled by a neonatal intensive care unit (NICU) employee, and the screener needs to be prepared to see some children even at half-week intervals. Currently, this is usually done by physician examiners but most likely will be photographically screened in the future, as mentioned above.

Currently, laser treatment is the best therapy available. It causes less effusion than cryotherapy and has results at least as good from an anatomic and visual standpoint. In the not too distant future, it may be that pharmacologic therapy may be possible. This would eliminate the need to destroy half to two-thirds of the retina with laser.

## **Anti-Vascular Endothelial Growth Factor Therapy**

Multiple reports and series have demonstrated the use of intravitreal bevacizumab (Avastin; Genentech, South San Francisco, CA), an anti-VEGF agent originally approved by the US Food and Drug Administration (FDA) for the treatment of metastatic colon cancer, for various stages of ROP.<sup>47</sup> Intravitreal bevacizumab has been used as monotherapy, as well as in combination with conventional laser therapy or with vitrectomy.<sup>48-62</sup> Ranibizumab (Lucentis; Genentech), a humanized monoclonal Fab fragment of

bevacizumab and FDA approved for treatment of various adult retinal conditions, has also been reported in several ROP studies.<sup>63,64</sup> However, there are no authoritative studies yet, such as CRYO-ROP or ETROP, that show how anti-VEGF agents should be incorporated into the care of children with treatment-requiring ROP.

The largest study thus far was comprised of 150 infants with zone I or posterior zone II ROP with stage 3 and plus disease, who were randomized to laser or intravitreal bevacizumab.<sup>65</sup> It appeared that bevacizumab was more beneficial for zone I disease, but unfortunately, many design flaws did not allow support of its conclusions and left unanswered many questions. Below are several points of discussion placed in context of recent developments in the field.

First, the study suggested that bevacizumab does not enter the systemic circulation, but numerous studies have shown systemic VEGF suppression and circulating bevacizumab in neonates after bevacizumab injections.<sup>66-68</sup> No long-term studies have been performed yet at the time of writing to determine whether bevacizumab may affect the development of other organ systems.

Second, the study suggested that only one bevacizumab injection is required to manage ROP, but this is a dangerous assumption.<sup>69</sup> Late recurrence of neovascularization is well described after anti-VEGF treatment of ROP.<sup>70,71</sup> As a pediatric retina surgical referral practice, we have also managed numerous infants who were referred for extensive traction retinal detachment after anti-VEGF injections for stage 3 disease.<sup>72</sup> We observed that the majority of these eyes underwent a “crunch” phenomenon, where the fibrovascular proliferation of stage 3 disease quickly progressed to retinal detachment. These detachments are often posterior and assume tight circumferential tractional vectors. Vigilant long-term screening after anti-VEGF treatment and access to a pediatric vitreoretinal surgeon should be readily available.

The study also suggested that bevacizumab allows full retinal vascularization, but numerous other studies have shown with fluorescein angiography that this is not the case, and late reactivation, persistent avascular peripheral retina, and other peripheral vascular abnormalities are common.<sup>70,71</sup> Animal studies

have also suggested that global retinal functioning may be affected with anti-VEGF treatment.<sup>73</sup>

Finally, the laser failure rate of 42% in zone I eyes in the study is very high. The success rates in previously published studies are significantly better.<sup>74-77</sup> Larger studies are underway to hopefully provide a clearer understanding of the role of anti-VEGF agents in ROP care.<sup>78</sup>

## Therapeutic Oxygen

Increasing oxygen has been shown to reduce VEGF activity. Because of this effect, the STOP-ROP study was undertaken to increase the oxygen saturation in infants whose transcutaneous oxygen saturation is less than 94% in hopes that the increased oxygen would decrease VEGF activity and allow the genetically driven development of retinal vessels to regain control. The STOP-ROP study did not show a statistically significant effect, while causing increased risk of pulmonary events.<sup>79</sup>

## Stages 4 and 5 Preoperative Evaluation

Preoperative evaluation of a child with stage 4 or 5 ROP necessitates special considerations. It may be difficult to determine the visual function of the child. The examiner or parent often forms a clinical impression on the basis of the child's behavior after exposure to a bright light. Many authors<sup>80</sup> have tried to define electrophysiologic criteria for visual acuity in infants. In our experience, the awake visual evoked potential (VEP) or electrical evoked potential (EEP) seems the most reliable. The VEP is perhaps the most easily accessible and reliable piece of clinical information. The VEP is valuable if a child is without clinical light perception vision but does have a recordable VEP. The positive VEP response supports that the child has an objective demonstration of functional retina, and we would proceed with surgery. In the absence of a VEP response and clinical light response in screening children for surgical intervention, these findings indicate less possibility of favorable visual results after surgery. It is possible for children to have a clinical light response and a nonrecordable VEP (false-negative VEP exam).

Preoperatively, it is important to assess corneal clarity and anterior chamber depth, as well as size of the eye and intraocular pressure. Children with ROP can have greatly elevated intraocular pressure (up to 50–70 mm Hg) and not have the clinical symptoms of elevated intraocular pressure and cloudy cornea. Glaucoma may be a cause of vision loss in such cases. We have found that the buphthalmic eye with ROP frequently contains large amounts of subretinal blood. This can often be demonstrated by ultrasound or magnetic resonance imaging showing layered fluid in the subretinal space. These eyes have a poor prognosis.

Ultrasonographic evaluations can be performed when the retrolenticular tissue is opaque or the funnel of retinal detachment is closed and the entire configuration of the retinal detachment cannot be determined clinically. In this circumstance, ultrasound is used to define the configuration of the detachment or composition of the subretinal fluid. If a preoperative ultrasound is needed, the offset water bath ultrasound placed directly on the eye, with the patient either under anesthesia or sedation, seems to be the most helpful. However, because of the convolutions of the redundant retinal architecture and solid and liquid conformations of the vitreous, we frequently find ultrasound to be of little value, though it may allow one to find a surgical space for access.

## **Surgical Therapy**

The choice of surgical techniques depends on the stage of ROP and the specific features of each case.

### **Scleral Buckling**

Scleral buckling has been suggested for stage 4 ROP. In two series it has been demonstrated that scleral buckling for stage 4 eyes has a success rate of 66–70% for stage 4A and 67% for stage 4B retinal detachment.<sup>29,81</sup> Encirclement is performed with or without drainage of subretinal fluid. If subretinal fluid is not drained, a paracentesis must be performed. Although scleral buckling has not to date been studied in a randomized, prospective clinical trial, data from the Cryotherapy for Retinopathy of Prematurity study suggest

that if stage 4 retinal detachment involves eight of 34 ROP sectors of the retina, there is an 88% chance of progression to stage 5 ROP.<sup>82</sup> It would seem from these data that scleral buckling would be a reasonable alternative in a predominantly effusive stage 4 ROP retinal detachment. With the use of laser, predominantly effusive eyes are rare.

Division of the encircling scleral buckling material should be performed after reattachment of the retina, usually at about 3 months after scleral surgery. Originally we believed this was to allow growth of the eye, but have found the buckle can induce a great deal of anisometropia (5–9 diopters). This anisometropia is reduced when the scleral buckle is divided. With the advent of lens-sparing vitrectomy (LSV), we rarely perform scleral buckling for nonrhegmatogenous retinal detachment.

## Lens-Sparing Vitrectomy for Stage 4A ROP

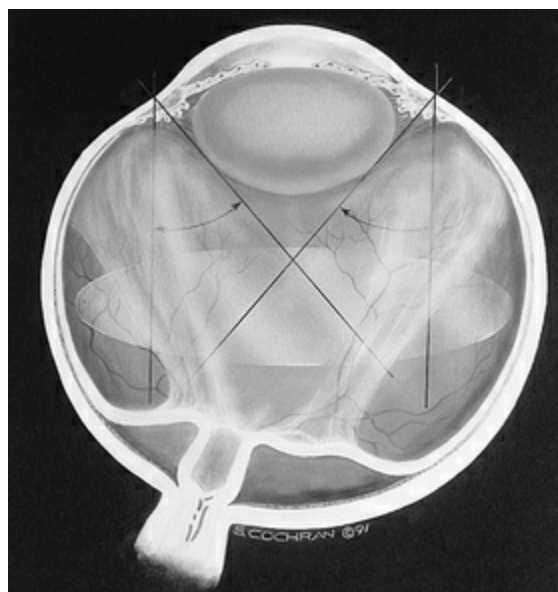

In addition to the changes in the appearance of the eyes requiring peripheral ablation over the last 15 years, the appearance of retinal detachment following laser treatment has also changed. With less effusion from laser treatment than cryotherapy, there is less blood in the subretinal space and the eyes are vascularly quieter at an earlier time, allowing vitreous intervention in a vascularly quiet eye where the macula has not detached (stage 4A). This basic principle of retinal detachment repair “that a macula-on retinal detachment is an urgent operation” is also true in ROP. The natural history part of the CRYO-ROP study showed that a child with an 8-sector 4A ROP detachment at their due date (40 weeks PMA) had a high risk of going on to an unfavorable outcome or total retinal detachment (stage 5).<sup>82</sup> Two studies have shown 90% or better anatomic success rates with LSV.<sup>83,84</sup>

The development of the infusion light pipe, miniaturized contact lenses, which can be used on the anterior surface of the eye, and the binocular indirect ophthalmoscopy (BIOM) non-contact system, allowing wide-angle viewing in children with a smaller anterior segment, for visualization in the phakic state are perhaps the most significant changes in pediatric vitreoretinal surgery in the recent past (Fig. 118.11). A wide-view infusion light pipe used with the

BIOM allows visualization and peripheral dissection without the need for scleral indentation, a practice that can create retinal tears in children with redundant retina. These developments also allow us to deal with the tractional detachment of the posterior pole, leaving the lens in position (Fig. 118.12). Children having this type of procedure can retain clear lenses for many years. Current follow-up suggests that lenses can remain clear at least 10–15 years.<sup>85–87</sup>

**FIG. 118.11** Infusion light pipe at the time of delivering air into the eye during phakic vitrectomy in an infant.

**FIG. 118.12** Entry sites and the technique enabling dissection of the entire posterior pole.

In addition, the visual rehabilitation in these children, without the complications of aphakia, allows us to treat unilateral tractional detachment, as well as bilateral tractional detachments, more effectively. This greatly reduces the refractive rehabilitation and increases the cooperation of the patient and family with conventional forms of refractive and amblyopia therapy. Children with this level of tractional detachment and ROP can achieve levels of vision in the 20/100 to 20/60 level, assuming the central nervous system is able to process visual information.<sup>82,88</sup> Children who are operated with a true 4A retinal detachment can achieve visual acuity of 20/20.<sup>84</sup>

## Lens-Sparing or Non-Lens-Sparing Vitrectomy for Stage 4B ROP

Results for 4B ROP detachments can also be broken down anatomically and visually. A total of 76% of eyes reattached part or all of the retina. Some 15% achieved 20/60–20/300 vision; 30% achieved 20/60–20/800 vision; 48% achieved 20/60–20/1900 (ambulatory) vision; and 72% of eyes achieved 20/60-LP vision. A total of 28% of eyes had no light perception (NLP), despite surgery.<sup>82</sup> These results compare favorably with the natural history.

## Lensectomy, Vitrectomy, and Membrane Peeling for Stage 5 ROP

Perhaps the most important consideration in dealing with surgical therapy of stage 5 ROP is recognition of the configuration of retinal detachment. The funnel is defined as the retina from the ridge to the optic nerve area. Many years ago, it was known that retinal detachment of stage 5 has three basic configurations:

- An open central funnel (Fig. 118.13)

**FIG. 118.13** An open funnel retinal detachment with right folding of anterior retinal surface.

- A partially closed central funnel (Fig. 118.14)

**FIG. 118.14** (A) Partially closed retinal detachment with a narrow anterior open posterior configuration. (B) Partially closed retinal detachment, narrow posteriorly. This is the more commonly occurring partially closed configuration.

- A totally closed central funnel<sup>19,80</sup> (Fig. 118.15).

**FIG. 118.15** Closed funnel configuration of retinal detachment.

Detachments in eyes with stage 5 have many features not seen in other retinal detachments. The configuration of the retinal detachment can vary greatly between different quadrants of the same eye. The peripheral retinal trough can be shallow or deep (Fig. 118.16). Depending on differential contraction along the ridge, the funnel can be closed tightly centrally or can be eccentrically displaced toward the periphery in a crescent pattern (Fig. 118.17). It is also common to see the retina posterior to the ridge detached in a spiral configuration caused by differential, circumferential traction (Fig. 118.18). This causes confusion to the novice surgeon, who believes that radial division of epiretinal tissue is safe. Radial division when a spiral configuration is present is dangerous, and it is important to follow the spiral back toward the optic nerve.

**FIG. 118.16** In the same eye the peripheral trough can have a variety of depths. (Courtesy of Eugene de Juan, MD.)

**FIG. 118.17** Anterior crescentic appearance that occurs when the ridge is fixed in one area while other areas of the ridge are movable.

**FIG. 118.18** Spiral form of retinal detachment. If the vitreous organization was uniform and the peripheral trough of equal depth for 360°, the retinal ridge would “purse-string,” leading to symmetric, radially folded retinal detachment. Most of the time the amount of vitreous organization differs along its retinal surface and can result in a spiral easily seen here in this widely open funnel. However, these can be difficult to recognize as the funnel narrows or if only part of the retina is involved in this differential circumferential traction.

At the posterior pole, the retina most often shows dragging across the optic nerve head, causing a triple layer of retinal tissue (Fig. 118.19). This often interferes with a good view of the optic nerve. Thorough and careful dissection should be carried out to the posterior pole. This configuration can have an exaggerated form of retinal detachment with a large fold of retina dragged over the disc, often in the horizontal meridian (Fig. 118.20). This fold of retina can be dragged along the top of a radial fold, continuing far anteriorly, which can leave large areas of usually avascular retina attached (Fig. 118.21). If the retina surrounding this fold is attached, it is impossible to flatten the retina; however, if the fold of detached retina is over detached retina, surgical flattening is possible.

**FIG. 118.19** Dragging of the retina across the disc, leaving in some areas a triple thickness of retina.

**FIG. 118.20** The exaggerated dragging of the retina across the disc. The retina folded across the disc obscures the view of the optic nerve head.

**FIG. 118.21** Appearance of the exaggerated form of retinal fold when the fold is superimposed on a radially oriented area of retinal detachment. Naturally, the optic nerve head is not visible, and the seam between the apex of the fold and the radial detachment may be obscured by organized vitreous collagen. A clue to the edges of the fold is the emergence of retinal vessels from beneath the fold and the absence of retinal vessels along the anterior surface of the fold. This configuration may occur when the 360° ridge has several clock-hours very posterior in zone I or zone II and other clock-hours with the ridge are very anterior to zone II or zone III.

## Enzymatic Manipulation of the Vitreoretinal Junction

A subset of pediatric vitreoretinal surgery requires successful peeling of preretinal membranes or the posterior hyaloid to achieve repair. The vitreoretinal adhesion is mediated in part by laminin and fibronectin.<sup>89</sup> Autologous plasmin enzyme (APE) cleaves both laminin and fibronectin and produces vitreous liquefaction and posterior vitreous detachment in adult eyes after intravitreal injection.<sup>90</sup> Plasmin enzyme may facilitate the removal of such membranes and reduce the risk of creating an iatrogenic retinal break during membrane peeling.<sup>91,92</sup> In young children who cannot tolerate an intravitreal injection in the clinic, APE is injected into the

vitreous cavity approximately 30 min before the start of surgery.

Jetrea (Thrombogenics Inc., Leuven, Belgium) is a truncated recombinant form of plasmin, which retains the enzymatic activity of autologous plasmin.<sup>93</sup> Clinical trials in adults have shown that microplasmin can safely relieve vitreoretinal traction, and a clinical trial using microplasmin in pediatric vitreoretinal surgical cases is ongoing.<sup>94</sup>

## Surgical Approach

The surgical techniques used in stage 5 are confined to closed lensectomy, pars plicata vitrectomy (with membrane peeling accompanied occasionally by external drainage of subretinal fluid), and rarely, scleral buckling. Open-sky vitrectomy with intracapsular lensectomy and membrane peeling has also been used. The bulk of our experience has been in closed vitrectomy, and we reserve the open-sky vitrectomy for those eyes in which the anterior segment is severely clouded and will not allow the use of the closed vitrectomy technique. Open-sky vitrectomy has the advantage of allowing two-handed dissection through the large anterior incision, and it allows surgery in eyes with clouded corneas.<sup>95</sup> However, operating in an unpressurized eye has higher risk of hemorrhagic choroidal detachments and bleeding during dissection of tissues.

The technique we prefer in mild to moderately clouded corneas is a two- to three-staged approach. During the first surgery, we perform a lensectomy and careful removal of the lens capsule. An iridectomy is also performed if there is severe anteriorization of ocular structures. This is to avoid iris–retina adhesion, which is nearly impossible to dissect subsequently. During these maneuvers to debulk the anterior segment, a plane will be formed between the corneal endothelium and underlying iris and/or lens. Healon can be injected into the plane to gently dissect the adherent tissues from the cornea. After completion of the lensectomy, capsulectomy, and synechiolysis, the eye is closed.

The second stage of the surgery is scheduled for several weeks subsequently, depending on the degree of corneal clouding. Not only does this allow the cornea to clear, but the retina moves

posteriorly after release of the traction from the lensectomy. During the second stage, we initiate plaque dissection under the improved view. Rarely, a third staged surgery may be needed to complete the membrane dissection for severe cases. The initial membrane dissection makes the retina more mobile, and the subretinal fluid resorbs between the second and third surgeries, which can allow visualization of more counter-traction for a safer third surgery.

### **Ab Interno Incision**

A modification of the lens-sparing vitrectomy technique, called an “ab interno incision,” is used in infants in which the surgical entry space between the lens and the retina is too small for current vitrectomy instrumentation.<sup>86,96</sup> In circumstances where retinal folds, organized vitreous, and/or fibrotic tissue are in close approximation to the lens for several clock-hours, standard lens-sparing entry into the eye may not be possible. In this setting, an ab interno incision is used. With this technique, once the sclera is entered, the microvitreoretinal (MVR) blade is first directed carefully posterior and then inserted into the space or tissue between the retina and posterior lens capsule (Figs. 118.22A–C). Once the MVR blade is located between the posterior lens capsule and retinal tissue, anterior retinal traction is relieved and a posterior relaxation of the retina is immediately apparent. The incision can be extended for many clock-hours by sweeping in the surgical space parallel to the lens capsule using the sclerotomy as a pivot point or by sliding the blade like a saw to release any tractional vectors (Figs. 118.22A,D). Damage to the retina or lens is a possible complication of this technique, and care should be taken to avoid violating the lens equator or causing an unintentional retinal break. This provides standard vitrectomy instrumentation a safe entry to complete the posterior vitrectomy (Figs. 118.22A,E–F) and allows for dissection along the retinal surface once more surgical space is created.

**FIG. 118.22** (A) The microvitreoretinal blade is inserted through the pars plicata with great care. (B) The microvitreoretinal blade is advanced into the space between the lens capsule and retinal surface, cutting through any tissue between the retina and the lens. (C) The microvitreoretinal blade is advanced further into the space between the lens capsule and retina, and as anterior retinal traction is relieved, the posterior relaxation of the retina is immediately apparent. (D) The ab interno incision can be extended by sweeping parallel to the lens capsule or by sliding the blade like a saw to release any additional tractional vectors. (E) Standard vitrectomy instrumentation is inserted into the space between the lens capsule and retina. (F) As the vitrectomy proceeds, further relaxation of the retina can be observed, and dissection along the retinal surface can be performed.

## Techniques for Closed Lensectomy Pars Plicata Vitrectomy

Because the infant's eye does not have a pars plana, entry into the eye in the closed vitrectomy is through the pars plicata, iris root, or limbus.<sup>27,80,97,98</sup> After entry into the eye, a complete lensectomy is performed, including capsular removal in eyes with open funnel

configuration. The main reason for failure caused by reproliferation and redetachment often can be traced to incomplete removal of lens epithelium. A two-handed cross action opening of the retrolenticular tissue is performed with two disposable no. 26 needles. This causes little peripheral traction. The resulting central vertical slit in the membrane is then extended using intraocular scissors with continuous Healon infusion (Fig. 118.23). Then two-handed dissection with forceps and scissors or spatula lamellar dissection is used to divide the retrolenticular tissue.<sup>99</sup>

**FIG. 118.23** (A) Intraocular scissors being used to expand the vertical slit in the retrolenticular membrane under Healon. (B) The membrane peeler cutter set-up to allow continuous infusion of Healon.

After lensectomy, if the retina is continually pushed into the center of the eye, a fluid–Healon exchange is performed. After the center of the funnel is opened, dissection is continued posteriorly under Healon if the retina is pushed toward the center of the eye. The Healon is added under low pressure to avoid forcing the retina open. This opening of the funnel then allows two-handed dissection of the posterior pole. As previously described, the cells that organize the vitreous collagen and result in traction detachment probably come from the ridge and disc; therefore, careful dissection of tissue at the disc is important.

Because our surgical goal is to flatten the posterior pole, this is one of the most important areas for dissection. Often, the smaller folds across the optic nerve are left alone. After the central funnel of detached retina is opened, the anterior peripheral trough is approached. Two-handed dissection is used to delaminate this tissue at the ridge where possible. Some ridge tissue cannot be

dissected (Fig. 118.24).

**FIG. 118.24** Two-hand dissection technique to allow controlled delamination at the ridge.

After removal of as much proliferative tissue as possible, a Healon–fluid exchange can be performed. Next a fluid–air exchange is performed. If the retina is freely movable, the base of the peripheral trough can be seen, and the fluid is thick and unlikely to reabsorb, then drainage of subretinal fluid is performed. Though sometimes there may be postoperative pressure rises, we often leave Healon as a tamponade.

After surgery the child is placed face down for 24 hours. This is done to flatten the posterior retina quickly and displace the subretinal fluid. The subretinal fluid is often very viscous and contains cholesterol crystals. The bulk of subretinal fluid reabsorbs in 2–4 months; some eyes may still reabsorb subretinal fluid/blood for months and years. As soon as the posterior retina flattens, the child is given spectacles and begins vision training. When both open-sky and closed vitrectomy are used, the anatomic success rate has been 50% for reattachment of zone I of the retina in eyes with stage 5 ROP without peripheral ablation. The reattachment rates vary from 60% to 70% reattachment of zone I with open funnel retinal detachments to 26% reattachment rates for closed funnel detachments (Hirose, pers. comm.).<sup>80,91,100,101</sup> We reserve reoperation

for eyes that have shown visual improvement and later develop redetachment of, or that obscures, the posterior pole.

The long-term anatomic and visual results with a nearly 4-year follow-up showed that appropriate intervention with peripheral ablation and 4B/5 retinal detachment intervention yielded 76% of eyes with attachment of the posterior pole and 15% of eyes with 20/300–20/60 vision; 30% of eyes with 20/800 to 20/60 vision; 48% of eyes with 20/1900–20/60 vision; and 72% of eyes with light perception or better. Some 30% required more than one operation, other than peripheral ablation.<sup>82</sup> With timely laser ablation (success rate 90%) and 4A lens-sparing vitrectomy, 90% anatomic success and function as good as 20/20 can be achieved. This results in only 1% of eyes with poor outcomes. The visual results of stage 5 ROP suggest that timing of intervention is important. Intervening as early as possible after retinal detachment in a vascularly inactive eye is more favorable than waiting for spontaneous vascular involution. The belief is that this period of visual deprivation may be irretrievable in these young infants.<sup>101</sup> The ideal time is when the eye is vascularly quiet and the macula is still attached (stage 4A).

Although ROP remains a challenging form of pediatric retinal detachment, many advances have been made in recent years including (1) the earlier use of laser photocoagulation to achieve peripheral ablation with less in the way of an inflammatory response; (2) the added therapy of lens-sparing vitrectomy techniques, which have given the surgeon a very effective way of dealing with traction retinal detachments involving the posterior pole; and (3) data emerging in regard to the use of vitrectomy for 4A is most encouraging and makes physiologic sense to avoid foveal detachment in the developing visual system. All three of these newer surgical approaches generate better anatomic and visual results.

Although much is left to be done worldwide, great strides have been made in the management of ROP.

**Conclusions**

## **General Aspects**

### **Development of the Child's Eye and**

## Surgical Consequences

The development of spatial vision and binocular fusion (sensitive period) begins in the human infant at the age of 3–4 months.<sup>1</sup> A reduction in the visual acuity of one or both eyes with morphologic intactness is termed amblyopia. The child's age at exposure to an amblyopia-inducing condition is the most important determinant for its development. Children up to 8 years of age can develop an amblyopia; development later is rare. The therapy of choice for all forms of amblyopia is an appropriate occlusion therapy which sometimes must be continued until the child is 12 or 13 years old in order to avoid a recurrence.

Untreated anisometropia resulting from vitreoretinal operations induces amblyopia, especially in small children (Table 119.1).<sup>2</sup> Whereas a refractive error averaging  $-2.75$  diopters (D) is induced by an encircling scleral buckle in the adult,<sup>3</sup> the anisomyopia resulting from a cerclage may be greater in pediatric eyes. Myopia occurs as a result of the axial elongation induced by the encircling band, and this has a more pronounced effect on refraction due to the very short axial length of the infant eye. Furthermore, buckling surgery with a cerclage induces forward displacement of the lens, which can cause severe myopia in the infant lens with its relatively high refractivity.<sup>4</sup> Still, this refractive change is generally less than 6 D and amblyopia is rarely manifest, since patients still have sharp near vision.<sup>5</sup> These patients can usually be fitted with spectacles. High axial myopia of  $-11$  to  $-15$  D following buckling surgery in infants with retinopathy of prematurity (ROP) is more difficult to treat. Therefore, once successful reattachment of the retina has been achieved, the encircling band can be cut, thus reducing the refractive error to values around  $-5$  D.<sup>4</sup>

**TABLE 119.1**  
**Deprivation Caused by Vitreoretinal Disease<sup>2</sup>**

Stimulus Deprivation	Stimulus Deprivation and Suppression
Bilateral deprivation: amblyopia due to media opacity of the same severity, e.g., bilateral congenital cataract or bilateral vitreous hemorrhage	1. All predominantly unilateral stimulus deprivations or bilaterally differing stimulus deprivations
	2. Relative amblyopia: congenital or early manifestation of defects in the foveal region
	3. Uncorrected anisometropia because of blurred

image and aniseikonia (e.g., anisomyopia due to cerclage anisohyperopia in silicone oil tamponade, cycloplegic eye drops)
4.Acquired medium opacity

Source: Hanse<sup>2</sup>

A silicone oil tamponade also increases the risk of amblyopia development, since hyperopic refractive correction of +5 to +6 D is required regardless of the lens status. If pediatric eyes filled with silicone oil are not optically corrected, the anisohyperopia causes severe amblyopia. Another result is pronounced refractive anisometropia. The first-line corrective therapy for eyes filled with silicone oil or aphakic eyes is a contact lens. Extended-wear contact lenses are suitable for very young children. Pathologic structures affecting vision (e.g., cataracta congenita, persistent hyperplastic primary vitreous, vitreous hemorrhage) and resulting in amblyopia ex anopsia require treatment. Attention must also be paid to “relative amblyopia,” which may be superimposed on an organic lesion (e.g., macular scar). The danger of monocular deprivation must be considered in prolonged postoperative atropinization of the operated eye.

The most obvious and important anatomic consideration in pediatric retinal surgery is the relatively smaller size of the child's globe and orbit compared with that of the adult (Table 119.2). At birth, the average axial eye length is 17.5 mm; which is 70% of the axial length of an adult eye. In the first year of life eyeball length increases by nearly 3.5 mm. From age 3–14, the eye grows very slowly; an average of 0.1 mm/year.<sup>6</sup> The average horizontal and vertical corneal diameters are 9.8 ± 0.33/10.4 ± 0.35 mm (newborn boys) and 10.1±0.33/10.7 ± 0.29 mm (newborn girls). By age 7, the cornea has an average diameter of 11.7 mm.<sup>7</sup> In the newborn, the anterior segment already comprises 80% of its final area, while the surface of the posterior segment comprises only 20% of an adult eye; in the first 6 months of life, the posterior segment surface increases by 50%. The lens of the newborn is spherical and is relatively thicker than the adult lens. As the lens flattens, the power of the lens is reduced by approximately 8 D; in the first 2 years, it is reduced by approximately 11.5 D, and it reaches adult values between 7 and 10 years.<sup>8</sup> Since the cornea flattens, its power is also reduced: in the first 6 weeks of life, the power is reduced from 51 D

to 44 D.<sup>9</sup>

A vision-dependent feedback mechanism is necessary for the development of emmetropia.<sup>10</sup> It is assumed that various forms of stimulus deprivation induce a myopic shift during development.<sup>11</sup> Dense hemorrhages persisting in the neonatal vitreous for 4 weeks or longer appear to cause axial myopia and severe amblyopia. Surgical intervention before this time should be considered to avert deprivation amblyopia and to retard axial myopia.<sup>12</sup>

The ciliary body of the eye is divided into the pars plicata ciliaris and the pars plana ciliaris. The pars plicata of the mature newborn is nearly adult in size, whilst the pars plana is relatively small (Table 119.3).<sup>13,14</sup> The pars plana of mature newborns measures 1.6–2.0 mm.<sup>6</sup>

**TABLE 119.3**

**Developmental Morphology of the Pars Plana and Pars Plicata in the Postnatal Phase**

Reproduced with permission from Aiello AL, Tran VT, Rao NA. Postnatal development of the ciliary body and pars plana. A morphometric study in childhood. *Arch Ophthalmol* 1992;110:802–5.

The anterior–posterior extension of the pars plana begins in the

postnatal phase (Fig. 119.1). In a 6-month-old infant, the pars plana is  $>3.0$  mm.<sup>6,14</sup> This means that in infants younger than 6 months, the pars plana width is  $<3.0$  mm. However, the extension of the entire ciliary body is quite variable in individual eyes; its total extension in the age group 24 months ranges from 3.75 to 5.5 mm. A total of 75% of the final length of the ciliary body at adulthood is reached by 24 months.<sup>14</sup> A positive correlation between the anteroposterior diameter of the eye and the distance from the sclerocorneal limbus to the ora serrata was demonstrated in the four meridians.<sup>13</sup>

**FIG. 119.1** Histologic section of the ciliary body shows the width of the pars plana in: (A) the eye of a mature newborn; (B) in a 6-month-old infant; (C) in a 12-month old child; (D) in a 24-year-old man (hematoxylin and eosin, original magnification  $\times 32$ ).

The results of the morphometric investigations are of great importance for the choice of the vitreoretinal-surgical entrance. The anterior-posterior expansion of the ciliary body corresponds approximately to the distance from the corneoscleral limbus measured externally (in millimeters). For an accurate external

determination of the location of the ora serrata, 0.3–0.4 mm must be added to the measured distance starting from the corneoscleral limbus for the values of the ciliary body extension.<sup>14</sup> Accordingly, in babies, one must select a pars plicata entrance for a vitrectomy. Only then is it ensured that the retina will not be damaged. The disadvantage of this entrance is the direct proximity of the lens, and therefore manipulations and lens-saving operations are often not possible. Because of the relatively larger size of the lens in relation to the anterior segment in children compared with adults, special care is required if the eye is operated on without removing the lens. For a standard three-port vitrectomy, the width of the pars plana should be at least 3 mm<sup>6</sup> so that the earliest age that a pars plana approach can be selected is approximately a 1-year-old child. The measurements mentioned here are based exclusively on histologic slides, i.e., after appropriate fixation of the material. The real dimensions are therefore larger.

Scleral thickness is clearly age-dependent. During the first half-year of life the average scleral thickness is approximately 0.4 mm; by age 2, the thickness has doubled. After that age, the scleral thickness increases very slowly, and the tissue becomes stiffer with age.<sup>15</sup>

The vitreous body is avascular, transparent, and gel-like in consistency, and comprises 80% of the eyeball volume. The vitreous body is attached to the surrounding structures; a firm attachment exists within the area of the vitreous base, and Wiegers ligament forms the firm attachment between the soft crystalline lens and anterior vitreous. The posterior vitreous cortex (posterior vitreous hyaloid) is 100–110  $\mu\text{m}$  thick and consists of closely packed collagen fibrils. In pediatric eyes the posterior vitreous cortex lies adjacent to the retinal surface. This structure is known as the vitreoretinal border region, the vitreoretinal junction, or the vitreoretinal interface. The vitreoretinal interface consists of the internal limiting membrane (ILM) and the posterior hyaloid. In the newborn, the vitreous body appears homogeneous with a fine radial stripe pattern. It is interspersed with so-called transvitreal channels. With increasing age vitreous strands develop, and in the adult eye these form typical concentrically arranged diaphragm-like condensations.<sup>16</sup> The secondary vitreous in the term infant without

ocular disease consists of a very dense collagenous gel. Some authors believe that in term infants there is no hyaluronic acid present until 4 years of age. There are, however, many diseases that are associated with a lack of densely formed vitreous (e.g., myopia, retinitis pigmentosa, ROP, familial exudative vitreoretinopathy [FEVR], Goldmann–Favre disease, and congenital retinoschisis). In pediatric eyes, the attachment between the vitreous cortex and retina is very firm. Formed vitreous and increased scarring seem to be correlated. It is believed that children develop proliferative vitreoretinopathy (PVR) more frequently than adults.

## Examination of Pediatric Patients

A child is often referred for one of the following diagnoses: leukocoria, no red reflex, unexplained strabismus, suspected retinal detachment, history of trauma, a change in visual function, or unexplained irritability. The most important component of the diagnostic evaluation of infantile vision loss is the exclusion of malignant tumors and systemic and heritable diseases. The examiner must often rely on physical examination techniques, as pediatric patients are frequently unable to verbalize their visual complaint and are often uncooperative during the examination. Therefore, the examination must be very thorough yet brief enough as to not lose the cooperation of the child. Observing the child interacting with his or her environment may be the most vital piece of information one can obtain. It is always critical to judge the apparent presence or absence of light perception. A past history of the child and family are important. The history should include birthweight; conceptual age (i.e., weeks from conception to the present); gestational age (i.e., weeks from conception to birth); the mother's due date; pregnancy data (e.g., illness, trauma, drug use, human immunodeficiency virus (HIV) status); and familial ocular and systemic diseases. The examination technique varies depending on the child's age. An infant younger than 1 year may be quite tolerant of being swaddled and undergoing scleral depression using an indirect ophthalmoscope and a 30-D lens. The decision to perform an examination under anesthesia should be made if additional information can be gained that can help with the child's

management.

## Preoperative Treatment

All patients are given atropine eye drops twice for preoperative pupil dilation. The dosage of atropine (preoperative evening and morning) is determined depending on age (0–3 months: atropine 0.125%; 3–6 months: atropine 0.25%; 6–12 months: atropine 0.5%; >1 year: atropine 1%). The drops are first given in the preoperative evening. Directly before the operation tropicamide-phenylephrine eye drops (tropicamide 0.5%; phenylephrine 1%) three times every 15 minutes are given. If sufficient mydriasis cannot be achieved, healthy children can be given an injection of 0.1 cm<sup>3</sup> epinephrine (adrenaline: 1:10000) into the anterior chamber or applied over the vitrectomy infusion line after consultation with the anesthesiologist.

## Surgical Considerations and Techniques

### Cornea and Keratoprosthesis

If corneal edema develops during the vitrectomy, 50% glycerin can be used to dehydrate the cornea.

If the cornea does not clear up, the corneal epithelium is removed. If substantial Descemet folds arise, the anterior chamber is filled with Healon.

In the case of extensive corneal opacities with insufficient visibility of the fundus the employment of a temporary intraoperative keratoprosthesis can be considered in order to enable a vitreoretinal operation to be performed for internal reconstruction.

The placement of a temporary keratoprosthesis (e.g., Eckhardt keratoprosthesis, DORC) or Landers keratoprosthesis (Ocular instruments) allows a clear view for vitreoretinal surgery, which is then followed by a corneal transplant. Several retrospective studies have documented acceptable outcomes with combined surgery in adults, but only a few cases with children have been well documented.<sup>17-19</sup> The best outcome was of a 7-year-old boy whose

operation included usage of a keratoprosthesis followed by lensectomy, scleral buckling, vitrectomy, C<sub>3</sub>F<sub>8</sub>-fluid–gas exchange, and penetrating keratoplasty. At 10 months postoperatively, the best corrected visual acuity was 20/30.<sup>17</sup> In surgical summaries, 10 of 17 corneal grafts in children remained clear in the follow-up period, but in 16 eyes, visual acuity did not exceed finger counting. Phthisis occurred in about 40%.<sup>17–19</sup>

In general, the prognosis of keratoplasty in children is poorer than in adults. There is a greater risk of an immune reaction with development of neovascularization. Perforating keratoplasties in children following trauma have a poorer general prognosis, especially in cases of aphakia and after injuries involving the posterior segment of the eye as opposed to phakic eyes and after isolated injuries to the anterior segment. In a meta-analysis,<sup>20</sup> 55–100% of transplants were not opaque 1 year after keratoplasty in children.

Some special surgical aspects must be considered if using a keratoprosthesis on the pediatric eye. The decreased scleral rigidity relative to that of the adult eye means that children's eyes can collapse more easily with greater risk of intraocular tissue extrusion. It is therefore imperative that a Flieringa scleral fixation ring be sewn on. The keratoplasties heal relatively quickly, but since a higher rate of vascularization has been observed, it is advisable to use only interrupted sutures, which can be removed or replaced.

The corneal sutures in children can be removed much sooner than in adults. Removal should be performed within the time intervals specified in [Table 119.4](#), in order to enable immediate provision of contact lenses, especially in aphakic eyes.<sup>21</sup>

---

**TABLE 119.4**

**Recommendation for Removal of Corneal Suture by Age**

---

Age	Removal of Corneal Suture
1–6 months	4–6 weeks
6–12 months	6–8 weeks
12–24 months	8–12 weeks
24–48 months	12–16 weeks
5–15 years	4–6 months

## Lens Management

During the early period of pediatric vitreoretinal surgery, lensectomy was routinely performed. Later, favorable anatomic and functional outcomes were reported with lens-sparing vitrectomy in selected cases of infantile retinal detachment. The instruments are introduced into the eye via a pars plicata or pars plana approach, parallel to the visual axis to avoid lens injury. Many eyes show no evidence of postoperative cataract formation. Lens preservation may optimize optical rehabilitation and stimulation of the developing visual system.

In some cases, especially in eyes with a high risk of developing proliferative vitreoretinopathy, such as after severe open-globe injury and in uveitis, an intraocular lens (IOL) should not be implanted. Opacity of the remaining capsule fragments with optically disadvantageous postcataract membranes is usually inevitable. In addition, remnants of the lens capsule and the zonular fibers lead to development of synechiae with distortion of the pupil which is associated with a reduction in the visibility of the peripheral retina. Surgical treatment of retinal detachment is therefore impeded. For this reason, complete removal of the entire lens, including the complete capsule, should be planned for eyes with a high risk of developing PVR. In addition, one study demonstrated a significantly increased endophthalmitis risk if an intraocular lens was placed in eye immediately after open-globe injury.<sup>22</sup>

The risk of a severe intraocular fibrin reaction is one of the further drawbacks of intraocular lens implantation in children. After operation for a nontraumatic cataract in a pediatric eye, a significantly less pronounced fibrin reaction is observed after pars plana lensectomy than with the limbal approach that is necessary for optimal implantation of an intraocular lens.<sup>23,24</sup> In darkly pigmented eyes, an even more intense fibrin reaction is frequently observed. Further disadvantages of primary intraocular lens implantation are the imprecise biometry and unclear prognosis

concerning eye growth.

A lensectomy during vitrectomy is accomplished by aspiration. Phacoemulsification of the lens in children is unnecessarily traumatic. The soft juvenile lens can be removed solely by means of aspiration, if no vitreous is involved. Furthermore, the use of 23-gauge (G) instruments is sufficient for removal of pediatric lens material with a 23G cutter with a cutting rate of 450 revolutions per minute and relatively low suction power (maximum 450 mmHg).

The empty lens bag is completely removed at the end of the operation, preferably bimanually, with forceps holding the capsule on traction and the cutter removing the zonular fiber attachments. Removal of the capsule with forceps alone should be avoided as aberrant attachments of zonular fibers, the so-called zonular traction tufts, may create peripheral retinal tears. These traction tufts are described as connections of retina to one or more posteriorly inserting zonular fibers. If silicone oil is instilled, an inferior iridectomy is performed.

Optimal visual rehabilitation can be achieved without the need for contact lens wear by IOL implantation. Implantation of an intraocular lens has the advantage of attaining an immediate optical improvement, but is associated with the substantial drawbacks mentioned above.

Secondary lens implantation should only be considered in stable situations, when silicone oil has been removed and the retina is attached.

Postiridial iris claw lenses are our first choice and can be implanted quite easily. The preferred choice of secondary lens implantation should be the implantation of an iris claw lens in the posterior chamber or, as second choice, the suturing of an intraocular lens, a scleral-fixated IOL, or an iris-fixated IOL. The indications for suturing an intraocular lens should be considered carefully.

## Posterior-Segment Surgical Techniques

The smaller size of infant eyes results in differences in surgical landmarks, relative instrument size, and fluid dynamics of vitreous surgery (Fig. 119.2) in addition to increased vitreoretinal adhesion.

These specific issues are addressed below.

**FIG. 119.2** Comparison of a globe from a neonate (A,B) with that of an adult (C,D) shows different proportions.

Buckling surgery (see also [Chapter 104, Techniques of scleral buckling](#)): after a peritomy, traction sutures (silk 5/0) are placed beneath the insertion of two to four rectus muscles. Then the retinal holes are located, marked, and a transscleral cryoretinopexy is performed under ophthalmoscopic control. Depending on location of the hole, appropriate radial or circumferential scleral buckles are placed and fixed, if necessary with an additional segmental silicone-rubber sponge. For an encircling procedure, one suture per quadrant is placed, and the ends are secured with a sleeve. Due to spatial considerations, the sleeve is preferably placed in the lower temporal quadrant. The perfusion of the central retinal artery must be checked. Rarely, a paracentesis is necessary. The scleral thickness

is less than in adult eyes, therefore thinner (6/0) suture (polyester fiber, polyamide fiber) should be used for partial-thickness scleral sutures in babies. We also recommend the use of flat spatula needles (0.28 mm diameter).

A child's eyes are more prone to vigorous cellular re proliferation than those of an adult. This can be attributed to the biochemistry of this age group which supports cell growth more actively, or to a longer delay between the time of detachment and the establishing of diagnosis and therapy. For primary detachments, we use a sculpted 3 × 5-mm sponge with an encircling 2.5-mm solid silicone band. It is often assumed that the children's orbits cannot accommodate a large sponge, but this type of exopant is well tolerated. Drainage of subretinal fluid is controversial.

Postoperative complications of scleral buckling in children range from refractive amblyopia to alteration of eye growth. To avoid these complications, the band is cut in all children younger than 3 years, approximately 3 months after the scleral buckling operation, once a stable reattachment has been achieved.<sup>4</sup> We choose to cut rather than to remove the element because we believe that continued support to the retina is provided by the encapsulated exopant. To reduce amblyopia development in the postoperative period, we prescribe 1% atropine drops for 5 days; if both eyes have good visual potential, we prescribe the drops for both eyes. In addition to amblyopia therapy, a refractive error needs to be treated with adequate prescriptions.

In combination with vitrectomy, we use an encircling band with a width of 2.0 mm in babies; in older children we use a circumferential buckle width of 2.5 mm. While a primary encircling band is fixed in the area of the equator, a cerclage placed during a vitrectomy is fixed somewhat anterior to the equator. Tightening of the band for stronger indentation is done during vitrectomy, after the central vitreous has been removed in order to facilitate visualization of the vitreous base.

Usually a three-port vitrectomy is performed in children. The infusion is preferably placed temporally. The sclerotomies are placed 3.5 mm behind the limbus in infants older than 2 years. In children younger than 2 years, the sclerotomies are performed within the range of the pars plicata and/or pars plana, in accordance

with [Table 119.5](#). In the infant eye, especially in babies, the scleral incisions are made posterior to the limbus with incisions through the pars plicata. Displacement of the conjunctiva for adequate coverage of the sclerotomies necessary for transconjunctival sutureless surgery is not possible.<sup>25</sup> Therefore, conjunctival dissection is preferred before the sclerotomy incisions are made. Because of the very thin sclera in babies and infants, we recommend using trocars beginning at age 2. In preschool children, we recommend placing the trocars perpendicular through the sclera. In young eyes, oblique placement of the trocars is associated with an increased risk of accidental dislocation, since the trocars have only a short path through the pediatric sclera compared to the longer path through an adult sclera. The insertion of a 25G trocar imparts significantly more force on the globe than a 20G blade. A young patient age is a risk factor for intraoperative sclerotomy leakage: in a study of 322 eyes, 61% of patients aged <40 years needed intraoperative suture placement for leaking sclerotomies at the end of 23G transscleral vitrectomy.<sup>26</sup> Others report postoperative hypotony in up to 40% after 25G vitrectomy in children.<sup>27</sup>

**TABLE 119.5**

**Distance of Sclerotomies From the Limbus as a Function of Age**

	Age (months)				
	<3	>3–6	>6–12	>12–24	>24
Distance of sclerotomy from limbus (mm)	1.5	2.0	2.5	3.0	3.5

Due to the decreased scleral stiffness and the increased elasticity of young sclera, suturing of sclerotomies in children is necessary to ensure a leakproof closure. Especially if eyes have ocular disorders which are associated with neovascular tissue, the sclera should be sutured to prevent postoperative intraocular hemorrhages from the vascular ridge in case of postoperative hypotony.<sup>28</sup> Furthermore, children often rub their eyes after surgery. For the closure of the conjunctiva, absorbable Vicryl 10/0 can be used.

A complete range of small incision instruments that permit a complete vitrectomy through small (23G and 25G) incisions has been developed. Performing surgical maneuvers with smaller

instruments allows the surgeon to work more precisely and increases the potential for minimizing surgical trauma. We prefer the use of 23G instruments, but case selection remains important. In case of very dense cellular membranes, the 23G or 25G cutter cannot adequately address this tissue, and additional instrumentation may be necessary. In more complicated cases, such as traction retinal detachments, eyes with extensive fibrovascular proliferation, complex retinal detachments requiring scleral buckles for proliferative vitreoretinopathy, and giant retinal tears, surgical maneuvers can be performed with small-gauge instruments, but they are often more easily performed using 20G instrumentation.<sup>29</sup> For cases requiring enhanced panoramic illumination, it is possible to use the 20G shielded bullet light pipe instead of the 23G illumination light pipe. The sclerotomies are made with a 23-MVR blade. In babies, we use a 23G disposable Tornambe infusion cannula (DORC 1272). Larger sclerotomies may allow for better manipulation of the 23G or 25G cutter within the sclerotomy, avoiding unintentional bending of the instrument and potential damage to the lens or retina.<sup>25</sup>

Minimizing infusion pressure may diminish the risk of corneal clouding and retinal incarceration during instrument withdrawal. Occasionally, the anterior chamber is so shallow that is difficult to avoid dragging the iris while creating sclerotomies. This increases the risks of iridodialysis, hemorrhage, and traction on the peripheral retina. Proliferations may develop anteriorly, often along the ciliary body, and dissection of these peripheral proliferations may be necessary to enable the widest possible dilatation. The use of flexible iris retractors has greatly facilitated this goal without significantly complicating the operation.

Vitrectomies are always performed with wide-angle observation systems. In addition, wide-field vitrectomy contact lenses are specifically designed to facilitate pediatric vitreoretinal surgery.<sup>30</sup>

The wide-angle observation systems for vitreous surgery (binocular indirect ophthalmomicroscope, vitreopanfundoscope, and stereoscopic diagonal inverter) have many advantages: (1) wide angle of view; (2) large depth of field; (3) stereopsis; (4) good visualization in hazy media, even with narrow pupil; (5) upright, true-to-side image; (6) magnification with the microscope zoom; (7)

beam splitter for the assistant; (8) good visualization in gas-filled or silicone-filled eyes; (9) free mobility of the eye for peripheral surgery. With these systems, surgery is possible from the posterior pole to the vitreous base and the anterior loop traction, regardless of whether the eye is phakic, pseudophakic, or aphakic. The vitreous body can be removed with a 23G high-speed cutter with a cutting rate of 5000 revolutions/minute and a suction power of 400 mmHg. With the cutter near the peripapillary retina, suction should be applied to separate the posterior hyaloid from the retina in slow circular movements. Special attention is necessary to create a posterior vitreous detachment; "tenting of the retina" is a sign of very strong vitreoretinal adherence and poses a high risk for development of iatrogenic retinal holes. A compromise is a judicious core vitrectomy, leaving as thin a layer of cortical vitreous on the retina as possible. If it is not possible to remove vitreous in the periphery, a thorough shaving is necessary. This can be performed by a small-gauge high-speed cutter; if 20G instruments are used, special 20G shaver-cutters are available. Creation of a posterior vitreous detachment with suction alone to lift the vitreous off of the optic nerve is more difficult with small gauge vitrectomy probes. The smaller port opening decreases the ability to engage and hold the vitreous. Creating a posterior vitreous detachment in a child with adherent posterior hyaloid remains substantially easier with 20G instruments because of larger port sizes and greater flow rates.<sup>29</sup> For small-gauge vitrectomies, higher infusion rate in the range of 35–50 mmHg are necessary to ensure adequate intraocular fluid dynamics. Due to the lower systolic blood pressure of babies and infants, iatrogenic occlusion of the central retinal artery can be induced, and the surgeon has to observe the optic nerve.<sup>31</sup> Retinal breaks should be prevented because they are often difficult to treat. Posterior drainage retinotomies are associated with profound postoperative proliferation. Iatrogenic breaks are best avoided by abandoning peeling in favor of bimanual dissection with forceps and scissors. If a retinotomy is unavoidable, it must be performed as close as possible to the ora serrata and following diathermy coagulation. Retinopexy of retinotomy edges is done with argon laser coagulation. If the extension of the retinotomy is larger than 2 clock-hours, a silicone oil tamponade is used. Diagnostic vitrectomy

can be used to evaluate conditions such as inflammatory conditions and amyloidosis. The cytopathologic analysis of ocular fluids obtained for diagnostic purposes has proven to be effective for establishing and confirming the diagnosis.

Pharmacologic agents have become available to assist in separating the youthful posterior cortical vitreous from the retina. The goals of enzymatic vitrectomy (dispase, plasmin, tissue plasminogen activator, or chondroitinase) are either to disinsert the posterior hyaloid from the retinal surface in an atraumatic, precise, cleavage plane or to try to disinsert the peripheral vitreous from the neurosensory retina. Enzymatic (collagenase or hyaluronidase) manipulation of the central vitreous in terms of liquefaction has been evaluated. At present microplasmin is used in clinical studies.<sup>32,33</sup> This is certainly only the beginning of this type of vitreous surgery, whether adjuvant or alternative.

## Silicone Oil and Gas Tamponade

The physical properties of silicone oil include a combination of specific gravity, refractive index, and surface tension. Heavy silicone oil may be of interest for inferior traumatic retinal detachments. Use of 1000 centistokes or 5000 centistokes silicone oil can be considered in the management of pediatric complex retinal detachments associated with multiple etiologies.<sup>34</sup> The choice of viscosity offers an optimal balance between easy injection and a longtime tamponade. Indications and the long-term results of pars plana vitrectomy in children are comparable with those in the adult. Retinal reattachment and preserved visual acuity can be achieved in the majority of eyes using silicone oil retinal tamponade. In complicated retinal detachments, especially after injuries, an approach with primary silicone oil injection and later silicone oil removal has proved useful. In children, who usually have a long life expectancy, timely removal of silicone oil is vital for maintaining the function of the eye.

Intraocular gas has a limited use in children and is complicated by difficulties in adequate positioning, intraocular pressure monitoring, and corneal clouding.

Biostaining of the ILM and intraocular membranes is a technique

that is still evolving, and despite good results in adults, it should be used in children with utmost care. We recommend trypan blue and brilliant blue G<sup>35</sup> as “safe” dyes for staining, assuming they have nontoxic or at least minimal toxic effects.<sup>36</sup> Visualization of the stained posterior hyaloid greatly facilitates complete removal and reduces surgical time. Control staining following membrane removal is possible, preferably by the use of triamcinolone to check if all gel and membranes have been successfully removed.

## Injuries

(See also [Chapter 102, Pathophysiology of ocular trauma](#), and [Chapter 104, Techniques of scleral buckling](#).)

### Direct Injury

#### Open-Globe Injury

Some 29–47% of pediatric open-globe injuries involve both the anterior and posterior segments of the eye.<sup>37–40</sup> Whereas the primary surgery typically includes external reconstruction of the globe, internal reconstruction can be performed simultaneously with the primary wound closure or, in most cases, in a second step.

The timing of secondary comprehensive anatomic internal reconstruction is crucial. Various authors have recommended a secondary vitreoretinal operation for internal reconstruction in the period between the 7th and 10th posttraumatic day in adults;<sup>41–43</sup> whereas others recommend 3–10 days after trauma.<sup>42,44</sup> The general rule is to delay comprehensive anatomic reconstruction of the seriously injured eye for approximately 1 week, when the risk of intraoperative hemorrhage is dramatically reduced and a separation of the posterior vitreous begins to develop.<sup>41,42</sup> Kuhn et al. recommend early vitrectomy within 3 days to prevent development of vitreoretinal proliferation.<sup>42</sup>

Immediate intervention is, however, necessary if signs of infection are recognizable or in rare cases of retinal detachment at the time of wound closure.

The value of a prophylactic encircling band in severe globe-opening injuries is controversial. There are no prospective studies

documenting the advantage in children. In adults, the frequency of retinal detachment may be less after applying an encircling band. An encircling buckle procedure is recommended in the presence of a corneoscleral or scleral wound >5 mm with ciliary body involvement with marked vitreous loss and vitreous hemorrhage.<sup>45-47</sup> Despite optimal follow-up, the functional results after combined pediatric anterior and posterior segment injuries are limited: about 12%<sup>34</sup> to 69%<sup>39</sup> of the children attain a visual acuity of 0.1 or better after primary wound closure and secondary surgery for reconstruction of the anterior and posterior segments.

Children may develop more extensive postoperative inflammation, scarring, and severe proliferative vitreoretinopathy than adults, and this affects the anatomic and functional outcomes.<sup>48</sup> The results after pediatric vitreoretinal surgery depend greatly on the extent and severity of the primary damage (Fig. 119.3). A wound size exceeding 10 mm, a lens lesion, and a patient age under 4 years are factors with unfavorable prognoses. Further negative influential factors include severe intravitreal bleeding, poor initial vision, and gunshot injuries. Retinal detachment always correlates with significantly poorer results. Preoperative macular attachment is a crucial prognostic factor for attaining a postoperative vision better than 0.1.<sup>49,50</sup>

**FIG. 119.3** (A) Suture in a 12-year-old boy for a corneal perforation caused by a knife. (B) Vitreous hemorrhage and retinal dialysis were diagnosed in the posterior segment of the same eye. (C) Scarring and pigmentation at the exit site of the eye of a 13-year-old boy, who had sustained a perforating injury from a shotgun pellet (D) and was treated with a pars plana vitrectomy with silicone oil injection.

There is strong support for scleral buckling as the standard primary surgery for treatment of trauma-associated retinal detachment in children. Differently from adults, the vitreous is rarely detached and complete vitrectomy is impossible. Furthermore, remnants of vitreous are responsible for development of severe PVR following vitrectomy. Indications for primary scleral buckling include absence of cataract, minimal vitreous hemorrhage, and clear identification of retinal breaks; significant vitreal opacities and giant or posterior retinal breaks require primary vitrectomy.<sup>40</sup> Traumatically ruptured globes occur rarely in children.

Predisposition for rupture of pediatric eyes includes diseases associated with thin sclera, e.g., Ehlers–Danlos syndrome and osteogenesis imperfecta. Even blind eyes should be treated, as enucleation can often be prevented.

## Closed-Globe Injury

### Oradialysis.

A common finding in closed injuries is an oradialysis. An oradialysis is located most often inferotemporally, and it may become symptomatic only years after the trauma. In the absence of cataract, minimal vitreous hemorrhage, or significant haze, treatment consists of a circumferential segmental buckle. The edge of the segmental buckle should exceed the edge of the dialysis by twice.<sup>51</sup> Anatomic reattachment has been achieved in 67–88% of cases, whereas the rate of PVR was (Figs. 119.4A–B).<sup>52,53,54</sup>

**FIG. 119.4** (A) Oradialysis, macular hole, and vitreous hemorrhage in a 12-year-old boy caused by a soccer. (B) 4 weeks postoperatively, after cryoretinopexie, and segmental buckle the retina is attached. (C) The spectral-domain optical coherence tomography

showed the full-thickness traumatic macular hole. (D)  
The hole resolved spontaneously 6 days after trauma.

### Traumatic Macular Hole.

Most traumatic macular holes result from closed-globe contusion injuries, but the formation of a macular hole secondary to a penetrating injury was documented in an 8-year-old boy.<sup>55</sup>

Traumatic macular holes may result from blunt trauma when it causes separation of the vitreous from the retina, contusion necrosis, or subfoveal hemorrhage. The cause of visual deterioration is necrosis resulting from contrecoup forces or tearing of the retina by a sudden separation of the posterior vitreous face from the retinal surface.<sup>56</sup> However, in one report, the posterior vitreous was detached from the macula in only 5% of eyes with traumatic macular holes.<sup>57</sup> This supports the theory that rupture of the macula caused by retinal stretching occurs as a result of either ocular deformity in the equatorial region or from the strong force of impact on the macula.<sup>57</sup> Small, full-thickness traumatic macular holes with a size of 0.1–0.2 disc diameter (DD) can resolve spontaneously in 64–100% of pediatric cases 3–4 months following trauma, and this may be associated with good visual recovery in most cases even as excellent as 20/20.<sup>58–61</sup> In contrast to spontaneous closure of small macular holes (100–200  $\mu\text{m}$ ), closure of large holes (400–600  $\mu\text{m}$ ) has been rarely described (Figs. 119.4C–D).<sup>62</sup>

In preschool children, the timing of surgery should be based on the fact that traumatic macular holes may be amblyogenic. We therefore recommend vitreous surgery for the treatment of traumatic macular hole after 4 weeks. In elderly children, a period of observation of 3–4 months before vitreoretinal surgery is recommended.<sup>59</sup>

Common features of patients with spontaneous closure of traumatic macular hole are young age (<25 years), small size of the macular hole (0.1–0.2 DD), no posterior vitreous detachment, and no epiretinal membrane.<sup>59</sup>

Vitreous surgery for traumatic macular holes can lead to anatomic success in 92–100% and visual acuity improvement in 92–100% of pediatric patients.<sup>55,59,63</sup> Recent studies recommend surgical

procedures including removal of the posterior hyaloid, the epiretinal membrane, and ILM and expanding gas–air mixture tamponade.<sup>59,63,64</sup> Studies with adjunctive treatments have been published and describe the successful use of platelet concentrate<sup>65</sup> and plasmin (0.4 IU of autologous plasmin) for enzyme-assisted pars plana vitrectomy.<sup>63</sup> In young patients, poor compliance with face-down positioning may be a factor in surgical failure. It is difficult for a child to maintain a face-down position postoperatively, therefore the use of silicone oil is advocated in children who need long-term intraocular tamponade after vitreoretinal surgery. However, additional surgery for silicone oil removal is necessary.

### **Vitreous Hemorrhage.**

Trauma remains the first among all causes of pediatric vitreous hemorrhages, and the differential diagnosis for spontaneous intraocular hemorrhages in infants includes vasculitis, ocular tumors, FEVR, X-chromosomal retinoschisis, retinal breaks, *Toxocara* infection, and systemic disorders (e.g., hematologic disorders, diabetic retinopathy, hepatorenal dysfunction, sepsis).<sup>66</sup> Complications of infantile vitreous hemorrhage include epiretinal membrane formation, pigmentary retinopathy, strabismus, high anisometropic myopia, and occlusion amblyopia.<sup>10</sup> These serious complications occur as early as 5 weeks after the onset of the vitreous hemorrhage. Vitrectomy is an acceptable early therapy for infantile vitreous hemorrhage, and we recommend that this be considered as early as 5 weeks after the onset of a dense, infantile, vitreous hemorrhage in an attempt to avert serious complications of the hemorrhage.<sup>12,67</sup> In suspicious cases of infectious etiology diagnostic vitreous biopsies should be performed, e.g., histopathologic confirmation of tuberculosis.

Furthermore, early removal of severe vitreous blood clots and severe vitreous hemorrhaging is recommended for injured eyes. Traction retinal detachments arise as a result of contracting epiretinal membranes, and vitrectomy appears to reduce the incidence of these traction retinal detachments in open-globe injuries.<sup>41,68</sup> The timing of vitrectomy for the removal of vitreous hemorrhage remains crucial. If retinal and/or choroidal

involvement are not present, serial ultrasonography is necessary to detect complications. In individual cases, vitreous hemorrhage may absorb spontaneously, but because of the danger of amblyopia, vitrectomy may nevertheless be indicated.

## Indirect Injury

### Terson Syndrome

Terson syndrome is characterized by intraocular hemorrhage secondary to subarachnoidal or subdural hemorrhage. Vitreous hemorrhage in patients surviving subarachnoid hemorrhage appears to be more common than previously thought, underscoring the need for routine fundusoscopic screening. In the only published prospective case series of nonabuse instances of intracranial hemorrhage in children,<sup>69</sup> 2% had intraocular hemorrhages. The authors estimate the incidence of Terson syndrome in children with intracranial hemorrhage to be less than 8%. There is a low incidence of spontaneous intracranial hemorrhage in infants.

Only a few case reports of Terson syndrome in babies, from 4 weeks to 7 months old, due to a ruptured angiodyplasia or an aneurysm have been published.<sup>70,71</sup> The hemorrhages can occur within the sensory retina, in the subretinal space, and in the vitreous cavity. In approximately one-third of these eyes, a premacular accumulation of blood termed a "hemorrhagic macular cyst (HMC)" may be found.<sup>72</sup> Based on the blood's relation to the ILM, two types of HMC can be distinguished in Terson syndrome. A HMC is preretinal if the blood is located anterior to all layers of the retina and submembranous if the blood has accumulated beneath the ILM.<sup>72</sup> The anterior cyst wall may initially be formed by the posterior hyaloid face and later by proliferation. This newly formed membrane may present even if the blood has cleared from the cyst. Hemorrhagic macular cysts are more often submembranous than preretinal. At the vitreous base and in the equatorial zone, attachment plaques are present between the ILM and the Müller cells. Because attachment plaques are missing in the posterior zone, where the ILM is much thicker, a retinal hemorrhage is capable of detaching the ILM from the retina in that area. The presence of attachment plaques is considered in relation

to centripetal vitreous traction, which is absent in the area of the posterior precortical vitreous pocket (PPVP). The posterior wall of the PPVP therefore probably coincides exactly with the thick part of the ILM in the posterior zone.<sup>73</sup> Most cases of vitreous and retinal hemorrhages in Terson syndrome do not require surgery because of spontaneous resorption. However, young individuals with a healthy vitreous gel may have delayed hemorrhage clearance, but babies and preschool-age infants can develop deep amblyopia within a few weeks. The formation of epiretinal membranes in severe cases is associated with the development of PVR. To prevent this complication, some authors advocate close follow-up and early, extensive treatment in Terson syndrome.<sup>74</sup> Complete cyst removal should be performed, i.e., including contents and anterior wall, to prevent blood-related complications and to allow early rehabilitation of macular function (Fig. 119.5).<sup>72</sup>

**FIG. 119.5** (A) Submembranous hemorrhagic macular cyst (HMC) seen in a 6-year-old child suffering from Terson syndrome caused by a subdural hemorrhage; the striae show stress on the internal limiting membrane. (B) Postoperatively the fundus showed a perimacular light line corresponding to the edge of the HMC.

If a pars plana vitrectomy is performed, the possibility of a hydraulically dissected ILM has to be considered. Indications for vitrectomy therefore include dense vitreous hemorrhage, bilateral hemorrhage, premacular HMC and/or dense vitreous hemorrhage

if spontaneous resorption has failed after 4 weeks, development of esotropia, and/or PVR. Postoperatively, perimacular retinal folds or fibrotic lines may occur.<sup>75</sup> Whereas the prognosis of vitrectomy for Terson syndrome is excellent in adults, it remains relatively poor in visually immature children. Amblyopia, despite early intervention, and permanent brain damage are potentially responsible for this limited visual outcome. We recommend surgical intervention, management of amblyopia, correction of refractive errors, and intensive orthoptic treatment.

Spontaneous Terson syndrome is one of the differential diagnoses for intraocular hemorrhages in infants with suspected abusive head trauma. Distinguishing characteristics are the mild severity and confinement of retinal findings to the posterior pole in spontaneous Terson syndrome, which are in contrast to the usually severe, multilayered intraocular hemorrhages extending to the retinal periphery in abusive head trauma.

## **Shaken-Baby Syndrome**

In shaken-baby syndrome, retinal hemorrhages are the most common fundus finding, and dome-shaped hemorrhages are the most distinctive form of hemorrhage (Fig. 119.6). The dome-shaped hemorrhages are most often seen in the macular area, but can be found in any area of the retina on histopathologic examination. They can be caused by separation of the ILM or a more vision-threatening deep retinoschisis. Studies have shown that handheld spectral domain optical coherence tomography (OCT) is helpful in the evaluation of patients with shaken-baby syndrome to detect vitreoretinal abnormalities, e.g., multilayered retinoschisis, disinsertion of the ILM, and foveal detachment.<sup>76,77</sup> In some cases, the blood breaks through the ILM and/or hyaloid face and causes a vitreous hemorrhage. This can occur immediately after injury or a few days after the cerebrovascular accident from rupture of the ILM over a dome-shaped hemorrhage.

**FIG. 119.6** (A) Typical appearance of a fresh submembranous hemorrhagic macular cyst (HMC) seen in shaken-baby syndrome in an 8-month-old

baby. (B) Fundus photograph after opening and (C) removing of the anterior cyst wall of the HMC. (D) Optical coherence tomography shows blood accumulation beneath the internal limiting membrane. (E) Noncontrast computed tomogram of the 8-month-old baby shows a massive hemorrhage due to abusive head trauma. (F) On follow-up 2 weeks later, he was able to fix and follow with both eyes.

In addition to extensive retinal and preretinal hemorrhages, bilateral symmetric white ring-shaped retinal folds are seen encircling the macula outside the vascular arcades. These retinal folds may be a hallmark of shaking injuries in child abuse victims.<sup>78</sup> Short-term follow-up is necessary with large dome-shaped hemorrhages because they can induce severe amblyopia by themselves or can break into the vitreous and linger for months in these visually immature patients. We recommend vitrectomy for large premacular hemorrhage and/or after absence of vitreous hemorrhage clearing after 4 weeks. If esotropia develops, vitrectomy should be performed promptly. During vitrectomy, the hyaloid is peeled and the membrane covering the macula is completely removed, i.e., the ILM is ruptured: following careful incision of the anterior wall of the HMC with a bent microvitrectomy blade in a selected macular quadrant, the flap is grasped by end-gripping forceps and the membrane is slowly torn in a motion respecting the visible edge of the HMC. In most eyes, this is a nearly circular motion concentric to the fovea. Vitreous surgery for HMC leads to excellent anatomic success,<sup>75</sup> and it offers immediate visual rehabilitation.

All maculas show retinal folds or demarcation lines postoperatively. These correspond to the edge of the HMC, i.e., the edge of the hemorrhagic detachment of the ILM.

## Diseases of the Pediatric Retina

### Myopia

Myopia is one of the important predisposing factors of nontraumatic rhegmatogenous retinal detachment in childhood.<sup>79</sup> In east Asia, about 40% of children younger than 18 years who

underwent surgery for retinal detachment suffered from high myopia ( $>-6$  diopters).<sup>80</sup> Up to one-third of pediatric retinal detachment is related to myopia.<sup>81</sup> In most cases retinal detachment in pediatric myopic eyes is associated with round holes in the presence of lattice degeneration; horseshoe tears occur rarely.<sup>54,82</sup> According to the results of the scleral buckling versus primary vitrectomy in rhegmatogenous retinal detachment study (SPR-study)<sup>83</sup> and the results of other studies in most phakic pediatric eyes, primary treatment should be performed with a scleral buckling procedure.<sup>54,82</sup> Primary vitrectomy is reserved for posterior tears, severe PVR, or for cases with obscured ocular media. The value of an additional encircling buckle is controversial, but we recommend it for eyes with PVR.

In a study<sup>84</sup> of highly myopic children  $<10$  years of age, the authors found retinal holes in 4%; lattice degeneration in 20%, and white without pressure in 11% of the eyes. The authors recommend performing laser photocoagulation of retinal holes and prophylactic laser photocoagulation of lattice degenerations because children are less likely to report symptoms, thus delaying diagnosis and treatment of retinal detachment.<sup>84</sup> Prophylactic laser photocoagulation remains a controversial issue; to date the database on prophylactic treatment in children is lacking. (See also [Chapter 110, Prevention of retinal detachment.](#))

## **Subfoveal Membranes**

Choroidal neovascularization membranes (CNVMs) in children are rare. The causes of the CNVMs are due to ocular histoplasmosis syndrome, idiopathic membranes, optic nerve coloboma and drusen, ocular toxoplasmosis, *Toxocara canis*, rubella retinopathy, serpiginous choroidopathy, trauma, degenerative myopia, and Best disease. The treatment of CNVM is a controversial topic, and the natural history of idiopathic CNVM is not necessarily associated with a profound loss of vision.<sup>85</sup> Photodynamic therapy is impractical in babies and infants, and surgical excision might have visually threatening risks. Worsening of visual acuity, protracted neurosensory detachment with the development of cystoid macular edema, or subfoveal hemorrhage may be factors that make treatment of CNVM by intravitreal anti-VEGF a favorable option.

Various authors reported children (aged 19 months to 15 years) with CNVM that regressed with documented improvement in visual acuity following treatment with intravitreal anti-VEGF.<sup>86–89</sup> Some authors used bevacizumab in a dose of 1.25 mg/0.05 mL;<sup>86,88,89</sup> others employed ranibizumab, in a dose of 0.25 mg/0.025 mL to 0.5 mg/0.05 mL.<sup>87,89</sup> Most patients required 2–5 injections of the anti-VEGF agent. No ocular or systemic adverse events were observed in any of our treated patients.

## Coats Disease

Coats disease is characterized by exudative retinitis and telangiectasias of the retina.<sup>90</sup> Usually (95%) only one eye is affected, and the etiology is unknown.<sup>91</sup> The typical morphologic features of Coats disease are multiple, saccular aneurysmal retinal vascular dilations with exudative features. The angiographic characteristics of Coats disease include areas of nonperfusion, telangiectatic capillaries most prominent in the temporal macula, and “light bulb” aneurysm. Additional findings are vascular leakage, tortuosity, and blockage from overlying exudate.<sup>92,93</sup>

A classification of Coats disease has been proposed by Shields and Shields.<sup>91</sup> Stage 1 is characterized by telangiectasia only and Stage 2 by telangiectasia and exudation. In stage 2A, the fovea is not involved by exudation, whereas eyes with stage 2B show foveal exudation. A dense yellow-gray nodule, a macular fibrosis, centered within the foveal exudation is usually associated with a worse visual outcome.<sup>94</sup> Stage 3A disease is characterized by subtotal retinal detachment, and (Fig. 119.7) stage 3B disease by total retinal detachment. Stage 4 disease shows total retinal detachment with glaucoma, and stage 5 disease is defined as a blind, nonpainful eye with a total retinal detachment, often with cataract and phthisis.<sup>91</sup>

**FIG. 119.7** (A) Fundus photograph of a 7-year-old girl with Coats disease shows massive lipid exudation and retinal detachment inferiorly (stage 3A). The retinal telangiectasias are located in the peripheral retina, between the equator and ora serrata in the upper half. (B) Three years after 4× cryocoagulation of the peripheral telangiectasias and injection of bevacizumab, there is a complete resolution of the exudates development of peripheral scars with surrounding pigment changes.

The main goal of treatment of Coats disease should be to eradicate telangiectasias and ischemic retina by photocoagulation with green laser light (532 nm) or cryocoagulation. Preferred method of cryotherapy is a double freeze–thaw technique applied directly to the telangiectasias. But excessive cryotherapy can induce an increase in the extent of retinal detachment. Therefore, in cases with diffuse telangiectasias involving all quadrants, it is advisable to initially treat two quadrants only and the other quadrants 4 weeks later. A second treatment of the same area should be withheld for 3 months because resolution of exudation is a very slow process.<sup>95</sup>

Recent studies<sup>96</sup> have shown that Coats disease is associated with an increased intraocular VEGF level, and therefore intravitreal anti-VEGF injection can be a valuable adjunctive treatment in combination with laser photocoagulation or cryotherapy to reduce leakage and prevent neovascular complications.<sup>88,97</sup> Sigler et al.<sup>92</sup> recommend injection of 1.25 mg/0.05 mL bevacizumab, followed by argon laser photocoagulation in a single session. Alternatively the

use of ranibizumab in a dose of 0.5 mg (0.05 mL) is possible.<sup>98</sup> The authors performed intravitreal injection in nine eyes in patients who suffered from Coats disease in stage 3B and 4 after transscleral subretinal fluid drainage by using a 30G needle; additional photocoagulation (up to 7 times) or cryocoagulation (up to 10 times) were performed and eight eyes achieved retinal reattachment. Another recent study<sup>99</sup> described the treatment of 24 eyes suffering from stage 3 Coats disease via a two-port pars plana nonvitrectomy approach; two incisions were made 3 mm posterior to the corneal limbus, and laser was applied directly on the abnormal blood vessels. Additional subretinal fluid was drained, and 17 eyes received intravitreal anti-VEGF-injections. In 96% of treated eyes the retina reattached. A further study<sup>100</sup> described 14 pediatric eyes with Coats disease in stage 2, 3A, and 3B after primary intravitreal injection of 1.25 mg bevacizumab; partial resorption of subretinal fluid and partial regression of exudates, and telangiectasis were observed, but additional laser photocoagulation or cryocoagulation was performed.

Other authors<sup>101</sup> observed the development of vitreoretinal fibrosis and traction retinal detachment in four of eight eyes with stage 2 to 3B disease treated with bevacizumab and adjuvant modalities, others<sup>102</sup> had seen fibrotic vitreoretinopathy in five of nine eyes after injection of ranibizumab and adjuvant treatment. The development of vitreoretinal fibrosis and traction was a common complication after anti-VEGF and adjuvant treatment.

The optimal time period between injection and coagulation treatment is unclear. Most authors used a dosage for bevacizumab of 1.25 mg/0.1 mL (14–17 years old)<sup>92,100,101</sup> to 2.5 mg/0.1 mL (6 months to 12 years old).<sup>103</sup> Patients received up to three injections.

It is paramount that ophthalmologists maintain a high clinical suspicion for the possibility of retinoblastoma before performing an injection that could spread tumor cells to the subconjunctival space and orbit.<sup>92,104</sup> Unless the retina and the abnormal telangiectatic vessels found in Coats disease can be examined by indirect ophthalmoscopy, no injection should be performed, even with the absence of calcification on B-scan. Furthermore, a diffuse infiltrating retinoblastoma and advanced Coats disease can be indistinguishable from each other on magnetic resonance imaging.

Therefore, enucleation should usually be performed in patients with poor visual potential and when it is impossible to rule out the possibility of retinoblastoma.<sup>105</sup>

## Hereditary Vitreoretinopathies

### Stickler Syndrome

Hereditary vitreoretinopathies are potentially blinding disorders characterized by an abnormal-appearing vitreous gel with associated retinal changes. Stickler et al.<sup>106,107</sup> described an autosomal dominant disorder with characteristic ophthalmologic and systemic abnormalities, orofacial features, deafness, and arthritis. Abnormalities of vitreous gel architecture are a pathognomonic feature, usually associated with high myopia, which is congenital and nonprogressive, and cataract (Fig. 119.8). Nonocular features show great variation in expression. Stickler syndrome type 1 (STL1) arises due to mutations in *COL2A1* gene and shows membranous vitreous phenotype, while type 2 (STL2) disease arises from mutations in *COL11A1* and affected patients have a fibrillar appearance of the vitreous.<sup>108</sup> Only patients with STL1 or STL2 show ocular changes. An ocular-only variants will have minimal or no associated systemic features; this subgroup exhibits mutations in *COL2A1* too,<sup>109</sup> whereas STL3 and STL 4 patients have no eye problems. More than 80% of affected patients have STL1.<sup>109,110</sup> Retinal features of Stickler syndrome are radial perivascular pigmented retinal degenerations, lattice degeneration, anterior giant retinal tears, and posterior retinal tears. The first retinal detachment (RD) is usually observed between the ages of 10 and 30 years; 8% of affected children have RD between 0 and 9 years, and 26% between the ages of 10 and 19 years.<sup>107,111</sup>

**FIG. 119.8** (A) Type 1 vitreous gel anomaly in an 11-year-old girl with Stickler syndrome; within 9 months the patient developed retinal detachment in both eyes. (B) The child suffered from sensorineural hearing deficit and high myopia and at birth showed a midline cleft of the hard and soft palate.

With a high rate of bilateral spontaneous retinal detachment, “unaffected” family members without retinal detachment or other associated symptoms of Stickler syndrome should be approached and offered molecular genetic analysis to rule out the presence and type of Stickler syndrome and should be examined regularly.<sup>112</sup>

Positive effects of prophylactic intervention have been described.<sup>109,110,113,114</sup> In a recent systematic review,<sup>112</sup> two principal retrospective cohort studies with control groups in populations with STL1 were analyzed. One study evaluated 360° cryotherapy ( $n=204$ ) on the post-oral retina and reported a statistically significant lower rate in the treatment group compared with the untreated STL1 group ( $n = 22$ ). Leiba et al.<sup>114</sup> performed a subgroup analysis based on age and reported that 0/6 eyes treated prophylactically by laser coagulation (circumferential treatment for eyes with extensive contiguous retinal lesions where lesions were present in at least three quadrants; focal laser treatment for eyes with small localized lesions of lattice degeneration or isolated breaks) in children aged  $\leq 13$  years detached compared with 1/4 eyes treated prophylactically in children aged  $\geq 13$  years. In the control group, which did not receive any prophylaxis, the retina detached in 46% eyes of children aged  $\leq 13$  year and in 60% of adolescents and adults aged  $\geq 13$  years in the follow-up of 1–15 years. However,

both studies were subject to a high risk of bias, and the optimal age for prophylaxis is uncertain.<sup>112</sup>

Despite complicated surgery and often multiple procedures, Stickler patients undergoing primary vitrectomy for rhegmatogenous detachment have good anatomic outcomes as well as useful functional visual results in comparison to outcomes of scleral buckling. Vitrectomy may be considered as the operation of choice in the Stickler group.<sup>111</sup> Almost three-quarters of redetachments occur within the first 4 postoperative months. Complications are predominantly redetachment and subsequently multiple surgeries. As such, the use of primary vitrectomy to improve the primary success rate is also likely to reduce the overall complication rate.

## **Kniest Dysplasia**

Kniest dysplasia is inherited in an autosomal dominant manner and presents with kyphoscoliosis, severe short-trunked dwarfism, cleft palate, flat face, hearing defects, and joint contractures.<sup>115-117</sup> Kniest dysplasia is associated with heterozygous (frequently de novo) *COL2A1* mutations. Patients with Kniest dysplasia have severe congenital myopia and vitreoretinal degeneration. The vitreous cavity contains fibrous, clouded, membranous structures floating in the retrolental space (Fig. 119.9). Other eyes have cortical and posterior subcapsular opacity of the lens, and also veil-like vitreous opacities in the periphery. The common retinal changes include perivascular lattice degeneration and white without pressure of various degrees. Bullous retinal detachment with Kniest dysplasia can be treated successfully, especially by vitreous surgery with silicone oil tamponade.<sup>118</sup>

**FIG. 119.9** (A,D) A 7-year-old girl with Kniest syndrome presented with a bilateral retinal detachment in both eyes. (C) The patient has characteristic severe short-trunked dwarfism, kyphoscoliosis, flat face, joint contractures, and sensorineural hearing defect; she is not able to walk and uses the vehicle for transport. (B,E) After cerclage, vitrectomy, and silicone oil tamponade, the retinas were reattached.

## Familial Exudative Vitreoretinopathy

Familial exudative vitreoretinopathy (FEVR) is a bilateral disorder of aberrant peripheral retinal development, including peripheral avascular retina, abnormal vascularization with retinal neovascularization, subretinal exudation, formation of an abnormal vitreoretinal interface, and retinal detachment (Fig. 119.10). The phenotype of FEVR resembles a form fruste of ROP, occurring in a larger and often term infant. Inheritance is autosomal dominant, autosomal recessive, or X-linked, or can affect individuals with no family history. Five genes have so far been identified that cause FEVR: *NDP*, *FZD4*, *LRP5*, *TSPAN12*, and *ZNF408*.<sup>119</sup> Aberrant vasculogenesis and subsequent abnormal angiogenesis are thought to cause the vitreoretinal abnormalities in FEVR.<sup>120</sup> FEVR patients have a mutation in the Norrie disease gene. This results in dysregulation of the Wnt-receptor/ $\beta$ -catenin pathway and has been associated with increased levels of vascular endothelial growth factor (VEGF). These can potentially explain the lifelong chronic

nature of FEVR, which is characterized by exacerbations in exudation secondary to upregulated vascular activity. The clinical classification is based on five stages. Wide-field angiography demonstrates aberrant circumferential peripheral vessels, venous and arterial tortuosity, late-phase disc leakage, central and peripheral telangiectasis, capillary anomalies, and capillary agenesis.<sup>121,122</sup>

**FIG. 119.10** Familial exudative vitreoretinopathy in a 13-year-old girl. (A) V-shaped area of avascular retinal periphery with extraretinal vascularization in stage 2. (B) Angiography shows avascular retinal periphery and leakage of the abnormal vessels. (C) The fundus of the same patient after photocoagulation. (D) A 9-year-old girl with familial exudative vitreoretinopathy with tractional retinal detachment involving the fovea and with subretinal exudates (stage 4) was subjected to pars plana vitrectomy, laser coagulation, and silicone oil injection (E).

Systemic associations are absent. The management of FEVR is similar to that for ROP: in the early stages, peripheral coagulation by laser or cryocoagulation of the avascular retinal periphery is used to reduce subretinal and intraretinal exudation. The presence of angiographic leakage, especially at the site of vascular–avascular junction, warrants prompt laser ablation of the area (green or red laser to the area of leakage and 0.5-disc- to 1-disc-diameter area surrounding it).<sup>122</sup> Anti-VEGF therapy may provide a valuable adjunctive treatment for FEVR. In one study,<sup>123</sup> three children (6–14 years), with persistent vascular activity and increasing exudation, despite aggressive laser photocoagulation and cryocoagulation, were successfully treated by intravitreal injection of pegaptanib sodium (Macugen; 0.3 mg per 0.09 mL). All patients showed a reduction of exudation, but two children developed vitreous hemorrhage due to traction retinal detachment and needed pars plana vitrectomy. After injection of bevacizumab (Avastin; 1.25 mg per 0.05 mL) in an adult patient, rapid regression and accelerated fibrosis of neovascular tissues was observed.<sup>124</sup>

In traction retinal detachment, scleral buckling should be performed in cases with peripheral traction anterior to the equator,<sup>125</sup> and vitreoretinal surgery is indicated to release posterior vitreous traction. The vitreoretinal adhesions are so strong in the peripheral avascular area that iatrogenic retinal breaks occur easily. A bimanual technique with vitreous scissors and forceps is preferred to dissect the vitreous membranes from the retinal surface. Dissection of the vitreous in the peripheral avascular area is very difficult, and if this procedure cannot successfully be performed, the prognosis is poor.<sup>121,126</sup> If an eye is symptomatic in the first 3 years of life, the prognosis is poor. Fibrovascular proliferation has a rich vascular component in patients younger than 3 years, and collagen fibers become more evident with advancing age.<sup>125</sup> Vitreoretinal surgery can preserve some degree of vision in FEVR patients but amblyopia, re-proliferation, and vitreous hemorrhage may limit long-term visual improvement.<sup>127</sup> The ultimate goal of prophylactic laser treatment in FEVR is the prevention of retinal detachment or secondary macular exudate.

## **Marfan Syndrome**

Retinal detachment is the most serious eye complication, occurring in up to 25% of patients with Marfan syndrome. A total of 75% of retinal detachments occur before patients are 20 years old.<sup>128</sup> Retinal detachment in Marfan syndrome is bilateral in about one-third of cases. Most Marfan syndrome patients with retinal detachment have a subluxated lens or have undergone previous lens surgery. Therefore, these patients should be checked especially carefully.<sup>129</sup>

Retinal detachment surgery can be complicated by insufficient pupil dilation, ectopia lentis, and multiple retinal breaks.<sup>130</sup> The edge of the clear or cataractous subluxated lens hampers evaluation of the peripheral fundus.

Primary scleral buckling is recommended if the clear lens is in proper position; if the clear subluxated lens is not interfering with visualization of fundus details; or if the retinal breaks are located near or anterior to the equator. The placement of scleral sutures for buckling is challenging due to the thin and collapsible sclera.

Vitreous surgery should be considered in the following situations: failed scleral buckling; proliferative vitreoretinopathy; a posteriorly dislocated lens; a subluxated or cataractous lens not allowing an adequate evaluation of the fundus periphery; and giant retinal tears.<sup>131</sup> Due to the thin sclera, the use of trochars should be avoided.

The results of surgery vary depending on the nature of the retinal tear and the presence of PVR. Generally, the results are comparable with those patients without Marfan syndrome and successful reattachment of the retina is achieved in 86%<sup>131</sup> to 100%<sup>130</sup> of cases. But poorer visual outcome is likely to be encountered when there is concomitant lens dislocation or a history of intraocular surgery.<sup>130</sup> The increased incidence of high myopia and peripheral lattice degeneration predisposes these eyes to retinal breaks. According to some authors the high bilateral rate of retinal detachment may justify prophylactic laser treatment of lattice degenerations in the fellow eye of these patients.<sup>130,132</sup>

## **Congenital X-Linked Retinoschisis**

Congenital X-linked retinoschisis (CX-LRS) is an inherited retinal disease characterized by abnormal Müller cell pillars that allow schisis cavities to form. In 98–100% of the cases, these cavities in the

foveal area, and the peripheral retinoschisis, usually inferotemporal, is present in about 50% of cases and is associated with severe vision-threatening complications, such as vitreous hemorrhage and retinal detachment. The most severe disease form, which manifests as bullous, peripheral retinoschisis cavities, occurs primarily in patients younger than 10 years. The age of onset follows a bimodal distribution with one group of patients presenting in infancy with strabismus and nystagmus and a second group with poor vision and reading difficulties presenting at school age.<sup>133</sup> There are a few case reports on children suffering from retinoschisis in the first year of life. In a series of five children who presented in the first 18 months of life, highly elevated bullous retinoschisis involving the macula was observed. In 9 of 10 eyes of these patients, the bullous retinoschisis cavity flattened, leaving only pigment demarcation lines within an observation time of 1–6.5 years.<sup>134</sup> Surgical intervention for congenital retinoschisis is frequently recommended under certain clinical conditions: rapid progression of the peripheral schisis cavity involving or threatening the macula, obscuration of the macula by the overhanging inner wall of a schisis cavity, dense nonclearing vitreous hemorrhage with a large schisis cavity hemorrhage, schisis combined with rhegmatogenous retinal detachment, and schisis combined with tractional retinal detachment, and macular pucker.<sup>135</sup> Prenner et al.<sup>136</sup> developed a new classification system for CX-LRS based on an improved understanding of the underlying pathologic lesion, and identified better surgical approaches (Table 119.6).

**TABLE 119.6**  
**Classification System for CXLRS**

CXLS Type	Foveal Cystic Schisis Clinical Examination	Flat or Lamellar Macula Schisis OCT Finding	Peripheral Schisis (Clinical Examination)
Type 1 foveal	+	–	–
Type 2 foveolamellar	+	+	–
Type 3 complex	+	+	+
Type 4 foveoperipheral	+	–	+

CXLRS, congenital X-linked retinoschisis; OCT, optical coherence tomography.

Congenital X-linked retinoschisis classification system. *Retina* 2006;26:S61–4.

Recent studies advocate vitrectomy for a bullous schisis cavity with or without hemorrhage in children with successful surgically induced posterior vitreous detachment.<sup>135,137,138</sup> García-Arumí et al.<sup>137</sup> performed posterior hyaloid dissection after injection of 0.05 mL of diluted preservative-free triamcinolone acetonide in an 8-month-old child. Trese<sup>139</sup> describes the adjuvant use of autologous plasmin for hyaloid separation. In pediatric eyes it is very difficult to mechanically achieve a complete posterior vitreous detachment. In most cases, the only way to relieve the vitreous traction is to remove the inner wall of the retinoschisis, since there is no effective way to remove the posterior cortical vitreous in children.<sup>140,141</sup> Because the area of retinoschisis corresponds to an absolute scotoma on the visual field, removing the inner wall of retinoschisis has no effect on the patient's visual field,<sup>140</sup> but it results in loss of retinal ganglion cells and interneurons, eliminating any chance for future schisis cavity adhesion. Furthermore, eyes that undergo inner-wall retinotomy are prone to proliferation along the anterior leaflet of the schisis. Trese recommends the application of autologous plasmin, since this method eliminates the need for inner-wall retinectomy in up to 82% of eyes.<sup>139</sup> They performed inner-wall retinectomy on eyes with type 4 CX-LRS only. Incision into the inner wall of the schisis cavity should be performed 2–3 mm anterior to the posterior border of the schisis cavity; some authors describe fluid drainage by use of a 42G cannula.<sup>137</sup> Photocoagulation should be applied to the border of the attached retina and the schisis cavity to prevent the progression of retinal splitting. Gas or silicone can be used for postoperative tamponade. Silicone oil is particularly recommended for younger children.

Authors described postoperative retinal reattachment in the pediatric eyes, but the functional results are limited; the visual acuity improved in only 53% of cases, best reported postoperative visual acuity was 20/50 attained by a 6-year-old child.<sup>137,141</sup> In a series of cases, the main indication for unilateral vitrectomy in a 7-year-old and bilaterally in a 17-year-old was foveal retinoschisis, which was associated with peripheral retinoschisis or peripheral inner holes. The vitreous surgery consisted of core vitrectomy, surgically induced posterior vitreous detachment, removal of the

ILM, and a 30% sulfur hexafluoride gas tamponade. Restoration of the foveal depression with flattening of the schisis cavity was achieved in the first surgery in all three eyes, and visual acuity improved in all cases. The anatomic result was normal foveal configuration with small cystoid spaces in the retina layer, but negative b-waves persisted in the affected eyes even 3 years after clinical resolution of the retinoschisis due to the inability of the intraretinal nerve fibers to reconnect despite repositioning of the retinoschisis.<sup>138</sup>

Others<sup>142</sup> reported results of vitrectomy with surgery-induced PVD in 17 eyes in which the premacular vitreous cortex was removed and the ILM of 2 to 3 disc diameters around the fovea was peeled. The authors avoid ILM-peeling over the very weakened retinoschisis area. Finally they used C<sub>3</sub>F<sub>8</sub> gas tamponade. In all operated eyes the macular schisis cavity resolved and mean visual acuity increased from 20/125 to 20/55.

Rhegmatogenous retinal detachment in retinoschisis occurs if outer- and inner-wall holes develop in an area of peripheral schisis. The surgical principle is to coagulate outer-wall breaks and perform scleral buckling, if the location and size of the outer-wall breaks allow for support along the element. The reported advantage of scleral buckling is that it is less invasive than vitrectomy and provides support to the vitreous base. If scleral buckling fails, vitrectomy is recommended because it allows improved treatment of the outer-wall break with laser after internal drainage and flattening the retina.<sup>135</sup> An additional indication for vitrectomy is tractional retinal detachment. In such cases, a combination of primary scleral buckling and vitrectomy is usually recommended. The surgical approach is scleral buckling for retinal detachment, particularly in the absence of PVR and in which the outer wall holes are located anterior to the equator and vitrectomy for vitreous hemorrhage or PVR. PVR is the major reason for reoperation, and multiple operations and the use of advanced vitreoretinal techniques to manage PVR-related complications are necessary for ultimate success in certain cases.<sup>143</sup>

## **Knobloch Syndrome**

Knobloch syndrome is a recessive syndrome of hereditary

vitreoretinal degeneration with retinal detachment, high myopia, cataract, telecanthus, hypertelorism, and a high-arched palate.<sup>144</sup> There is also a defect of the anterior midline scalp with involvement of the frontal bone. The presence of a congenital midline scalp defect should alert the clinician to possible underlying central nervous system and/or ocular pathology and should lead to consideration of further diagnostic evaluations and prophylactic measures. It has been reported that fellow eyes should be treated with prophylactic retinal cryotherapy, although the value of such therapy is unproven.<sup>145,146</sup>

## **Incontinentia Pigmenti**

Incontinentia pigmenti is a rare, X-linked, dominant disorder in which affected female infants develop characteristic abnormalities of the skin, central nervous system, hair, teeth, and eyes. Ocular abnormalities occur in about 35% of patients<sup>147,148</sup> and consist of nystagmus, strabismus, microphthalmos, ptosis, blue sclera, pigmentation of the conjunctiva, corneal changes, cataract, optic atrophy, vitreous hemorrhage, myopia, and in 11.5% of cases, fibroblastic retinal detachment secondary to ischemic vasculopathy similar in appearance to retinopathy of prematurity. Fluorescein angiography indicates profound peripheral retinal ischemia and abnormal arteriovenous connections in these eyes. The affected cases develop neovascularizations, followed by preretinal fibrotic tissue at the temporal equator, and in a late stage, an extensive fibrovascular tissue pulls the retina anteriorly behind the lens. It seems likely that most retinal detachments occur within the first year of life, and all retinal detachments occur within the first 3 years of life. Most of the ocular abnormalities are unilateral, and in those with bilateral involvement one eye is usually less affected. Patients with *NEMO* mutation may have an increased risk of retinal pathology.<sup>149</sup> For affected babies, retinal screening should usually be performed under anesthesia as soon as possible after birth, and fluorescein angiography should be performed when areas of avascular peripheral retina are noted by indirect ophthalmoscopy. Therapeutic intervention with indirect laser photocoagulation to the peripheral ischemic retina should usually be performed as soon as the diagnosis is made; some authors describe successful resolution

of the vasculopathy after early laser photocoagulation.<sup>150</sup> Today, the intravitreal injection of anti-VEGF could be a further adjunctive treatment option. Five days after intravitreal injection of 1.25 mg/0.05 mL bevacizumab in an 11-month-old boy, extensive neovascularization transformed into sclerotic ghost vessels, and vitrectomy was facilitated.<sup>151</sup>

## Norrie Disease

Norrie disease is a bilateral X-linked recessive syndrome of ocular dysgenesis with progressive auditory and mental impairment. Norrie disease is believed to result from mutations in the 28-kb Norrie disease protein (*NDP*) gene, located on chromosome Xp11.3.<sup>152</sup> The disease is characterized by a retinal falciform fold, retinal detachment, repeated vitreous hemorrhage, retrolental membrane formation, and finally clinical progression from these early retinal and vitreous changes to the more typical retrolental detached retina. There are large areas of avascular retina, but without neovascularization. Walsh et al.<sup>153</sup> hypothesize that the avascular retina is so dysgenic that it does not produce a significant vascular endothelial growth factor response, and they do not perform photo- or cryocoagulation. They recommend early diagnosis and vitrectomy to avoid the dismal natural history of Norrie disease, namely, no light perception (NLP) vision and phthisis. Dysplastic retina can be flattened by vitrectomy; children who achieved light perception were operated at a median age of 3.5 months (1 week to 14 months).<sup>153,154</sup>

## Anomalies of the Papilla

Several cavitory anomalies of the optic disc, including optic nerve coloboma, morning glory anomaly, and optic pit, are congenital disc abnormalities secondary to a colobomatous malformation of the optic nerve head. Molecular biology allows detection of the mutations in the *PAX2* gene in approximately 50% of cases. The observation of cavitory anomalies of the optic disc and/or coloboma of the fundus or related abnormality usually stimulates nephrologic investigations to check for renal hypoplasia, a potentially life-threatening disease.<sup>155</sup>

The cavity anomalies of the optic pit can be associated with the

development of a schisis-like thickening and serous macular detachment, most commonly in the second to fourth decades, onset in the early childhood has been reported in rare cases.<sup>156</sup> The unifying anatomic theme of these anomalies is the presence of a scleral (or lamina cribrosa) defect permitting anomalous communications between intraocular and extraocular spaces. These communications enable the critical pathogenic mechanism responsible for dynamic fluctuations in the gradient between intraocular and intracranial pressures that direct the movement of fluid (vitreous humor or cerebrospinal fluid) into and under the retina.<sup>155</sup>

As a result of abnormal anatomic features, the vitreous, subretinal, subarachnoid, and possibly orbital spaces may be variably interconnected through the relatively compliant and porous tissues comprising the excavated disc anomaly.<sup>155</sup>

Morning-glory disc is a unilateral markedly enlarged optic papilla with funnel-shaped excavation involving the optic disc and peripapillary retina. Furthermore it is characterized by a radial arrangement of retinal vessels, glial hyperplasia over the center of the disc, and a rim of elevated peripapillary pigmented tissue.

Morning-glory disc anomaly is a descriptive classification for a characteristic lesion of the optic nerve that is often associated with serous retinal detachment. Systemic associations are present in some patients. A wide range of posterior segment abnormalities can be observed. Retinal detachment occurs in one-third of cases and can be associated with a break at the optic disc margin<sup>157</sup> or within the optic disc cup.<sup>158</sup> Detachment may be limited to the peripapillary retina or be extensive. Retinal detachment is usually seen after the first year of life. The benefit of vitreous surgery with drainage of subretinal fluid, gas tamponade, or silicone oil, and peripapillary photocoagulation has been established.<sup>159</sup>

Congenital pits of the optic nerve vary in size, shape, depth, and location. They often appear as small, hypopigmented, yellow or whitish, oval or round excavated defects, most often within the inferior temporal portion of the optic cup. They are bilateral in 15% of patients, covered or filled with a veil of tissue. Some 40–60% of patients with optic pits develop nonrhegmatogenous serous macular detachments. A tear in the diaphanous tissue overlying the

optic nerve pit may be responsible for the development of this problem,<sup>160</sup> which is consistent with findings in similar conditions, such as retinal detachment, in association with chorioretinal coloboma. These tears may be quite subtle, and careful biomicroscopic examination is required to appreciate them. Initially, conservative management is recommended, as 25% of optic disc pit maculopathies resolve spontaneously (Figs. 119.11A–C).<sup>161</sup> The value of laser photocoagulation alone along the temporal disc margin is not very convincing, since even worse retinal detachments or redetachments have been observed.<sup>155,161</sup>

**FIG. 119.11** (A) Optical coherence tomography (OCT) of a 12-year-old boy with congenital pit of the optic nerve and serous macular detachment. (B) After 5 months, OCT demonstrates the spontaneous reattachment. (C) Fundus photograph shows the congenital pit of the optic nerve after regression of the

serous maculopathy. (D) A 14-year-old boy suffered from trisomy 22, the “cat-eye syndrome,” uveal coloboma of both eyes was associated on the left eye (E) with microphthalmus. The boy wears a flat glass prosthesis over the microphthalmic eye. (F) Retinal detachment in the right eye was treated by vitrectomy, cerclage, endolaser coagulation, and silicone oil tamponade. Two years after silicone oil removal, the eye shows retinal stability, a laser barrier after gentle laser coagulation seals the junction between the intercalary membrane and extra colobomatous retina.

In recent reviews of results of vitreoretinal surgery for treatment of an optic pit maculopathy, the most widely accepted treatment for both adult patients and children is a pars plana vitrectomy.<sup>155,161,162</sup>

There are several case reports on successfully performed vitrectomies in children aged 7–16 years old.<sup>160–163</sup> The removal of the posterior hyaloid face from the macula is an essential element of successful treatment, but this may be difficult to achieve in pediatric eyes. Georgalas et al.<sup>164</sup> reported that surgical PVD seemed impossible in the case of a 5-year-old boy with optic disc pit maculopathy, and therefore the posterior vitreous was peeled off from the macular area within the retinal arcades and air was used as an endotamponade. ILM peel may not improve outcomes, and no difference between short- or long-acting gas tamponade was observed in one report.<sup>162</sup> Others<sup>165</sup> found that vitrectomy alone without gas tamponade and laser photocoagulation is a safe and effective method for management of serous macular detachment resulting from optic pit.

Some authors<sup>165,166,167</sup> performed laser photocoagulation in the peripapillary area during vitrectomy, but more recent studies<sup>162,168</sup> found that vitrectomy with juxtapapillary laser coagulation had similar functional and anatomic outcomes compared with vitrectomy without juxtapapillary laser coagulation. Some authors<sup>155</sup> recommend a carefully titrated juxtapapillary laser photocoagulation (4 to 5 confluent rows in the temporal juxtapapillary area) with slit-lamp (647 nm) laserlight with a 200 µm spot size performed 1–2 hours before vitrectomy. As an alternative to laser photocoagulation, the successful use of a small plug of autologous sclera to create a barrier to the passage of

vitreous fluid into large optic pits was described in a 11- and 15-year-old patient.<sup>156</sup>

Migration of gas or silicone oil into the subretinal space has been reported as a surgical complication.<sup>169</sup> Furthermore, intracranial migration of silicone oil after vitreoretinal surgery for the treatment of optic disc maculopathy has been described.<sup>170</sup> Therefore, if possible, a gas tamponade should preferably be used.

## **Coloboma**

Coloboma of the fundus is a congenital defect caused by the faulty closure of the embryonal fissure. It occurs in 0.14% of the general population.<sup>171</sup> The literature quotes a 40% occurrence of retinal detachment in these patients, typically in the second decade of life.<sup>172</sup> Near the margin of the coloboma, the retina splits into two layers.<sup>173</sup> The inner layer continues as an intercalary membrane on to the coloboma, while the outer layer turns back, becomes disorganized, and fuses with the retinal pigment epithelium. The choroid is terminated as a distinct pigmented layer peripheral to this point of reversal. The split in the retinal layer has been identified at the level of inner nuclear layer or outer plexiform layer, or both. The junction where this reversal occurs is a locus minoris resistentiae. The intercalary membrane progressively becomes thinner as it is traced centrally. Breaks can occur at the junction and in the intercalary membrane. Peripheral retinal breaks are also observed. The preferred technique for treatment of retinal detachment associated with choroidal coloboma is vitrectomy with either long-acting gas or oil tamponade. The use of silicone oil has the advantage of being a long-term tamponade of the entire colobomatous border.

Breaks in the intercalary membrane can be identified pre- or intraoperatively, whereas the breaks at the locus minoris resistentiae are not identifiable but can be expected to be located along the coloboma border. Treatment of the pigmented fundus just beyond the coloboma with laser should close these breaks and eliminates the need to close the breaks in the intercalary membrane. The diode laser is preferred to the argon laser because it is less likely to damage the nerve fiber layer. Tansu et al. recommend an endolaser barrier of three to four rows along the border of the

coloboma. Near the optic disc and papillomacular bundle we perform a gentle endolaser coagulation as consistent with other authors.<sup>174</sup> If adequate chorioretinal adhesion can be achieved around the coloboma, laser of the papillomacular bundle and optic disc may not be necessary (Figs. 119.11D–F).<sup>175</sup> After vitrectomy and silicone oil removal, OCT showed persistent detachment of the intercalary membrane in most patients. These findings emphasize the importance of sealing the junction between the intercalary membrane and extra colobomatous retina with a laser barrier.<sup>174</sup>

The placement of an encircling band is performed on a purely empirical basis. Several authors observed no difference in the outcome between the buckled and nonbuckled eyes. Peripheral laser photocoagulation along the ora serrata may reduce the risk of recurrent retinal detachment after silicone oil removal.<sup>172,175</sup>

## **Persistent Hyperplastic Primary Vitreous**

Persistent hyperplastic primary vitreous (PHPV), also known as persistent fetal vasculature, is a congenital anomaly of the eye that results from failure of the embryologic, primary vitreous, and the hyaloid vasculature to regress. It typically presents unilaterally, without associated systemic findings in normal full-term infants. In rare cases, bilateral PHPV has also been described.<sup>176</sup> Most cases of PHPV are sporadic, but it can be inherited as an autosomal dominant or recessive trait.<sup>177</sup> PHPV is subclassified into three types: (1) most often an anterior PHPV (retrolental fibrovascular membrane, elongated ciliary processes, cataract, microphthalmia); (2) posterior PHPV (vitreous membrane and stalk, retinal fold, traction retinal detachment, hypoplastic optic nerve and macula, microphthalmia); (3) a combination of anterior and posterior PHPV (Fig. 119.12). Without surgery, most eyes with PHPV will develop severe glaucoma, retinal detachment, intraocular hemorrhage, and/or phthisis early in life. If it is left untreated, enucleation may become necessary. To prevent these complications, many authors recommend vitreoretinal surgery without delay if light perception is present, especially in rare cases of bilateral PHPV.<sup>178</sup> But in eyes with severe PHPV with an unrecordable visual evoked potential, no light perception, and intense afferent pupillary defect, an operation should not be performed.<sup>179</sup> Indications for surgical intervention

include recurrent or severe intravitreal hemorrhage, retinal detachment, progressive shallowing of the anterior chamber, and uncontrolled pressure secondary to anterior chamber angle closure.<sup>180</sup> The vitrectomy port location should be varied according to the age of the child, but in these often microphthalmic eyes, the ora serrata may be anteriorly displaced, the pars plana may be absent, or the anterior retina may insert directly onto the pars plicata ciliary body. It is recommended to place the sclerotomies as anteriorly as possible, especially if retinal detachment is determined by preoperative ultrasonography.<sup>181</sup> Transillumination is occasionally helpful to locate the ora serrata. To avoid manipulations of the vitreous base or peripheral retina, which may be drawn anteriorly, other authors prefer an approach for vitrectomy through the iris root; incisions are made at the limbus, but this is associated with the danger of severe iris lesions. After lensectomy, diathermy should be used when vessels are visible and the retrolental membrane has to be cut from the ciliary processes using the vitreous cutter. In case of nonaxial lens opacification, lens-sparing vitrectomy should be performed, and Shaikh and Trese<sup>182</sup> recommend dividing the stalk immediately on entry. After division of the stalk and hemostasis, with diathermy if necessary, vitrectomy should be carried out with dissection of epiretinal membranes in the posterior pole. The authors presume that the manipulation of the stalk by vitrectomy and diathermy before division result in damage to the lens capsule and resultant cataract formation.

**FIG. 119.12** (A) Lensectomy of congenital cataract via pars plan approach. (B) After aspiration of lens material dense capsular opacity and stalk of posterior persistent hyperplastic primary vitreous was visible. (C) The postoperative fundus photograph shows remnants of the central stalk and (D) capsular bag after anterior and posterior capsulorhexis.

Membrane peeling is necessary in cases of traction retinal folds or traction detachment. In the purely anterior form, the cataract should be removed to provide clear media for visual rehabilitation. Eyes with a posterior PHPV have poor visual results due to posterior pole abnormalities. However, despite posterior segment involvement, surgical treatment of PHPV can result in functional visual outcome. The degree of ocular malformation, however, will ultimately limit the amount of visual improvement. A total of 71% of patients undergoing vitrectomy for a combined form of anterior and posterior PHPV achieved 20/300 or better.<sup>181</sup> In another

study,<sup>179</sup> six of 24 eyes operated for PHPV maintained Snellen visual acuity and approximately 50% of patients undergoing surgery for persistent fetal vasculature may achieve useful vision. In a series of patients suffering from the rare condition of bilateral combined anterior and posterior PHPV, Walsh et al.<sup>178</sup> found that vitrectomy with or without lensectomy is beneficial: 69% of patients maintained at least light perception vision in at least one eye at the last follow-up. Of the 28 operated eyes in 16 patients with follow-up data, only 11% of eyes were phthisical at the last follow-up. A more recent study<sup>180</sup> suggested that early intervention at younger than or equal to 13 months of age offers improved visual potential. Their data suggest that a period of retinal “physical plasticity” extends to at least 13 months of age. All 10 patients who received surgical intervention within this time had reattachment of the retina with reversal of retinal dragging and decreased retinal folds. After surgery, every child should have a short trial (2 months) of occlusion therapy. This can be terminated if no visual improvement is noted, to avoid undue psychosocial impairment.<sup>181</sup> Early age at surgery, prompt optical correction with contact lens, and aggressive occlusion therapy are required for successful visual rehabilitation.

## **Retinopathy of Prematurity (ROP)**

ROP is discussed in [Chapter 118, Retinopathy of prematurity](#).

## **Conclusions**

Both the feasibility of surgical intervention and the growing sophistication of genetic counseling have created a renewed interest in the field of pediatric vitrectomy. The result is likely to be improved understanding of elusive truths that surround functional ocular development. The intravitreal use of VEGF inhibitors to treat vasoproliferative retinopathy in children is a new effective tool, but further results on safety and side-effects are needed. In addition, the use of pharmacologic agents to assist in detaching the cortical vitreous from the retina will hopefully improve outcomes in the future. Surgical innovations and disease-specific treatment strategies will improve the results in these patients.

**Introduction**

**Epiretinal Membranes**

**Vitreomacular Traction and Cystoid Macular Edema**

**Conclusion**

## **Introduction**

Disorders of the vitreomacular interface include a number of conditions such as macular hole, lamellar hole, vitreomacular traction, cystoid macular edema, and epiretinal membrane.<sup>1</sup> It is

increasingly recognized that these conditions lie on a spectrum of disease caused by abnormalities of the vitreomacular interface. Our understanding of these conditions has increased significantly with the introduction of optical coherence tomography (OCT) and has led to a new classification of vitreomacular adhesion, traction and macular hole based on OCT characteristics.<sup>1</sup> Here we look at each of these conditions as discrete entities, but it should be borne in mind that they have commonalities in both etiology and clinical presentation.

## Epiretinal Membranes

Epiretinal membrane (ERM) is a term used to describe cellular proliferation on the inner retinal surface. Premacular fibroplasia, macular pucker, cellophane maculopathy, and premacular gliosis have all been used to describe this condition. The variety of names given to this disorder reflects the wide spectrum of presentation and clinical findings as ERMs may range from a benign asymptomatic disorder to a condition associated with debilitating metamorphopsia and central visual loss. Appropriate management of patients presenting with an ERM relies on clinicians distinguishing between those that will benefit from surgery and those that will not.

## Prevalence of ERM

Evidence regarding the epidemiology of ERMs predominantly comes from two large population studies, the Beaver Dam Eye Study and the Blue Mountains Eye Study.<sup>2-4</sup> The overall prevalence of ERM in these populations was 7–11.8%, with a 5-year incidence of 5.3%.<sup>2-4</sup> Idiopathic ERMs were bilateral in 19.5–31%, with a 13.5% 5-year incidence of second eye involvement.<sup>2-4</sup>

The age distribution shows a peak between the ages of 70 and 79 (11.6%), with ERMs being uncommon before the age of 60 (1.9%).<sup>4</sup> The increased odds of ERM for persons over the age of 70 compared with those younger than 60 was 7.4.<sup>4</sup> ERMs were more commonly diagnosed in women in the Beaver Dam cohort but not in the Blue Mountains Study, and this difference may merely reflect

the greater survival rate of women in this age group.

The prevalence of ERM appears to vary with ethnicity.<sup>5,6</sup> Higher prevalence was noted in Chinese participants in a multiethnic epidemiologic study (39% in Chinese vs. 27.5% in Caucasians),<sup>6</sup> whereas lower rates have been observed in the Japanese (4%).<sup>5</sup> In the Blue Mountains Study, the prevalence of ERM was significantly increased following cataract surgery (16.8%) and retinal vein occlusion (12.5%);<sup>4</sup> 9.1% of patients with no retinal abnormality at baseline developed an ERM following cataract surgery.<sup>3</sup>

## Classification of ERM

The majority of ERMs have no associated ocular abnormality and are termed idiopathic. ERMs may be classed as secondary when a preexisting or coexisting condition has had a significant impact on development, and iatrogenic if they occur following medical or surgical intervention (Table 120.1).<sup>7</sup>

---

**TABLE 120.1**  
**Classification of Epiretinal Membranes**

---

<b>IDIOPATHIC</b>
<b>Secondary</b>
Retinal vascular disease
Vascular occlusion, e.g., BRVO, CRVO
Diabetic retinopathy
Telangiectasias
Macroaneurysm
Sickle-cell retinopathy
Intraocular inflammation
Trauma
Retinal detachment and retinal tears
Intraocular tumors
Retinal angiomas
Hamartomas
Retinal dystrophies
Retinitis pigmentosa
<b>IATROGENIC</b>
Postoperative
Cataract
Retinal detachment
Silicone oil
Retinopexy
Laser or cryotherapy

BRVO, branch retinal vein occlusion; CRVO, central retinal vein occlusion.

## Clinical Features

ERM is a spectrum of disease and may present in a number of ways.<sup>8</sup> A clinical grading system was proposed by Gass to describe the different stages of the disease.<sup>9</sup>

In Grade 0 (also termed cellophane maculopathy), a translucent membrane with no underlying retinal distortion is observed. These membranes are asymptomatic, and the diagnosis is often an incidental finding during routine examination (Fig. 120.1).

**FIG. 120.1** Color fundus photograph of a Grade 0 epiretinal membrane showing mild abnormality of the macular reflex.

An epiretinal membrane associated with irregular wrinkling of the inner retina is classed as Grade 1 (Fig. 120.2). When this involves the fovea, patients often complain of distorted or blurred vision. These symptoms may only be perceptible when the unaffected eye is covered, particularly if the ERM occurs in the nondominant eye. Other symptoms that patients may report include loss of binocularity, central photopsia, and macropsia and, rarely, monocular diplopia.<sup>8</sup> Eccentric Grade 1 ERMs that do not involve the fovea may be asymptomatic (Fig. 120.3).

**FIG. 120.2** Color fundus photograph of a Grade 1 epiretinal membrane showing vascular tortuosity.

**FIG. 120.3** Color fundus photograph of an eccentric Grade 1 epiretinal membrane.

A Grade 2 ERM is characterized by an opaque membrane causing obscuration of underlying vessels and marked full-thickness retinal distortion (Fig. 120.4). Increasing vascular tortuosity and size of vessel involved tend to be a sign of more advanced disease. ERMs with full-thickness retinal distortion may also be associated with cotton-wool spots, exudates, blot hemorrhages, and microaneurysms (Fig. 120.5). Cystoid macular edema (CME) is present in approximately 20–40% of patients (Fig. 120.6).<sup>10–12</sup> Vascularization of the ERM and underlying RPE disturbance are rare but indicate more severe disease. Although symptoms are more commonly associated with increasing severity of ERM, patients may have significant ERMs and remain asymptomatic.<sup>7</sup> Approximately 80% of patients with Grade 2 ERM will have

symptoms of blurred vision or metamorphopsia.<sup>13</sup>

**FIG. 120.4** Color fundus photograph of a Grade 2 epiretinal membrane, showing an opaque membrane with underlying vascular tortuosity.

**FIG. 120.5** Color fundus photograph of an epiretinal membrane with cotton-wool spots (*arrow*) and intraretinal hemorrhages (*arrowhead*).

**FIG. 120.6** Optical coherence tomography showing presence of intraretinal fluid (*arrowhead*) associated with an epiretinal membrane, which is seen as a hyperreflective layer on the surface (*arrow*).

A posterior vitreous detachment (PVD) is present in approximately 60–90% of patients at the time of diagnosis.<sup>10–12</sup> Those with partial PVD and persistent vitreomacular adhesion (VMA) are more likely to develop CME and present with a lower visual acuity (VA).<sup>12</sup> In cases where a PVD does not exist, the clinical findings may be very similar to those commonly seen in vitreomacular traction syndrome (VMTS). The subsequent evolution of a PVD can result in avulsion of the ERM in ~5% patients, and this may be observed as a “scroll” of tissue at the membrane edge or within the vitreous gel ([Fig. 120.7](#)).<sup>14</sup> Avulsion of the ERM is usually accompanied by a reduction in or resolution of symptoms.

**FIG. 120.7** Color fundus photograph of an avulsed epiretinal membrane in the vitreous cavity.

ERMs may also be associated with macular pseudoholes, lamellar holes, and much less commonly, with full-thickness macular holes,

presumably as a result of tangential traction. It is possible that lamellar holes form when retinal cysts associated with the ERM rupture forming inner neural defects. When contraction of the ERM distorts the underlying retina to form a steepened foveal contour that clinically resembles a macular hole, the term pseudohole is used (Fig. 120.8). This has been described in up to 20% of patients.<sup>15</sup>

**FIG. 120.8** (A) Color fundus photograph of an epiretinal membrane with a pseudohole. (B) Optical coherence tomography showing presence of an epiretinal membrane and a pseudohole.

Although rapid progression of the disease has been described,<sup>16</sup> the usual course is one of stability or slow progression over years with the VA rarely deteriorating below 20/200. In a study by Appiah et al., of 324 idiopathic ERMs with a mean follow-up of 33.6 months, 49.5% maintained a VA within 1 line of the initial acuity, 37.4% showed a reduction in vision, and 13.1% stayed the same.<sup>12</sup> In the Blue Mountains Study, the area of retina occupied by the ERM remained stable in 39%, regressed in 25.7%, and progressed in 28.6% in a 5-year period, where change was defined as a change in area of >25%.

## Pathogenesis

The initiating event or factors responsible for the development of ERM have yet to be elucidated fully; however, there is evidence that ERM formation represents a reactive gliosis in response to retinal injury or disease involving inflammatory and glial cells.

In general terms, ERMs have two main components: an extracellular matrix (consisting of collagen, laminin, tenascin, fibronectin, vitronectin, etc.) and cells of retinal and extra retinal origin (such as glial cells, neurites, retinal pigment epithelium [RPE], immune cells, and fibrocytes).<sup>17,18</sup> The relative abundance of these components within the ERM reflects the underlying etiology, severity of disease, or its duration. For example, ERMs secondary to proliferative vitreoretinopathy (PVR) are more heavily pigmented due to a high RPE content when compared with idiopathic ERMs, which are composed predominantly of glial elements (Fig. 120.9).<sup>19,20</sup> Similarly, ERMs that develop in response to retinal ischemia and neovascular proliferation may have a larger vascular component. Growth factors play an important role in the formation, progression, and transformation of membranes with differential expression being observed in membranes according to their etiology.<sup>21,22</sup> A summary of some of the growth factors involved in the development of idiopathic and secondary ERMs is given in Table 120.2.

**FIG. 120.9** Increased pigmentation observed in proliferative vitreoretinopathy membranes (A) compared with an idiopathic epiretinal membrane (B).

Data taken from Harada C, Mitamura Y, Harada T. The role of cytokines and trophic factors in epiretinal membranes: involvement of signal transduction in glial cells. *Prog Retin Eye Res* 2006;25(2):149-64.

Membranes appear to develop predominantly where Müller cells have proliferated and migrated onto the inner surface of the retina and where hypertrophied cell processes extend towards the vitreous cavity. In idiopathic ERMs, it is possible that vitreous separation at the time of PVD exerts traction on the retina and induces Müller cell gliosis, a process of cellular hypertrophy, upregulation of cellular proteins such as vimentin and GFAP (glial fibrillary acidic protein), and transient cellular proliferation. Müller cells are thought to migrate to the epiretinal surface via small defects in the internal limiting membrane (ILM),<sup>17</sup> which may occur naturally, such as those commonly seen near retinal vessels, or as a result of larger paravascular breaks observed following PVD.<sup>23,24</sup> Activation of Müller cells may continue even once the original stimulus has been withdrawn. In retinal detachment, activated Müller cells, that have penetrated the ILM and migrated on to the epiretinal surface, continue to proliferate even once retinal reattachment is achieved.<sup>25</sup> The degree of cellular proliferation may vary according to the underlying etiology of the ERM, with PVR membranes having the highest proliferation index when labeled with K<sub>i</sub>-67<sup>22</sup> (see [Chapter 31](#), Cellular effects of detachment and

reattachment on the neural retina and the RPE).

Where ERMs form in the absence of PVD, a period of vitreomacular traction may cause chronic irritation of Müller cells inducing gliosis and vascular leakage. In the absence of a PVD, glial cells appear to grow through the posterior hyaloid, which then in turn becomes incorporated into the membrane.<sup>23</sup> This may explain the mechanism behind spontaneous avulsion of ERMs following PVD.

More advanced ERMs have contractile components that exert traction on the underlying retina and distort the retinal vasculature with or without a breakdown of blood–retina barrier and fluid accumulation in the macula. In these membranes a higher content of contractile actin or myofibroblasts is observed. This is also described in some secondary ERMs such as those found in PVR and proliferative diabetic retinopathy (PDR), and in these cases ERMs may lead to detachment of the underlying retina. As the ERM matures the contractile nature of the membrane may change. This is characterized by an alteration in the expression of surface proteins, for example a reduction in GFAP and increase in  $\alpha$ -smooth-muscle actin are associated with increasing contractility.<sup>26</sup>

## Clinical Assessment and Differential Diagnosis

Assessment of patients presenting with an ERM should aim to distinguish an idiopathic ERM from one that is secondary or iatrogenic. A good ophthalmic and general medical history will elicit predisposing factors for secondary or iatrogenic ERMs. A VA that is lower than expected for the degree of ERM present may indicate underlying retinal disease and warrants further clinical investigation. Although idiopathic ERMs can present with small intraretinal hemorrhages, exudates, or cotton-wool spots, the presence of such abnormalities should also alert the clinician to the possibility that an underlying vascular abnormality may also be present.

The diagnosis of an ERM is usually straightforward; however, there are some conditions that may closely resemble an ERM and should be considered when making the diagnosis, such as VMT and

CME.

VMT, like ERM, may cause increased retinal thickness, CME, and lamellar or full-thickness macular holes.<sup>27</sup> ERMs may coexist with VMT in 26–83%, and it has been suggested that this is a distinct subgroup of the condition.<sup>28–30</sup> VMT is said to differ from ERM by the degree of vitreous separation in the midperiphery. In VMT with ERM the vitreous in the midperiphery is detached, whereas in ERM without PVD the vitreous is attached.<sup>31</sup>

CME may also have a similar appearance to an ERM, and it is discussed in more detail later in this chapter. CME differs from an ERM in that there is no distortion of the microvasculature, it is always centered on the fovea, and may be seen on fluorescein angiography as a “star pattern” in late pictures.<sup>8</sup> CME may be the final common pathway of many diseases and may also coexist with ERM, e.g., following a retinal vein occlusion, and management will depend on determining which is the primary condition. ERM surgery is considered if it is thought to be responsible for the CME or if more conservative management has failed.

## Diagnostic Investigations

### Optical Coherence Tomography

Although fluorescein angiography was once the first-line investigation for ERMs, this has now been largely replaced with OCT, detecting ERM in up to 90% of cases.<sup>15,32–34</sup> On OCT, an ERM can be seen as a hyperreflective layer on the surface of the retina. It may be associated with an underlying corrugation of the retinal surface, blunting of the foveal contour (Fig. 120.10), increased retinal thickness, and intraretinal cysts. Idiopathic ERMs tend to be adherent globally to the underlying retina, whereas secondary ERMs are more likely to be characterized by focal retinal adhesion (Fig. 120.11).<sup>35</sup>

**FIG. 120.10** Optical coherence tomography of an epiretinal membrane showing blunting of the foveal contour. The epiretinal membrane is seen as a hyperreflective layer on the retinal surface.

**FIG. 120.11** Optical coherence tomography of a secondary epiretinal membrane showing focal areas of adhesion with the underlying retinal surface.

The introduction of spectral domain OCT (SD-OCT), which offers higher axial resolution, has allowed more precise visualization of the effect of ERM on the underlying retinal layers. This has demonstrated that ERMs are also associated with thickening of the outer retina, increased central foveal thickness (CFT), disruption of the photoreceptor inner/outer-segment junction (IS/OS), and disruption of the cone outer-segment tips (COST).<sup>36-40</sup>

OCT may also be a useful tool to monitor the clinical course of ERMs both prior to and following surgery, and intraoperative OCT has been used at the time of surgery with some success.<sup>41</sup> Following successful ERM surgery macular thickness and foveal contour tend to improve on OCT, although neither returns to normal. This does not, however, preclude a gradual improvement in visual function.<sup>15</sup>

## Fluorescein Angiography

Despite the advantages of OCT, fluorescein angiography (FA) still remains a useful tool, particularly in cases where an underlying vascular event or choroidal neovascular membrane is suspected. FA can highlight the extent of retinal wrinkling, degree of retinal vascular tortuosity, and presence of macular edema (Fig. 120.12). Wise demonstrated diffuse leakage from retinal capillaries or small veins in the late venous phase; however, some ERMs showed no leakage despite having advanced disease with deep retinal edema.<sup>8</sup> Extensive leakage from retinal capillaries or veins was associated with more rapidly progressing lesions.<sup>8</sup> Displacement or distortion of the foveal capillary network may indicate foveal ectopia.

**FIG. 120.12** Fluorescein angiogram showing retinal vascular tortuosity as a result of an overlying epiretinal membrane (A). Vascular leakage is seen in the late venous phase due to traction from the overlying epiretinal membrane (B).

## Fundus Autofluorescence

The presence of retinal vessel printings on autofluorescence has demonstrated retinal vessel displacement which may be correlated with more severe metamorphopsia.<sup>42</sup>

## Surgical Management of ERM

### When to Offer Surgery and Prognostic Indicators

The principal indications for ERM surgery are patient-reported symptoms of reduced VA with or without metamorphopsia.

Although surgery is usually reserved for patients with a reduction in acuity to  $\leq 20/60$ , improvements in surgical techniques have led to patients undergoing surgery with better VA if disturbed by symptoms of metamorphopsia or diplopia and for occupational reasons.

Following surgery there is often a period of several weeks without any noticeable visual improvement. Patients can expect a visual improvement of two or more lines in 60–85% of cases 6–12 months after surgery, with 44–55% achieving a VA of 20/50 or better.<sup>13,15,43,44</sup> A poor presenting VA is associated with a greater visual improvement following surgery, in one series a mean improvement of 4.1 lines was achieved in those with preoperative acuity of 20/200 or worse.<sup>43</sup> However, multiple regression analysis has shown that a higher preoperative VA is associated with a higher final acuity at 6 and 12 months, even though the percentage improvement may be less.<sup>45,46</sup> Both idiopathic and secondary ERMs appear to benefit to an equal extent from surgery; however, in some cases a preexisting macular pathology may limit the visual recovery.<sup>43</sup>

Other parameters of visual function such as contrast sensitivity have been shown to improve significantly following surgery, even when VA does not.<sup>47</sup> Contrast sensitivity appears more closely correlated with improvements in Quality of Life measures than VA and may therefore be a better indicator of the benefits of surgery.<sup>48</sup> Stereopsis has also been shown to be significantly worse in patients presenting with ERM as compared with controls.<sup>49</sup> Successful surgery may result in a significant improvement but does not return to normal levels within 6 months. There are conflicting reports that the degree to which stereopsis is affected may be related to changes in microstructure on SD-OCT such as CFT, macular volume, and mean inner nuclear layer (INL) thickness.<sup>49–51</sup>

The variability in visual results following successful surgery has led to a search for favorable prognostic factors. The available studies are largely retrospective and must therefore be interpreted with caution. A systematic review of the current published literature found only 19 studies of adequate quality.<sup>44</sup> Preoperative VA was the only variable consistently associated with postoperative acuity. There is also evidence that integrity of the

IS/OS junction, severity of metamorphopsia, COST integrity, and fundus autofluorescence (FAF) may also impact postoperative outcomes.<sup>44</sup>

CFT was found to be significant in studies using time domain OCT but not in SD-OCT. More robust studies are required to determine prognostic factors before a prediction model can be developed.

## **Surgical Techniques**

Epiretinal membrane surgery usually starts with a standard pars plana vitrectomy, the degree of vitreous clearance is surgeon-dependent but should avoid any risk of lens trauma or retinal breaks. In most cases a PVD will be present at the start of surgery. In those where the posterior hyaloid is attached, removal should be as atraumatic as possible due to the presence of ILM attachments through the vitreous. In cases where the posterior hyaloid is attached, triamcinolone may be used to assist visualization and removal, particularly over the macular area. Following vitrectomy vital dyes are commonly used to assist visualization of the ERM, as noted below.

Nonvitrectomizing surgery has also been reported for ERM, particularly with the introduction of small-gauge instrumentation. This has the potential benefit of reducing cataract formation postoperatively. The benefit of this technique may be limited by the continued presence of floaters and vitreous debris compared with standard ERM techniques.<sup>52,53</sup>

## **Use of Vital Dyes to Assist in ERM Peeling**

Vital dyes are a useful adjunct to ERM surgery, and there is some evidence that they may improve visual outcomes.<sup>54-56</sup> A number of dyes are in use with different affinities for intraocular collagen and cellular elements. Commonly used dyes in clinical practice include indocyanine green (ICG), trypan blue (TB), and brilliant blue.

Although ICG has been associated with toxicity in macular hole surgery, a study comparing ILM peeling with or without ICG in idiopathic ERM found no difference in outcomes.<sup>57-59</sup> ICG has greater affinity for ILM than ERM and may be more useful when viewed as a negative stain, i.e., the ERM will be seen as an area free

of stain while the surrounding ILM will be clearly visible.<sup>60,61</sup> A number of studies reporting ICG toxicity have been published with varying incubation times, osmolarity, and concentrations. In general, RPE toxicity has been more commonly demonstrated with a solution that has an osmolarity <270 mOsm, a concentration above 0.5%, and incubation time >30 seconds.<sup>62</sup> Additional factors that may be associated with RPE toxicity include application technique and duration of light exposure.<sup>62</sup> A similar approach of negative staining can be employed using brilliant blue (0.25 mg/mL). Brilliant blue stains ILM but does not appear to have the concerns regarding toxicity of ICG and thus may be a good alternative.<sup>62</sup>

Trypan blue highlights ERMs due to its strong affinity for glial cells, allowing good visualization of the extent of the membrane and thus aiding peeling. The facilitation of peeling with dyes does not appear to correlate with improvement in visual outcomes although there is a trend favoring the use of trypan blue.<sup>54-56</sup> Providing that the dye does not enter the subretinal space, there has been no evidence of RPE toxicity.<sup>63-65</sup>

## **Techniques for Engaging and Peeling ERMs**

Once the ERM is visualized adequately, there are a number of techniques that may be used to engage the ERM. In some cases, the edge of the ERM is clearly visible and can be engaged directly with end-grabbing forceps. Where an edge cannot be clearly identified, it may be created prior to peeling using a surgical pick, a bent-tipped microvitrectomy (MVR) blade, or a diamond-dusted scraper. When using a pick or an MVR blade, gentle traction at the edge of the ERM may also elevate it from the retinal surface, facilitating the subsequent peeling with a membrane forceps.

An alternative technique is to directly seize the surface of the ERM with a pair of fine end-grabbing forceps. The forceps are opened slightly and gently pressed onto the surface of the ERM, closed, and then raised by applying tangential traction, which is less likely to cause a retinal tear. However, the limited view of the underlying retina with this technique may increase the risk of trauma to the retina and RPE. This risk may be reduced by slightly reopening the forceps when the initial tractional force is applied and then regripping, allowing any retina trapped within the forceps

to be released.

In some cases, the membrane may be very adherent with no clearly defined tissue planes, and this may result in strands of white glial tissue adhering to the membrane leaving areas of retinal whitening underneath. When such an area of adherent ERM is encountered, the ERM peel may be completed by finding an alternative edge and peeling this toward the adherent area. This may be repeated until only the adherent area remains, allowing it to be gently peeled without exerting traction on surrounding areas of retina.

## **Benefit of Peeling Internal Limiting Membrane in ERM Surgery**

Although patches of ILM are often removed at the time of ERM surgery,<sup>66</sup> there is debate as to the potential benefit of completing an ILM peel following the removal of ERM. It has been proposed that removal of ILM at the time of surgery removes the scaffold for myofibroblast proliferation and any residual microscopic ERM, thus reducing the risk of recurrence as well as improving visual outcomes.<sup>66–69</sup> Conversely, there are concerns that loss of retinal tissue and damage to Müller cell footplates may adversely affect visual function and that rates of recurrence are not affected.<sup>70,71</sup> Although there may be variations in VA initially, postoperatively, these do not appear to be sustained at 12 months.<sup>68,69</sup> There is currently no high-level evidence to inform this debate with published series being either small in number, retrospective, or with variable staining and peeling techniques.

## **Complications of ERM Surgery**

### **Intraoperative Complications**

Small petechial hemorrhages from the perifoveal capillary bed have been reported in 19% of cases, but these do not appear to be associated with reduced visual outcome.<sup>72</sup> Preretinal hemorrhages are usually self-limiting and do not require any treatment.

Peripheral retinal breaks are observed intraoperatively in 4–9% of patients following 20-gauge vitrectomy.<sup>43,73</sup> More recent data suggest that the incidence of entry site breaks is reduced further

with 23-gauge systems to as low as 1%.<sup>74,75</sup> If present, such retinal breaks are treated at the time of surgery with cryotherapy or laser, according to their position, followed by gas or air tamponade.

Lens touch may occur in approximately 0.9% of patients during surgery.<sup>76</sup> In most cases, this will not prevent successful removal of the ERM; however, if the view is significantly impaired, a lensectomy may be required. Patients with a lens touch cataract will show rapid progression postoperatively and may exhibit more postoperative inflammation. Removal of cataract in these patients is also more technically challenging with an increased risk of posterior capsular rupture.

## **Postoperative Complications**

### **Cataract.**

The most common complication following ERM surgery is the formation or progression of cataract. This is true of all vitrectomy surgery and has been reported to occur with an incidence of 6–100% depending on the underlying condition, duration of follow-up, and method of measuring cataract formation.<sup>43,77</sup> The incidence of cataract within the first year ranges from 30% to 65% and increases with increasing length of follow-up.<sup>73</sup>

The combination of cataract progression with delayed visual recovery following ERM surgery often means that patients do not achieve their target vision until the cataract has been removed. Increasingly surgeons are electing to perform cataract surgery at the time of ERM peeling.<sup>76</sup> Both techniques appear to produce equivalent outcomes.<sup>78</sup>

### **Retinal Detachment.**

Retinal detachment following ERM surgery occurs in 2–14% of eyes.<sup>43,79</sup> The most common source of detachment is unidentified entry site breaks at the time of surgery. This emphasizes the importance of careful search for retinal tears using scleral indentation at the end of surgery.

### **Recurrence.**

Recurrence of ERM occurs in less than 20% of patients and is rarely

visually significant and results in further ERM surgery in approximately 5% of cases.<sup>68</sup> Recurrences tend to occur approximately 20 months postoperatively (range 3–96 months).<sup>68</sup> Rates of recurrence appear to be higher in younger patients (25%).<sup>7</sup>

Other rarer complications include endophthalmitis, retinal toxicity from the use of vital dyes, phototoxicity, visual field defects, and subretinal neovascularization.

## Vitreomacular Traction and Cystoid Macular Edema

Macular edema contributes to vision loss by altering the functional cell relationship in the retina and promoting an inflammatory reparative response.<sup>80,81</sup> Macular edema associated with vitreous traction, first described over 50 years ago,<sup>82</sup> represents a particular tissue reaction due to the mechanical distortion of the retina. However, it is often difficult to differentiate whether edema is linked to the fact that the vitreous is pulling actively on the retina or to the fact that it is simply adherent. In certain circumstances the changes at the vitreoretinal interface may represent the cause and in some others, the effect of vitreoretinal traction.<sup>83</sup>

## Anatomy of Macular Edema With Vitreoretinal Traction

The central area of the retina is predisposed to develop edema due to its unique anatomy, which is characterized by an extremely high cell count with increased metabolic activity and a central avascular zone creating a watershed arrangement between the choroidal and retinal circulation which decreases resorption of extracellular fluid.<sup>84–87</sup> In the foveal region, the fibers of the Henle layer demonstrate a loose arrangement allowing accumulation of fluid leaking from perifoveal capillaries. However, it has been shown that the cystoid spaces can also form in the outer nuclear, inner nuclear (INL), inner plexiform, and even the ganglion cell layer (GCL).<sup>88</sup> The presence of cystoid spaces in the GCL might be explained with the assumption that epiretinal membranes,

thickened internal limiting membrane (ILM), and/or adherence of the vitreal cortex to the retina disturb the fluid movement between the vitreous and retina.<sup>89</sup>

## Pathophysiology of Macular Edema With Vitreoretinal Traction

In a normal steady state several mechanisms maintain a balance of osmotic forces, hydrostatic forces, capillary permeability, and tissue compliance, with the result that the rate of capillary filtration equals the rate of fluid removal from the extracellular retinal tissue.<sup>81,90</sup>

The vitreous has been implicated as a cause of macular edema via several mechanisms. One of the most constructive hypothesis on how vitreomacular traction (VMT) may result in macular edema was given by Schubert in 1989 and was summarized by Bringmann and Wiedemann in 2009.<sup>17,91</sup> Vitreous fibers, which adhere to Müller cell end-feet at sites of vitreoretinal attachments after partial detachment of the vitreous, exert tractional forces onto the cells; this activates Müller cells and results in cell hypertrophy, proliferation, and vascular leakage.<sup>17,91</sup> Furthermore, long-lasting mechanical stress of astrocytes and Müller cells induced by vitreal fibers adhering to the cells can stimulate the release of inflammatory factors such as basic fibroblast growth factor (bFGF), inducing local inflammation and blood–retinal barrier (BRB) breakdown promoting vascular leakage and macular edema.<sup>92</sup> Vitreoretinal traction can also exert forces at the level of the RPE, which can eventually result in morphologic RPE changes.<sup>93,94</sup> Furthermore, VMT has been shown to induce pigment epithelial detachment and RPE tearing.<sup>95</sup> It is a well-known phenomenon in many retinal vascular diseases that direct traction on the macula or on the RPE may induce not only induce local inflammation but also increase of vascular endothelial growth factor (VEGF) locally with subsequent macular edema formation.<sup>96–98</sup> Mechanical traction can also cause macular edema by direct distortion of the surrounding intraretinal vessels resulting in leakage due to disturbance of the macular microcirculation with reduced capillary blood flow and a loss of apposition between the retina and the RPE pump.<sup>99</sup>

It is less well known that the vitreous may also play an important

role in the pathophysiology of macular edema through other mechanisms than the obvious direct tractional components. Sebag and others have found enzyme-mediated vitreous crosslinking and nonenzymatic glycation in the diabetic vitreous, and they have suggested that the abnormal crosslinking might affect the collagen structure and destabilize the attached vitreous gel strengthening the adhesion of the posterior vitreous cortex to the ILM, which in turn produces stronger vitreoretinal attachment with subsequent macular edema.<sup>100,101</sup>

Furthermore, the vitreous in various pathologic conditions may act as a sink for factors influencing macular edema themselves. The breakdown of the BRB, for example, usually leads to an increased concentration of intravitreal serum-derived chemoattractants, which may provide a stimulus for cellular migration into the attached premacular posterior hyaloid. Cellular contraction may potentially lead to tangential traction with consequent leakage and macular edema.<sup>102,103</sup> In turn, leakage from the vascular bed aggravates chemoattractant outflow, thus creating an inexorable vicious circle.

It has also been shown that several growth factors such as VEGF, interleukin (IL)-6, platelet-derived growth factor (PDGF), and others are secreted in large amounts into the vitreous during proliferative vasculopathies such as diabetic retinopathy or retinal vein occlusion,<sup>104-106</sup> and these factors may increase vasopermeability and promote macular edema. Furthermore, during aging, VEGF is increasingly bound by altered vitreous collagen fibrils at the interface between retina and posterior vitreous cortex potentiating the effects of these growth factors.<sup>107</sup>

## Clinical Signs of Cystoid Macular Edema With Vitreoretinal Traction

Clinically, macular edema can be best detected using the slit lamp and either a handheld, non-contact lens (e.g., +78 D), or a contact lens (e.g., Goldmann flat lens). These changes may be better visible using green light, while retroillumination can help to delineate the polycystic spaces. A thorough examination of the anterior segment should always complement the clinical evaluation as incarcerated

vitreous or an intraocular lens irritating the iris or ciliary body may be the underlying cause of macular edema.<sup>89</sup> Clinical symptoms range from loss in distance VA, contrast sensitivity, color vision, and reading acuity to a reduction in reading speed as well as metamorphopsia and micropsia.<sup>108–111</sup>

## Imaging of Cystoid Macular Edema With Vitreoretinal Traction

### Angiography

Fluorescein angiography has for many years been one of the most useful tests in detecting macular edema of various etiologies showing cystoid spaces located in the outer plexiform layer (Henle's layer) displayed as the classic petaloid staining pattern in the macula or a honeycomb-like appearance in the more peripheral regions.<sup>86,112–114</sup> Reasons for so-called “silent” angiograms may be very long-standing changes within the retina, such as intraretinal cysts, which have become impermeable to the fluorescein dye diffusion. Macular edema can also occur without vascular leakage, when the fluid clearance through glial and RPE cells is impaired.<sup>90</sup>

### Optical Coherence Tomography (OCT)

Optical coherence tomography (OCT) is able to accurately measure the retinal thickness allowing a more precise and reproducible assessment than fluorescein angiography<sup>115–117</sup> with a particular efficacy in the volumetric analysis of macular edema and the characterization of the vitreoretinal interface. Several authors have proposed different patterns and classifications of macular edema according to the underlying pathology based on OCT findings.<sup>28,113,118–122</sup>

### OCT and Diabetic Macular Edema.

In diabetic macular edema, there are several broad nonexclusive categories: diffuse retinal thickening, cystoid macular edema, serous retinal detachment, and OCT identified vitreomacular interface abnormality, which includes the presence of epiretinal membranes, and/or vitreomacular traction.<sup>123</sup> Vitreomacular

traction is identified by a hyperreflective band that is in apposition with the inner surface of the retina at discrete site(s) and elevated above the surface of the retina elsewhere.<sup>118,121</sup> Ghazi et al.<sup>124</sup> demonstrated that in eyes with persistent diabetic macular edema vitreomacular interface abnormalities may be found in up to 52–67% on OCT and concluded that OCT was nearly twice as sensitive as traditional techniques in detecting vitreomacular interface abnormalities.

Kim et al.<sup>118</sup> proposed five different morphologic patterns at OCT evaluation of diabetic macular edema in relation to vitreoretinal traction: *Pattern I* is a diffuse increased retinal thickening, with areas of reduced intraretinal reflectivity; *Pattern II* is macular edema as described above; *Pattern III* shows posterior hyaloidal traction, which appears as a highly reflective band over the retinal surface; *Pattern IV* exhibits serous retinal detachment not associated with posterior hyaloidal traction, which appears as a dark accumulation of subretinal fluid beneath a highly reflective dome-like elevation of detached retina; *Pattern V* shows posterior hyaloidal traction and traction retinal detachment, which appear as a peak-shaped detachment with a highly reflective signal arising from the inner retinal surface and with an area of low signal beneath the highly reflective border of detached retina (Table 120.3). More recent reports have also shown unequivocal proof of proliferative changes on the retinal and vitreal surface of the diabetic ILM<sup>125</sup> while others have quantified the frequency of vitreomacular interface pathologies in diabetic macular edema in general<sup>126</sup> and in particular in the presence of an incomplete posterior vitreous detachment and vitreopapillary adhesion.<sup>127</sup>

**TABLE 120.3**

**Morphologic Subtypes of Diabetic Macular Edema on Optical Coherence Tomographic Imaging**

Morphologic Subtype	Number of Scans (%)	Mean Thickness (μm)	Range (μm)
DRT	97	409.3	215–772
DME	55	485.1	235–772
SRD without PHT	7	551.6	376–760
PHT without TRD	12.7	576.8	376–759
PHT with TRD	2.9	459.1	255–765

hyaloidal traction; SRD, serous retinal detachment; TRD, traction retinal detachment. Reproduced with permission from Kim BY, Smith SD, Kaiser PK. Optical coherence tomographic patterns of diabetic macular edema. *Am J Ophthalmol* 2006;142:405–412.

### OCT in Vitreoretinal Traction Syndrome.

Vitreoretinal traction syndrome can be characterized most easily using OCT, which frequently shows a perifoveal vitreous detachment, a thickened hyperreflective posterior hyaloid, as well as an epiretinal membrane (Fig. 120.13). Koizumi et al.<sup>122</sup> described two different OCT patterns of vitreous attachment in VMT using spectral-domain OCT: foveal cavitation defined as the formation of cystoid cavity located in the inner part of the central fovea secondary to mechanical forces and CME that was defined as intraretinal cyst-like cavities extending beyond the foveal region. Sometimes a neurosensory retinal detachment occurs while the macular traction may resolve in the formation of a lamellar-macular hole.<sup>114</sup>

**FIG. 120.13** (A) Preoperative optical coherence

tomography (OCT) image of the right eye of a 43-year-old male patient suffering from vitreomacular traction syndrome. Best corrected visual acuity (BCVA) was 20/60. (B) Postoperative OCT image 6 weeks after 23-gauge vitrectomy and peeling of the posterior hyaloid and internal limiting membrane. BCVA has increased to 20/20 with an associated important reduction in macular thickness.

Odrobina et al. (28) also advocated that vitreous surface adhesion and persistence of ERM on OCT may be the prognostic factors for the natural course of the vitreomacular traction. They observed spontaneous resolution of vitreomacular traction in eyes with less vitreous surface adhesion and without ERMs while eyes with higher vitreous surface adhesion or coexisting ERM suggested a surgical intervention.<sup>28</sup> Similar observations have been made on vitreomacular traction in retinal vein occlusion.<sup>128</sup>

### **OCT for Vitreomacular Traction in Age-Related Macular Degeneration.**

With the advent of OCT, the theory that vitreomacular traction may be pathophysiologically related to age-related macular degeneration (AMD) has gained more and more momentum.

The initial observations were made using B-scan ultrasound, which showed that AMD patients have a high rate of persisting vitreous attachment using ultrasound<sup>129</sup> and other means of diagnosis.<sup>130-132</sup> But more recently, using high-resolution OCT, vitreomacular adhesions and traction have confirmed the high incidence of attached vitreous of up to 79%.<sup>98</sup> The main remaining questions are: what role if any is the vitreous playing? Is it a causative role, or is it simply aiding progression of the AMD? The answers to these questions are still to be elucidated.

## **Surgical Treatment of Traction Macular Edema**

### **Rationale for Vitrectomy**

#### **Tractional Origin of Macular Edema.**

The initial rationale for using vitrectomy in cases of macular edema was entirely structural, i.e., aimed at the removal of vitreous traction on the macula.<sup>133,134</sup> As Newton's third law states: To any action there is always an equal reaction in the opposite direction. The force of vitreoretinal traction will thus be met by an equal and opposite force in the retina, resulting in the manifold pathologic reactions described previously. Vitrectomy may thus conceptually relieve traction on Müller and RPE cells that had resulted in vascular leakage, but it may also suppress the release of inflammatory factors previously induced by the mechanical stress on these cells. Additionally, vitrectomy may reduce the tractional disturbance of the macular microcirculation, and it may restore the apposition between the retina and the RPE pump.<sup>135</sup>

### **Nontractional Origin of Macular Edema.**

Recent discoveries have shown that vitrectomy may not only be beneficial in the presence of macular traction, but also in cases where no particular deformation of the macula can be identified. This is particularly true for macular edema of vascular origin, such as diabetes or retinal vein occlusion. The beneficial effect of vitrectomy is thought to be based – at least in part – on two mechanisms. Firstly, it has been found that oxygenation of the posterior segment of the eye is increased after vitrectomy.<sup>136-139</sup> Others have shown that pharmacologic vitreolysis also improves vitreal O<sub>2</sub> levels and that it increases the rate of O<sub>2</sub> exchange within the vitreous cavity.<sup>140,141</sup> This may also be the mechanism behind the observation that vitrectomy may reduce the extent of the foveal avascular zone as seen on fluorescein angiography.<sup>142</sup> Secondly, it has been shown that several growth factors such as VEGF, IL-6, platelet-derived growth factor, and others are secreted in large amounts into the vitreous during proliferative vasculopathies such as diabetic retinopathy or retinal vein occlusion,<sup>105,106,143,144</sup> and it is conceivable that a complete vitrectomy will remove this excess of growth factors mechanically with the desired effect of a restitution of the BRB.<sup>93</sup> The rapid clearance of VEGF and other cytokines may thus help to prevent macular edema and retinal neovascularization in ischemic retinopathies, such as diabetic retinopathy and retinal vein occlusions. Vitreous clearance of growth factors may indeed

have the same effect as the presence of, for example, VEGF antibodies in the vitreous cavity.<sup>135,145,146</sup>

## **Rationale for Internal Limiting Membrane Peeling**

ILM may thicken due to an increased content of extracellular matrices and cellular proliferation on the vitreous surface in cases of diabetic macular edema.<sup>147</sup> It has been hypothesized that ILM changes contribute to the structural and functional disturbance of water movement between the vitreous and the retina<sup>147</sup> and eventually retain proteins in the interstitial space avoiding diffusion of proteins to the vitreous space leading to macular edema.<sup>148</sup> Additionally, the diffusion of oxygen from the fluid in the vitreous cavity into the retina would be retarded by a thickened ILM.<sup>149</sup> Also, the absence of the vitreous gel would increase the transport of cytokines, such as VEGF, from the retina into the vitreous cavity, and the absence of ILM would further speed up this clearance of cytokines from the retina.<sup>135</sup> The efficacy of ILM delamination may be caused by the removal of a growth factor reservoir, which may have accumulated in the ILM and in cellular elements on its vitreous side. Vitreous remnants may be present even after surgical vitreous separation<sup>150</sup> and ILM delamination allows a more complete removal of vitreous elements.<sup>147,150</sup> In uveitis and in vitreomacular traction complicating AMD it has been speculated that intraocular inflammation, through the release of chemokines and cytokines into the vitreous, may result in a firmer attachment of the posterior hyaloid to the macula and/or contraction of the ILM creating tangential traction on the retina and the development of macular edema. In such cases, macular edema may be refractive to medical treatment and it may only be relieved by vitrectomy with separation of the posterior hyaloid and/or peeling of the ILM (Fig. 120.14).<sup>151</sup>

**FIG. 120.14** (A) Preoperative optical coherence tomography (OCT) image of the left eye of an 86-year-old woman suffering from exudative age-related macular degeneration (AMD) with initial response to anti-VEGF therapy. Prior to referral the patient had become refractory to the injections and a possible tractional component of the macular edema was suspected. Best corrected visual acuity (BCVA) was 20/50. (B) Postoperative OCT image 3 weeks after 23-gauge vitrectomy and peeling of the posterior hyaloid, BCVA has increased to 20/30 with an associated important reduction in macular thickness. (C) Postoperative OCT image of the left eye 1 year after surgery and after seven additional intraocular anti-

VEGF injections showing a stable BCVA of 20/30.

## Clinical Entities With Macular Edema Associated With Vitreomacular Traction

### Diabetic Macular Edema

#### Role of Vitrectomy in DME.

It has been shown that the risk of developing diffuse diabetic macular edema (DME) may be 3.4-fold lower in the group of eyes with complete PVD or complete vitreoretinal separation compared to the eyes with incomplete PVD.<sup>152</sup> Moreover, a small prospective study by Hikichi and colleagues strongly suggested that vitreomacular separation can cause spontaneous resolution of diabetic macular edema.<sup>153</sup> This evidence suggests that surgical separation of the VMA is imperative in certain cases to treat DME. In 1992 Lewis et al. were the first to report the resolution of macular edema in 80% of cases after vitrectomy for diabetic edema associated with posterior hyaloidal traction.<sup>133</sup> Other studies have also suggested a beneficial result of vitrectomy for traction DME.<sup>154,155</sup> The functional prognosis was considered to be better when vitrectomy is performed at an early stage.<sup>156</sup> In 2010 the Diabetic Retinopathy Clinical Research Network evaluated vitrectomy for diabetic macular edema in eyes with at least moderate vision loss and vitreomacular traction. They found retinal thickening to be reduced in most eyes postoperatively. The median change in VA increased on average at 6 months after surgery by 3 letters, with VA improving by more than or equal to 10 letters from baseline to 6 months in 38% and worsening by more than or equal to 10 letters in 22%. Reduction in central macular thickness as shown by OCT to be less than 250  $\mu\text{m}$  occurred in almost half, and most eyes had a thickness reduction of more than or equal to 50%.<sup>157</sup> Since 1990, several other authors have confirmed that vitrectomy is beneficial for diffuse DME combined with a taut thickened posterior hyaloids, presumably with tangential hyaloidal traction.<sup>158</sup> Pendergast et al.<sup>159</sup> reported stability or improvement in 91% of eyes and complete disappearance in 92% of patients after vitrectomy for

diffuse DME associated with a taut posterior hyaloid. Studies on vitrectomy for DME in the absence of traction have reported mixed results. Some studies suggested positive outcomes, others have shown anatomic but not visual improvement after surgery, while some studies suggested that vitrectomy is not beneficial in eyes with DME without traction.<sup>155–157</sup>

### **Role of Internal Limiting Membrane Peel in DME.**

Despite several clinical studies over the past few years, the role of ILM peeling in DME is still far from clear. Some studies have reported a favorable outcome following vitrectomy and ILM peeling opposed to the natural course of diabetic macular edema.<sup>160,161</sup> In contrast, others found good anatomic but less impressive visual results.<sup>162,163</sup> Kumar et al. compared the effectiveness of vitrectomy and ILM peeling with grid laser photocoagulation in patients with diffuse diabetic macular edema and found that vitrectomy with ILM peeling was beneficial by inducing a statistically significant reduction of macular thickness and macular volume. However, the comparative VA outcome analysis between the two groups was not significantly different.<sup>164</sup> Gentile et al. have advocated that a taut ILM on its own can still cause diffuse diabetic macular edema after vitrectomy, and that its removal can restore the normal foveal contour and improve VA.<sup>165</sup> In a recent randomized controlled study, Hoerauf et al.<sup>149</sup> demonstrated a favorable anatomic effect of additional ILM removal in vitrectomy for cystoid diabetic macular edema without evident vitreomacular traction although the visual improvement was not significant.

### **Surgical Technique for Vitreomacular Traction in DME**

#### **Pars Plana Vitrectomy.**

A standard three-port pars plana vitrectomy is performed. A PVD is induced, if not present, by suction over the optic nerve disc until the Weiss ring is identified. Simple suction may not result in complete PVD in cases of taut posterior hyaloid, and the membrane on the retinal surface needs to be engaged initially with a pick or a bent MVR blade and formally removed using membrane forceps.

Occasionally, a diamond-dusted scraper may also have to be used to create an edge for the cutter to engage the vitreous. Following this, the peripheral vitrectomy is completed and fibrovascular membranes, if present, needs to be delaminated.<sup>166</sup>

### **Role of Triamcinolone.**

The injection of intravitreal triamcinolone can be used to better visualize the posterior hyaloid and thus facilitate PVD induction. Furthermore, triamcinolone acetate has been shown to facilitate fluid absorption from the edematous retinal tissue both by stimulating endogenous adenosine signaling in Müller cells<sup>167</sup> and by downregulating vascular endothelial growth factor (VEGF) production.<sup>168</sup> It can thus be used as an adjuvant also at the end of the surgery to reduce macular edema and postsurgical inflammation in general.

### **Internal Limiting Membrane Peel.**

The ILM peel may be initiated with a slight incision of the ILM temporal to the fovea, or the ILM may be grasped directly with the forceps. In this area it is less likely to slice nerve fibers and cause small paracentral scotoma. Alternatively, a diamond-dusted brush can be used. Once the ILM is lifted, it is peeled tangentially and circumferentially like a capsulorhexis.<sup>169</sup> Visibility of the ILM can be greatly improved using brilliant blue G.<sup>170</sup>

## **Retinal Vein Occlusion**

### **Role of Vitrectomy in Retinal Vein Occlusion.**

Pars plana vitrectomy with complete adherent hyaloid removal has been reported as a potential treatment for macular edema related to both central (CRVO) and branch retinal vein occlusion (BRVO).<sup>171</sup> Several studies found improvement of VA after vitrectomy with complete posterior hyaloid removal in patients with ischemic CRVO.<sup>172,173</sup> It appears that the vitreous level of VEGF is significantly higher in CRVO patients with less improvement of best corrected visual acuity (BCVA) after vitrectomy.<sup>172</sup> It is thought that high VEGF levels may be associated with permanent photoreceptor cell damage due to macular ischemia. Soluble ICAM-

1 and pigment epithelium-derived factor (PEDF) may also influence the visual prognosis and the response of macular edema after vitrectomy.<sup>174</sup> Yamasaki et al. also reported both a significant improvement of VA and retinal thickness after vitrectomy for BRVO-related macular edema and a significant positive correlation between the vitreous levels of VEGF and improvement of macular edema.<sup>175</sup> A more recent retrospective study has characterized extrafoveal vitreoretinal traction in a large proportion of retinal vein occlusions causing macular edema and macular detachment. Evidence of traction was defined as (a) areas where the retina was elevated or thickened and where there was deformity at the traction site and (b) where the posterior hyaloid or vitreous strands changed angle. Conversely, vitreous adherence without traction was defined as vitreous attachment not associated with inner retinal deformity.<sup>176</sup>

### **Role of ILM Peel in Retinal Vein Occlusion.**

Vitrectomy and ILM peeling for macular edema secondary to central retinal vein occlusion and hemiretinal vein occlusion have shown anatomic improvement, which persists up to 5 years, and VA improvement, at least in perfused CRVO and HRVO.<sup>177</sup> Others have reported that vitrectomy, ILM peel, and panretinal photocoagulation for macular edema secondary to central retinal vein occlusion reduced foveal thickness at final follow-up; however, anatomic improvement did not correlate with a statistically significant improvement in VA.<sup>178</sup>

## **Uveitic Macular Edema**

### **Role of Vitrectomy in Uveitic Macular Edema.**

The value of vitreous surgery in uveitic macular edema is based on the assumption that many inflammatory mediators accumulate in the vitreous and particularly in the posterior hyaloid, and a removal of these mediators may have a beneficial effect on macular edema. In addition, inflammation often results in the formation of epiretinal membranes (ERM), and vitrectomy associated with an ERM peel is thought to be of benefit.<sup>179</sup> There have been few reports on the outcome of pars plana vitrectomy in uveitis cases

unresponsive to medical treatment.<sup>180-188</sup> Dugel et al.<sup>186</sup> investigated the efficacy of vitrectomy in 11 eyes of nine patients with intraocular inflammation-related CME that was unresponsive to corticosteroids and reported improvement of VA and regression of macular edema. Wiechens et al.<sup>189</sup> investigated the role of vitrectomy in refractive uveitic CME and found that the response to vitrectomy was variable according to the type of underlying form of uveitis. Stavrou et al.<sup>190</sup> studied the effect of vitrectomy without ILM peel in 37 eyes with intermediate uveitis and reported resolution of CME in 32.4% of the cases, which allowed discontinuation of immunosuppressive treatment in 16% patients. Kiryu et al.<sup>183</sup> reported visual improvement of 2 or more Snellen lines in 56% of 18 studied eyes within 12 months after vitrectomy for CME secondary to sarcoid uveitis. Tranos et al.<sup>180</sup> found angiographic improvement in one-third of the patients that underwent vitrectomy for macular edema secondary to chronic uveitis in a randomized controlled pilot study. Vitrectomy may thus be a useful therapeutic alternative in selective cases which include unresponsiveness to medical treatment, significant inflammatory vitreous debris which compromises clinical assessment, and cases associated with epiretinal membranes and/or an obvious tractional component.<sup>191</sup>

### **Role of ILM Peel in Uveitic CME.**

The role of ILM peel is not well defined. Only a handful of small studies have shown mixed results, with both good results in terms of macular edema and VA<sup>151</sup> and a more mitigated outcome.<sup>192</sup>

## **Postoperative Macular Edema**

### **Role of Vitrectomy in Postoperative Macular Edema.**

Postoperative CME is thought to be an inflammatory process<sup>193</sup> and is the most frequent cause of decreased vision in patients following cataract surgery.<sup>194</sup> Clinically significant CME has a reported incidence of 1–2% after cataract surgery,<sup>195</sup> while angiographic CME is more common and has been reported to occur after about 20% of cataract surgeries.<sup>196,197</sup> Its incidence is higher when associated with complicated surgery that may include capsule rupture, vitreous

loss, vitreous wick with potential traction, and retained lens fragments.

Vitrectomy has been used especially in cases refractory to medical treatment, which either show traction through vitreous incarceration in the corneal wound or have persistent residual lens fragments. The Vitrectomy–Aphakic–Cystoid Macular Edema Study, a prospective multicenter study of patients with vitreous adherent to the corneoscleral wound and with chronic aphakic cystoid macular edema, showed significant improvement in VA following vitrectomy.<sup>134,198</sup> Harbour et al. reported vitrectomy results of 24 eyes with chronic pseudophakic macular edema, unresponsive to medical treatment, and evidence of either vitreous adhesions to anterior segment structures or iris capture of the intraocular lens. VA improved in all patients, with 71% of subjects experiencing postoperative visual improvement of three or more lines.<sup>199</sup> Visual outcome was better when a complete vitrectomy was performed compared to a limited anterior vitrectomy. Pendergast et al.<sup>200</sup> reported a significant improvement in VA after vitrectomy in cases of pseudophakic CME even without vitreous incarceration in the wound.

In summary, the beneficial role of vitrectomy has been clearly demonstrated for CME associated with aphakia and vitreous incarceration in the wound. In cases of CME associated with pseudophakia, the current results suggest that vitrectomy is most likely beneficial in cases of traction from vitreous incarceration in the corneal wound after complicated cataract surgery and in cases of residual lens fragments. Vitrectomy may also be considered in cases of chronic CME that is unresponsive to topical antiinflammatory medications and after failure of other therapeutic alternatives such as periocular and intraocular steroids.

## **Vitreomacular Traction Syndrome and Epiretinal Membrane**

### **Role of Vitrectomy in VMTS.**

Vitrectomy with peeling of any tangential tractional components usually results in resolution of retinal thickening and visual improvement in patients with VMTS.<sup>83</sup> Hikichi et al.,<sup>201</sup> in a study

regarding the natural history of vitreomacular traction in the pre-OCT era, reported that 64% of the eyes lost 2 lines of vision over the course of follow-up. Since a report by Smiddy et al.<sup>202</sup> described an equally successful surgery for nondiabetic eyes with macular traction and visual decrease, many surgeons have elected to operate rather than to follow patients with evident vitreomacular traction and significant visual impairment.<sup>157</sup> Davis et al.<sup>203</sup> in a recent study reported improvement of more than 2 lines in 50% of eyes after vitrectomy for vitreofoveal traction syndrome and complete resolution of traction on OCT in all eyes while cystic changes improved markedly or resolved in 86% of eyes. Patients with symptoms for less than a 6-month duration ( $p=.048$ ) were more likely to obtain a VA of 20/40 or better postoperatively. Vitrectomy surgery with peeling of the ERM and the posterior hyaloid is able to relieve all of the traction and has been shown to be associated with good visual outcome and resolution of the CME.<sup>204–206</sup> Konstantinidis et al.<sup>207</sup> reported that the concomitant administration of intravitreal triamcinolone acetonide after pars plana vitrectomy may speed up and improve the anatomic and functional outcome considerably. A more recent meta-analysis of pars plana vitrectomy for VMTS confirmed that this surgical procedure yields good VA recovery.<sup>208</sup>

## **Vitreomacular Traction in Age-Related Macular Degeneration**

### **Role of Vitrectomy for AMD.**

There have been several hypotheses linking vitreomacular traction with AMD, although it is still debated whether this relationship is causal or not. Chronic traction on the retina may cause degeneration or alteration of the RPE or Bruch membrane, and traction has also been shown to induce low-grade inflammation and VEGF release, which in turn may influence the progression of AMD. Furthermore, an adhesion between the vitreous and the retina may create anatomic structures, which facilitate a sustained contact of free radicals or other angiogenic cytokines in the vitreous gel with the retina, thus promoting the evolution of AMD. In addition, an attached posterior vitreous face may also prevent

oxygen diffusion or nutrient exchange.<sup>209</sup> It has also been shown that VMA in exudative AMD may lead to a decreased response to anti-VEGF therapy causing either increased numbers of intravitreal injections<sup>210</sup> or poorer visual outcomes.<sup>211</sup>

In some recent publications it has thus been proposed that vitrectomy for vitreous adhesion and traction on the macula in patients with exudative ARMD has a therapeutic effect on the neovascular portion of the disease (Fig. 120.14). In a series of 12 eyes of 11 patients and a follow-up of 6 months, 6 eyes showed regression of choroidal neovascularization (CNV). In 2 eyes the CNV disappeared completely. VA improved vision in 4 eyes, was unchanged in 4 eyes, and there was worsening of vision in 4 eyes.<sup>212</sup> Roller et al.<sup>213</sup> found in a pilot study that vitrectomy was associated with a reduced progression of geographic atrophy or CNV. In summary, the role of vitreous in AMD remains at present speculative and the role of vitrectomy in AMD remains currently unclear.

## **Vitreomacular Traction in Retinitis Pigmentosa**

Garcia-Arumi et al.<sup>214</sup> has evaluated the role of vitrectomy accompanied by ILM peeling in 12 eyes with retinitis pigmentosa and CME refractory to medical therapy and reported anatomic and functional improvement. Their results showed a decrease in macular thickness of >40% in 10 eyes (83.3%) while the mean VA increased from 20/115 to 20/45, with an average of 3 lines of improvement. These positive results were not confirmed in a case report by Hagiwara et al.<sup>215</sup>

## **Pharmacologic Vitreolysis**

Pharmacologic vitreolysis can potentially relieve vitreoretinal traction and increase vitreal O<sub>2</sub> levels and the rate of O<sub>2</sub> exchange within the vitreous cavity.<sup>141,216</sup> Different substances have been investigated, including chondroitinase, dispase, hyaluronidase, plasmin, and microplasmin.<sup>217</sup> When used as an adjunct to vitrectomy, plasmin showed promising results in diabetic macular edema facilitating PVD induction.<sup>218</sup> The main drawback of plasmin is that it is not easily available for clinical use. Autologous

plasminogen has to be isolated from the patient's own blood and then converted in vitro to plasmin by streptokinase. This procedure has to be done immediately before surgery as it yields a highly unstable product.<sup>219</sup> Microplasmin is currently the agent that shows the greatest clinical potential. It is a recombinant product that contains only the catalytic domain of human plasmin and shares all of its catalytic properties. It is much more stable than the original molecule, which greatly simplifies storage and administration.<sup>219</sup> Phase II trials have shown that intravitreal microplasmin is well tolerated in patients with diabetic macular edema and vitreomacular traction maculopathy,<sup>220</sup> and the ease of PVD induction during surgery was found to be dose- and time-dependent.<sup>221</sup> Further trials by the MIVI-TRUST (Traction Release without Surgical Treatment) showed an overall release rate of the VMA in 26.5% at 28 days compared to 10.1% in the placebo group.<sup>222</sup> The release rate was improved to around 35% in young phakic patients with no epiretinal membrane and a width of the vitreoretinal adhesion below 1,500  $\mu\text{m}$ .<sup>222</sup> Closure of macular holes was achieved in 37% if the diameter was below 400  $\mu\text{m}$  and in 58% if the hole diameter was below 250  $\mu\text{m}$ .<sup>222</sup> The latest results have confirmed that the most likely candidates in whom the resolution of the VMA was achieved after 1 month are phakic patients younger than 65 years, without an epiretinal membrane, and with a VMA that measures less than 1,500  $\mu\text{m}$  in diameter.<sup>223</sup> Ocriplasmin has also been used to treat VMA associated with AMD, achieving a PVD in 24% in treated eyes compared to 12% in the sham injected eyes, which was associated with a reduction of the numbers of intravitreal anti-VEGF injections from 6 to 4 in the patients who responded to ocriplasmin.<sup>224</sup>

The rate of nonresponse to this enzymatic therapy may be explained by the fact that the treatment decision is based primarily on an anatomic assessment, whereas the biological strength of the adhesion is not known and may not be related to the anatomic situation.<sup>223,225</sup> It has been argued that a prolonged observation time, or watchful waiting, may be enough to see an increased rate of spontaneous VMA resolution. In a recent observational study of patients, who were included using to the MIVI criteria detailed above, up to 44% of cases showed spontaneous VMA release during

a 24 month follow-up.<sup>226</sup> Others have observed that spontaneous separation of vitreomacular traction may occur much more often if there is isolated inner retinal distortion on OCT.<sup>227</sup>

Several authors have described potential side-effects associated with ocriplasmin use, such as photopsia, blurred vision, dyschromatopsia, and visual field loss, and further functional and anatomic evaluations have shown a transient disruption in the ellipsoid layer on OCT.<sup>228–230</sup> Significant electroretinogram (ERG) abnormalities have also been reported after ocriplasmin injection for vitreomacular traction and macular holes.<sup>229,231,232</sup> Although the cone-mediated changes appear to be transient, the rod-mediated ERG trace is depressed for a much longer period and the changes in the ellipsoid layer on OCT and the ERG appear to be linked. The massive ERG changes only concerned two patients, in whom the macular hole was closed after ocriplasmin injection. One patient with no treatment response showed only very moderate ERG changes, whereas the five other patients had no therapy response and no ERG changes.<sup>232</sup> It is not yet known why certain patients are more susceptible to show such retinal changes than others.

Other pharmacologic agents, which interfere with integrins, a family of proteins facilitating the attachments between cells and the extracellular matrix, have been investigated to induce vitreoretinal separation. Luminate®, for example, is an integrin peptide antagonist that interferes both with the process of neovascularization and in the maintenance of the vitreoretinal adhesion by inhibiting the integrin  $\alpha 5 \beta 1$ .<sup>233,234</sup> In recent not yet published phase I and II studies Luminate® has been shown to induce a full or partial PVD in 55–65% of patients with diabetic macular edema at 90 days after injection versus 10% in the placebo group.

## Treatment of Vitreomacular Traction Syndrome With Intravitreal Gas Injection

It has been reported that a single intravitreal injection of fluid can induce a posterior vitreous detachment in up to 25% of patients,<sup>235</sup> and in view of the high costs of ocriplasmin, cost options to treat VMTS have been investigated by several authors. McHugh et al.

proposed, for example, the injection of 0.3 mL of pure C<sub>3</sub>F<sub>8</sub> gas to induce a PVD detachment as the gas bubble expands. This technique was successful in a series of patients with diabetic maculopathy resulting in a PVD associated with an improvement of vision and the reduction of macular thickness on OCT in all patients.<sup>236</sup> These results compare well with another study, which also showed separation of VMT in 40% of patients at 1 month and 60% at 3 months following injection of C<sub>3</sub>F<sub>8</sub>.<sup>237</sup> More recently, Day et al. injected 0.3 mL of pure SF<sub>6</sub> gas intravitreally in nine eyes with VMTS. In five patients (55.6%) the expansile gas was able to detach the posterior hyaloid from the macula, resulting in a resolution of the VMTS or the closure of small macular holes at 1 month after injection.<sup>238</sup>

## Conclusion

An understanding of the factors responsible for the development of vitreomacular interface disorders together with prognostic factors, and potential complications of surgery will allow clinicians to inform and educate patients while making a choice between continuing follow-up and the appropriate timing of a surgical intervention. OCT has become an invaluable tool in the early diagnosis of these disorders. Further the increased number of therapeutic interventions available have led to an excellent prognosis of this retinal pathology.

## Introduction

Macular hole (MH) is a round full-thickness opening in the foveal center. In most cases it is primary, i.e., due to abnormal vitreofoveal traction. The role of the vitreous cortex in the pathogenesis of MH started to be better understood with the biomicroscopic

observations of Gass.<sup>1,2</sup> The advent of optical coherence tomography (OCT), which showed the partially detached posterior hyaloid, clarified the understanding of MH formation. Spectral domain OCT (SD-OCT) subsequently provided more detailed views of the initial foveal changes induced by vitreofoveal traction. MH are known since the nineteenth century. However, they only aroused renewed interest after Kelly and Wendel<sup>3</sup> had shown that pars plana vitrectomy (PPV) combined with vitreous cortex detachment and fluid–gas exchange could close MH in a significant proportion of cases, although it was assumed that the retina would be unable to heal. The success rate of MH surgery gradually increased progressively, and this surgery is now one of the most successful vitreoretinal surgery.

## History

MH was first described in 1869 by Knapp<sup>4</sup> in a traumatic case. Noyes<sup>5</sup> in 1871 gave a detailed ophthalmoscopic description of a traumatic case, and in 1900 Ogilvie<sup>6</sup> was the first to use the term of “hole at the macula.” Early in the 20th century Kuhnt (1900)<sup>7</sup> and Coats (1908)<sup>8</sup> suggested that the origin of MH was degenerative, although Zeeman<sup>9</sup> (1912) and Lister<sup>10</sup> (1924) attributed it to a vitreoretinal tractional mechanism. The modern history of MH started with Gass, who proposed a staging system ranging from impending to full-thickness MH, on the basis of his biomicroscopic observations.<sup>11–13</sup> Kelly and Wendel<sup>3</sup> performed the first successful surgery of MH, and Hee et al.<sup>14</sup> were the first to describe the stages of MH on OCT scans (see Frangieh<sup>15</sup> and Ho,<sup>16</sup> for review)

## Epidemiology and Risk Factors for Primary Full-Thickness Macular Holes

### Prevalence

The prevalence of MH reported in the literature varies greatly. It was 3.3 per 1000 in the Baltimore Eye Study,<sup>17</sup> 0.2 per 1000 in the Blue Mountains Study,<sup>18</sup> 0.9 per 1000 in the Beijing study,<sup>19</sup> and 1.7

per 1000 in a study in Southern India.<sup>20</sup> In the Beaver Dam Study the prevalence was 4 per 1000 in a population of subjects aged 63–102 years.<sup>21</sup> The incidence of MH was studied in the United States in a county of Minnesota and had been found to occur in 7.8 persons per 100,000 and per year, with a female-to-male ratio of 3.3 to 1. MH was bilateral in 11.7% of patients.<sup>22</sup>

## Incidence in the Fellow Eye

The data on the incidence of bilateral MH vary considerably from 5 to 16 %. In a retrospective study of 84 cases followed up for 39 months in average, Akiba<sup>23</sup> found that 16.6% of patients had an MH in the fellow eye, and that the proportion rose to 36.8% when that eye presented with a foveal cyst or a central yellow spot. However, no MH occurred in the fellow eye when the vitreous was detached.<sup>23</sup> In a retrospective study by Lewis<sup>24</sup> the incidence was 13% in 4 years; it was 15.6% at 5 years in a prospective study of 144 patients by Ezra,<sup>25</sup> and 7.6% at 6 years in another prospective study of 122 patients.<sup>26</sup> In 2004 Chan et al.<sup>27</sup> proposed the concept of stage zero MH to designate fellow eyes with a normal macular profile on OCT but a posterior hyaloid still attached to the foveal center. In their prospective study of 94 fellow eyes, MH occurred only in 4.5% of cases without visible vitreofoveal adhesion and in 42% of cases with a stage zero MH. However, Chan et al.'s study was limited by the use of OCT1, which at this time did not allowed sufficiently accurate assessment of vitreofoveal adhesion. In 2011, Takahashi<sup>28</sup> selected 42 fellow eyes of 176 patients with MH, examined with OCT3, and presented with persistent vitreofoveal adhesion and early stage 1 intrafoveal lesions. MH occurred in 11.9% of these eyes during the 5-year follow-up period. In a cohort of 43 fellow eyes, the same author has identified five eyes with intrafoveal microstructural changes, including foveolar detachment, two of which evolved to a MH over a 6-month follow-up period.<sup>29</sup>

## Risk Factors

Age 65 or older and female gender are the only two relevant systemic risk factors yet identified. Several authors have found that these factors were present in 67–72% of MH cases.<sup>21,30–32</sup> In a cohort

of 1045 patients undergoing MH surgery, the age at presentation was 70.3 years with a 2.2 : 1 female preponderance.<sup>33</sup>

## **Pathogenesis, From Posterior Vitreous Detachment to Impending Macular Hole**

### **History of Theories on the Pathogenesis of Macular Hole**

#### **Vitreomacular Traction**

Vitreomacular traction (VMT) has long been suspected to be a cause of MH formation, but until the advent of OCT it was difficult to visualize the vitreofoveal interface routinely. However, various indications of the role of the vitreous had been given in the literature. Thus, in 1952 Grignolo provided histologic evidence of strong vitreomacular adherence to the fovea.<sup>34</sup> In particular cases, biomicroscopic observations strengthened the hypothesis that anteroposterior traction of vitreous fibers on the fovea played a role in the formation of MH.<sup>35–40</sup> The biomicroscopic observation of opercula also strengthened the possibility that anteroposterior traction is the cause of MH.<sup>36,41</sup>

#### **Foveal Cyst**

The existence of a foveal cyst in the fellow eye of an eye with MH was shown histologically by Kornzweig in 1950<sup>42</sup> and by Frangieh and Green in 1981.<sup>15</sup> Also in 1981, Bronstein,<sup>43</sup> and in 1982 McDonnell et al.,<sup>44</sup> analyzed a series including fellow eyes and eyes with MH. They concluded that idiopathic macular cysts and holes were part of the same disorder and described the role of the vitreous body in their formation. On the basis of scanning laser ophthalmoscope observations Kishi et al.<sup>45</sup> deduced, in 1995, that foveal cyst formation due to vitreous traction was the first step in MH formation. In 1998, Folk et al.,<sup>46</sup> who used laser slit-lamp photography, were able to obtain a direct image of the foveal cysts which they considered to be a prehole condition. This was

confirmed in the same year by Hee et al.<sup>14</sup> using OCT, which showed, for the first time, the vitreous cortex attached on the roof of a foveal cyst. Foveal cyst appeared then to be an initial change in the foveal structure that predisposes to the risk of progression to MH.<sup>47,48</sup>

## **Contraction of the Premacular Vitreous Cortex**

In 1988 Gass revised the biomicroscopic description of MH and proposed a new interpretation of the role of the vitreous in the pathogenesis of MH. He also proposed a system of MH staging, from impending to full-thickness MH. In his initial description in 1988, Gass postulated that the tangential contraction of the prefoveal “posterior hyaloid membrane” resulted in the detachment of the central photoreceptors and then in the opening of the fovea.<sup>2</sup> The process of MH formation was divided in four stages that are still used today, despite the changes in their interpretation due to OCT findings. Lastly, Gass proposed the use of a surgical approach design to prevent impending MH from evolving into full-thickness MH by peeling off or dissecting the posterior hyaloids.<sup>2</sup>

## **Update on the Pathogenesis of Macular Hole Based on SD-OCT**

For the first time, OCT has shown routinely the status of the posterior hyaloid or vitreous cortex, making it possible to combine in a single explanation, oblique anteroposterior vitreous traction, and the occurrence of intrafoveal microstructural changes even before the occurrence of a foveal cyst. SD-OCT has now refined the description of the initial stages of impending MH by showing discrete changes in the foveal tissue such as discrete elevation of the interdigitation zone (IdgZ), minute foveolar detachment, subtle vertical line across the foveal center, or paracentral foveal splits.<sup>28,29,49,50</sup>

## **Early Stages of Posterior Vitreous Detachment**

The process of posterior vitreous detachment (PVD) is not yet clear, but its understanding has progressed thanks to the images obtained with OCT of the posterior hyaloid in normal eyes, and in fellow eyes of eyes with MH. It was usually thought that PVD occurred suddenly after a long period of vitreous gel liquefaction, intravitreal lacunae formation, and posterior hyaloid erosion by one of these lacunae, thus suddenly giving the liquefied vitreous access to the preretinal space.<sup>51-54</sup> However, contrary to this belief, both OCT studies<sup>55</sup> and ultrasonographic observations<sup>56</sup> have established that in normal individuals, the process of PVD starts gradually at the posterior pole, around the fovea, and occurs relatively early in life, long before detachment of the Weiss ring.<sup>57</sup> This aspect is also known as vitreous macular adhesion and is normal in the process of PVD<sup>58</sup> (Fig. 121.1A).

**FIG. 121.1** Vitreomacular adhesion and vitreomacular traction in fellow eyes of macular holes. (A) Vitreomacular adhesion: horizontal optical coherence tomography (OCT) B-scan showing the posterior hyaloid (*arrows*) slightly detached from the macular surface but still adherent to the fovea. The foveal curvature and structure are normal. (B) Horizontal OCT scan showing most of the posterior hyaloid (*blue arrow*) detached from the macular surface, except at the edge of the foveal pit to which it still adheres. (Inset) Detail of panel B: Change in the inner foveal curvature at the point of traction exerted by the posterior hyaloid (*red arrow*). The ellipsoid zone (EIIZ, *yellow arrow*) is intact, but a small section of the interdigitation zone (IdgZ) is detached (*yellow arrow*).

The attachments of the posterior hyaloid to the foveal center and optic disc are the last to be released. The reason for posterior hyaloid detachment from the retina remains unclear. It might be due to the action of oblique anteroposterior forces that follows the

direction of the collagen fibers of the vitreous body. An alternative explanation, which takes into account the presence of the precortical vitreous pocket,<sup>59-61</sup> might be the passage of liquefied vitreous behind the thinned posterior hyaloid which, combined with ocular movements, would extend its detachment. Both mechanisms might lead to the creation of oblique tractional forces on the foveal floor.

## Impending Macular Hole

### Early Changes in Foveal Tissue (Figs. 121.1B and 121.2)

Based on the observation that in patients with macular hole OCT of the fellow eye often showed PVD around the fovea,<sup>14,47,48</sup> Chan et al.<sup>27</sup> have found that cases with partial perifoveal vitreous detachment, but no foveal cyst, were at risk of developing MH. At present, in such cases, SD-OCT shows, even in asymptomatic eyes, a variety of changes in the foveolar structure and impending MH are considered as a special circumstance of VMT occurring in the fellow eye of a MH.<sup>58</sup> SD-OCT is able to detect a slight focal elevation of the inner curvature of the foveal center due to the traction exerted by the posterior hyaloids.<sup>49</sup> Minor changes in the interdigitation zone<sup>62</sup> and foveolar detachment may correspond to the central yellow spot observed by Gass in impending MH.<sup>29</sup> Subtle changes in the reflectivity of the center of the foveola, along an anteroposterior axis extending from the internal limiting membrane (ILM) to the ellipsoid zone, may also be detected by high-definition SD-OCT scans. In other cases, the foveal floor is elevated by the traction exerted by the posterior hyaloid, which is detached around the foveola but still attached at its center (Fig. 121.3 online).<sup>47,48</sup> Some dissociated Henle fibers are often visible inside the cyst, but the retinal outer layers may be intact.<sup>28,48</sup> In such cases the photoreceptor ellipsoid zone may be normal or elevated or even disrupted at the foveal center (Fig. 121.4). Finally, these various anomalies may be combined and include a disruption of the outer part of the photoreceptors and of the Henle fiber layer, only the ILM remaining intact. These cases may be considered as occult MH and correspond to what has been described as stage 1B

MH<sup>13,28,29,47,48,63</sup> (Fig. 121.5).

**FIG. 121.2** Vitreomacular traction in a fellow eye of macular hole. Partial detachment of the posterior hyaloid, which still adheres to the foveal floor, creating two small elevations of the foveal pit contour (*blue arrows*). (Inset) Detail of panel A: Foveal elevation of the EILZ and IdgZ. A hyperreflective columnar structure links the internal and external limiting membranes. The eye is asymptomatic, and vision is 20/20.

**FIG. 121.4** Impending macular hole with vitreomacular traction. (A) Horizontal 9-mm optical coherence tomography scan showing a cyst in the inner part of

the fovea (*asterisk*) due to the traction exerted by the incompletely detached posterior hyaloid (*arrows*). (B) Magnification of panel A showing that the central cyst is divided into several cystic spaces (*asterisks*) by septa. The ellipsoid zone (EIZ) is intact, but the interdigitation zone (IdgZ) is elevated at the foveal center.

**FIG. 121.5** Impending macular hole with vitreomacular traction. The posterior hyaloid (*PH*) is still attached to the roof of the cyst. The cystic space extends posteriorly, and there is a break in the photoreceptor layer. Note also the cystic cavities around the central defect. This impending macular hole is an occult macular hole.

**FIG. 121.3** Impending macular hole with vitreomacular traction (same case as in Fig. 121.4). (A) Autofluorescence photograph of the macula showing that the clear spaces of the cystic spaces encroach on the xanthophyll. (B) Reconstruction of the volume of the vitreoretinal interface showing the cone of the posterior hyaloid (*PH*) adherent to the top of the foveal pit (*arrow*). (C) and (D) Three-dimensional views of the foveal surface showing the elevation of the roof of the foveal cyst into the foveal pit.

At any stage, complete normalization of the fovea may occur after vitreofoveal separation.

## Clinical and Imaging Features of Full-Thickness Macular Holes

### Biomicroscopy Observations of Full-Thickness Macular Hole

A classification of MH based on biomicroscopy has been provided by Gass in 1988 and updated in 1995.<sup>13,64</sup> Stage 2 MH was described as an eccentric oval, crescent, or horseshoe-shaped retinal defect on the edge of the yellow ring. This was interpreted as a tear in the contracted prefoveolar vitreous tissue bridging the round retinal hole, with no loss of foveolar retina.<sup>13</sup> According to the Gass definition, the Stage 3 MH was a central round retinal defect of more than 400  $\mu\text{m}$  in diameter, with a rim of elevated retina, with or without prefoveolar pseudo-operculum (Fig. 121.6) and without a Weiss ring. OCT has now changed the understanding and staging of MH.

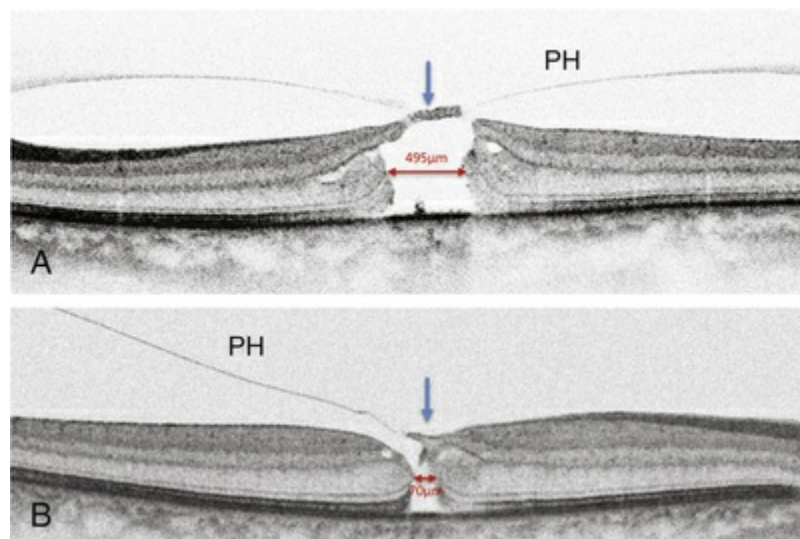

**FIG. 121.6** Full-thickness macular hole. (A) Color photograph showing the hole and its rim of detached and thickened retina. (B) Laser slit-lamp photograph showing the thickened edge of the macular hole and the operculum in front of the hole (*arrow*); the posterior hyaloid is not visible by slit-lamp photography.

## OCT Classification of Macular Hole

OCT has now replaced biomicroscopy for the diagnosis of MH, and a new classification has been proposed based on both the MH diameter and the status of the vitreous attachment at the hole edge.

It has indeed been shown that the hole size was correlated with the need for ILM peeling,<sup>65</sup> face-down positioning,<sup>66,67</sup> or the indications of enzymatic vitreolysis.<sup>68</sup> The presence of a vitreoretinal attachment is also the target of enzymatic vitreolysis, although its presence is not related to the hole size.<sup>58,69</sup>

When the vitreous is still attached to the hole edge, the incompletely detached operculum is pulled in an oblique direction by the posterior hyaloid.<sup>14,47</sup> Recent observations by Takahashi<sup>29,50</sup> showed that neuronal elements formed a constitutive part of the operculum at least in some cases, which supports the histologic findings of Ezra showing the presence of cone constituents in two-thirds of the opercula he examined<sup>70</sup> (Fig. 121.7).

**FIG. 121.7** Full-thickness macular holes with vitreomacular traction. (VMT). (A) Large macular hole with VMT. The posterior hyaloid (PH) is still attached to the operculum (arrow). The operculum is only partially detached from the hole edge. The hole diameter is 495  $\mu\text{m}$ . (B) Small macular hole with VMT. The posterior hyaloid (PH) is detached from the temporal part of the macula only and adheres to the operculum (arrow). The hole diameter is small, 70  $\mu\text{m}$ .

At a later stage in the course of MH, the posterior hyaloid is completely detached from the retinal surface over the posterior pole and not connected to the hole edge whereas it remains attached to the optic disc (Fig. 121.8). Finally, the PVD becomes complete with

a Weiss ring visible on biomicroscopy.

**FIG. 121.8** Full-thickness macular hole with the posterior hyaloid (*PH*) detached from the macular surface and containing an operculum (*blue arrow*). The edge of the hole is thickened by cystic spaces, and the photoreceptors are elevated (*black arrows* mark the end of the outer segments of the elevated photoreceptors).

## Measurement of the Macular Hole Diameter

The aperture size is measured using the caliper function on SD-OCT devices. The minimum hole width is measured at the narrowest hole point in the mid retina, using the OCT caliper function, as a line parallel to the retinal pigment epithelium.<sup>58</sup> Empirically it corresponds to a line drawn between the terminations of the detached photoreceptor outer segments (Fig. 121.6). Other methods have also been described,<sup>71,72</sup> but the minimum hole width tends to be a standard.

## International Vitreomacular Traction Study Group Classification

An OCT-based FTMH classification system was based on the hole size, the presence or the absence of a VMT, and the cause of the hole. The VMT was defined as present or absent. The hole size (diameter) was defined as small, medium, or large. Small holes have an aperture size less than 250  $\mu\text{m}$ . These small holes usually represent less than 10% of operated MH. A medium hole is defined by an aperture size ranging between 250 and 400  $\mu\text{m}$ . Almost half

of FTMHs are large (diameter >400 μm) at the time of diagnosis<sup>58</sup> (Tables 121.1 and 121.2).

**TABLE 121.1**  
**Classification of Macular Holes**

Classification Commonly Used for Full-Thickness MH	International VMT Study
Stage 2: small hole	Small or medium FTMH with VMT
Stage 3: large hole	Medium or large FTMH with VMT
Stage 4: FTMH with PVD	Small, medium, or large FTMH without VMT

FTMH, full-thickness macular hole; PVD, posterior vitreous detachment; VMT, vitreomacular traction.

**Correspondence of the Macular Hole Classification**

Stage	Biomicroscopy (Gass) <sup>13</sup>	Interpretation (Gass) <sup>13</sup>	OCT <sup>27,29,47,48</sup>	International VMT Classification <sup>58</sup>
Stage 0 MH			Perifoveolar detachment of posterior hyaloid with normal fovea contour. <sup>27,28</sup>	VMA
Stage 1A Impending MH	Central yellow spot, loss of foveolar depression, no vitreofoveolar separation	Early serous detachment of foveolar retina	Perifoveolar detachment of posterior hyaloid. Foveal cyst in the inner foveola, and/or foveolar detachment of the cone outer segment tip line <sup>28</sup>	VMT
Stage 1B Impending MH	Yellow ring with bridging interface, loss of foveolar depression, no vitreofoveolar separation	Serous foveolar detachment with lateral displacement of xanthophyll, or Central occult foveolar hole with bridging contracted prefoveolar cortex	Perifoveolar detachment of posterior hyaloid. Foveal cyst extending in the outer retina, causing a break in the photoreceptor layer. "Occult Macular Hole"	VMT
Stage 2 Macular	Eccentric oval, crescent, or	Hole (tear) in contracted	Hole of various size. Partial opening of the roof of the cyst,	Small or medium

hole	horseshoe retinal defect Inside edge of yellow ring	prefoveolar vitreous bridging round retinal hole, no loss of foveolar retina	the operculum staying still attached to the edge of the hole. Partial detachment of the posterior hyaloid, which is still attached at the operculum. The operculum contains retinal elements	FTMH with VMT
	Central round retinal defect retina, with or without prefoveolar opacity	Hole with pseudo-operculum, rim of retinal detachment		Small or medium FTMH with VMT
Stage 3 Macular hole	Central round $\geq 400 \mu\text{m}$ diameter retinal defect, no Weiss ring, rim of elevated retina, with or without prefoveolar opacity	Hole with pseudo-operculum, no posterior vitreous detachment	Hole of various size. Posterior hyaloid detached from the macular surface, but still attached to the optic disc, most often containing an operculum	Medium or large FTMH with VMT
Stage 4 Macular hole	Central round defect, rim of elevated retina. Weiss ring with prefoveolar opacity	Hole with pseudo-operculum and posterior vitreous detachment from optic disc and macula	Hole of various size, with complete PVD on biomicroscopy. The posterior hyaloid is not visible on OCT	Small, medium, or large FTMH without VMT

FTMH, full-thickness macular hole; MH, macular hole; OCT, optical coherence tomography; PVD, posterior vitreous detachment; VMA, vitreomacular adhesion; VMT, vitreomacular traction.

This classification does not take into account the possible presence of an epiretinal membrane (ERM) around the hole, which is more frequent in large MH.

## Macular Hole and Epiretinal Membrane (Fig. 121.9)

A noncontractile ERM may cover the macular surface around the hole. It is especially well visualized on blue reflectance photographs.<sup>73</sup> The frequency of the formation of an ERM increases with the hole stage, duration, and size.<sup>73-75</sup> They are mainly composed of glial cells and hyalocytes and do not show any sign of contraction in small MH.<sup>76,77</sup> Their presence does not affect the surgical outcome once the membrane has been peeled off during

surgery.

**FIG. 121.9** Stage 3 full-thickness macular hole, blue reflectance photograph. The contours of a noncontractile epiretinal membrane are visible around the hole (*arrows*).

## Differential Diagnosis

Differentiating a full-thickness MH from other roundish anomalies of the fovea is no longer a problem since the advent of OCT, which clearly shows the characteristic profiles of lamellar MH and macular pseudoholes, as well as foveal cysts of various origins.

## Lamellar Macular Hole

The term lamellar macular hole (LMH) was coined by Gass in 1975 to characterize a macular lesion resulting from the opening of the central cyst of a cystoid macular edema. On biomicroscopy, LMH differ from FTMH because they are rarely round but rather bi- or trilobulated. Their center is reddish like that of FTMH, but their edge is thin, whereas the FTMH edge is thick and elevated. The term lamellar hole was used to describe both the endstage of a cystoid macular edema<sup>15</sup> and the aborted process of formation of a

MH.<sup>78</sup> With the advent of high resolution or SD-OCT, the irregular thickness of the foveal center due to the contraction of an ERM was also referred to as a LMH.<sup>79</sup>

## **Histology of Lamellar Macular Hole**

Frangieh et al.<sup>15</sup> described the histology of 17 cases of LMH of various etiologies. The cases were characterized by thinning of the foveal tissue leaving the RPE and photoreceptor layers intact, but causing partial loss of the inner nuclear layer. A cleft between the inner and outer retina was present at the edges of the LMH, as well as cystic changes. In some cases remnants of vitreous bands adhered to the lamellar hole edge. An ERM was found in several cases around the lamellar hole edge<sup>15,80</sup> and was thought to be the cause of certain LMH.<sup>80,81</sup>

## **Optical Coherence Tomography (Fig. 121.10)**

LMH, i.e., defects in the inner fovea due to the avulsion of the roof of a foveal cyst (either tractional or due to cystoid macular edema), is characterized on OCT by irregular thinning of the foveal floor, a cleavage between the inner and outer retina at the lamellar hole edge, and the absence of a contractile ERM.<sup>78,82</sup> An epiretinal proliferation is present in about 30% of cases but differs from conventional ERMs. It looks like an amorphous material of medium reflectivity with no evidence of traction, especially on en face OCT images, where no retinal folds are seen.<sup>82,83</sup> Moreover, this proliferation has a dense yellow appearance with a fluffy consistency and histology shows that, unlike conventional ERMs, this proliferation does not contain myofibroblasts.<sup>84,85</sup>

**FIG. 121.10** Lamellar macular hole. (A) Color photograph showing a roundish, lobulated, red central area corresponding to the thinning of the fovea after avulsion of the roof of a foveal cyst. (B) En face optical coherence tomography (OCT) image of the same case. The dark area (*white arrow*) indicates the extent of the central defect and corresponds to the cleft between the inner and outer retina inside the edge of the lamellar hole. (C) OCT scan showing the irregular base of the lamellar hole and the cleft between the inner and outer retina inside the edge of the lamellar hole (*blue arrow*).

## Macular Pseudoholes

The term of macular pseudohole was coined by Allen and Gass<sup>86</sup> in 1976 to designate a roundish centrofoveal image seen on biomicroscopy, which was due to the centripetal contraction of an ERM. This contraction induces the verticalization of the edge of the foveal pit. Vision may remain relatively good, and there are no microscotomas.

## Optical Coherence Tomography (Fig. 121.11 online)

**FIG. 121.11** Pseudo macular hole. (A) Color photograph showing a roundish, red, central area surrounded by the reflex of an epiretinal membrane (ERM). (B) En face optical coherence tomography (OCT) image focused on the retinal surface showing the retinal folds induced by the ERM. (C) A horizontal OCT scan shows the typical appearance of a U-shaped foveal pit with vertical edges, due to the contraction of the ERM (*arrows*).

OCT examination makes diagnosis of macular pseudoholes easy, by showing the thickening of the macula contracted by an ERM, and the U or V shape of the fovea. There is no loss of retinal tissue at the umbo of the fovea.<sup>78</sup> Some aspects of macular pseudoholes have been mistaken for LMH because of a stretching of the Henle fibers on the edge of the fovea.<sup>79</sup> However, en face OCT and surgical outcome show that these aspects are a peculiar form of macular pseudohole,<sup>82</sup> and histopathology confirmed the presence of

myofibroblasts in ERMs while they were absent in LMHs.<sup>84</sup>

## Secondary Macular Hole

Orbital Trauma and High Myopia (Fig. 121.12 online)

**FIG. 121.12** Posttraumatic macular hole. (A) Color photograph showing the macular hole, and in the upper part of the posterior pole, a greyish area resulting from the trauma. (B) Autofluorescence of the same case showing, in the upper part of the posterior pole, deep hypoautofluorescence due to damage to the retinal pigment epithelium, as well as loss of

photoreceptors in the contused area. The vertical line indicates the orientation of the OCT scan. (C) On the optical coherence tomography (OCT) map, the upper part of the macular area is atrophic (deep blue, *asterisk*). (D) The edge of the macular hole is asymmetric, i.e., thicker in its lower than upper part. The upper limit of the hole is adjacent to the area of retinal atrophy. The limit between the relatively normal and atrophic area of the outer retina is about 500  $\mu\text{m}$  from the hole edge (*white arrow*).

These MH usually occur in children and young male adults as accidents at work in the home, or during ball games.<sup>87,88</sup> They are due to sudden axial compression of the eye resulting in equatorial expansion and retinal rupture of the fovea. The hole may be combined with other fundus lesions such as choroidal or Bruch's membrane disruption, commotio retinae, sclopetaria, or peripheral breaks. The visual prognosis depends not only on the closure of the hole but also on the topography of the other lesions. If a choroidal disruption passes through the fovea, or if the postcontusive RPE atrophy includes the foveal center, the visual prognosis will be poor. Unlike what occurs in idiopathic MH, the vitreous is not detached at all from the posterior pole. Surgery is usually successful, but a traumatic MH may also sometimes close spontaneously within the first weeks of its occurrence.<sup>89-91</sup>

## High Myopia

MH are one of the complications of high myopia together with posterior staphyloma and choroidal atrophy. Their pathogenesis may be different from that of nonmyopic eyes because the vitreous cortex often remains adherent to the retinal surface. Some of these MH occur after a progressive decrease in vision due to the worsening of foveoschisis.<sup>92</sup> Others may be asymptomatic and may only be disclosed by OCT examination of the fundus.<sup>93</sup> Despite progress in vitreous cortex and ILM removal, the anatomic and visual postoperative prognosis for MH in high myopia remains lower than for idiopathic MH<sup>94,95</sup> (see [Chapter 117](#), High myopia and the vitreoretinal complications).

## Other Rare Causes

Many other rare causes of secondary MH have been described, of which the most significant are listed in [Box 121.1](#).

### Rare Causes of Secondary Macular Holes

Alport syndrome<sup>96</sup>

Behçet disease<sup>97</sup>

Best macular dystrophy<sup>98</sup>

Cat scratch disease<sup>99</sup>

Central retinal artery occlusion<sup>100</sup>

Drusen<sup>101</sup>

Electrical shock injury<sup>102</sup>

Fungal endophthalmitis<sup>103</sup>

Idiopathic parafoveal telangiectasia<sup>93</sup>

Laser pointer<sup>104</sup>

Nd:YAG laser injury<sup>105</sup>

Nd:YAG posterior capsulotomy<sup>106</sup>

Retinal arterial macroaneurysm<sup>107</sup>

Retinitis pigmentosa<sup>108</sup>

Stargardt disease<sup>109</sup>

Syphilis<sup>110</sup>

Toxoplasmic choroiditis<sup>111</sup>

Valsalva retinopathy<sup>112</sup>

Vitrectomy<sup>113</sup>

Vogt–Koyanagi–Harada disease<sup>114</sup>

X-linked juvenile retinoschisis<sup>115</sup>

## Surgery for Macular Hole

### Introduction

Kelly and Wendel first initiated successful surgery for MH and reported their results for 52 cases in 1990.<sup>3</sup> Their success rate was 58% with a technique combining extensive vitrectomy, detachment of the posterior vitreous cortex, peeling of any ERM around the hole, thorough fluid–gas exchange, and postoperative face-down positioning. Two years later in a larger series of 170 eyes, the closure rate reached 73%.<sup>116</sup> The technique of posterior vitreous cortex removal had benefitted from the attempt made by de Bustros et al. to prevent surgically the progression of impending hole to full-thickness hole.<sup>117</sup>

### How Do Vitrectomy and Gas Work to Close the Hole?

#### Releasing Vitreous Traction on the Hole Edge

OCT has shown that the posterior vitreous cortex remained attached to the hole edge only in a minority of cases<sup>118</sup> regardless of the hole size. The role of vitreous traction release has been shown in certain cases of spontaneous closure of small MH<sup>119</sup> and after vitreoretinal separation provoked by vitreolysis<sup>120</sup> in MH smaller than 400  $\mu\text{m}$ . Surgery also acts in releasing VMT in these cases. However, in a majority of cases the MH edge is already no longer under the traction of the vitreous because the vitreous cortex is separated from the posterior pole or even from the optic disc. The role of vitrectomy is then rather to enable maneuvers such as ERM or ILM peeling and mainly to make room for gas.

The role of gas in MH closure has been extensively debated. The more likely role is that the gas bubble acts first by dehydrating the

hole edge and then by preventing fluid currents from hampering the healing process. (See Discussion by Berger and Brucker<sup>121</sup>.) However, even gas tamponade is not always essential for hole closure since for small MH the mere release of vitreous attachment by vitreolysis may result in hole closure with a rate of almost 60% in MH smaller than 250  $\mu\text{m}$ ,<sup>120</sup> although gas tamponade raises the success rate in these small holes to 98% or more. In large holes (more than 400  $\mu\text{m}$ ), an effective gas tamponade is mandatory to obtain a success rate of over 90%, where nonsurgical vitreolysis does not close any hole.<sup>68</sup>

### The Healing Process, Histology, Animal Models, and Early OCT (Fig. 121.13)

It has been shown, both in man and in animal models, that MH closure is due to the proliferation of glial cells, which close the break caused by vitreous traction on the foveal center.

Histopathologic studies of four eyes with surgically closed MH all showed that the hole was sealed by the proliferation of Müller cells, but that a residual defect persisted in the photoreceptor layer, which measured 16 to 250  $\mu\text{m}$ .<sup>122-124</sup>

**FIG. 121.13** Postmortem photomicrograph of a healed macular hole, obtained 3 years after vitreous surgery. A glial scar seals the hole (*between arrowheads*). The broken part of the photoreceptor line is only 50  $\mu\text{m}$

long, between the arrows (paraphenylenediamine; phase contrast, x 218). (Reproduced from Funata M et al.

Clinicopathologic study of bilateral macular holes treated with pars plana vitrectomy and gas tamponade. *Retina* 1992;12:289-298. With permission from Masuyama K, Yamakiri K, Arimura N, et al. Posturing time after macular hole surgery modified by optical coherence tomography images: a pilot study. *Am J Ophthalmol* 2009;147(3):481-8 e2.)

A rabbit model of retinal hole closure was constructed, which enabled the steps involved to be followed histologically.<sup>125</sup> By the fourth day after gas tamponade, glial cell proliferation had occurred at the hole edge, and by the seventh day, the hole had been closed by glial tissue.

Optical coherence tomography has also occasionally been performed through silicone oil<sup>126</sup> or through the gas bubble.<sup>127,128</sup> These OCT observations showed that on the day after surgery the hole edge had flattened and that the hole had become smaller or had closed. Another observation made with SD-OCT is that MH closed within 1–3 days depending on the hole size.<sup>129</sup>

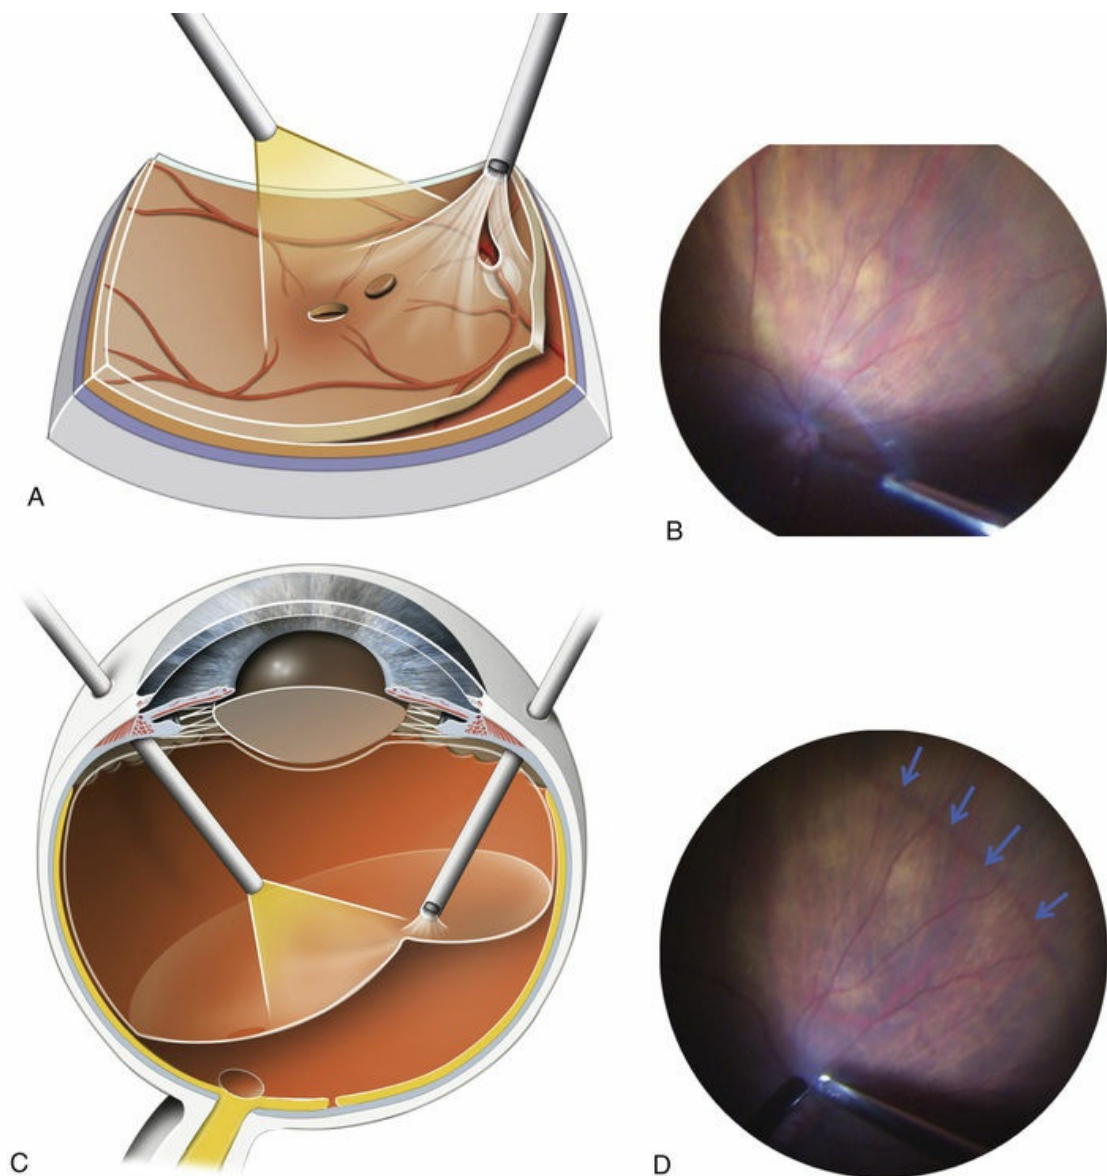

## Principles and Techniques of Macular Hole Surgery

MH surgery has greatly benefitted from the advent of small-gauge transconjunctival sutureless vitrectomy, especially 25-G incisions.

### Posterior Hyaloid Detachment (Fig. 121.14 and Video 121.1 online)

Detachment of the posterior hyaloid (PH) is a crucial step in MH with VMT, in which the vitreous still adheres to the hole edge and optic disc, but also in MH in which the vitreous still adheres to the optic disc. The concept of detaching the posterior vitreous cortex after completing core vitrectomy was introduced in the late 1980s by the group headed by Ron Michels (S de Brustos, personal communication). Histopathology showed that the substance that was separated from the retinal surface exactly corresponded to the vitreous cortex.<sup>130</sup> Various tools have been used for this separation, including an aspirating cannula with a rigid or soft tip, a microvitreoretinal blade<sup>131</sup> or an aspirating forceps,<sup>132</sup> and the

vitreous probe. The 23- and even 25- or 27-G vitreous probes, whose aspirating port is narrower and closer to the tip of the probe, are now very effective for firm aspiration and detachment of the posterior hyaloid. Direct aspiration of the vitreous fibers attached to the Weiss ring appears to be the most effective way of lifting the vitreous cortex en bloc and gradually extending its detachment to the equator in all the quadrants of the fundus. Before starting PH detachment, it is also possible to inject diluted triamcinolone or brilliant blue G in front of the posterior pole for clearer visualization of the vitreous cortex.

**FIG. 121.14** Steps in hyaloid detachment in stage 2

and 3 macular holes. (A) Schematic representation: detachment of the Weiss ring by aspiration over the optic disc with the vitreous probe. (B) Peroperative photograph: the Weiss ring (*arrow*) is almost completely detached by the vitreous probe. (C) Enlargement of the vitreous detachment by the gradual exertion of traction on the posterior hyaloid using aspiration by the vitreous probe. (D) Peroperative view: The limit of the detachment of the posterior hyaloid appears as an arcuate line (*arrows*). (See Video 121.1 online.📺)

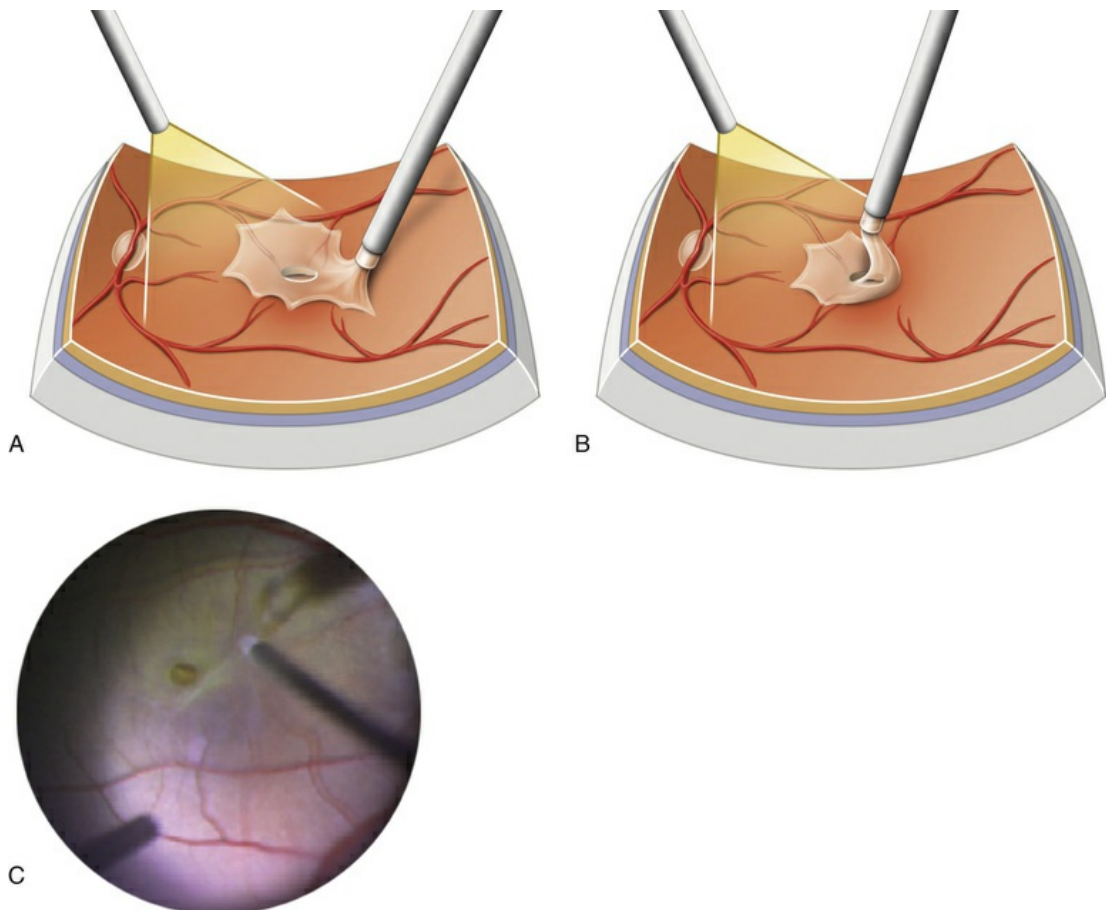

## Extensive Vitrectomy

Although there is no way of proving that extensive vitrectomy is better than partial vitrectomy, there are several arguments in favor of the most extensive vitrectomy possible. Extensive vitrectomy means detachment of the PH up to the equator, followed by shaving of the vitreous base. The removal of as much vitreous as possible allows more gas mixture to be injected into the eye and subsequently prolongs the effect of the gas tamponade. Shaving the vitreous base, especially in the lower periphery, also reduces the risk of postoperative lower retinal breaks and detachment by preventing the gas bubble from exerting traction on the remaining vitreous fibers.<sup>133,134</sup>

## Epiretinal Membrane Peeling (Fig. 121.15 and Video 121.2 online📺)

When present, the ERM around the hole should be peeled off.<sup>73,74</sup> ERM are usually soft and friable. They can be removed by brushing the retinal surface with the soft tip of a back-flush cannula, which is more efficient than forceps. These ERM adhere firmly to the thickness of the hole edge. If a dye that stains the ILM, such as brilliant blue, is used before removing the ERM, the ERM is not stained and appears as a “negative” at the surface at the ILM. The ERM can also be removed en bloc together with the ILM.

**FIG. 121.15** Schematic representation of the dissection of an epiretinal membrane around a macular hole. (A) This soft epiretinal membrane is being detached from the retinal surface to which it is slightly adherent, by gently brushing the surface with the soft tip of a back-flush cannula. (B) The membrane has gradually been detached around the hole. It often adheres firmly to the hole edge. (C) Peroperative view of the dissection of an epiretinal membrane around a macular hole. (See Video 121.2 online.🔊)

### **Internal Limiting Membrane Peeling (Fig. 121.16 and Video 121.3 online🔊)**

ILM peeling as a method of improving the MH closure rate was first described by Eckardt et al. in 1997.<sup>135</sup> The technique has evolved, and the use of dyes has greatly helped ILM visualization. End-gripping forceps are used to pinch and tear a flap of ILM without touching the optic nerve fibers. The ILM is then peeled off in a circular movement, thus creating a “maculorrhexis.”<sup>136</sup> The use

of a diamond-dusted scraper has been proposed to initiate and complete ILM peeling<sup>137</sup> or to disrupt the ILM,<sup>138</sup> but this instrument could be more dangerous for the optic nerve fibers than a forceps.<sup>139,140</sup> More recently Michalewska et al. have proposed not to remove the dissected ILM from the eye but to cover the hole with an ILM flap, especially in myopic eyes and large or refractory MH.<sup>141,142</sup>

**FIG. 121.16** Internal limiting membrane (ILM) peeling. (A) Schematic drawing: a flap of ILM is torn off with an end-gripping forceps. (B) Peroperative view of the ILM dissection: after staining with brilliant blue, a flap of the ILM is progressively detached around the hole in a circular direction to create a maculorhexis. (See Video 121.3<sup>1</sup>)

## Vital Dyes

The use of dyes to stain the ERM and ILM, also known as chromovitrectomy,<sup>143</sup> has made the peeling of the retinal surface more precise, more complete, and less traumatic. (Please refer to [Chapter 126](#), Diagnostic and therapeutic vitrectomy for uveitis.)

### Indocyanine Green and Infracyanine.

Indocyanine green (ICG) was introduced by Kadodono<sup>144</sup> in 2000 for ILM staining and is still widely used, despite concern in some

quarters regarding its safety. ICG has a selective affinity for the ILM and was initially used at the concentration of 0.5%, but on account of changes in the RPE and visual field defects, this concentration has been reduced to 0.125% and even 0.05%, which makes the staining paler but still useful. Nevertheless, Engelbrecht et al. using an ICG concentration at 0.12% concentration observed RPE changes in half their cases.<sup>145</sup> A meta-analysis of ILM peeling in 837 cases showed worse functional results after the use of ICG at the higher concentration of 0.5%.<sup>146</sup> The osmolarity of the ICG solution might have a harmful effect on the retina. Initially a 0.5% ICG solution was used, which had an osmolarity of 250 mOsm. The use of a concentration of 0.05%, whose osmolarity is 290 mOsm, combined with a brief contact time not exceeding 30 sec, with the retina, seems to give no sign of RPE toxicity.<sup>147</sup> Infracyanine, an iodine-free product, diluted in 5% glucose, results in an iso-osmolar solution that might be safer for the retina.<sup>148</sup> However, infracyanine also enters the RPE cells, which it may stain for months after surgery, and like ICG<sup>149</sup> also stains the axons of the retinal ganglion cells.<sup>150,151</sup>

Finally, as exposure to light seems to increase the risk of damage to the retina, the light should be turned off during the short time of ICG contact with the retina.<sup>152</sup> Opinion among vitreoretinal surgeons remains divided on the possible toxicity of ICG application to the retina. ICG should therefore only be used at the minimal concentrations of 0.025–0.05% (0.25–0.5 mg/ml) and for a short time.

### **Trypan Blue.**

Trypan blue (TB) stains well the ERM but poorly the ILM. Nevertheless, it remains an alternative to ICG. To improve TB staining of the ILM, it must be used after fluid–gas exchange. Alternatively, it is easier to mix the dye isovolumetrically in 10% glucose to create heavy TB, which falls onto the posterior pole and results in an acceptable staining after a 2-min contact.<sup>153</sup> However, it has been suggested that this may also increase its osmolarity to toxic levels.<sup>154,155</sup> Alternatively, ready-to-use solutions combining TB with a viscosity- and density-increasing agent or another dye are also available in some countries. In most studies, TB showed no

signs of toxicity to the RPE or neuronal tissue.<sup>156</sup>

### **Brilliant Blue.**

Brilliant blue (BB) has a selective affinity for the ILM and gives a good staining in an iso-osmolar solution of 0.25 mg/ml (0.025%). The staining occurs after a brief contact with the dye injected onto the retinal surface. In animal experiments, the safety profile of BB was good,<sup>157</sup> and it seems the best alternative to ICG. (For a review of the use of dyes in vitreoretinal surgery, see Rodrigues<sup>158</sup> and Farah.<sup>159</sup>)

### **Type of Gas to Use in Macular Hole Surgery.**

Various gases have been used for MH surgery, including  $C_3F_8$ ,  $C_2F_6$ ,  $SF_6$ , and air. The rationale for preferring one gas to another is based on the expected duration of the gas bubble. If we assume that most MH close within 3–7 days of tamponade, a bubble large enough to insulate the macula from intraocular fluid during this period will be sufficient. This, for instance, is the case for a 17%  $C_2F_6$ –air mixture, provided the vitrectomy is large enough to create a large gas bubble. With this mixture, the gas bubble still covers the macula 1 week after surgery if the head is in the upright position, and still fills more than 70% of the vitreous cavity. The essential characteristic of the gas mixture is not so much to persist for a long time in the eye as to decrease slowly in quantity during the first postoperative week. If the hole is small and a 3-day tamponade is assumed to be sufficient, 20%  $SF_6$ –air, or even air alone, might be enough, but it may be preferable for the patient to remain face-down during that time.

### **Use of Silicone Oil in Macular Hole Surgery.**

Silicone oil has been used to avoid the need for positioning in patients unable to maintain the face-down position, to allow air travel after surgery, or to ensure prolonged tamponade in case of failure of the initial surgery. In such cases, some authors stressed the advantages of the use of silicone oil, which gave good results.<sup>160–163</sup> Others noted that the anatomic results were no better with silicone oil than with gas, or that the visual results were

worse.<sup>164-166</sup> Consequently, silicone oil should be used sparingly in MH surgery.<sup>167</sup>

### Use of Healing Adjuvants.

Soon after MH surgery was introduced, attempts were made to improve MH closure by applying healing adjuvants. Bovine transforming growth factor-beta (TGF- $\beta$ ) was used at first and gave favorable results in a randomized study,<sup>168</sup> but these results were not reproduced with recombinant TGF- $\beta$ .<sup>169</sup> Autologous serum has not proved effective in improving MH closure,<sup>170</sup> but autologous platelet concentrates successfully increased the closure rate of MH in a randomized study,<sup>171</sup> although they are not used routinely. Recently, however, autologous blood<sup>172</sup> or autologous platelets<sup>173</sup> have been used again in high myopic eyes or chronic MH or after failure of a first operation.

## Peroperative Complications

Specific peroperative complications are rare. Those that do occur are usually due to vitreous detachment and ILM peeling. In stage 2 and 3 MH, the posterior hyaloid has to be detached from the optic disc and the retina, which may result in retinal breaks at the equator or, very occasionally, paravascular breaks.<sup>174,175</sup> If extensive vitrectomy is accompanied by shaving of the vitreous base, intrabasal vitreous breaks may also occur, although today they are less frequent thanks to the high cutting speed and improved fluidics of the new vitrectomy machines.<sup>176</sup> Nevertheless, rates of 10–20% are currently reported for peripheral retinal breaks that occur during vitrectomy for MH.<sup>175</sup> This highlights the imperative need to check the retinal periphery before performing fluid–gas exchange, in order to treat any peripheral breaks by laser or cryotherapy and avoid the risk of retinal detachment.<sup>133,175</sup>

Complications of ILM peeling such as punctuate damage to the RPE by retinal compression at the ILM gripping point, or fascicular defects due to pinching of the optic nerve fibers, should be avoided by a very cautious approach to the retinal surface. Appropriate staining of the ILM makes its removal safer. Nevertheless, retinal petechiae are common, and bleeding may sometimes occur during

the tangential traction exerted during ILM peeling.

## Postoperative Positioning (Fig. 121.17)

Although Kelly and Wendel considered that strict face-down positioning for at least a week was essential to the success of vitrectomy for MH,<sup>3</sup> attempts to reduce or suppress the burden of positioning started as early as 1997 with a pilot study by Tornambe et al.<sup>177</sup> The authors of this study postulated that the most important function of the gas bubble was to isolate the hole from vitreous fluid and argued that if the bubble was large enough to cover the hole, successful closure would be possible regardless of the patient's position. The same authors discussed the negative effect of the long duration of the hole on the success rate. It is clearer today that the indication for an alleviated position should take into account the hole diameter<sup>67</sup> and be kept for small holes.

**FIG. 121.17** Schematic drawing of the vitreous cavity filled by gas mixture when the head is in the upright position. The gas bubble should cover the macula until the hole is closed.

As regards the positioning itself, it should be borne in mind that the aim of positioning is to keep the MH insulated from liquid

currents until the healing process has started to close the hole. The upright position allows the gas bubble to cover the macula for a period of time that depends on the extent of the vitrectomy, the surgery of the lens, the way in which the vitreous cavity is filled with air, the tightness of the sclerotomies, and how fast the gas mixture is resorbed. The time for which a tamponade is needed depends on the duration of the healing process, which is certainly related to hole diameter. In actual fact, if the gas mixture injected is able to cover the macula for a week, even in the upright position, MH with a diameter of up to 400  $\mu\text{m}$  may be candidates for non-face-down positioning. In such cases, the patient will only be advised to avoid the supine position, even during the night. At least two meta-analyses have now confirmed the absence of benefit of the positioning in MH smaller than 400  $\mu\text{m}$ .<sup>178,179</sup>

## Results of Surgery

### Anatomic Results

As stated above, in the initial series of 52 cases published by Kelly and Wendel in 1990<sup>3</sup> the successful closure rate for MH surgery was 58%, but in the series of 170 eyes published a year later the rate rose to 73%.<sup>116</sup> However, in 1996, a randomized prospective study of vitrectomy for stage 3 and 4 MH versus observation only achieved a success rate of 69% in the vitrectomy group,<sup>180</sup> thus showing that at the time surgery for MH was still in the learning curve phase. Today the closure rate is currently 90–95% or more.<sup>167,181,182</sup>

### Results According to Hole Size

The concept that the success rate for MH surgery depends on hole diameter emerged in 2002 with the publications by Ip<sup>183</sup> and Ulrich.<sup>184</sup> Ip showed that the closure rate was 92% for MH smaller than 400  $\mu\text{m}$  but only 56% for MH of 400  $\mu\text{m}$  or more, as measured on OCT.<sup>183</sup> Subsequent observations confirmed the importance of the size of the hole for its closure. In a series of MH, which had closed spontaneously, mean hole diameter at baseline was less than 200  $\mu\text{m}$ .<sup>119</sup> In a randomized study in which the MH closure rates were compared after intravitreal injection of ocriplasmin and after

placebo, MH smaller than 250  $\mu\text{m}$  had a closure rate of 58.3%.<sup>120</sup>

These findings highlighted the prognostic value of MH diameter for the efficacy of treatment and opened the way to the introduction of the idea of individual treatments tailored to the initial size of the hole.

## **Results According to Internal Limiting Membrane Peeling**

Since the publication by Eckardt<sup>135</sup> showing that the MH closure rate might improve if the ILM was peeled off, many publications, all of them retrospective, have reported closure rates of 87–100% in relatively large series of cases after peeling of the ILM.<sup>185–188</sup> Some of these studies also have compared ILM peeling and nonpeeling in large series of eyes and gave success rates comprised between 77 and 89% without peeling compared to 92–97% with peeling.<sup>188–190</sup> For instance, in a retrospective study Kugamai obtained 92% MH closure after ILM peeling in 175 MH compared to 81% closure without ILM peeling in 417 MH. An interesting observation by this author was that the initial success rate for holes measuring more than 400  $\mu\text{m}$  was significantly less than that for holes measuring less than 400  $\mu\text{m}$ .<sup>189</sup> So far, however, only three prospective randomized studies of ILM peeling versus nonpeeling in MH surgery have been published. Success rates in the peeling groups ranged from 84 to 92% compared to only 32–48% in the nonpeeling groups.<sup>191–193</sup> These results for nonpeeling are far below the success rate of 58% initially obtained by Kelly and Wendel in 1991.<sup>3</sup> The discrepancy between the results for the control groups in the above randomized studies and those of other retrospective studies seems to indicate that other conditions, in addition to ILM peeling, are necessary for MH closure.

On the other hand, it appears that the need for ILM peeling may depend on the size of the hole. In a retrospective study Tadayoni et al.<sup>65</sup> showed that ILM peeling had a positive effect on MH closure in a series of 84 eyes (100% MH closure with peeling vs. 83.3% without). However, this effect did not apply to MH smaller than 400  $\mu\text{m}$  (100% closure in both group). For MH larger than 400  $\mu\text{m}$ , the difference between the effects of peeling and nonpeeling increased (100% closure with peeling vs. 73.3% without). This

tendency was confirmed by a multicenter randomized trial in which the results for ILM peeling were compared to those for nonpeeling in a series of 80 MH larger than 400  $\mu\text{m}$ , and in which the success rate for peeling was 94.9% compared to 73.2 without peeling.<sup>194</sup>

## **Results According to Postoperative Positioning**

From the beginning of MH surgery, face-down positioning for at least a week has been considered of crucial importance for MH closure. However, as early as 1997 Tornambe obtained a reasonable success rate of 79% for hole closure without any face-down positioning.<sup>177</sup> Several other studies that only included a few patients variously combined phacoemulsification, ILM peeling, the use of air or gas mixtures, brief face-down positioning (1–3 days), or none, and obtained success rates of 87–90%. In a randomized prospective trial comparing face-down and seated positioning, face-down positioning was found to give a better closure rate. However, there was no difference between the rates for the two positions when MH were smaller than 400  $\mu\text{m}$  in diameter.<sup>181</sup> Another prospective randomized study compared face-down positioning and an alleviated position for MH not larger than 400  $\mu\text{m}$  in diameter after surgery without ILM peeling and found an equally high success rate of over 90% for both positions.<sup>67</sup> Another study has also compared the results between face-down positioning and nonsupine positioning in MH larger than 400  $\mu\text{m}$  after surgery, including ILM peeling: a similar success rate of at least 90% was found in both groups.<sup>66</sup> It therefore appears in a meta-analysis<sup>178</sup> that face-down positioning after MH surgery is not essential, provided that the gas bubble stays in contact with the macula until the healing process has started to close the hole, and the needed duration depends on the hole size.<sup>195</sup> For this purpose, various gas mixtures can be used, as long as the volume of the gas bubble remains large enough for 3–5 days to make an effective tamponade of the macula in the upright position. Holes larger than 600  $\mu\text{m}$  may, on the contrary, require longer face-down positioning and a longer - acting gas mixture.

## Visual Outcome

### Overall Results

There are few recent prospective studies in which visual acuity has been recorded in a controlled procedure. Moreover, due to the high rate of postoperative cataract, visual acuity (VA) measurement gives pertinent information concerning the value of MH surgery only once the cataract has been operated on, or after combined cataract and MH surgery. In a retrospective study of 74 eyes operated on successfully for a MH, Scott et al.<sup>196</sup> found that after cataract surgery median VA was 20/40 and that 58% of eyes had a VA of 20/40 or more. Among 99 patients with closed MH, 91% of whom were pseudophakic at the end of follow-up, Haritoglou et al.<sup>197</sup> also found that VA improved from a median of 20/100 to 20/40. Three other series showed that VA improved with time and that mean VA reached 20/32 or more 1 and 2 years after surgery.<sup>198–200</sup> After MH closure, preferred retinal locus shifts from an eccentric location on the edge of the hole to a more central position, but the new location is not always in the middle of the hole. A relative or absolute microscotoma detected by microperimetry persists in some cases.<sup>201,202</sup> Visual acuity improves mainly because of the improvement in fixation stability.<sup>203</sup>

### Visual and Anatomic Closure Correlation (Fig. 121.18)

Long-lasting and large size are MH characteristics that are considered poor prognostic factors for MH surgery.<sup>183,184,204,205</sup> Today, however, this may not always be the case, because ILM peeling has improved the anatomic prognosis for large holes, which is nearly the same as for smaller ones, and even long-standing MH may benefit from surgery.<sup>206</sup> However, the hole size affects visual outcome because the closure of large holes may leave a larger glial scar than the closure of smaller ones.<sup>199</sup> In this connection it has indeed been shown on OCT that the morphology and thickness of the foveal photoreceptor layer correlated with final visual acuity.<sup>207,208</sup> The length of the defect in the interdigitation zone<sup>209</sup> or external limiting membrane or ellipsoid zone<sup>210</sup> has been found to correlate postoperatively with the final VA.<sup>211,212</sup>

**FIG. 121.18** Macular holes closed after surgery with various degrees of photoreceptor loss. (A) Left: Horizontal optical coherence tomography (OCT) scan showing a good macular profile after closure of the hole. Right: Detail showing a very small disruption of the ellipsoid zone (*white arrow*). The outer nuclear layer (ONL) is almost continuous at the foveal center. (B) Left: Horizontal OCT scan showing a macular profile thinner than normal after closure of the hole. Right: Detail showing disruption of the ellipsoid zone (*between white arrows*). A central outer cavitation persists in the outer retina. In the foveal center, the ONL has been replaced by scar tissue (*blue arrow*). (C) Left: Horizontal OCT scan showing an abnormal macular profile with a deep foveal pit after closure of the hole. Right: Detail showing great disruption of the ellipsoid zone (*between white arrows*). At the foveal center, most of the ONL has been replaced by a hyperreflective scar (*blue arrow*).

### Visual Outcome and ILM Dye-Assisted Peeling

Although ILM peeling has been proved to improve the closure rate at least of MH larger than 400  $\mu\text{m}$ , it may also have harmful effects

on optic fiber and ganglion cell layers, either through a mechanical effect or the use of ICG to stain the ILM. Several studies have compared visual outcome of eyes in which ILM was stained by ICG or brilliant blue G (BBG) and shown a significantly better outcome in visual acuity with BBG than with surgery using ICG.<sup>213-215</sup> A trend for a lower VA improvement when ICG was used has also been found in a meta-analysis.<sup>216</sup>

## Postoperative Complications of Surgery

### Retinal Detachment

Retinal detachment (RD) may complicate MH surgery as it does for other vitrectomy procedures. At the beginning of MH surgery an especially high proportion of RD (up to 14%) was reported,<sup>217</sup> mainly due to postoperative inferior breaks. These breaks have been attributed to the traction exerted by the gas bubble on the inferior vitreous in the upright position. In more recent publications the rate of retinal detachment tended to decrease to 5% in a meta-analysis of randomized studies<sup>218</sup> and even under 2% for more recent studies,<sup>67,219,220</sup> probably due to a more efficient search for retinal breaks during surgery and to more thorough removal of the inferior peripheral vitreous. However, some other authors still find a higher rate of retinal detachment after MH surgery than after ERM surgery.<sup>133</sup>

### Adverse Anatomic Effects of Internal Limiting Membrane Peeling

ILM peeling results in corrugations of the retinal surface, called dissociated optic nerve fiber layer (DONFL), first observed on blue light reflectance retinographies.<sup>221</sup> The damage to the optic nerve fiber layer could be more important when the cleavage plane is created with a diamond-dusted scraper than with a forceps.<sup>140</sup> OCT B-scan has further shown that this aspect corresponded to dimples in the retinal nerve fiber layer,<sup>222</sup> which are clearly shown on en face

OCT segmented at the retinal surface.<sup>223</sup> DONFL were first thought to have no adverse effect on visual function. However, it has been shown that they were often associated with ganglion cell layer defects<sup>224,225</sup> and microperimetric loss of retinal sensitivity<sup>226,227</sup> (Fig. 121.19).

**FIG. 121.19** Macular holes closed after surgery with dissociated optic nerve fiber layer (DONFL). (A) Blue light reflectance photo showing the arcuate striae of the DONFL (*arrows*). Limit of the area of internal limiting membrane peeling (*arrowheads*). (B) Horizontal B-scan showing more or less deep dimples in the optic nerve fiber layer corresponding to the DONFL. (C) DONFL seen on en face OCT mode,

segmented at the inner retinal surface (*arrows*). (D) Ganglion cell layer thickness map showing a defect in the temporal part of the macula. (E) Ganglion cell layer thickness deviation from normal: note the loss of ganglion cell (in red) in the temporal part of the macula, where the DONFL are maximum.

ILM peeling may also affect ganglion cell layer thickness, especially in the temporal part of the macular area, mostly in cases in which ICG has been used to stain the ILM,<sup>225,228</sup> although another study using brilliant blue-assisted ILM peeling did not find any reduction in ganglion cell layer thickness.<sup>229</sup>

## Visual Field Defects

Inferotemporal sectorial visual field defects were first described in young patients who had undergone pars plana vitrectomy with fluid–gas exchange,<sup>230</sup> and were attributed to retinal nerve fiber layer damage to the nasal portion of the optic nerve rim, probably due to traction during cortical vitreous peeling.<sup>231</sup> Another hypothesis was that injury to the nerve fiber layer by dehydration during the fluid-air exchange might cause visual field defects.<sup>232</sup> In a prospective study in 1997, visual field defects were observed in 23% of cases,<sup>233</sup> but in another series published in 2001, this incidence was only 1%.<sup>234</sup> In any case, sectorial field defects do not significantly affect the outcome of MH surgery.

## Reopening of Macular Hole

Late reopening of MH after successful surgery, i.e., reopening of the hole several months or years after its closure, has been attested on OCT in 5–7% of cases before the era of ILM peeling.<sup>235,236</sup> The reason for reopening remains unclear, but in most cases it might be the proliferation of a secondary ERM around the hole,<sup>74</sup> rather than a side-effect of cataract surgery, as sometimes suggested. Systematic ILM peeling seems to lower the risk of MH reopening to less than 2%.<sup>197,237,238</sup> Reopening might be a complication specific to large MH,<sup>186</sup> which are precisely those whose initial closure rate is improved by ILM peeling. Once a MH reopens, reoperation, with

peeling of the ILM and any ERM, if this was not done during the first operation, usually results in hole closure and visual improvement. If ILM has already been removed, the presence of a tangential traction at the limit of ILM ablation should be investigated and removed. It may also be suggested to dissect a patch of ILM in the posterior pole and to cover the MH, or to use healing adjuvants, but none of these methods has been validated. Otherwise, a simple fluid–gas exchange may be enough to close the hole again.

## Cataract

Cataract is a common complication of pars plana vitrectomy after the age of 60, which explains the high rate of its occurrence after MH surgery. The postoperative rate of pseudophakia at 3 or 5 years is commonly 85–98%.<sup>196,239</sup> This observation has led many surgeons to propose performing combined cataract and MH surgery. In a comparative retrospective study, Muselier et al.<sup>240</sup> have shown that visual results and complications were no different, whether the cataract had been removed after or during MH surgery, but that combined surgery shortened the period required for visual recovery.

## Vitreolysis as a Nonsurgical Treatment for Macular Hole

Ocriplasmin (ThromboGenics NV, Leuven, Belgium) is a recombinant containing the catalytic domain of plasmin and has the same catalytic properties as the human plasmin used for vitreolysis. It has been used in several clinical trials to create a posterior vitreous detachment.<sup>241</sup> The authors of one phase III study compared the respective effects at one month of a single intravitreal injection of ocriplasmin and placebo, on the closure rate of stage 2 MH smaller than 400  $\mu\text{m}$ . The overall success rate for the ocriplasmin group was 40.6% compared to 10.6% in the placebo group. For MH with a diameter of 250  $\mu\text{m}$  or less, the success rate rose to 58.3%, but for holes with a diameter of 250–400  $\mu\text{m}$ , it was

only 24.6%.<sup>120</sup> The proportion of small holes with persistent VMT being small, the indications of enzymatic vitreolysis remain limited so far.
