[1 Fluorescein Angiography](#)

Basic Principles

Equipment (Box 1.1)

Technique

Developing a Photographic Plan

Interpretation

Abnormal Fluorescein Angiogram

Acknowledgments

References

## 2 Clinical Applications of Diagnostic Indocyanine Green Angiography

Introduction

History

Chemical and Pharmacokinetics

Toxicity

Instrument Comparison

Injection Technique

Indocyanine Green Angiography Interpretation

References

## 3 Optical Coherence Tomography

Physical Principles of Optical Coherence Tomography

Quantitative Analysis of OCT Datasets

Normal Macular Anatomy

SD-OCT in Retinal Disorders

OCT Angiography

Future Directions

Disclosures

Acknowledgments

References

## 4 Autofluorescence Imaging

Basic Principles

Techniques of Fundus Autofluorescence Imaging

Interpretation of Fundus Autofluorescence Images

Clinical Applications

Functional Correlates of Fundus Autofluorescence Abnormalities

References

## 5 Wide-Field Imaging

Introduction

Historical Perspective and Terms

Historical Wide-Field Imaging Systems

Modern Wide-Field Imaging Systems

Overview of Imaging Capabilities and Optical Principles

Clinical Utility of Wide-Field Imaging

Limitations

Future Directions

Conclusion

References

## 6 Intraoperative Optical Coherence Tomography Imaging

Background and Historical Prospective

OCT in the Operating Room: Integrative Advances

Surgeon Feedback Platform Enhancements

Surgical Findings With Intraoperative OCT in Vitreoretinal Conditions

Conclusion

References

## 7 Advanced Imaging Technologies

Introduction: Retinal Imaging to Date

Smartphone Ophthalmoscopy – Replacing the Direct Ophthalmoscope?

Adaptive Optics: Imaging of Single Cells in the Retina

Doppler Imaging: Assessment of Blood Flow

Spectral Imaging: Assessment of Retinal Oxygenation

Photoacoustic Imaging: Assessment of Retinal Absorption

Magnetic Resonance Imaging

Molecular Imaging

Conclusions and Future Directions

Disclosure

References

## 8 Image Processing

Introduction

History of Retinal Imaging

History of Retinal Image Processing  
Current Status of Retinal Imaging  
Fundus Imaging  
Optical Coherence Tomography Imaging  
Areas of Active Research in Retinal Imaging  
Clinical Applications of Retinal Imaging  
Image Analysis Concepts for Clinicians  
Fundus Image Analysis  
Optical Coherence Tomography Image Analysis  
Multimodality Retinal Imaging  
Future of Retinal Imaging and Image Analysis  
References

## 9 Electrogenesis of the Electroretinogram

Introduction  
Generation of Extracellular Potentials: General Concepts  
Approaches for Determining the Origins of the Electroretinogram  
Standard ERG Tests in the Clinic  
Origin of the a-Wave  
Origin of the b-Wave  
Origin of the d-Wave  
Origin of the Photopic Fast-Flicker ERG  
Origin of the Multifocal ERG  
ERG Waves From Proximal Retina

Closing Remarks

References

## 10 Clinical Electrophysiology

Standard Full-Field ERG

Focal ERG

Other Special Responses or Techniques in ERG

Electro-Oculogram

Visual Evoked Potential

Simultaneous Recording of Focal Macular ERG and VEP

References

## 11 Diagnostic Ophthalmic Ultrasound

Introduction

Ultrasound – Past and Present

Examination Techniques

Ultrasound in Intraocular Pathology

Ultrasound Imaging Used to Differentiate Ocular Disease

Future Developments

Acknowledgments

References

## 12 Color Vision and Night Vision

Overview

Rod and Cone Functions

Visual Pathways for Rod and Cone Functions

Dark Adaptation Functions: Assessment of the Shift From Day Vision to Night Vision

Color Vision

Variations in Human Color Vision

Clinical Evaluation of Color Vision

New Developments in Color Vision Research

Adaptive Optics (AO) Retinal Imaging System

References

### 13 Visual Acuity and Contrast Sensitivity

Visual Acuity Tests

Contrast Sensitivity Tests

References

### 14 Visual Fields in Retinal Disease

Introduction

Principles of Perimetry

Methods of Visual Field Testing

Perimetry in Specific Retinal Diseases

Future of Perimetry in Retinal Disease

Conclusions

References

## **Part 2 Basic Science and Translation to Therapy**

# Section 1 Anatomy and Physiology

---

## 15 The Development of the Retina

Introduction

Embryology of the Eye

The Eye Field

Patterning the Retinal, RPE, and Anterior Domains of the Optic Cup

Histogenesis of the Retinal Cell Types

Inner Retinal Development

Photoreceptor Development

Ganglion Cell Death

Retinal Maturation

Conclusion

References

## 16 Structure and Function of Rod and Cone Photoreceptors

Introduction

Photoreceptor Fundamentals

Photoreceptor Outer-Segment Structure

Phototransduction

Inner Segment and Connecting Cilia

Photoreceptor Synaptic Terminal

Photoreceptor Dysfunction and Disease

References

## 17 Function and Anatomy of the Mammalian Retina

Visual Illusions and Multiple Channels

Neuronal Communication: Chemical and Electrical

Gross Retinal Morphology

Classification of Retinal Cells

Gene Therapy to Cure Color Blindness

New Tools to Identify Ganglion Cell Types

Clinical Relevance of Functional Anatomy

Conclusions

Acknowledgments

References

## 18 Cell Biology of the Retinal Pigment Epithelium

Embryology

Anatomy and Histology

Specialized Functions of the RPE

References

## 19 Cell Biology of Retinal Glia

Introduction

Retinal Microglia

Retinal Astrocytes

Müller Glial Cells

References

## 20 Retinal and Choroidal Vasculature

Introduction

History of Retinal Ischemia

Normoxia

Hyperoxia

Hypoxia

Adult Retinal Hypoxia and Etiology

Adult Choroidal Ischemia

Conclusions

References

## 21 Mechanisms of Normal Retinal Adhesion

Models for Measuring Retinal Adhesion

Adhesive Force and Environmental Factors

Mechanical Forces Inside the Subretinal Space

Pharmacologic Modification of Adhesion

Implications for Vitreoretinal Surgery

Pathophysiology of Serous Detachment

Conclusions and General Implications

References

## 22 Structure, Function, and Pathology of Bruch's Membrane

Introduction, History, Embryology

Structure of Bruch's Membrane in the Young Adult Eye

Bruch's Membrane in an Aged Eye

Function of Bruch's Membrane  
Pathology of Bruch's Membrane  
Conclusion  
References

## 23 Vitreous and Vitreoretinal Interface\*

Biochemistry  
Anatomy and Histology  
Physiology  
Pathology  
References

## **Section 2 Basic Mechanisms of Injury in the Retina**

---

### 24 Mechanisms of Oxidative Stress in Retinal Injury

Overview of Oxidative Stress in the Retina  
Retinal Diseases Related to Oxidative Stress  
Oxidative Injury to the Retina  
Retinal Therapies Targeting Oxidative Stress  
Conclusions  
References

### 25 Mechanisms of Endoplasmic Reticulum Stress in Retinal Disease

Introduction  
The Endoplasmic Reticulum

ER Stress and Unfolded Protein Response Signaling

Retinal Diseases Associated With ER Stress

Summary

References

## 26 Cell Death, Apoptosis, and Autophagy in Retinal Injury

Introduction

Modes of Cell Death

Autophagy and Cell Maintenance

Age-Related Retinal Cell Loss

Retinal Damage: Death and Repair

Therapeutic Options

Conclusions

References

## 27 Inflammation and Immune Responses in Retinal Health and Disease

Introduction

Innate Defenses in the Maintenance of Retinal Health

Autoinflammation and Autoimmunity

Inflammation, Vascular Regulation, and Pathologic Angiogenesis (Neovascularization)

Inflammation and AGE-Related Macular Degeneration

Targeting Inflammation Through Molecular Stratification: Genetics and Beyond

Conclusion

## References

### 28 Basic Mechanisms of Pathologic Retinal and Choroidal Angiogenesis

Introduction

Mechanisms of Choroidal Angiogenesis

Angiogenic and Antiangiogenic Factors in Neovascularization

Conclusions

References

### 29 Blood–Retinal Barrier, Immune Privilege, and Autoimmunity

Introduction

Blood–Ocular Barrier

Basic Concepts of Immunology

The Eye as an Immune-Privileged Site

Retinal Autoimmunity

Conclusion

References

### 30 Mechanisms of Macular Edema and Therapeutic Approaches

Introduction

Macular Edema as a Result of Various Disease Mechanisms

Clinical Endpoints in Macular Edema

Treatment of Macular Edema

Discussion and Conclusion

References

## 31 Cellular Effects of Detachment and Reattachment on the Neural Retina and the Retinal Pigment Epithelium

Introduction

Use and Limitations of Animal Models in the Study of Retinal Detachment

Cellular Changes in Response to Retinal Detachment

Chronic Retinal Detachment and Proliferative Vitreoretinopathy

Retinal Reattachment

References

## 32 Serous and Hemorrhagic Detachment of the Sensory Retina and Pigment Epithelium

Introduction

Anatomic Constituents

Mechanism of Normal Attachment

Mechanisms of Impairment

Clinical Manifestations of PED and Serous Retinal Detachments

Conclusion

References

## **Section 3 Genetics**

---

### 33 Genetic Mechanisms of Retinal Disease

Introduction

Basic Concepts in Human Genetics

The Human Genome

Genetic Testing Methods

Future Prospects

References

### 34 Mitochondrial Genetics of Retinal Disease

Mitochondrial Origins

Mitochondrial Structure

Mitochondrial DNA (mtDNA)

Mitochondrial Function

Electron Leakage and ROS Formation

Localization of Mitochondria Within the Retina and Optic Nerve

Influences of mtDNA on Cell Function

References

### 35 Epigenetic Mechanisms of Retinal Disease

Introduction

Major Factors of Epigenetic Regulation

Epigenetic Factors in the Retina

Epigenetic Mechanisms in Retinal Development

Epigenetic Mechanisms in Retinal Diseases

Perspectives and Challenges of Epigenetics

References

## **Section 4 Translational Basic Science**

---

## 36 Gene Therapy for Retinal Disease

Background: Preclinical Gene Therapy Studies

History of Retinal Gene Therapy

Current Status of Retinal Gene Therapy Trials: Retinal Diseases Evaluated in Human Clinical Trials

Promises and Challenges of Bringing Retinal Gene Transfer From Bench to Bedside

Conclusion

References

## 37 Stem Cells and Cellular Therapy

Stem Cells as Therapeutics to Treat Retinal Disease

Definitions

Retinal Stem and Müller Glial Cells

RPE Cells

Adult Bone Marrow-Derived Endothelial Progenitor Cells

Human Clinical Trials Using Stem Cells for the Treatment of Retinal Diseases

Discerning the Legitimacy of A Human Stem Cell Treatment

Concluding Remarks

Acknowledgments

References

## 38 Nanomedicine in Ophthalmology

Introduction

General Principles of Nanotechnology and Nanomedicine

Properties of Nanomachines

Applications to Ophthalmology

Obstacles to Incorporation of Nanotechnology Into Ophthalmology

Conclusion

References

## 39 Neuroprotection

History and Definitions

Neuroprotection Through the Serotonin Pathway

Neurotrophic Factors for Retinitis Pigmentosa

CNTF Protein and Historical Selection

CNTF Phase I Trial for Human Photoreceptor Degeneration

New Technology for Endpoints for Photoreceptor Degenerations

Delivery of Neurotrophins

References

## 40 Drug Delivery

Introduction

A Brief History of the Field of Drug Delivery

Drug Delivery

Gene Delivery

Cellular Delivery for Sustained Drug Delivery

Routes of Delivery to the Retina

Pharmacokinetics in the Eye

References

## 41 Retinal Laser Therapy

Introduction

Basics of Lasers

Interactions of Light With Tissue

Monitoring Retinal Temperature

References

# **Volume Two Medical Retina**

## **Section 1 Retinal Degenerations and Dystrophies**

## 42 Retinitis Pigmentosa and Allied Disorders

Introduction

Early History

Typical Retinitis Pigmentosa

Complicated Retinitis Pigmentosa

Differential Diagnosis – Phenocopies of Retinitis Pigmentosa

Differential Diagnosis: Pseudoretinitis Pigmentosa

Basic Science

Genetic Consultation

Support Services

Treatment

Future Management

Acknowledgment

References

## 43 Hereditary Vitreoretinal Degenerations

Snowflake Vitreoretinal Degeneration

The Chromosome 5q Retinopathies

Chondrodysplasias Associated With Vitreoretinal Degeneration

X-Linked Retinoschisis

Retinal Nuclear Receptor (NR2E3)-Related Diseases

Other Vitreoretinal Degenerations and Vitreoretinopathies

References

## 44 Macular Dystrophies

Introduction

The Initial Approach to a Patient With Macular Dystrophy

Best Macular Dystrophy

Stargardt Disease

Stargardt-Like Dominant Macular Dystrophy (SLDMD)

*PROM1*-Associated Macular Dystrophy

Pattern Dystrophy

Sorsby Fundus Dystrophy

Autosomal Dominant Radial Drusen (Doyme Honeycomb Retinal Dystrophy, Malattia Leventinese)

North Carolina Macular Dystrophy

Spotted Cystic Dystrophy

Dominant Cystoid Macular Dystrophy

Fenestrated Sheen Macular Dystrophy (FSMD)

Glomerulonephritis Type II and Drusen

Maternally Inherited Diabetes and Deafness

Acknowledgments

References

## 45 Hereditary Choroidal Diseases

Introduction

Choroidal Atrophy Phenotypes

Gyrate Atrophy of the Choroid and Retina

Choroideremia

Clinical Phenotypes Resembling Hereditary Choroidal Diseases

Conclusion

References

## 46 Abnormalities of Rod and Cone Function

Introduction

Disorders of the Cone System

Congenital Stationary Night Blindness

Progressive Cone Dystrophies

Conclusions

References

## **Section 2 Retinal Vascular Disease**

### 47 The Epidemiology of Diabetic Retinopathy

Introduction

Incidence and Progression of Diabetic Retinopathy and Incidence of Clinically Significant Macular Edema

## The Relationship of Race/Ethnicity to Diabetic Retinopathy

Genetic Factors

Sex

Age and Puberty

Type 2 Diabetes in Children and Adolescents

Duration of Diabetes

Age at Diagnosis

Glycemia

C-Peptide Status

Exogenous Insulin

Blood Pressure

Proteinuria and Diabetic Nephropathy

Serum Lipids and Lipid Lowering

Smoking

Alcohol

Body Mass Index (BMI)

Physical Activity

Socioeconomic Status

Hormone and Reproductive Exposures in Women

Comorbidity and Mortality

New Medical Interventions

Public Health Applications of Epidemiologic Data

Conclusion

References

## 48 Diabetic Retinopathy

Introduction

Anatomic Lesions

Biochemical Mechanisms in the Pathogenesis of Diabetic Retinopathy

Genetic Factors in the Pathogenesis of Diabetic Retinopathy

Other Ocular Factors

Retinopathy in Different Forms of Diabetes

Animal Models in the Study of Diabetic Retinopathy

Cell Culture Studies

Conclusion

Acknowledgments

References

## 49 Diabetes Mellitus

Introduction

Prevalence of Retinopathy

Glycemic Control and Retinopathy

Goals of Treatment

Glycemic Control: Pharmacologic Treatment

Initiation and Titration of Therapy

References

## 50 Nonproliferative Diabetic Retinopathy and Diabetic Macular Edema

Natural Course of Nonproliferative Diabetic Retinopathy

Clinical Evaluation of Nonproliferative Diabetic Retinopathy

Clinical Evaluation of Diabetic Macular Edema

Management of Nonproliferative Diabetic Retinopathy and Diabetic Macular Edema

Conclusion

References

## 51 Proliferative Diabetic Retinopathy

Pathogenesis of Proliferative Diabetic Retinopathy

Origin and Early Recognition of Preretinal New Vessels

Natural Course of Proliferative Diabetic Retinopathy

Relationship of Proliferative Diabetic Retinopathy to Type and Duration of Diabetes

Proliferative Diabetic Retinopathy and Blood Glucose Control

Early Worsening of Retinopathy With Improved Glycemic Control

Absence of Proliferative Diabetic Retinopathy in Individuals With Diabetes of Extreme Duration

Systemic Medications and Proliferative Diabetic Retinopathy

Peripheral Diabetic Retinal Lesions and the Risk of Retinopathy Progression

Other Risk Factors for Proliferative Diabetic Retinopathy

Management of Proliferative Diabetic Retinopathy

Current Techniques of Panretinal Photocoagulation

Regression of New Vessels After Initial Photocoagulation and Indications for Retreatment

Complications of PRP

Antiangiogenic Therapies for Proliferative Diabetic Retinopathy

Indications for Vitrectomy

Telemedicine Approaches for the Detection of Proliferative Diabetic Retinopathy

Conclusion

References

## 52 Hypertension

Introduction

Hypertensive Retinopathy

Hypertensive Choroidopathy

Hypertensive Optic Neuropathy

Future Directions

Conclusion

References

## 53 Telescreening for Diabetic Retinopathy

Introduction

Guidelines for Telescreening Program

Steps of Telescreening

Technical Considerations

Operational Considerations

Quality Assurance

Evaluating Telescreening Programs

Advances in Telescreening

Conclusion

## References

Introduction

Drainage Retinotomy

Retinotomy to Gain Access to the Subretinal Space

Relaxing Retinotomy and Retinectomy

Focal or Diffuse Retinal Contraction

Anterior Retinal Displacement

Retinal Shortening Because of Proliferative Vascular Retinopathy

Management of Retinectomy

Results

Complications

References

### 113 Giant Retinal Tear

Introduction

Etiology

Pathogenesis

History of Management of Giant Retinal Tear

Preoperative Evaluation and Planning

Role of Nonsurgical Treatment

Role of Simple Scleral Buckling

Vitreous Surgery

Results

Management of the Fellow Eye

References

## 114 Surgery for Ocular Trauma

Extent of Ocular Injuries

Ocular Trauma Classification

Closed-Globe Injuries

Open-Globe Injuries

Sympathetic Ophthalmia

Application of Online Resources and Newer Technology to Ocular Trauma

Prevention

References

## 115 Surgery for Proliferative Diabetic Retinopathy

Introduction

Indications and Timing of Surgery

Preoperative Evaluation and Informed Consent

Surgery

Surgical Procedure

Postoperative Care

Complications

Results of Surgery as Indicated by Evidence-Based Trials

Conclusion

Online Resources and Apps

### 120 Epiretinal Membranes, Vitreoretinal Traction, and Cystoid Macular Edema

Introduction

Epiretinal Membranes

Vitreomacular Traction and Cystoid Macular Edema

Conclusion

References

### 121 Macular Hole

Introduction

History

Epidemiology and Risk Factors for Primary Full-Thickness Macular Holes

Pathogenesis, From Posterior Vitreous Detachment to Impending Macular Hole

Clinical and Imaging Features of Full-Thickness Macular Holes

Differential Diagnosis

Secondary Macular Hole

Surgery for Macular Hole

Results of Surgery

Postoperative Complications of Surgery

Vitreolysis as a Nonsurgical Treatment for Macular Hole

References

## 122 Surgical Management of Choroidal Neovascularization and Subretinal Hemorrhage

Choroidal Neovascular Membranes

Submacular Hemorrhage

Conclusion

References

## 123 360-Degree Macular Translocation

Background and Rationale

Principles of Foveal Relocation

Preoperative Considerations

Surgical Technique for Macular Translocation

Early Postoperative Management

Functional Outcomes for Macular Translocation Surgery

Postoperative Surgical Complications Following Macular Translocation

Advantages of Macular Translocation and Future Directions

References

## 124 Retinal Pigment Epithelium and Choroid Translocation in Patients With Age-Related Macular Degeneration

Epidemiology

Alternative Treatments for AMD

Surgical Treatment

Rationale for Reconstitution of Retinal Pigment Epithelium

Transplantation of a Full-Thickness Patch From the Midperiphery

Surgery

Results in Exudative AMD

Retinal Pigment Epithelium Transplantation in Dry AMD

Surgical Aspects in Dry AMD

Conclusions for Patient Benefit in Geographic Atrophy

Retinal Pigment Epithelium–Choroid Translocation and Future Stem Cell Treatments for AMD

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

## VOLUME 1, PART 1 Retinal Imaging and Diagnostics

### 6.1 Comparing Handheld and Microscope-Mounted Optical Coherence Tomography Imaging Systems

*Justis P. Ehlers, Cynthia A. Toth – Chapter 6*

### 6.2 Three-Dimensional Reconstruction of a Full-Thickness Macular Hole with Associated Vitreomacular Traction Utilizing a Microscope Integrated Swept Source Optical Coherence Tomography System

*Justis P. Ehlers, Cynthia A. Toth – Chapter 6*

### 6.3 Real-Time Volumetric Peeling with Forceps Visualized with a Swept Source Optical Coherence Tomography System

*Justis P. Ehlers, Cynthia A. Toth – Chapter 6*

6.4 Real-Time Volumetric Peeling with Diamond-Dusted Membrane Scraper Visualized with a Swept Source Optical Coherence Tomography System

*Justis P. Ehlers, Cynthia A. Toth – Chapter 6*

6.5 Intraoperative Optical Coherence Tomography Feedback during Macular Hole Surgery

*Justis P. Ehlers, Cynthia A. Toth – Chapter 6*

**VOLUME 1, PART 2 Basic Science and Translation to Therapy**

36.1 Perfluoruron Placement and Subretinal Injection Procedure

*Albert M. Maguire, Jean Bennett – Chapter 36*

**VOLUME 3, PART 1 Surgical Retina**

**SECTION 2 Retinal Reattachment: General Surgical Principles and Techniques**

104.1 Techniques of Scleral Buckling

*Paul Sullivan – Chapter 104*

106.1 A Case of Primary Vitrectomy for Treating Rhegmatogenous Retinal Detachment

*Young Hee Yoon – Chapter 106*

## 106.2 Primary Vitrectomy for Rhegmatogenous Retinal Detachment

*Hiroko Terasaki – Chapter 106*

## 109.1 Optimal Procedures for Retinal Detachment Repair

*Louisa Wickham, G.W. Aylward – Chapter 109*

### **SECTION 3 Complicated Forms of Retinal Detachment**

## 111.1 Relaxing Retinotomy and Retinectomy for Scarred Contracted Retina and Recurrent Inferior Retinal Detachment due to Proliferative Vitreoretinopathy

*Ian J. Constable, Manish Nagpal – Chapter 111*

### **SECTION 4 Vitreous Surgery for Macular Disorders**

## 121.1 Posterior Hyaloid Detachment

*Alain Gaudric, Ramin Tadayoni – Chapter 121*

## 121.2 Epiretinal Membrane Peeling

*Alain Gaudric, Ramin Tadayoni – Chapter 121*

## 121.3 Internal Limiting Membrane Peeling

*Alain Gaudric, Ramin Tadayoni – Chapter 121*

## SECTION 5 Vitreous Surgery: Additional Considerations

### 131.1 Subluxated Intraocular Lens without Haptics

*Renaud Duval – Chapter 131*

### 131.2 Posterior Synechiae and Small Pupil during Vitrectomy

*Ehab N. El Rayes – Chapter 131*

### 131.3 Induction of Posterior Vitreous Detachment in Retinal Detachment

*Andre V. Gomes – Chapter 131*

### 131.4 Induction of Posterior Vitreous Detachment in High Myopia

*Ramin Tadayoni – Chapter 131*

### 131.5 Iatrogenic Retinal Breaks During Peeling

*Manish Nagpal – Chapter 131*

### 131.6 Internal Limiting Membrane Peeling

*Sjakon G. Tahija – Chapter 131*

### 131.7 Subretinal Injection of Brilliant Blue

*Arturo Alezzandrini, Francisco J. Rodriguez – Chapter 131*

## 131.8 Reopening of Peripheral Retinal Breaks during Surgery for Submacular Hemorrhage

*Carl D. Regillo – Chapter 131*

## 131.9 Surgical Management of Hypotony Maculopathy

*Jose Garcia Arumi – Chapter 131*

## 131.10 Intraoperative Choroidal Detachment

*Homayoun Tabandeh – Chapter 131*

## 131.11 Massive Suprachoroidal Hemorrhage (SCH)

*Jose Garcia Arumi – Chapter 131*

## 131.12 Suprachoroidal Hemorrhage during Cataract Surgery

*Kazuaki Kadonosono – Chapter 131*

## 131.13 Subretinal Perfluorocarbon Bubble

*Maria H. Berrocal – Chapter 131*

## 131.14 Perfluorocarbon-Induced Macular Hole

*Yusuke Oshima – Chapter 131*

## 131.15 Giant Retinal Tear with Slippage on Encircling Scleral Buckle

*Carl D. Regillo – Chapter 131*

131.16 Proliferative Vitreoretinopathy and  
Subretinal Membrane

*Stanislao Rizzo – Chapter 131*

131.17 A Problem during 27G Vitrectomy

*Carl Claes – Chapter 131*

131.18 Vitreous Incarceration in Sclerotomies

*Maria H. Berrocal – Chapter 131*

131.19 Argus II Array Implantation

*J. Fernando Arevalo – Chapter 131*

131.20 Subretinal SF<sub>6</sub> Gas after Retinal Detachment  
Surgery

*Stratos Gotzaridis – Chapter 131*

131.21 Removal of a Large Glass Intraocular Foreign  
Body

*Grazia Pertile – Chapter 131*

**VOLUME 3, PART 2 Tumors of the Retina, Choroid, and Vitreous**

**SECTION 2 Tumors of the Choroid**

## 151.1 Surgical Resection of Choroidal Melanoma

*Bertil E. Damato – Chapter 151*

Associate Professor  
Department of Ophthalmology and Visual Sciences  
University of Illinois at Chicago  
Chicago, IL, USA

**Antonio Capone Jr., MD**

Associated Retinal Consultants  
William Beaumont Hospital  
Royal Oak, MI, USA

**David Carruthers PhD, FRCP**

Consultant Rheumatologist

Sandwell & West Birmingham Hospitals NHS Trust  
Birmingham, UK  
Honorary Senior Lecturer in Rheumatology  
Institute of Inflammation and Ageing  
University of Birmingham  
Birmingham, UK

**Jerry D. Cavallerano OD, PhD**

Associate Professor of Ophthalmology  
Harvard Medical School  
Staff Optometrist  
Beetham Eye Institute  
Joslin Diabetes Center  
Boston, MA, USA

**Usha Chakravarthy MD**

Professor of Ophthalmology and Vision Science  
Queens University of Belfast  
Consultant in Ophthalmology  
Belfast Health and Social Care Trust  
Belfast, Northern Ireland, UK

**Helen Chan MBBS (Hons)**

Ophthalmology Registrar  
Royal Victorian Eye and Ear Hospital  
Melbourne, VIC, Australia

**Steve Charles MD**

Clinical Professor of Ophthalmology  
University of Tennessee  
College of Medicine  
Memphis, TN, USA

**David G. Charteris MD**

Professor of Ophthalmology  
Institute of Ophthalmology  
Consultant Vitreoretinal Surgeon  
Service Director, Vitreoretinal Unit  
Moorfields Eye Hospital

London, UK

**Jeannie Chen PhD**

Professor

Zilkha Neurogenetic Institute

Departments of Cell & Neurobiology and Ophthalmology

Keck School of Medicine

University of Southern California

Los Angeles, CA, USA

**Carol Yim-lui Cheung PhD**

Assistant Professor

Department of Ophthalmology and Visual Sciences

The Chinese University of Hong Kong

Hong Kong, China

**Emily Y. Chew MD**

Deputy Director of Division of Epidemiology and Clinical Applications

Deputy Clinical Director

National Eye Institute

National Institutes of Health

Bethesda, MD, USA

**Allen Chiang MD**

The Retina Service of Wills Eye Hospital

Mid Atlantic Retina

Assistant Professor of Ophthalmology

Thomas Jefferson University

Philadelphia, PA, USA

**Michael F. Chiang MD**

Knowles Professor

Departments of Ophthalmology & Medical Informatics and Clinical Epidemiology

Casey Eye Institute

Oregon Health & Science University

Portland, OR, USA

**Rao V. Chundury MD, MBA**

Oculofacial and Orbital Surgery  
Assistant Professor of Ophthalmology  
Assistant Residency Program Director  
Eugene and Marilyn Glick Eye Institute  
Indiana University  
Indianapolis, IN, USA

**Dennis O. Clegg PhD**

Wilcox Family Chair in Biomedicine  
Co-Director, Center for Stem Cell Biology and Engineering  
Professor, Department of Molecular, Cellular and Developmental  
Biology  
University of California, Santa Barbara  
Santa Barbara, CA, USA

**Ian J. Constable FRANZCO, FRCSE, DSc(hon)**

Professor of Ophthalmology  
Lions Eye Institute  
University of Western Australia  
Perth, Australia

**Gabriel Coscas MD**

Professor of Ophthalmology  
Department of Ophthalmology  
University of Paris XII  
Créteil, France

**Alan F. Cruess MD**

Professor  
Department of Ophthalmology and Visual Sciences  
Dalhousie University  
Halifax, Nova Scotia, Canada

**Emmett T. Cunningham Jr., MD, PhD, MPH**

Director, The Uveitis Service  
West Coast Retina  
Clinical Professor of Ophthalmology  
California Pacific Medical Center

San Francisco, CA, USA  
Adjunct Clinical Professor of Ophthalmology  
Stanford University School of Medicine  
Stanford, CA, USA

**Christine A. Curcio PhD, FARVO, Eminent Scholar in Retina**  
Director, AMD Histopathology Lab  
Department of Ophthalmology  
The University of Alabama at Birmingham  
Birmingham, AL, USA

**Stephen P. Daiger PhD**  
TS Matney Professor  
Human Genetics Center  
School of Public Health and Ruiz Department of Ophthalmology  
The University of Texas Health Science Center  
Houston, TX, USA

**Bertil E. Damato MD, PhD**  
Professor of Ophthalmology and Radiation Oncology  
University of California, San Francisco  
San Francisco, CA, USA

**Sudipta Das MS**  
International Faculty  
C-MER (Shenzhen) Dennis Lam Eye Hospital  
Shenzhen, China

**Janet L. Davis MD**  
Leach Distinguished Professor of Ophthalmology  
Bascom Palmer Eye Institute  
University of Miami  
Miller School of Medicine  
Miami, FL, USA

**Matthew D. Davis MD**  
Emeritus Professor of Ophthalmology and Visual Sciences  
University of Wisconsin  
School of Medicine and Public Health

Madison, WI, USA

**Shelley Day MD**

Partner

Austin Retina Associates  
Clinical Assistant Professor  
Dell Medical School  
University of Texas-Austin  
Austin, TX, USA

**Carlos Alexandre de Amorim Garcia Filho, MD**

Retina Specialist  
Universidade Federal Do Rio Grande Do Norte  
Natal, RN, Brazil

**Patrick De Potter MD, PhD**

Professor of Ophthalmology  
Chairman of Ophthalmology  
Ocular Oncology Unit  
Saint Luc University Hospital  
Catholic University of Leuven  
Brussels, Belgium

**Marc D. de Smet MDCM, PhD, FRCSC, FRCOphth, FEBOphth**

Retina and Uveitis Division, MIOS sa.  
Lausanne, Switzerland

**Alastair K. Denniston MRCP, FRCOphth, PhD**

Consultant Ophthalmologist  
University Hospitals Birmingham NHS Foundation Trust  
Birmingham, UK  
Honorary Reader in Ophthalmology  
Institute of Inflammation and Ageing  
University of Birmingham  
Birmingham, UK

**Ranjit S. Dhaliwal MD, FRCSC, FACS**

Vitreoretinal Surgeon  
Retina Consultants PC

Augusta, GA, USA  
Adjunct Faculty  
Department of Ophthalmology  
Emory University  
Atlanta, GA, USA  
Adjunct Faculty  
Department of Ophthalmology  
Queen's University  
Kingston, Ontario, Canada

**Andrew D. Dick MBBS, MD, FRCOphth, FRSB, FMedSci**

Professor of Ophthalmology  
Academic Unit of Ophthalmology  
University of Bristol  
Bristol, UK  
Duke Elder Chair of Ophthalmology  
Institute of Ophthalmology  
University College London  
London, UK

**Xiaoyan Ding MD, PhD**

Professor, Retina Division  
Zhongshan Ophthalmic Center  
Sun Yat-Sen University  
Guangzhou, Guangdong, China

**Diana V. Do MD**

Professor of Ophthalmology  
Byers Eye Institute  
Stanford University  
School of Medicine  
Palo Alto, CA, USA

**Jay S. Duker MD**

Professor and Chair of Ophthalmology  
New England Eye Center  
Tufts Medical Center  
Tufts University School of Medicine  
Boston, MA, USA

**Jacque L. Duncan MD**

Professor of Ophthalmology  
Vice Chair of Medical Student Affairs  
Department of Ophthalmology  
University of California, San Francisco  
San Francisco, CA, USA

**Justis P. Ehlers MD**

The Norman C. and Donna L. Harbert Endowed Chair for  
Ophthalmic Research  
Cole Eye Institute  
Cleveland Clinic  
Cleveland, OH, USA

**Dean Elliott MD**

Associate Director, Retina Service  
Massachusetts Eye and Ear  
Associate Professor of Ophthalmology  
Harvard Medical School  
Boston, MA, USA

**Lisa J. Faia MD**

Partner  
Associated Retinal Consultants, PC  
Royal Oak, MI, USA  
Associate Professor of Ophthalmology  
William Beaumont Oakland University  
School of Medicine  
Rochester, MI, USA

**Benedetto Falsini MD**

Associate Professor of Ophthalmology  
Department of Ophthalmology  
Università Cattolica del S. Cuore  
Rome, Italy

**Sharon Fekrat MD, FACS**

Associate Professor of Ophthalmology and Surgery  
Duke University Medical Center

Associate Chief of Staff for Surgical Services  
Durham VA Medical Center  
Durham, NC, USA

**Steven E. Feldon MD, MBA**

Professor and Chair  
Department of Ophthalmology  
Flaum Eye Institute  
University of Rochester  
School of Medicine and Dentistry  
Rochester, NY, USA

**Henry A. Ferreyra MD**

Associate Clinical Professor  
Department of Ophthalmology  
UC San Diego School of Medicine  
La Jolla, CA, USA

**Deborah A. Ferrington MD**

Associate Professor  
Department of Ophthalmology  
University of Minnesota  
Minneapolis, MN, USA

**Frederick L. Ferris III, MD**

Director, Division of Epidemiology and Clinical Applications  
Clinical Director, National Eye Institute  
National Institutes of Health  
Bethesda, MD, USA

**Paul T. Finger MD**

Director, The New York Eye Cancer Center  
Clinical Professor of Ophthalmology  
New York University  
School of Medicine  
New York, NY, USA

**Steven K. Fisher PhD**

Research Professor

Neuroscience Research Institute  
Professor Emeritus  
Molecular, Cellular and Developmental Biology  
University of California, Santa Barbara  
Santa Barbara, CA, USA

**Gerald A. Fishman MD**

Professor Emeritus  
Department of Ophthalmology  
University of Illinois at Chicago  
Chicago, IL, USA  
Director, The Pangere Center for Hereditary Retinal Diseases  
Chicago, IL, USA

**Monika Fleckenstein MD**

Consultant  
Department of Ophthalmology  
University of Bonn  
Bonn, Germany

**Harry W. Flynn Jr., MD**

J. Donald M. Gass Chair in Ophthalmology  
Bascom Palmer Eye Institute  
University of Miami  
Miller School of Medicine  
Miami, FL, USA

**Wallace S. Foulds CBE, MD, FRCS**

Emeritus Professor of Ophthalmology  
University of Glasgow  
Glasgow UK  
Senior Consultant (Research)  
Singapore Eye Research Institute  
Singapore National Eye Centre  
Singapore

**Austin R. Fox BS**

Research Fellow  
Laboratory of Immunology

National Eye Institute  
National Institutes of Health  
Bethesda, MD, USA

**William R. Freeman MD**

Distinguished Professor of Ophthalmology  
Director of the Jacobs Retina Center  
University of California, San Diego  
La Jolla, CA, USA

**Martin Friedlander MD, PhD**

Professor  
Department of Cell Biology  
The Scripps Research Institute  
Division of Ophthalmology  
Department of Surgery  
Scripps Clinic  
La Jolla, CA, USA

**Laura J. Frishman PhD**

Professor  
Department of Basic Vision Science  
College of Optometry  
University of Houston  
Houston, TX, USA

**Arthur D. Fu MD**

West Coast Retina  
Chief of Retina Service  
Clinical Professor of Ophthalmology  
California Pacific Medical Center  
San Francisco, CA, USA

**David M. Gamm MD, PhD**

Associate Professor  
Department of Ophthalmology and Visual Sciences  
Emmett A. Humble Distinguished Director  
McPherson Eye Research Institute  
Sandra Lemke Chair in Eye Research

Waisman Center Stem Cell Research Program  
University of Wisconsin  
Madison, WI, USA

**Enrique Garcia-Valenzuela MD, PhD**

Vitreoretinal Surgeon  
Midwest Retina Consultants, SC  
Des Plaines, IL, USA

**Sunir J. Garg MD, FACS**

MidAtlantic Retina  
The Retina Service of Wills Eye Hospital  
Professor of Ophthalmology  
Thomas Jefferson University  
Philadelphia, PA, USA

**Alain Gaudric MD**

Emeritus Professor of Ophthalmology  
Université Paris Diderot  
Sorbonne Paris Cité  
AP-HP, Hôpital Lariboisière  
Paris, France

**Mary Gayed MRes, MRCP**

Specialist Registrar in Rheumatology  
University Hospitals Birmingham NHS Foundation Trust  
Birmingham, UK  
Honorary Research Associate  
Institute of Inflammation and Ageing  
University of Birmingham  
Birmingham, UK

**Heinrich Gerding MD, FEBO, FMH**

Professor of Ophthalmology  
Director  
Pallas Kliniken  
Olten, SO, Switzerland

**Andrea Giani MD**

Assistant Professor  
Department of Biomedical and Clinical Sciences “Luigi Sacco”  
Eye Clinic – Sacco Hospital  
University of Milan  
Milan, Italy

**Morton F. Goldberg MD**

Joseph Green Professor of Ophthalmology and Director Emeritus  
Wilmer Eye Institute  
Johns Hopkins University  
School of Medicine  
Baltimore, MD, USA

**Lingam Gopal MS, FRCSEd, DNBE**

Consultant  
Vitreoretinal Services  
Sankara Nethralaya  
Medical and Vision Research Foundations  
Chennai, India

**Caroline Gordon MD, FRCP**

Professor of Rheumatology  
Institute of Inflammation and Ageing  
University of Birmingham  
Birmingham, UK  
Honorary Consultant Rheumatologist  
Sandwell & West Birmingham  
Hospitals NHS Trust  
Birmingham, UK

**Hiroshi Goto MD**

Chairman/Professor  
Department of Ophthalmology  
Tokyo Medical University  
Tokyo, Japan

**Evangelos S. Gragoudas MD**

Professor of Ophthalmology  
Department of Ophthalmology

Harvard Medical School  
Retina Service  
Massachusetts Eye and Ear Infirmary  
Boston, MA, USA

**Maria B. Grant MD**

Professor  
Department of Pharmacology and Therapeutics  
University of Florida, Gainesville  
Director of Translational Research  
Department of Ophthalmology  
Gainesville, FL, USA

**Ronald G. Gregg PhD**

Professor and Chair  
Department of Biochemistry & Molecular Biology  
University of Louisville  
Louisville, KY, USA

**Kevin Gregory-Evans MD, PhD, FRCS, FRCOphth, FRCSC**

Professor and Julia Levy BC Leadership Chair in Macular Research  
Department of Ophthalmology and Visual Science  
University of British Columbia  
Vancouver, British Columbia, Canada

**Carl Groenewald MD**

Consultant Ophthalmologist  
Department of Ophthalmology  
Royal Liverpool University Hospital  
Liverpool, UK

**Hans E. Grossniklaus MD**

Professor  
Department of Ophthalmology  
Emory University  
School of Medicine  
Atlanta, GA, USA

**Sandeep Grover MD**

Associate Professor, Ophthalmology  
Director, Inherited Retinal Diseases & Electrophysiology  
University of Florida at Jacksonville  
Jacksonville, FL, USA

**Vamsi K. Gullapalli MD, PhD**

Associate  
Central Minnesota Retina Specialists  
Sartell, MN, USA

**Rudolf F. Guthoff MD**

Professor of Ophthalmology  
Department of Ophthalmology  
University of Rostock  
Rostock, Germany

**J. Silvio Gutkind PhD**

Professor, Department of Pharmacology  
Associate Director of Basic Science  
Moore's Cancer Center  
University of California, San Diego  
San Diego, CA, USA

**Paul Hahn MD, PhD**

NJ Retina  
Teaneck, NJ, USA

**Julia A. Haller MD**

Ophthalmologist in Chief  
Wills Eye Hospital  
Philadelphia, PA, USA

**James T. Handa MD**

Robert Bond Welch Professor  
Wilmer Eye Institute  
Johns Hopkins School of Medicine  
Baltimore, MD, USA

**Christos Haritoglou FEBO**

Chief Ophthalmologist  
Herzog Carl Theodor Eye Clinic  
München, Germany

**Sara Haug MD, PhD**

West Coast Retina  
Clinical Professor of Ophthalmology  
California Pacific Medical Center  
San Francisco, CA, USA

**Barbara S. Hawkins PhD, FSCT**

Professor Emeritus of Ophthalmology (School of Medicine)  
Professor of Epidemiology (Bloomberg School of Public Health)  
The Wilmer Eye Institute  
Johns Hopkins University  
Baltimore, MD, USA

**Shikun He MD**

Associate Professor  
Departments of Pathology and Ophthalmology  
Keck School of Medicine  
USC Eye Institute  
University of Southern California  
Los Angeles, CA, USA

**Martina C. Herwig-Carl MD, FEBO**

Assistant Professor  
University Eye Hospital Bonn  
Bonn, Germany

**Florian M.A. Heussen MD**

Ophthalmology Fellow  
St. Paul's Eye Unit  
Royal Liverpool University Hospital  
Liverpool, UK

**David R. Hinton MD**

Gavin S. Herbert Professor of Retinal Research  
Professor of Pathology and Ophthalmology

USC Roski Eye Institute  
Keck School of Medicine  
University of Southern California  
Los Angeles, CA, USA

**Nickisa M. Hodgson MD, MAS**

Resident Physician  
Department of Ophthalmology  
UC San Diego School of Medicine  
La Jolla, CA, USA

**Frank G. Holz MD, FEBO**

Professor, Head of Department  
Department of Ophthalmology  
University of Bonn  
Bonn, Germany

**Samuel K. Houston MD**

Florida Retina Institute  
Orlando, FL, USA

**Yan-Nian Hui MD**

Professor  
Department of Ophthalmology  
Xijing Hospital  
Fourth Military Medical University  
Xi'an, China

**Mark S. Humayun MD, PhD**

Cornelius J. Pings Chair in Biomedical Sciences  
Director, Institute for Biomedical Therapeutics  
USC Eye Institute  
University of Southern California  
Los Angeles, CA, USA

**Yasushi Ikuno MD**

Invited Professor of Ophthalmology  
Osaka University  
Graduate School of Medicine

Clinical Professor  
Kanazawa University  
Graduate School of Medicine  
Director and Founder  
Ikuno Eye Center  
Osaka, Japan

**David Isaac MD, PhD**

Associate Professor  
Department of Ophthalmology  
Federal University of Goias  
Goiania, GO, Brazil

**Tatsuro Ishibashi MD, PhD**

Vice Dean  
Department of Ophthalmology  
Kyushu University  
Fukuoka City, Japan

**Douglas A. Jabs MD, MBA**

Professor of Ophthalmology and Professor of Medicine  
Chairman Emeritus  
Department of Ophthalmology  
Director, Mount Sinai/New York Eye and Ear Eye and Vision  
Research Institute  
Icahn School of Medicine at Mount Sinai  
New York, NY, USA  
Adjunct Professor of Epidemiology  
The Johns Hopkins University  
Bloomberg School of Public Health  
Baltimore, MD, USA

**Glenn J. Jaffe MD**

Professor of Ophthalmology  
Duke University Eye Center  
Durham, NC, USA

**Lee M. Jampol MD**

Louis Feinberg Professor in Ophthalmology

Department of Ophthalmology  
Northwestern University  
Feinberg School of Medicine  
Chicago, IL, USA

**Leonard Joffe MD, MB, BCH, FCS (SA), FRCS**

Retina Specialists of Southern Arizona  
Tucson, AZ, USA

**Mark Johnson PhD**

Professor  
Departments of Biomedical Engineering Mechanical Engineering  
and Ophthalmology  
Northwestern University  
Evanston, IL, USA

**Mark W. Johnson MD**

Professor  
Department of Ophthalmology and Visual Sciences  
University of Michigan  
Ann Arbor, MI, USA

**Robert N. Johnson MD**

West Coast Retina  
Clinical Professor of Ophthalmology  
California Pacific Medical Center  
San Francisco, CA, USA

**Antonia M. Jousen MD**

Professor and Chair  
Department of Ophthalmology  
Charité, University Medicine Berlin  
Berlin, Germany

**Karina Julian MD**

Uveitis Specialist  
Eye Institute  
Cleveland Clinic Abu Dhabi  
Abu Dhabi, United Arab Emirates

**J. Michael Jumper MD**

West Coast Retina  
Clinical Professor of Ophthalmology  
California Pacific Medical Center  
Co-Director, Vitreoretinal Fellowship Program  
San Francisco, CA, USA

**Peter K. Kaiser MD**

Chaney Family Endowed Chair in Ophthalmology Research  
Professor of Ophthalmology  
Cleveland Clinic Lerner College of Medicine  
Cleveland, OH, USA

**Maarten Kamermans PhD**

Professor  
Retinal Signal Processing Lab  
Netherlands Institute for Neuroscience  
Amsterdam, The Netherlands

**Anselm Kampik MD, FEBO, FARVO**

Chairman Emeritus  
Department of Ophthalmology  
Ludwig Maximilians University  
Munich, Germany

**Rustum Karanjia MD, PhD**

Assistant Professor  
University of Ottawa Eye Institute  
Ottawa Hospital Research Institute  
Ottawa, ON, Canada  
Researcher  
Doheny Eye Institute and  
Doheny Eye Centers UCLA  
Department of Ophthalmology  
David Geffen School of Medicine  
University of California, Los Angeles  
Los Angeles, CA, USA

**Amir H. Kashani MD, PhD**

Assistant Professor of Clinical Ophthalmology  
USC Eye Institute  
Department of Ophthalmology  
University of Southern California  
Keck School of Medicine  
Los Angeles, CA, USA

**Pearse A. Keane MD, MSc, FRCOphth, MRCSINIHR**  
Clinician Scientist and Consultant Ophthalmologist  
Moorfields Eye Hospital NHS Foundation Trust and  
UCL Institute of Ophthalmology  
London, UK

**M. Cristina Kenney MD, PhD**  
Professor  
Director of Research  
Gavin Herbert Eye Institute  
Ophthalmology Research Laboratories  
University of California, Irvine  
Irvine, CA, USA

**S. Khizer R. Khaderi MD, MPH**  
Adjunct Associate Professor  
Moran Eye Center  
University of Utah  
Salt Lake City, UT, USA

**Mohamad A. Khodair PhD**  
Pharmacology, Physiology and Neuroscience  
New Jersey Medical School  
Rutgers University  
Newark, NJ, USA

**Ivana K. Kim MD**  
Associate Professor of Ophthalmology  
Department of Ophthalmology  
Harvard Medical School  
Retina Service  
Massachusetts Eye and Ear Infirmary

Boston, MA, USA

**Jonathan W. Kim MD**

Director of Retinoblastoma Service  
Children's Hospital Los Angeles  
Associate Professor of Ophthalmology  
USC Keck School of Medicine  
Los Angeles, CA, USA

**Tae Wan Kim MD, PhD**

Associate Professor  
Department of Ophthalmology  
Seoul National University  
Seoul, South Korea

**Bernd Kirchhof MD**

Department of Vitreo-Retinal Surgery  
Center of Ophthalmology  
University of Cologne  
Cologne, Germany

**Szilard Kiss MD**

Department of Ophthalmology  
Weill Cornell Medical College  
New York-Presbyterian Hospital  
New York, NY, USA

**Barbara E.K. Klein MD, MPH**

Professor  
Department of Ophthalmology and Visual Sciences  
University of Wisconsin  
School of Medicine and Public Health  
Madison, WI, USA

**Ronald Klein MD, MPH**

Professor  
Department of Ophthalmology and Visual Sciences  
University of Wisconsin  
School of Medicine and Public Health

Madison, WI, USA

**Michael A. Klufas MD**

Retina Division  
Stein Eye Institute  
University of California, Los Angeles  
Los Angeles, CA, USA

**Anton M. Kolomeyer MD, PhD**

Resident  
Eye and Ear Institute  
University of Pittsburgh Medical Center  
Pittsburgh, PA, USA

**Lazaros Konstantinidis MD**

Hôpital Ophtalmique Jules-Gonin  
University of Lausanne  
Lausanne, Switzerland

**Renu Kowluru PhD, FARVO**

Professor  
Ophthalmology, Anatomy/Cell Biology & Endocrinology  
Wayne State University  
Kresge Eye Institute  
Detroit, MI, USA

**Igor Kozak MD, PhD**

Senior Academic Consultant  
King Khaled Eye Specialist Hospital  
Riyadh, Saudi Arabia

**Baruch D. Kuppermann MD**

Professor of Ophthalmology and Biomedical Engineering  
University of California, Irvine  
The Gavin Herbert Eye Institute  
University of California, Irvine  
Irvine, CA, USA

**Ajay E. Kuriyan MD, MSc**

Assistant Professor, Ophthalmology  
University of Rochester  
School of Medicine and Dentistry  
Rochester, NY, USA

**Leanne T. Labriola MD**

Clinical Assistant Professor of Ophthalmology  
Medical Retina Service  
University of Pittsburgh  
School of Medicine  
Pittsburgh, PA, USA

**Dennis Lam MD**

Director  
Dennis Lam & Partners Eye Center  
Central, Hong Kong  
Director  
C-MER (Shenzhen) Dennis Lam Eye Hospital  
Shenzhen, China  
Director  
State Key Laboratory (Ophthalmology)  
Sun Yat-Sen University  
Guangzhou, China

**Linda A. Lam MD, MBA**

Associate Professor  
Vice Chair of Clinical Satellite Affairs  
USC Roski Eye Institute  
Department of Ophthalmology  
USC Keck School of Medicine  
Los Angeles, CA, USA

**Anne Marie Lane MPH**

Instructor in Ophthalmology  
Department of Ophthalmology  
Harvard Medical School  
Retina Service  
Massachusetts Eye and Ear Infirmary  
Boston, MA, USA

**Erin B. Lavik ScD**

Professor

Department of Chemical, Biochemical, and Environmental  
Engineering

University of Maryland  
Baltimore, MD, USA

**James F. Leary PhD**

Professor Emeritus

Purdue University  
West Lafayette, IN, USA

**Richard W.J. Lee BMedSci (Hons), BMBS, MRCS (Eng),  
MRCOphth, PhD**

Consultant Senior Lecturer

University of Bristol  
Bristol, UK

Lead for Experimental Medicine (Inflammation and  
Immunotherapy)

National Institute for Health Research Biomedical Research Centre  
at Moorfields Eye Hospital NHS Foundation Trust

UCL Institute of Ophthalmology  
London, UK

**Sun Young Lee MD, PhD**

Vitreoretinal Surgery Fellow

Department of Ophthalmology

University of Iowa  
Iowa City, IA, USA

**Thomas C. Lee MD**

Associate Professor of Ophthalmology

Vision Center, Children's Hospital Los Angeles and USC Eye  
Institute

Los Angeles, CA, USA

**Vincent Lee FRCSEd, FCSHK**

Faculty

Dennis Lam & Partners Eye Center

Central  
Hong Kong, China

**Loh-Shan B. Leung MD**

Clinical Assistant Professor of Ophthalmology  
Department of Ophthalmology  
Stanford University School of Medicine  
Palo Alto, CA, USA

**Geoffrey P. Lewis PhD**

Research Biologist  
Neuroscience Research Institute  
University of California, Santa Barbara  
Santa Barbara, CA, USA

**Anita Leys MD, PhD**

Professor of Ophthalmology  
Department of Medical Retina  
Department of Ophthalmology  
Catholic University of Leuven  
Leuven, Belgium

**Xiaoxin Li MD**

Professor of Ophthalmology  
Xiamen Eye Center of Xiamen University  
Xiamen, China

**Sandra Liakopoulos MD**

Professor of Ophthalmology  
Department of Ophthalmology  
University of Cologne  
Cologne, Germany

**Chang-Ping Lin MD**

Lecturer  
Department of Ophthalmology  
National Taiwan University  
College of Medicine  
National Taiwan University Hospital

Taipei, Taiwan

**Phoebe Lin MD, PhD**

Assistant Professor of Ophthalmology  
Casey Eye Institute  
Oregon Health and Science University  
Portland, OR, USA

**Enchun M. Liu MD**

Vitreoretinal Surgeon  
Retina Associates of South Texas  
San Antonio, TX, USA

**Shirley Liu PhD**

Resident  
C-MER (Shenzhen) Dennis Lam Eye Hospital  
Shenzhen, China

**Noemi Lois MD, PhD, FRCSEd, FRCOphth**

Clinical Professor of Ophthalmology  
Queen's University  
Honorary Consultant Ophthalmic Surgeon  
The Belfast Health and Social Care Trust  
Belfast, Northern Ireland, UK

**Nikolas J.S. London MD, FACS**

Retina Consultants San Diego  
Poway, CA, USA

**Lin Lu PhD**

Professor  
Zhongshan Ophthalmic Center  
Sun Yat-Sen University  
Guangzhou, China

**Brandon J. Lujan MD**

West Coast Retina  
Clinical Professor of Ophthalmology  
California Pacific Medical Center

San Francisco, CA, USA  
Assistant Clinical Professor  
University of California, San Francisco  
San Francisco, CA, USA

**Yan Luo MD, PhD**

Professor, Retina Division  
Zhongshan Ophthalmic Center  
Sun Yat-Sen University  
Guangzhou, Guangdong, China

**Gerard A. Luty PhD**

G. Edward and G. Britton Durell Professor of Ophthalmology  
Wilmer Eye Institute  
Johns Hopkins University  
School of Medicine  
Baltimore, MD, USA

**Robert MacLaren FRCOphth**

Professor of Ophthalmology  
Nuffield Laboratory of Ophthalmology  
Department of Clinical Neurosciences  
University of Oxford  
Oxford University Eye Hospital  
Oxford, UK  
Honorary Consultant Vitreoretinal Surgeon  
Moorfields Eye Hospital  
London, UK

**Steven Madreperla MD, PhD**

Assistant Clinical Professor  
Institute of Ophthalmology and Visual Science  
New Jersey Medical School  
Rutgers University  
Newark, NJ, USA

**Albert M. Maguire MD**

Professor  
Co-Director of Center for Advanced Retinal and Ocular

Therapeutics (CAROT)  
Department of Ophthalmology  
Scheie Eye Institute  
University of Pennsylvania  
Perelman School of Medicine  
Philadelphia, PA, USA

Professor and Chairman  
Cleveland Clinic Cole Eye Institute  
Cleveland, OH, USA

**Stephen C. Massey PhD**  
Elizabeth Morford Professor and Research Director  
Department of Ophthalmology and Visual Science

University of Texas Medical School  
Houston, TX, USA

**Maureen A. McCall PhD**

Professor  
Department of Ophthalmology and Visual Sciences  
University of Louisville  
Louisville, KY, USA

**Tara A. McCannel MD, PhD**

Assistant Professor  
Director of Ophthalmic Oncology Center  
Department of Ophthalmology  
The Jules Stein Eye Institute  
University of California, Los Angeles  
Los Angeles, CA, USA

**J. Allen McCutchan MD, MAS**

Professor of Medicine  
Medical Center  
University of California, San Diego  
San Diego, CA, USA

**H. Richard McDonald MD**

West Coast Retina  
Clinical Professor of Ophthalmology  
California Pacific Medical Center  
Co-Director, Vitreoretinal Fellowship Program  
San Francisco, CA, USA

**Petra Meier MD**

Associate Professor  
Department of Ophthalmology  
University of Leipzig  
Leipzig, Germany

**Travis A. Meredith MD**

Professor and Chair Emeritus  
Department of Ophthalmology

University of North Carolina, Chapel Hill  
Chapel Hill, NC, USA

**Carsten H. Meyer MD, FEBO, FMH**

Professor of Ophthalmology  
Head of the Department  
Department of Ophthalmology  
Pallas Clinics  
Aarau, AR, Switzerland

**William F. Mieler MD**

Cless Family Professor and Vice-Chairman  
Illinois Eye and Ear Infirmary  
Department of Ophthalmology and Visual Sciences  
University of Illinois, Chicago  
Chicago, IL, USA

**Joan W. Miller MD**

Henry Willard Williams Professor of Ophthalmology  
Chief of Ophthalmology  
Mass Eye and Ear and Massachusetts General Hospital  
Chair, Department of Ophthalmology  
Harvard Medical School  
Boston, MA, USA

**Rukhsana G. Mirza MD**

Associate Professor  
Department of Ophthalmology  
Northwestern University  
Feinberg School of Medicine  
Chicago, IL, USA

**Sayak K. Mitter PhD**

Research Fellow  
Department of Ophthalmology  
Indiana University School of Medicine  
Indianapolis, IN, USA

**Robert A. Mitra MD**

Assistant Clinical Professor  
University of Minnesota  
Minneapolis, MN, USA

**Yozo Miyake MD, PhD**

Chairman of the Board of Directors  
Aichi Medical University  
Aichi, Japan

**Carlo Montemagno PhD**

Director, Ingenuity Lab  
Professor of Chemical Engineering and Material Science  
University of Alberta  
Edmonton, Alberta, Canada

**Anthony T. Moore MD**

Professor of Ophthalmology  
Department of Ophthalmology  
University of California, San Francisco  
San Francisco, CA, USA

**Prithvi Mruthyunjaya MD, MHS**

Associate Professor of Ophthalmology  
Director, Ocular Oncology Service  
Byers Eye Institute  
Stanford University  
Palo Alto, CA, USA

**Cristina Muccioli MD, PhD**

Associate Professor of Ophthalmology  
Department of Ophthalmology  
Federal University of São Paulo  
São Paulo, Brazil

**Robert F. Mullins PhD**

Professor  
Department of Ophthalmology and Visual Sciences  
Wynn Institute for Vision Research  
University of Iowa

Iowa City, IA, USA

**A. Linn Murphree MD**

Professor Emeritus  
Children's Hospital Los Angeles  
USC Keck School of Medicine  
Los Angeles, CA, USA

**Robert P. Murphy MD**

Retina Group of Washington  
Washington, DC, USA

**Philip I. Murray PhD, FRCP, FRCS, FRCOphth**

Professor of Ophthalmology  
Institute of Inflammation and Ageing  
University of Birmingham  
Birmingham, UK  
Honorary Consultant Ophthalmologist  
Sandwell & West Birmingham Hospitals NHS Trust  
Birmingham, UK

**Timothy G. Murray MD, MBA, FACS**

Director, Miami Ocular Oncology and Retina  
Miami, FL, USA  
Professor  
Department of Ophthalmology  
Bascom Palmer Eye Institute  
Miami, FL, USA

**Manish Nagpal MS, DO, FRCS(UK)**

Vitreoretinal Consultant  
Retina Foundation  
Shahibag, Ahmedabad, India

**Perumalsamy Namperumalsamy MS, FAMS**

Chairman Emeritus and Professor of Ophthalmology  
Retina-Vitreous Service  
Aravind Eye Care System  
Madurai, Tamil Nadu, India

**Sumit K. Nanda MD**

Clinical Associate Professor  
Department of Ophthalmology  
Integris Baptist Medical Center  
Oklahoma City, OK, USA

**Hossein Nazari MD**

Department of Ophthalmology and Visual Sciences  
University of Texas Medical Branch  
Galveston, TX, USA

**Quan Dong Nguyen MD, MSc**

Professor of Ophthalmology  
Byers Eye Institute  
Stanford University  
Palo Alto, CA, USA  
Ocular Imaging Research and Reading Center  
Menlo Park, CA, USA

**Robert B. Nussenblatt MD, MPH (posthumously)**

Chief  
Laboratory of Immunology  
National Eye Institute, NIH  
Bethesda, MD, USA

**Patrick Oellers MD**

Vitreoretinal Surgery Fellow  
Harvard Medical School  
Department of Ophthalmology  
Massachusetts Eye and Ear  
Boston, MA, USA

**Masahito Ohji MD**

Professor and Chairman  
Department of Ophthalmology  
Shiga University of Medical Science  
Otsu, Shiga, Japan

**Kyoko Ohno-Matsui MD, PhD**

Professor  
Department of Ophthalmology and Visual Sciences  
Tokyo Medical and Dental University  
Tokyo, Japan

**Daniel Palanker PhD**

Professor  
Department of Ophthalmology  
Hansen Experimental Physics Laboratory  
Stanford University  
Stanford, CA, USA

**Thanos D. Papakostas MD**

Retina Fellow  
Massachusetts Eye and Ear  
Harvard Medical School  
Boston, MA, USA

**Avni V. Patel MD, MBA**

Massachusetts Eye and Ear Infirmary  
Department of Ophthalmology  
Harvard Medical School  
Boston, MA, USA

**Purnima S. Patel MD**

Associate Professor of Ophthalmology  
Emory University  
School of Medicine  
Atlanta Veterans Affairs Medical Center  
Atlanta, GA, USA

**Anna C. Pavlick MD**

Professor of Medicine and Dermatology  
Department of Medicine  
New York University  
School of Medicine  
New York, NY, USA

**S. Louise Pay BSc**

Graduate Student  
Department of Ophthalmology  
Indiana University  
School of Medicine  
Indianapolis, IN, USA

**David M. Peereboom MD**

Professor of Medicine and Director of Clinical Research  
The Rose Ella Burkhardt Brain Tumor and Neuro-Oncology Center  
Cleveland Clinic  
Cleveland, OH, USA

**Mark E. Pennesi MD, PhD**

Associate Professor  
Department of Ophthalmology  
Casey Eye Institute  
Oregon Health & Science University  
Portland, OR, USA

**Jay S. Pepose MD, PhD**

Medical Director  
PeposeVision Institute  
Professor of Clinical Ophthalmology  
Washington University  
School of Medicine  
St. Louis, MO, USA

**Julian D. Perry MD**

Director  
Orbital and Oculoplastic Surgery  
Cole Eye Institute  
Cleveland Clinic Foundation  
Cleveland, OH, USA

**Polly A. Quiram MD, PhD**

Vitreoretinal Surgery, PA  
Minneapolis, MN, USA

**Rajiv Raman MS, DNB**

Consultant  
Department of Vitreo-Retinal Services  
Sankara Nethralaya  
Chennai, India

**Rajeev S. Ramchandran MD, MBA**

Associate Professor  
Department of Ophthalmology  
Flaum Eye Institute  
University of Rochester  
School of Medicine and Dentistry  
Rochester, NY, USA

**P. Kumar Rao MD**

Associate Professor of Ophthalmology and Visual Sciences  
Department of Ophthalmology  
School of Medicine  
Washington University in St Louis  
St Louis, MO, USA

**Narsing A. Rao MD**

Professor of Ophthalmology and Pathology  
USC Eye Institute  
Keck School of Medicine  
University of Southern California  
Los Angeles, CA, USA

**Sivakumar R. Rathinam FAMS, PhD**

Professor of Ophthalmology  
Head of Uveitis Service  
Uveitis Service  
Aravind Eye Hospital & Postgraduate Institute of Ophthalmology  
Madurai, India

**Franco M. Recchia MD**

Vitreoretinal Surgeon  
Tennessee Retina, PC  
Nashville, TN, USA

**Kristin J. Redmond MD, MPH**

Assistant Professor  
Department of Radiation Oncology and Molecular Radiation  
Sciences  
Johns Hopkins University  
School of Medicine  
Baltimore, MD, USA

**David Reed MD**

Attending Physician  
Ophthalmic Consultants of Boston  
Boston, MA, USA

**Thomas A. Reh PhD**

Professor  
Department of Biological Structure  
University of Washington  
School of Medicine  
Seattle, WA, USA

**Andreas Reichenbach MD**

Professor  
Paul Flechsig Institute of Brain Research  
University of Leipzig  
Faculty of Medicine  
Leipzig, Germany

**Kourous A. Rezaei MD**

Senior Partner, Illinois Retina Associates  
Director of Vitreoretinal Fellowship  
Associate Professor of Ophthalmology  
Rush University Medical Center  
Chicago, IL, USA

**William R. Rhoades MD**

Associated Retinal Consultants  
Grand Rapids, MI, USA

**Benjamin Rhodes MD**

Consultant Rheumatologist  
University Hospitals Birmingham NHS Foundation Trust  
Birmingham, UK

**Robert Ritch MD**

Shelley and Steven Einhorn Distinguished Chair  
Professor of Ophthalmology  
Surgeon Director Emeritus and Chief, Glaucoma Services  
The New York Eye and Ear Infirmary of Mount Sinai  
New York, NY, USA

**Anthony G. Robson PhD**

Consultant Electrophysiologist & Honorary Senior Lecturer  
Moorfields Eye Hospital & Institute of Ophthalmology  
University College London  
London, UK

**Philip J. Rosenfeld MD, PhD**

Professor of Ophthalmology  
Bascom Palmer Eye Institute  
Department of Ophthalmology  
University of Miami  
Miller School of Medicine  
Miami, FL, USA

**Teisha J. Rowland PhD**

Postdoctoral Fellow  
Cardiovascular Institute and Adult Medical Genetics Program  
University of Colorado  
Denver Anschutz Medical Campus  
Aurora, CO, USA

**Gary S. Rubin PhD**

Helen Keller Professor of Ophthalmology  
Department of Visual Neuroscience  
UCL Institute of Ophthalmology  
London, UK

**SriniVas R. Sadda MD**

President and Chief Scientific Officer  
Doheny Eye Institute  
Professor of Ophthalmology  
David Geffen School of Medicine  
University of California, Los Angeles  
Los Angeles, CA, USA

**Alfredo A. Sadun MD, PhD**

Thornton Professor of Vision  
Doheny Eye Institute  
Professor and Vice-Chair  
Department of Ophthalmology  
For Doheny Eye Centers  
David Geffen School of Medicine  
University of California, Los Angeles  
Los Angeles, CA, USA

**Alapakkam P. Sampath PhD**

Associate Professor  
Jules Stein Eye Institute  
Department of Ophthalmology  
David Geffen School of Medicine  
University of California, Los Angeles  
Los Angeles, CA, USA

**Amit A. Sangave MD**

PGY-4 Ophthalmology Resident  
Department of Ophthalmology  
Flaum Eye Institute  
University of Rochester  
School of Medicine and Dentistry  
Rochester, NY, USA

**Andrew P. Schachat MD**

Vice Chairman  
Cole Eye Institute  
Cleveland Clinic Foundation  
Cleveland, OH, USA

**Sid Schechet MD**

Department of Ophthalmology and Vision Sciences  
University of Maryland  
School of Medicine  
Baltimore, MD, USA

**Steffen Schmitz-Valckenberg MD, FEBO**

Professor, Senior Consultant  
Department of Ophthalmology  
University of Bonn  
Bonn, Germany

**Stephen G. Schwartz MD, MBA**

Associate Professor and Medical Director, Naples  
Bascom Palmer Eye Institute  
University of Miami  
Miller School of Medicine  
Naples, FL, USA

**Adrienne W. Scott MD**

Assistant Professor of Ophthalmology  
Retina Division, Wilmer Eye Institute  
Johns Hopkins University  
School of Medicine  
Baltimore, MD, USA

**J. Sebag MD, FACS, FRCOphth, FARVO**

Founding Director  
VMR Institute for Vitreous Macula Retina  
Huntington Beach, CA, USA

**Johanna M. Seddon MD, ScM**

Founding Director, Ophthalmic Epidemiology and Genetics Service  
New England Eye Center  
Tufts Medical Center  
Professor of Ophthalmology  
Professor in Department of Medicine  
Tufts University School of Medicine  
Professor, Tufts Clinical and Translational Science Institute

Tufts University  
Boston, MA, USA

**Michael I. Seider MD**

Ocular Oncology and Vitreoretinal Surgery  
The Permanente Medical Group  
San Francisco, CA, USA

**H. Nida Sen MD, MHS**

Director, Uveitis and Ocular Immunology Fellowship Program  
National Eye Institute  
National Institutes of Health  
Bethesda, MD, USA

**Yasir Jamal Sepah MBBS**

Senior Research Scientist  
Byers Eye Institute  
Stanford University  
Palo Alto, CA, USA  
Director  
Ocular Imaging Research and Reading Center  
Menlo Park, CA, USA

**Sanjay Sharma MD, MSc(Epid), MBA**

Professor of Ophthalmology and Epidemiology  
Queen's Medical College  
Kingston, Ontario, Canada

**Tarun Sharma MD, FRCSEd, MBA**

Professor of Ophthalmology  
Director, Shri Bhagwan Mahavir Vitreoretinal Services  
Sankara Nethralaya  
Medical Research Foundation  
Chennai, India

**Shwu-Jiuan Sheu MD**

Professor  
Department of Ophthalmology  
Kaohsiung Veterans General Hospital

Kaohsiung  
National Yang Ming University  
Taipei, Taiwan

**Carol L. Shields MD**

Co-Director, Ocular Oncology Service  
Wills Eye Hospital  
Thomas Jefferson University  
Philadelphia, PA, USA

**Jerry A. Shields MD**

Co-Director, Ocular Oncology Service  
Wills Eye Hospital  
Thomas Jefferson University  
Philadelphia, PA, USA

**Kei Shinoda MD, PhD**

Professor  
Department of Ophthalmology  
Saitama Medical University  
Faculty of Medicine  
Saitama, Japan

**Dhananjay Shukla MS, MAMS**

Senior Consultant and Director  
Retina-Vitreous Service  
Ratan Jyoti Netralaya  
Gwalior, Madhya Pradesh, India

**Paul A. Sieving MD, PhD**

Director  
National Eye Institute  
National Institutes of Health  
Bethesda, MD, USA

**Paolo S. Silva MD**

Assistant Professor of Ophthalmology  
Harvard Medical School  
Staff Ophthalmologist and Assistant Chief of Telemedicine

Beetham Eye Institute  
Joslin Diabetes Center  
Boston, MA, USA

**Claudio Silveira MD, PhD**  
Department of Ophthalmology  
Federal University of São Paulo  
São Paulo, Brazil

**Joshua Singer PhD**  
Associate Professor  
Department of Biology  
University of Maryland  
College Park, MD, USA

**Arun D. Singh MD**  
Professor of Ophthalmology and Director of Ophthalmic Oncology  
Cole Eye Institute, Cleveland Clinic  
Cleveland, OH, USA

**Alison Skalet MD, PhD**  
Assistant Professor of Ophthalmology  
Casey Eye Institute  
Oregon Health and Science University  
Portland, OR, USA

**Mario Skugor MD, FACE**  
Associated Professor of Medicine at CCLCM of CWRU  
Endocrinology and Metabolism  
Cleveland Clinic  
Cleveland, OH, USA

**Sylvia B. Smith PhD, FARVO**  
Regents' Professor and Chair  
Department of Cellular Biology/Anatomy  
Medical College of Georgia  
Professor of Ophthalmology  
Co-Director James and Jean Culver Vision Discovery Institute  
Augusta University

Augusta, GA, USA

**Lucia Sobrin MD, MPH**

Associate Professor of Ophthalmology  
Massachusetts Eye and Ear Infirmary  
Harvard Medical School  
Boston, MA, USA

**Akrit Sodhi MD, PhD**

Assistant Professor  
Retina Division  
Wilmer Eye Institute  
Johns Hopkins School of Medicine  
Baltimore, MD, USA

**Elliott H. Sohn MD**

Associate Professor  
Director, Retina Fellowships  
Department of Ophthalmology and Visual Sciences  
Wynn Institute for Vision Research  
University of Iowa  
Iowa City, IA, USA

**Gisèle Soubrane-Daguet MD, PhD**

Professor of Ophthalmology  
Department of Ophthalmology  
University of Paris V  
Paris, France

**Leigh Spielberg MD, FEBO**

Vitreoretinal Surgeon  
Department of Ophthalmology  
Ghent University Hospital  
Ghent, Belgium

**Sunil K. Srivastava MD**

Staff Physician  
Cole Eye Institute  
Cleveland Clinic Foundation

Cleveland, OH, USA

**Oliver Stachs PhD**

Professor of Experimental Ophthalmology  
Department of Ophthalmology  
University of Rostock  
Rostock, Germany

**Giovanni Staurenghi MD, FARVO**

Professor of Ophthalmology  
Chairman Eye Clinic  
Director, Residency Program  
Department of Biomedical and Clinical Sciences “Luigi Sacco”  
Sacco Hospital  
University of Milan  
Milan, Italy

**Paul Sternberg Jr., MD**

G. W. Hale Professor and Chair  
Vanderbilt Eye Institute  
Chief Medical Officer  
Vanderbilt Medical Group  
Chief Patient Experience Officer  
Associate Dean for Clinical Affairs  
Assistant Vice Chancellor for Adult Health Affairs  
Nashville, TN, USA

**Jay M. Stewart MD**

Associate Professor of Ophthalmology  
University of California, San Francisco  
Chief of Ophthalmology  
San Francisco General Hospital  
San Francisco, CA, USA

**Alan Stitt PhD**

Professor and McCauley Chair of Experimental Ophthalmology  
Centre for Experimental Medicine  
Queen's University Belfast  
Belfast, Northern Ireland, UK

**Edwin M. Stone MD, PhD**

Professor

Director, Wynn Institute for Vision Research  
Department of Ophthalmology and Visual Sciences  
University of Iowa  
Iowa City, IA, USA

**Ilene K. Sugino MA**

Principal Research Associate

Institute of Ophthalmology and Visual Science  
New Jersey Medical School  
Rutgers University  
Newark, NJ, USA

**Lori S. Sullivan PhD**

Faculty Associate

Human Genetics Center  
School of Public Health  
University of Texas Health Science Center  
Houston, TX, USA

**Paul Sullivan MBBS, MD, FRCOphth**

Consultant Ophthalmic Surgeon

Director of Education  
Moorfields Eye Hospital  
London, UK

**Jennifer K. Sun MD, MPH**

Associate Professor of Ophthalmology

Harvard Medical School  
Staff Ophthalmologist and Chief  
Center for Clinical Eye Research and Trials  
Beetham Eye Institute  
Joslin Diabetes Center  
Boston, MA, USA

**Janet S. Sunness MD**

Medical Director

Richard E. Hoover Low Vision Rehabilitation Services

Greater Baltimore Medical Center  
Clinical Professor, Department of Ophthalmology and Vision  
Sciences  
University of Maryland  
School of Medicine  
Baltimore, MD, USA

**R.C. Andrew Symons MBBS, PhD, FRANZCO**

Head of Ophthalmology  
Royal Melbourne Hospital  
Clinical Associate Professor  
University of Melbourne  
Melbourne, VIC, Australia

**Ramin Tadayoni MD, PhD**

Professor of Ophthalmology  
Université Paris Diderot  
Sorbonne Paris Cité  
AP-HP, Hôpital Lariboisière  
Chairman of the Department of Ophthalmology  
Paris, France

**Shibo Tang MD, PhD**

Professor of Ophthalmology  
Dean, Aier School of Ophthalmology  
Central South University  
Director, Aier Eye Institute  
Aier Eye Hospital Group  
Changsha, Hunan, China

**Hiroko Terasaki MD**

Professor and Chair  
Department of Ophthalmology  
Nagoya University  
Graduate School of Medicine  
Nagoya, Japan

**Aristomenis Thanos MD**

Associated Retinal Consultants

William Beaumont Hospital  
Royal Oak, MI, USA

**Matthew A. Thomas MD**

Clinical Professor of Ophthalmology  
The Retina Institute  
Washington University  
St Louis, MO, USA

**John T. Thompson MD**

Partner, Retina Specialists  
Department of Ophthalmology  
Greater Baltimore Medical Center  
Baltimore, MD, USA

**Cynthia A. Toth MD**

Joseph A.C. Wadsworth Professor of Ophthalmology  
Professor of Biomedical Engineering  
Duke University Medical Center  
Durham, NC, USA

**Brian Toy MD**

Department of Ophthalmology  
Stanford University School of Medicine  
Palo Alto, CA, USA

**Michael T. Trese MD**

Professor of Ophthalmology  
Oakland University  
William Beaumont School of Medicine  
Associated Retinal Consultants  
Royal Oak, MI, USA

**Julie H. Tsai MD**

Assistant Professor of Clinical Ophthalmology  
Albany, NY, USA

**Nitin Udar PhD**

Gavin Herbert Eye Institute

Ophthalmology Research Laboratories  
University of California, Irvine  
Irvine, CA, USA

**J. Niklas Ulrich MD**

Assistant Professor of Ophthalmology  
Department of Ophthalmology  
University of North Carolina, Chapel Hill  
Chapel Hill, NC, USA

**Allison C. Umfress MD**

Vanderbilt Eye Institute  
Vanderbilt University Medical Center  
Nashville, TN, USA

**Russell N. Van Gelder MD, PhD**

Professor and Boyd K. Bucey Memorial Chair  
Department of Ophthalmology  
Adjunct Professor  
Departments of Biological Structure and Pathology  
University of Washington  
School of Medicine  
Seattle, WA, USA

**Jan C. van Meurs MD, PhD**

The Rotterdam Eye Hospital  
Erasmus University  
Rotterdam, The Netherlands

**Daniel Vítor Vasconcelos-Santos MD, PhD**

Adjunct Professor of Ophthalmology  
Universidade Federal de Minas Gerais  
Hospital São Geraldo / HC-UFMG  
Belo Horizonte, MG, Brazil

**Demetrios G. Vavvas MD, PhD**

Associate Professor of Ophthalmology  
Massachusetts Eye & Ear Infirmary  
Department of Ophthalmology

Harvard Medical School  
Boston, MA, USA

**G. Atma Vemulakonda MD**

Chief of Vitreoretinal Surgery  
Department of Ophthalmology  
Palo Alto Medical Foundation  
Palo Alto, CA, USA

**Nadia K. Waheed MD, MPH**

Associate Professor of Ophthalmology  
New England Eye Center  
Department of Ophthalmology  
Tufts University School of Medicine  
Boston, MA, USA

**James Weiland PhD**

Professor  
Department of Biomedical Engineering  
University of Michigan  
Ann Arbor, MI, USA

**Richard G. Weleber MD**

Department of Ophthalmology  
Casey Eye Institute  
Oregon Health & Science University  
Portland, OR, USA

**Adam S. Wenick MD, PhD**

Assistant Professor of Ophthalmology  
The Wilmer Eye Institute  
Johns Hopkins University  
Baltimore, MD, USA

**Moody D. Wharam Jr., MD**

Professor of Radiation Oncology  
Department of Radiation Oncology and Molecular Radiation  
Sciences  
The Sidney Kimmel Comprehensive Cancer Center

Johns Hopkins CRB II  
Baltimore, MD, USA

**Louisa Wickham FRCOphth, MSc, MD**

Clinical Director  
Consultant Ophthalmologist  
Department of Vitreoretinal Surgery  
Moorfields Eye Hospital  
London, UK

**Peter Wiedemann MD**

Professor and Chair  
Department of Ophthalmology  
University of Leipzig  
Leipzig, Germany

**Henry E. Wiley MD**

Staff Clinician  
Division of Epidemiology and Clinical Applications  
National Eye Institute  
National Institutes of Health  
Bethesda, MD, USA

**C.P. Wilkinson MD**

Distinguished Emeritus Chairman  
Department of Ophthalmology  
Greater Baltimore Medical Center  
Professor, Department of Ophthalmology  
John Hopkins University  
Baltimore, MD, USA

**David Wilson MD**

Professor and Chair of Ophthalmology  
Director, Casey Eye Institute  
Oregon Health & Science University  
Portland, OR, USA

**Sebastian Wolf MD, PhD**

Department of Ophthalmology

Inselspital, Bern University Hospital  
University of Bern  
Bern, Switzerland

**Thomas J. Wolfensberger MD, MBA**  
Hôpital Ophtalmique Jules-Gonin  
University of Lausanne  
Lausanne, Switzerland

**David Wong FRCOphth**  
Honorary Clinical Professor  
Department of Ophthalmology, LKS  
Faculty of Medicine  
The University of Hong Kong  
Hong Kong, China

**Ian Y. Wong FRCOphth**  
Clinical Assistant Professor  
Department of Ophthalmology, LKS  
Faculty of Medicine  
The University of Hong Kong  
Hong Kong, China

**Tien Y. Wong MD, PhD**  
Professor & Medical Director, Singapore National Eye Center  
Chair of Ophthalmology & Vice-Dean of Clinical Sciences  
Duke-NUS Medical School  
National University of Singapore

**Frances Wu BS**  
Medical Student  
UC San Diego School of Medicine  
La Jolla, CA, USA

# Dedication

---

The original and all subsequent editions of *RETINA* are dedicated to the clinicians and scientists who have contributed to the education in our field of medical students, residents, and fellows, and especially to retina specialists and all ophthalmologists who participate in continuing medical education. We recognize that we are all students and committed to lifelong learning, especially in our field of retina.

The Second Edition included a special dedication to **Ronald G. Michels (1942–1991)**, who was vitally involved in the planning of the original edition and in the recruitment of our initial team of editors and authors. Ron was an enthusiastic and talented leader in vitreoretinal surgery. His teaching and innovations had a major impact on the other editors of *RETINA* specifically and on the entire field of ophthalmology generally. We are thankful for the privilege of having known and worked with Ron.

For the Third Edition we offered an additional special dedication to **A. Edward Maumenee (1913–1998)**, a true giant who influenced virtually every field and subspecialty in ophthalmology. While most of his later contributions

involved anterior segment surgery, his original observations regarding macular degeneration provided a basis for subsequent clinical and research investigations in this area. As a gifted teacher, relentless investigator, and treasured mentor, Ed inspired the editors and many authors of this textbook, as well as a multitude of academicians and clinicians around the world. He was the Professors' Professor.

For the Fourth Edition we added a special dedication to **Arnall Patz (1920–2010)**, who was an editor of the original edition. Arnall was a pioneer and leader in the establishment of the field of medical retina. He founded the Retinal Vascular Center at the Wilmer Institute and, subsequently, he became the Director of the Wilmer Institute. He trained many of today's leaders in the field and many contributing authors to RETINA. Arnall was an inspiration for the multitude of retinal specialists around the world.

For the Fifth Edition we wished to stress the development of knowledge and the contribution of the international community of retinal specialists. From the time of the First Edition in 1989 we have benefited from the rapid evolution of science – basic and clinical – in all fields related to biology and medicine, and especially in relation to ophthalmology and our chosen specialty of retina. The evolution of knowledge and contributions of colleagues from around the world have shown that there are no borders; the free exchange of information directly benefits our patients in the prevention of the most common forms of blindness caused by retinal diseases. Thus, we felt it was wholly appropriate that the Fifth Edition of RETINA be dedicated to the **international community of retinal**

## **clinicians and educators.**

The Editors dedicate this Sixth Edition to **Stephen J. Ryan**. Steve was born in Honolulu in 1940. A Johns Hopkins University medical graduate, he was recruited to the University of Southern California to become the first fulltime chairman of the Ophthalmology Department. Under his leadership, the department became one of the leading eye departments in the country. In 1991 he became Dean of the medical school at USC, which became the Keck School of Medicine. This book was his idea and we hope the current edition reflects well on his legacy.

### **Stephen J. Ryan MD 1940–2013**

**Stephen J. Ryan MD**, founding Editor-in-Chief of *RETINA* (Editions 1 through 5), received his MD degree from Johns Hopkins University and launched his academic career at the Wilmer Eye Institute of Johns Hopkins. In 1974, he was recruited to the University of Southern California, Los Angeles, as Chairman of the Department of Ophthalmology and President of the Doheny Eye Institute. Throughout the ensuing 39 years, he devoted his talent and energy to building the Doheny Eye Institute as a

center of excellence for ophthalmology education, patient care, and vision research.

Author of nine books and more than 250 peer-reviewed articles, Dr. Ryan received numerous honors, including the American Academy of Ophthalmology Laureate Award, the Association for Research in Vision and Ophthalmology Kupfer Award, and election to the National Academy of Sciences Institute of Medicine. By his many friends, Dr. Ryan is remembered as a brilliant scholar, scientist and visionary.

Bradley R. Straatsma MD, JD

---

# Preface

---

*Ryan's RETINA* intends to provide both a roadmap and resource for those who study, diagnose, and treat diseases of the retina. In 1958, Duke-Elder's *System of Ophthalmology* addressed the entire scope of ophthalmology in 14 volumes with a 15th volume for the index; retina was covered in one volume. When Steve Ryan set out to develop the first edition of this retina text in the late 1980s, the book contained three volumes – basic science and tumors, medical retina, and surgical retina. But, with the explosion of medical knowledge in the 20th century, three volumes, while “hitting more than just the highlights,” cannot lay claim to covering all that a reader may want to learn or know about the subject. And, as we present the 6th Edition in the second half of the second decade of the 21st century, this is truer than ever. The editors have encouraged the authors to seek out and supply the key references for each of the chapters. We hope that each chapter provides an in-depth resource for each disease or condition, but by no means should each chapter be viewed as complete. For those who want or need more, we anticipate the key words to search on should be there, and searching on those and delving into the references I hope will lead readers to what they hope to learn about the topic being addressed.

We have updated and revised the book at approximately five-year intervals. Medicine generally and ophthalmology specifically change quickly. When the book first came out, laser treatment for retinal vascular disease was the new standard. In Duke-Elder's time, diabetic retinopathy was blinding in perhaps 50% of eyes; shortly before the first edition of *Ryan's RETINA*, laser therapy as demonstrated by the Diabetic Retinopathy Study and Early

Treatment Diabetic Retinopathy Study, if applied in a timely manner, should reduce blindness rates to 1–2%. Now, laser therapy is mainly supplanted by anti-vascular endothelial factor drugs with much greater chances for improvement. Similarly, retinal surgery has moved from open sky vitrectomy to 20-gauge and now 25- or smaller gauge surgery. The “artificial retina” has US Food and Drug Administration approval, gene therapy trials are underway, and advances in our field are remarkable. To bring all this to the reader would require a 15-volume Duke-Elder-like work. I doubt too many of us would buy such a book nowadays. So, as we have added new material with entire new chapters in each section of the book, we have also removed less important or more dated aspects which appeared in earlier editions. A mantra was “the book should not gain weight.”

We salute the authors, who are leading experts in specific fields from around the world. In particular, I (A.P.S.) recognize and thank my collaborating editors who have upheld Steve Ryan's vision and standards for the book – David R. Hinton, Srinivas R. Sadda, C.P. Wilkinson, and Peter Wiedemann. We thank the team at Elsevier, led by Russell Gabbedy, Nani Clansey, and Joanna Souch. Importantly, I thank my mentors who helped guide me, A.E. Maumenee, Stuart Fine, Arnall Patz, Morton F. Goldberg, and Alfred Sommer. I also recognize my retina colleagues at the Cole Eye Institute led by Daniel F. Martin. Most thanks go of course to Steve Ryan, who allowed me to participate, and to my wife, Robin.

Since their introduction in the late 1960s, fundus photography and fluorescein angiography have been valuable in expanding our knowledge of the anatomy, pathology, and pathophysiology of the retina and choroid.<sup>1</sup> Initially, fluorescein angiography (FA) was used primarily as a laboratory and clinical research tool; only later was it used for the diagnosis of fundus diseases in the infant stages in the field of medical retina.<sup>1-4</sup> The landmark text *Atlas of Macular Diseases* by Dr. J. Donald Gass set a new standard for the use of stereoscopic FA in fundus diagnosis.<sup>2</sup> An understanding of FA and the ability to interpret fluorescein angiograms are essential to accurately evaluate, diagnose, and treat patients with retinal vascular and macular disease.

This chapter discusses the basic principles of FA and the equipment and techniques needed to produce a high-quality angiogram. Potential side-effects and complications of fluorescein injection are also discussed. Finally, interpretation of FA, including fundus anatomy and histology, the normal fluorescein angiogram, and conditions responsible for abnormal fundus fluorescence are described.

## Basic Principles

To understand fluorescein angiography, knowledge of fluorescence is essential. Likewise, to understand fluorescence, one must know the principles of luminescence. Luminescence is the emission of light from any source other than high temperature. Luminescence occurs when energy in the form of electromagnetic radiation is absorbed and then re-emitted at another frequency. When light energy is absorbed into a luminescent material, free electrons are elevated into higher energy states. This energy is then reemitted by spontaneous decay of the electrons into their lower energy states. When this decay occurs in the visible spectrum, it is called luminescence. Luminescence therefore always entails a shift from a shorter wavelength to a longer wavelength. The shorter wavelengths represent higher energy, and the longer wavelengths represent lower energy.

## Fluorescence

Fluorescence is luminescence that is maintained only by continuous excitation. In other words, excitation at one wavelength occurs and is emitted immediately through a longer wavelength. Emission stops at once when the excitation stops. Fluorescence thus does not have an afterglow. Sodium fluorescein is a hydrocarbon that responds to light energy between 465 and 490 nm and fluoresces at a wavelength of 520–530 nm. The excitation wavelength, the type that is absorbed and changed, is blue; the resultant fluorescence, or emitted wavelength, is green–yellow. If blue light between 465 and 490 nm is directed to unbound sodium fluorescein, it emits a light that appears green–yellow (520–530 nm).

This is a fundamental principle of FA. A patient, whose eyes have been dilated, is seated behind the fundus camera, on which a blue filter has been placed in front of the flash. Fluorescein is then injected intravenously. Eighty percent of the fluorescein becomes bound to protein and is not available for fluorescence, but 20% remains free in the bloodstream and is available for fluorescence. The blue flash of the fundus camera excites the unbound fluorescein within the blood vessels or the fluorescein that has leaked out of the blood vessels. The blue filter shields out (reflects or absorbs) all other light and allows through only the blue excitation light. The blue light then changes those structures in the eye containing fluorescein to green–yellow light at 520–530 nm. In addition, blue light is reflected off fundus structures that do not contain fluorescein. The blue reflected light and the green–yellow fluorescent light are directed back to the fundus camera. A filter is placed that allows the green–yellow fluorescent light through but keeps out the blue reflected light. Therefore, the only light that penetrates the filter is true fluorescent light (Fig. 1.1).

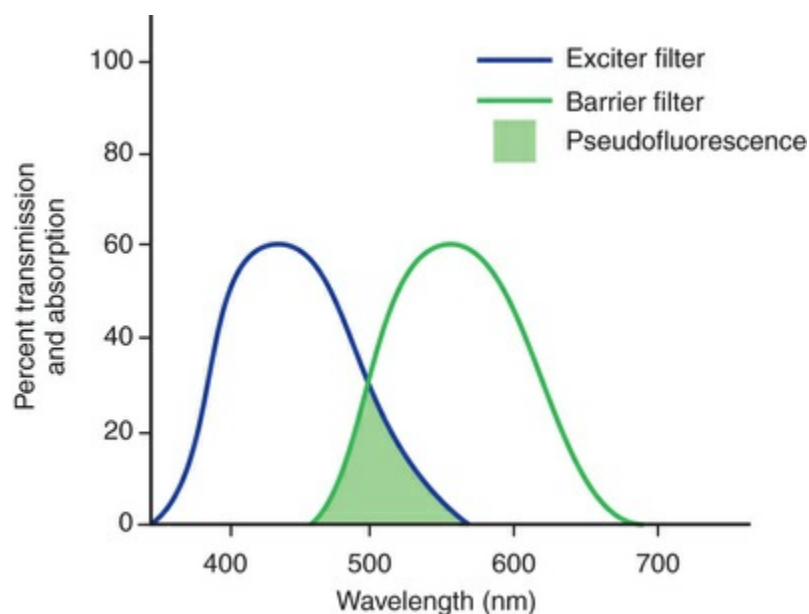

**FIG. 1.1** Absorption and emission curves of sodium fluorescein dye. The peak absorption (excitation) is at 465–490 nm (blue light). The peak emission occurs at 520–530 nm (yellow–green light).

## Pseudofluorescence

Pseudofluorescence occurs when nonfluorescent light passes through the entire filter system. If green–yellow light penetrates the original blue filter, it will pass through the entire system. If blue light reflected from nonfluorescent fundus structures penetrates the green–yellow filter, pseudofluorescence occurs (Fig. 1.2).

Pseudofluorescence can confuse the physician interpreting the fluorescein angiogram and lead him or her to think that certain fundus structures or materials are fluorescing when they are not. Pseudofluorescence also causes decreased contrast, as well as decreased resolution. The background illumination from pseudofluorescence is especially heightened if there are white or yellowish-white areas of the fundus, such as highly reflective hard exudates. Pseudofluorescence must be avoided. Therefore, the excitation (blue) and barrier (green–yellow) filters are carefully matched so that the overlap of light between them is minimal.

**FIG. 1.2** Pseudofluorescence. The blue exciter filter overlaps into the yellow–green zone, and the yellow–green barrier filter overlaps into the blue zone. The combination results in pseudofluorescence.)

## Equipment (Box 1.1)

### Camera and Auxiliary Equipment

Today's widely used cameras differ in the degree of fundus area included in the photographs. In clinical retinal practice, cameras ranging from 35° to 200° are routinely used. Regardless of range, a camera with the ability to yield high resolutions of the posterior pole is essential for most macular problems, especially when laser treatment is to be done, as with background diabetic retinopathy, **Box 1.1** vein occlusion, or choroidal neovascularization.

### Equipment and Materials Needed for Angiography

Fundus camera and auxiliary equipment

Matched fluorescein filters (barrier and exciter)

Digital photoprocessing unit (computer-based) and software user interface

23-gauge scalp vein needle

5 mL syringe

5 mL of 10% fluorescein solution

20-gauge, 1/2-inch needle to draw the dye

Armrest for fluorescein injection

Tourniquet

Alcohol swabs

Bandage

Standard emergency equipment

Wide-angle angiography ([Chapter 5](#), Wide-field imaging) has the

benefit of capturing a single image of the retina in high resolution well beyond the equator. The potential for clinical efficiency and sensitivity in detecting neovascularization in the far periphery as well as acquiring an excellent clinical picture of the degree of capillary retinal nonperfusion is an exciting development in FA (Fig. 1.3).<sup>3</sup> Modern angiography systems also allow for video recording of the entire filling process in real time which combined with wide-field views allows for precise imaging of the exact time that structures fill or leak.<sup>4</sup>

**FIG. 1.3** Optos wide-field images. (A) Nonperfusion detected in the left eye with wide-field fluorescein imaging. (B,C) Wide-field angiography of the right and left eyes of a patient with diabetic retinopathy. Note the multiple areas of leakage corresponding to areas of retinal neovascularization associated with capillary nonperfusion. It is often difficult in certain wide-field images to determine the presence of small neovascular complexes versus leakage from capillary nonperfusion, unless areas are magnified further. (Panel A courtesy of Umar Mian, MD. Image taken by Carolina Costa. Panels B and C courtesy of Szilárd Kiss, MD.)

FA can also be performed using the camera application on a smartphone, which is a low-cost portable alternative useful in patients with physical ailments that prevent positioning at a standard camera or in poor resource settings.<sup>5</sup> Finally, the ability to share images for screening purposes for conditions such as diabetic retinopathy and age-related macular degeneration will likely expand. Thus far, teleophthalmology has been limited to color fundus images and optical coherence tomography images, but angiographic images for diseases such as new-onset choroidal neovascularization maybe cost-effective without leading to

significant treatment delays.<sup>6</sup>

## Matched Fluorescein Filters

FA uses both exciter and barrier filters, which are typically included in modern camera units. The exciter filter must transmit blue light at 465–490 nm, the absorption peak of fluorescein excitation. The barrier filter transmits light at 525–530 nm, the fluorescent, or emitted, peak of fluorescein. The filters should allow maximal transmission of light in the proper spectral range to achieve a good image without the use of an excessively powerful flash unit.

## Fluorescein Solution

Sodium fluorescein, an orange-red crystalline hydrocarbon ( $C_{20}H_{12}O_5Na$ ), has a low molecular weight (376.27 Da) and readily diffuses through most of the body fluids and through the choriocapillaris, but it does not diffuse through the retinal vascular endothelium or the pigment epithelium.

Solutions containing 500 mg fluorescein are available in vials of 10 mL of 5% fluorescein or 5 mL of 10% fluorescein. Also available are 3 mL of 25% fluorescein solution (750 mg). The greater the volume, the longer the injection time will be; the smaller the volume, the more likely a significant percentage of fluorescein will remain in the venous dead space between the arm and the heart. For this reason, we prefer 5 mL of 10% solution (500 mg fluorescein).

Fluorescein is eliminated by the liver and kidneys within 24 hours, although traces may be found in the body for up to a week after injection. Retention may increase if renal function is impaired. The skin has a yellowish tinge for a few hours after injection, and the urine has a characteristic yellow–orange color for most of the first day after injection.

Various side-effects and complications can occur with fluorescein injection (Box 1.2).<sup>7</sup> One complication of the injection is extravasation of the fluorescein under the skin. This can be extremely painful and may result in a number of uncomfortable symptoms. Necrosis and sloughing of the skin may occur, although

this is extremely rare. Superficial phlebitis also has been noted. A subcutaneous granuloma has occurred in a few patients after fluorescein extravasation. In each instance, however, the granuloma has been small, cosmetically invisible, and painless. Toxic neuritis caused by infiltration of extravasated fluorescein along a nerve in the antecubital area can result in considerable pain for up to a few

### **Box 1.2**

## **Side-Effects and Complications of Fluorescein Injection**

Extravasation and local-tissue necrosis

Inadvertent arterial injection

Nausea

Vomiting

Vasovagal reaction (circulatory shock, myocardial infarction)

Allergic reaction, anaphylaxis (hives and itching, respiratory problems, laryngeal edema, bronchospasm)

Nerve palsy

Neurologic problems (tonic-clonic seizures)

Thrombophlebitis

Pyrexia

Death

Nausea is the most frequent side-effect of fluorescein injection, occurring in about 5% of patients. It is most likely to occur in patients under 50 years of age or when fluorescein is injected rapidly. When nausea occurs, it usually begins approximately 30 seconds after injection, lasts for 2–3 minutes, and disappears slowly.

Vomiting occurs infrequently, affecting only 0.3–0.4% of

patients.<sup>7</sup> When it does occur, it usually begins 40–50 seconds after injection. By this time most of the initial-transit photographs of the angiogram will have been taken. Photographs can be taken after the vomiting episode has passed. A slower, more gradual injection may help to prevent vomiting.

Vasovagal attacks occur much less frequently during FA than does nausea and are probably caused more by patient anxiety than by the actual injection of fluorescein. Shock and syncope (more severe vasovagal reaction) consist of bradycardia, hypotension, reduced cardiovascular perfusion, sweating, and the sense of feeling cold. If the photographer and person injecting see that the patient is lightheaded, the patient should be allowed to bend over or lie down with the feet elevated. The patient's blood pressure and pulse should be carefully monitored. It is important to differentiate this from anaphylaxis, in which hypotension, tachycardia, bronchospasm, hives, and itching occur.

Hives and itching are the most frequent allergic reactions, occurring 2–15 minutes after fluorescein injection. Although hives usually disappear within a few hours, an antihistamine, such as diphenhydramine hydrochloride (Benadryl), may be administered intravenously for an immediate response. Bronchospasm and even anaphylaxis are other reactions that have been reported, but these are extremely rare. Epinephrine, systemic steroids, aminophylline, and pressor agents should be available to treat bronchospasm or any other allergic or anaphylactic reactions. Other equipment that should be readily available in the event of a severe vasovagal or anaphylactic reaction includes oxygen, a sphygmomanometer, a stethoscope, and a device to provide an airway. The skilled photographer observes each patient carefully and is alert to any scratching, wheezing, or difficulty in breathing that the patient may have after injection.

There are a few published and unpublished reports of death following intravenous fluorescein injection. The mechanism may be a severe allergic reaction or a hypotensive episode induced by a vasovagal reaction in a patient with preexisting cardiac or cerebral vascular disease. The cause of death in each case may have been coincidental. Acute pulmonary edema following fluorescein injection has also been reported.

There are no known contraindications to fluorescein injections in patients with a history of heart disease, cardiac arrhythmia, or cardiac pacemakers. Although there have been no reports of fetal complications from fluorescein injection during pregnancy, it is current practice to avoid angiography in women who are pregnant, especially those in the first trimester.

## Technique

### Aligning Camera and Photographing

The camera is equipped with a joystick with which the photographer can adjust the camera laterally and for depth. The camera is also equipped with a knob for vertical adjustment. The photographer finds the red fundus reflex, which is an even, round, sharply defined, pink or red light reflex. Most fundus cameras are equipped with an external fixation arm that has a very small LED bulb on the tip. The photographer begins by instructing the patient to follow this light to the desired position so that the correct field comes into view. The photographer moves the camera from side to side to ascertain the width of the pupil and the focusing peculiarities of the particular cornea and lens. The photographer studies the eye through the camera lens, moving the camera back and forth and up and down, looking for fundus details (e.g., retinal blood vessels). The photographer then determines the single best position from which to photograph (Figs. 1.4 and 1.5). With new wide-field angiography systems, the patient set-up is similar (Fig. 1.6).

**FIG. 1.4** The patient's arm rests on an adjustable armrest that is elevated so that the patient's arm is at or above the level of her heart. The armrest also facilitates easy placement of the intravenous needle and injection of fluorescein.

**FIG. 1.5** The patient's head is kept steady in the chinrest and headrest of the fundus camera. The photographer aligns the camera and focuses on the patient's right fundus. Each is in a comfortable position, facilitating the stability necessary to achieve a good fluorescein angiogram.

**FIG. 1.6** The patient is positioned at an Optos California Ultra Widefield retinal imaging machine with the photographer positioned behind the patient watching the angiogram in real time. The photographer is able to capture images throughout the angiogram without adjusting the camera or the patient's gaze.

Any abnormalities, such as an unusual light reflex or a poorly resolved image the photographer sees through the camera system, will appear on the photograph. If the ophthalmoscopic view seen through the camera is not optimal, the photograph will not be optimal (Fig. 1.7). A helpful concept for the photographer is “what you see is what you get (or worse – never better).”

**FIG. 1.7** Fundus photograph and reflexes. (A) Photograph of right fundus without reflexes. The camera was properly aligned and focused. (B) Note the bright red, yellow, and blue arc on the right side. The flash is reflecting off the iris. This can be remedied by repositioning the camera slightly to the right or left. (C) In this case the camera was placed at the proper distance from the fundus but was placed too far to one side (down and to the right), which allowed the bright white arc reflex to the lower right. (D) Note white reflex, especially above, in, and below the papillomacular bundle. In this case the camera was in proper alignment but was placed too far away from the patient's eye.

## Focusing

Achieving perfect focus is a major factor in the photographic process. Both the eyepiece crosshairs and the fundus details must

be in sharp focus to obtain a well-resolved photograph. The proper position of the eyepiece is determined by the refractive error of the photographer and the degree to which he or she accommodates while focusing the camera.

The photographer first turns the eyepiece counterclockwise (toward the plus, or hyperopic, range) to relax his or her own accommodation; this causes the crosshairs to blur. The photographer then turns the eyepiece slowly clockwise to bring the crosshairs into sharp focus. The eyepiece is focused properly when the crosshairs appear sharp and clear (Fig. 1.8 online). They must remain perfectly clear while the photographer focuses on the fundus with the camera's focusing detail. With experience, the photographer becomes expert in adjusting the eyepiece and in keeping the crosshairs in focus throughout the entire photographic sequence.

**FIG. 1.8** The photographer focuses the eyepiece of the camera by initially turning the eyepiece counterclockwise, then clockwise, and stopping when it is in exact focus. The photographer must be sure that the eyepiece crosshairs remain in perfect focus throughout the photographic procedure.

The best position for the eyepiece is the point at which the crosshairs are in focus while the photographer's accommodation is relaxed. Photographers learn to relax accommodation by keeping both eyes open. The photographer focuses the eyepiece with one

eye and, with the other eye, keeps a distant object, such as the eye chart, in sharp focus. This skill may be difficult for technicians without ophthalmic training, but it is seldom impossible to learn.

Keeping the crosshairs in sharp focus, the photographer then turns the focusing dial on the camera to focus the fundus detail. Some photographers focus the crosshairs just once at the beginning of each day and control their accommodation throughout the day. This is not a good idea because the photographer's accommodation may change during a photographic session; the photographer should be aware of this possibility and regularly check and readjust the eyepiece for focus. With the camera properly aligned and focused, the photographer is ready to start the preliminary photographs and angiograms.

## Using Stereo Photography

Stereoscopic photography allows the viewer to perceive depth by separating, photographically, the tissues of the eye for the observer. This facilitates the interpretation of stereo FA by visually separating retinal and choroidal circulation.<sup>8</sup> The photographic protocol for some clinical trials requires that FA, as well as fundus photos, be captured in stereo. Though not always necessary, well-resolved stereo images can aid in the interpretation of angiograms with, for instance, choroidal neovascularization associated with age-related macular degeneration.

Adequate stereo photographs can be achieved with a pupillary dilation of 4 mm, although dilation of 6 mm or more is best. The first photograph of any stereo pair is taken with the camera positioned as far to the photographer's right (the patient's left) of the pupil's center as possible (of course, without inducing reflexes). The second photograph of the stereo pair is taken with the camera held as far to the photographer's left (the patient's right) of the pupil's center as possible.

## Positioning the Patient

The patient is positioned at the camera with the chin in the chinrest and the forehead against the head bar. Because the most common cause of poor fluorescein photographs is involuntary movement of

the patient's head, the photographer should prepare and make adjustment for this before the fluorescein is injected. If so, the photographer can make some adjustment before injecting the fluorescein dye. Sometimes having an assistant hold the patient's head in the chinrest is helpful (Fig. 1.9 online). The photographer either may lower the entire camera and chinrest or raise the patient's chair. This causes the patient to lean forward in the chinrest and against the forehead bar, making it more difficult for the patient to pull back.

**FIG. 1.9** An assistant holds the patient's head as a reminder to the patient to keep the chin in the chinrest and forehead against the bar.

Before photography begins, and between shots, the photographer may ask the patient to blink several times. This usually makes the patient more comfortable and also moistens the cornea and keeps it clear. When the pictures are actually being shot, the patient should be instructed to blink as infrequently as possible.

The photographer should talk to the patient frequently during the procedure, informing the patient of the progress of the testing and assuring him or her that all is going well. Explanation and reinforcement produce better photographs.

## Injecting the Fluorescein

Color fundus photographs are taken first, followed by a red-free image of each macula. Once these images have been captured, the fluorescein can be injected. For injection, we recommend a syringe with a 23-gauge winged infusion set, or scalp-vein needle (Fig. 1.10 online). The scalp-vein needle has several advantages: it is small enough to enter most visible veins, and an intravenous opening is then available in the event of an emergency.

**FIG. 1.10** Ten percent fluorescein solution, 5 mL syringe, and 23-gauge scalp-vein needle.

Injection of the fluorescein is coordinated with the photographic process and is done after the first photographs (color fundus and control photographs; see next section) have been taken. When ready, the photographer will signal the physician. After inserting the needle, the physician will say “starting” aloud to indicate that the injection has commenced. The photographer immediately takes a control photograph which automatically starts the timer. This frame will show zero time on the photograph. In this way, the time from the beginning of injection is recorded on each subsequent angiographic photograph. When the injecting clinician has completed infusion, he or she announces “injection complete” and the photographer takes the “end-of-injection” image. A rapid injection of 2 or 3 seconds delivers a high concentration of fluorescein to the bloodstream in a short time and yields somewhat

better photographs than a slower injection. However, the more rapid the injection, the greater the incidence of nausea from a highly concentrated bolus of fluorescein. For this reason a slower injection (4–6 seconds) is preferable; the photographs will still be of good quality. Because some fluorescein dye remains in the tubing, the scalp-vein needle should have short, rather than long, tubing to ensure that more of the dye is injected (Fig. 1.11 online).

**FIG. 1.11** After the needle is placed in the vein, the lights can be turned off so that the photographer can become dark-adapted and see fluorescein flow in the eye. With the use of a hand light, the person injecting can carefully observe the injection site so as to be sure extravasation is not occurring. In this way the fluorescein solution can be injected while the room lights are out.

In angiograms in which videoangiography is not performed, the photographer should begin taking the initial-transit fluorescein photographs 8 seconds after the beginning of the injection of the dye if the patient is young and 12 seconds after injection for older patients. This is done so that these early photographs will not miss the appearance of fluorescein as it enters the fundus. Then, a rapid succession of images should be taken at intervals of 1.5–2 seconds, until all veins and arteries are full. If the photographer does not see fluorescein entering and filling the retinal vessels while the initial

transit photographs are taken, he or she must continue to photograph the fundus until filling takes place. If no dye appears, the photographer should check with the patient to see if they have a burning sensation around the injection site, indicating possible extravasation.

After the initial-transit photographs and approximately 20–30 seconds after injection, with sufficient fluorescein concentration in the eye, the photographer should take a photograph centered on the optic disc, followed by the macula and optic disc of the fellow eye and any other pertinent areas. It is important to photograph both discs and macula and any other areas of abnormal fluorescence and to note any areas that could not be photographed. This ensures that the physician will have adequate information for a complete interpretation of the angiogram.

The entire photographic process lasts 5–10 minutes. Late-stage angiographs are taken of the pertinent areas of each eye when 5 minutes have elapsed. Some pathologies such as central serous retinopathy (CSR) and cystoid macular edema (CME) are better visualized when taken at 7 minutes. In an angiogram of a diabetic patient, peripheral scans may be included at the request of the clinician surveying for neovascularization if wide-angle visualization is not available. In a patient with possible choroidal neovascularization due to age-related macular degeneration, additional photographs of the suspicious lesion may be useful. When inflammatory or postsurgical CME is suspected, late frame images of the optic nerve may be of value to assess for associated disk hyperfluorescence (“hot disk”).

At the end of the session the patient is asked regarding any sensations related to an allergic reaction and reminded that the urine will be discolored for about a day.

In the event of a technical difficulty, such as camera breakdown, repeat fluorescein injection or photography can be carried out with satisfactory results after a waiting period of 30–60 minutes.

The plan we have suggested allows the fluorescein angiogram to yield all the information necessary to make a proper and thorough interpretation.

**Box 1.3** provides a checklist of important steps in the FA procedure.

## Checklist for Fluorescein Angiography

- Inform patient about fluorescein angiography. Obtain written informed consent
- Dilate patient's pupil if necessary
- Prepare fluorescein solution, scalp-vein needle, and syringe
- Prepare fundus camera
- Clean front lens
- Focus eyepiece crosshairs
- Input patient identification and demographic data in computer database
- Position patient for alignment, focus, and comfort
- Align and focus camera
- Complete color photography
- Take red-free photos if indicated
- Insert scalp-vein needle
- Simultaneously start timer from zero and inject fluorescein dye
- Take preinjection photograph: these serve as controls in detecting auto- and pseudofluorescence
- Shoot at exact start of injection as timer is turned on and shoot second shot at exact finish of injection (length of time of injection is automatically recorded)
- Start fluorescein photograph 8 seconds after the start of injection in young patients and 12 seconds in older patients
- Follow fluorescein angiography plan

- When photography is done, reassure patient that urine will be discolored for a day or so
- At the discretion of the physician, have patient wait for observation for possible reactions to fluorescein

## Developing a Photographic Plan

To photograph a 30–50° fluorescein angiogram, we suggest following a comprehensive plan, designed to yield maximal angiographic information from each fundus and to facilitate a thorough and complete interpretation (Fig. 1.12). The photographic strategy essentially begins when the clinician has identified a condition or finding that requires angiographic study. The pathology dictates whether the photographic approach should image a magnified highly detailed finding versus a wider field of view for more diffuse disease. Narrower field limits with higher magnification yield optimal images for focal pathology in conditions such as maculopathies, optic nerve disorders, and small focal lesions. Wider field of view may sacrifice magnification, but is effective in documenting conditions involving the periphery, such as diabetic retinopathy and vascular occlusive disease. Elevated lesions such as tumors require great care in capturing high-quality stereo images.

	Inject fluorescein, when injection ends, begin angiography of primary macula Youth: 10 sec Elderly 12 sec	Preinjection photograph with fluorescein filters secondary macula	Preinjection photograph with fluorescein filters primary macula	Left eye macula	Right eye macula
Stereo pair Secondary macula	1–2 sec later primary macula	1–2 sec later primary macula	1–2 sec later primary macula	1–2 sec later primary macula	1–2 sec later primary macula
Stereo pair Secondary macula	Stereo pair Secondary macula	Stereo pair Primary disc	Stereo pair Primary disc	Stereo pair Primary macula	Stereo pair Primary macula
Patient rest period unless peripheral scans indicated	Angiophotograph other areas of importance in either eye according to fluorescein angiography or nature of case	Post venous filling Secondary macula and disc	Post venous filling Primary macula and disc	Stereo pair Secondary disc	Stereo pair Secondary disc
Late angiophotographs of other areas of importance		Late secondary disc	Late secondary macula	Late primary disc	Late primary macula

**FIG. 1.12** Photographic plan for fluorescein angiography of macular disease.

The photographer should be directed as to where to start the angiogram and the issues important for each specific angiogram. Wasted data storage and patient inconvenience can be avoided with good technique and a repeatable, accurate algorithm for angiography. Historically, because the roll of 35-mm negative film used for FA has 36 frames, it was convenient to think of the photograph session in terms of six rows of six frames each. With the advent of digital imaging, theoretically an unlimited number of frames can be acquired. However, to maximize efficiency of resources, digital storage of 20 frames per digital proof sheet is typically adequate for most clinical scenarios.

## Diabetic Retinopathy

Diabetic retinopathy presents a unique challenge for the photographer, as significant pathology may be located both within the macula and the periphery. A photographic plan must yield information regarding leakage contributing to diabetic macular edema and nonfilling from capillary nonperfusion. At the same time, peripheral scans confirming the presence of neovascularization in preproliferative and proliferative diabetic retinopathy must also be obtained. A similar sequence is then performed on the secondary eye. Wide-field camera systems with high resolution have been especially effective in visualizing peripheral neovascularization and fibrovascular proliferation while also simultaneously delivering excellent images of the optic disc and macula.<sup>9,10</sup>

## Interpretation

### Fundus Anatomy and Histology

FA graphically demonstrates fundus pathophysiology and we rely on histologic points of reference to interpret a fluorescein angiogram. Therefore, a thorough knowledge of the anatomy of the fundus and its microscopic layers is necessary to interpret fluorescein angiograms correctly. A logical place to begin this study is at the vitreous. In its normal state, and in a normal angiogram, the vitreous is clear and nonfluorescent. However, when it contains opacities that block the view of retinal and choroidal fluorescence, hypofluorescence occurs. The vitreous is also an important point of reference when intraocular inflammation or retinal neovascularization is present. In these cases fluorescein leaks into the vitreous, causing fluffy fluorescence as fluorescein molecules disperse into fluid vitreous and vitreous gel.

For the purpose of fluorescein angiographic interpretation, it is convenient to divide the sensory retina into two layers: the inner vascular half and the outer half, which is avascular. The inner vascular half extends from the internal limiting membrane to the inner nuclear layer. This portion of the retina contains the retinal blood vessels, which are located in two separate planes: the larger

retinal arteries and veins are located in the nerve fiber layer; the retinal capillaries are located in the inner nuclear layer. In a well-focused stereoscopic fluorescein angiogram, these two vascular layers can be seen as distinct planes in the retina. An extremely important fluorescein angiographic concept is that normal retinal blood vessels are impermeable to fluorescein leakage; that is, fluorescein flows through the normal retinal vessels without leakage into the retina.

The outer avascular half of the sensory retina comprises the outer plexiform layer, the outer nuclear layer, and the rods and cones. The outer plexiform layer is the primary interstitial space in the retina. When the retina becomes edematous, it is in this layer that fluid accumulates, causing cystoid spaces. Deep retinal hemorrhages and exudates (lipid deposits) may also be deposited in the outer plexiform layer.

The rods and cones are very loosely attached to the pigment epithelium, especially in the macular region, whereas the pigment epithelium is very firmly attached to Bruch's membrane. In FA interpretation the pigment epithelium is an extremely important tissue because it prevents fluorescein leakage from the choroid and blocks, to a greater or lesser extent, visualization of choroidal fluorescence.

Bruch's membrane separates the pigment epithelium from the choriocapillaris, which is permeable to fluorescein. Fluorescein passes freely from the choriocapillaris and diffuses through Bruch's membrane up to, but not into, the pigment epithelium. Beneath the choriocapillaris are the larger choroidal vessels, which are impermeable to fluorescein. Melanocytes are dispersed throughout the choroid but are most heavily concentrated in the lamina fusca, the thin layer between the choroid and sclera. The sclera lies beneath the choroidal vessels.

The ophthalmic artery gives rise usually to two main posterior ciliary arteries: the lateral and medial. However, three posterior ciliary arteries may be present, in which case the medial artery is the one usually duplicated less frequently. In rare instances there may be a superior posterior ciliary artery.

The posterior ciliary arteries supply the lateral and medial halves of the disc and choroid. During angiography a vertical zone of

slightly delayed filling may be seen passing through the papillomacular region, including the disc. Occasionally, there is an oblique orientation to this supply or even a superoinferior distribution. This border between the main posterior ciliary arteries has been termed the watershed zone, where patchy choroidal filling often can be seen on fluorescein angiograms.

Each main posterior ciliary artery divides into numerous short arteries and one long artery. On the temporal side the short posterior ciliary arteries supply small, variously sized, wedge-shaped choroidal segments, whose apices are centered near the macula. The lateral long posterior ciliary artery passes obliquely through the sclera. It supplies a wedge of choroid that begins temporal to the macular region and participates in the formation of the greater circle of the iris.

The choriocapillaris is made up of discrete units called lobules, thought to be approximately one-fourth to one-half of a disc diameter in size. The center of each lobule is fed by a precapillary arteriole (terminal choroidal arteriole), which comes from a short posterior ciliary artery. Each lobule functions independently in the normal state. It has been assumed that angiographic zones of delayed or patchy choroidal filling gradually fill in a transverse fashion, with one lobule spilling over into another. Careful inspection, however, indicates that these filling defects generally remain the same size, indicating a delayed filling from a posterior origin (its own arteriolar feeder). In the abnormal state, as when a choroidal vascular occlusion occurs, there is a freely connecting "spilling over" of blood flow from well-perfused choroid to the occluded area.

Around the margin of each lobule is a ring of postcapillary venules that drain each lobule. These postcapillary venules drain into the vortex veins, which drain the entire choroid. There are usually four vortex veins, and each functions as a well-defined quadrantic segmental drainage system for the entire uvea. In the case of a posterior ciliary artery obstruction, this occluded portion of the choroid can fill by a retrograde mechanism from an adjacent posterior ciliary artery by way of the choroidal venous system. This mechanism may provide adequate nourishment to prevent extensive ischemic changes until the occluded artery reopens.

Knowledge of each of these layers of the fundus is important in understanding fundus histopathology. The following six areas, however, are more important than others in the interpretation of abnormal fundus fluorescence:

1. Preretinal area, where contraction from an epiretinal membrane may influence the retinal circulation and where hemorrhage may be located
2. Vascular layers of the sensory retina, both superficial and deep
3. Avascular portion of the sensory retina, particularly the outer plexiform layer, the principal site of intraretinal edema and exudate
4. Retinal pigment epithelium, which has the potential for many manifestations, including proliferation, depigmentation, hyperpigmentation, and detachment
5. Choroidal circulation, including the choriocapillaris and the large choroidal vessels
6. Sclera, which lies beneath the choroid.

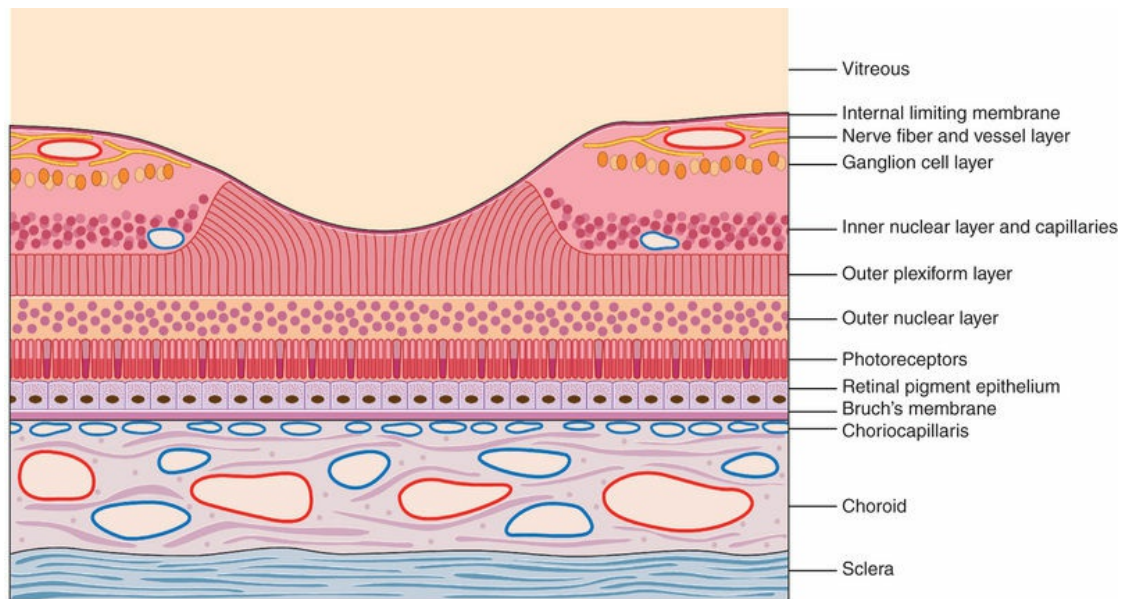

Throughout this chapter a modified schematic drawing relates various fluorescein angiographic abnormalities to fundus histopathologic changes (Fig. 1.13). The size and proportion of these various layers have been modified to include various pathologic manifestations and to illustrate the effects of these abnormalities on the angiogram. Because of its importance and various pathologic changes, the pigment epithelium is drawn to a larger scale in relation to other fundus structures. Only the inner portion of the sclera is represented because the outer portion of the sclera is usually of little importance to angiographic interpretation. The retinal and choroidal vessels are drawn larger and more numerous than they appear in a normal histopathologic section to emphasize the contribution of circulatory pathophysiologic interpretation.

**FIG. 1.13** Modified schematic drawing of a microscopic section of retina, pigment epithelium, and choroid.

Two specialized areas of the fundus warrant more detailed discussion: the macula ([Fig. 1.14](#)) and the optic nerve head. The fovea is the center of the macula and contains only four layers of the retina: (1) the internal limiting membrane; (2) the outer plexiform layer; (3) the outer nuclear layer; and (4) the rods and cones. No intermediate layers exist between the internal limiting membrane and the outer plexiform layer in the fovea, which in the macula is oblique. This is an important factor in understanding the stellate appearance of cystoid edema in the macula as opposed to the honeycomb appearance of cystoid edema outside the macula. Beyond the macular region the outer plexiform layer is perpendicular rather than oblique.

**FIG. 1.14** Modified schematic drawing of a microscopic section of the macula.

The pigment epithelial cells in the macula are more columnar and have a greater concentration of melanin and lipofuscin granules than in the remainder of the fundus.

Xanthophyll is present in the fovea, located probably in the outer plexiform layer. These differences in pigmentation are the chief factors responsible for producing the characteristic dark zone in the macular region on normal angiograms. The absence of retinal vessels in the fovea (i.e., the perifoveal capillary-free zone), in most cases approximately 400–500  $\mu\text{m}$  in diameter in the center of the fovea, is another cause of the dark appearance of the macula.

The optic nerve head, or disc, is the other highly specialized tissue of the posterior pole. The disc is fed by two circulatory systems: the retinal vascular system and the posterior ciliary vascular system. Widespread anastomotic channels exist between the posterior ciliary vasculature and the optic nerve and retinal vasculature and become exaggerated in certain pathologic conditions. The disc is made up of many layers of nerve fibers and glial supporting columns that contain the large retinal vessels.

The central retinal artery arises from the ophthalmic artery in close proximity to the main posterior ciliary arteries. In about 45% of the population, the central retinal artery and the medial posterior ciliary artery arise from a common trunk. In 12% of persons the central retinal artery originates from the ciliary artery. Therefore it

is impossible to have a choroidal infarction, anterior ischemic optic neuropathy, and a central retinal artery occlusion all due to a single site of obstruction.

The central retinal artery provides a major source of blood supply to the axial portion of the anterior orbital portion of the optic nerve. In the intraneural or axial course, short centrifugal branches arise but usually end a short distance behind the lamina cribrosa. There are then no further branches from the central retinal artery until it reaches the retina. If a cilioretinal artery is present, it supplies the corresponding segment of the disc.

The peripapillary nerve fiber layer is supplied by small, recurrent branches from the retinal arterioles at the peripapillary region. Emanating from these arterioles at the disc are the radial papillary capillaries. These capillaries are rather straight and long, have few anastomoses, and lie in the superficial portion of the peripapillary nerve fiber layer. The capillaries to the disc are continuous with these retinal peripapillary capillaries.

The short posterior ciliary arteries, or the recurrent branches from the peripapillary choroid, supply the retrolaminar portion of the optic nerve. The lamina cribrosa portion of the nerve is supplied by centripetal branches of the short posterior ciliary arteries. In this region a partial, or, rarely, a complete Zinn's vascular circle is occasionally found. The prelaminar portion is supplied by centripetal branches from the peripapillary choroid.

Because most of the disc is fed by the ciliary system, fluorescein appears simultaneously at the optic nerve head and the choroid and before it is apparent in the retinal arteries.

The main venous drainage of the disc is into the central retinal vein. The prelaminar portion empties into both the central retinal vein and the peripapillary choroid, thus providing potential collateral drainage in the case of obstruction of the central retinal vein behind the lamina cribrosa. Such large dilated collaterals are frequently seen following central retinal vein occlusion and are called retinociliary veins. Some mistakenly call them opticociliary shunts, a misnomer because they are not true shunts (defined as a congenital artery that empties into a vein and that skips the capillary bed, sometimes part of the Wyburn–Mason syndrome), and they are not because they emanate from the retina. They are,

most accurately, retinovenous to ciliovenous collaterals.

In summary, FA provides an *in vivo* understanding of the histopathologic and pathophysiologic changes of various fundus abnormalities. Therefore, an anatomic and, more specifically, a histologic understanding of important fundus landmarks is essential to fluorescein angiographic interpretation.

## Normal Fluorescein Angiogram

The normal fluorescein angiogram is distinguished by certain specific characteristics. Knowledge of these characteristics provides an essential frame of reference for interpreting abnormal fluorescein angiograms.

In the normal fluorescein angiogram ([Fig. 1.15](#)), the first true fluorescence begins to show in the choroid approximately 10–12 seconds after injection in young patients (e.g., adolescents) and 12–15 seconds after injection in older patients.

**FIG. 1.15** Normal fundus photos and fluorescein angiogram of left disc and macula taken with a 50° camera. (A) Montage photograph of multiple fields shows normal macula, fovea, and retinal vessels. (B) Early arterial phase of the fluorescein angiogram. Note the ground-glass fluorescence of the choriocapillaris. There is very little fluorescence in the retinal veins; just the margins of the veins are fluorescent. This is the earliest portion of the laminar filling phase of the vein.

Note some hyperfluorescence of choriocapillaris. These dark patches of the choroid are areas that have not fully filled, referred to as patchy choroidal filling. (C) The retinal arteries and capillaries have filled and the retinal veins have filled more substantially. Note the laminar flow in the retinal veins; this is indicated by the white line of fluorescence along the walls of the retinal veins. (D) Late venous phase. Laminar filling is no longer detectable and uniform filling is seen in both arterial and venous circulation. (E) Mid to later arteriovenous phase of fluorescein angiogram. Note that the ground-glass fluorescence of the choriocapillaris is complete. The retinal arteries and veins are completely filled. (F) Arteriovenous phase of fluorescein angiogram showing the disc. Again, there is diffuse fluorescence of the choriocapillaris. The arteries and veins have completely filled, and optic nerve fluorescence is normal.

Fluorescence can appear even earlier than 8 seconds in very young patients. The choroid occasionally begins to fluoresce 1 or 2 seconds before the initial filling of the central retinal artery. Early choroidal fluorescence is faint, patchy, and irregularly scattered throughout the posterior fundus. It is interspersed with scattered islands of delayed fluorescein filling. This early phase is referred to as the choroidal flush. When adjacent areas of choroidal filling and nonfilling are quite distinct, the pattern is designated as patchy choroidal filling.

Within the next 10 seconds (approximately 20–25 seconds after injection), the angiogram becomes very bright for about 5 seconds because of the extreme choroidal fluorescence. Choroidal fluorescence, however, is not visible in the macula because of the taller, more pigmented epithelium present in the fovea (retina). Therefore the macula remains dark throughout the angiogram.

If present, a cilioretinal artery usually begins to fluoresce as the choroid fluoresces, rather than as the retina fluoresces. Within 1–3 seconds after choroidal fluorescence is visible, or approximately 10–15 seconds after injection, the central retinal artery begins to fluoresce. The less dense the concentration of pigment in the pigment epithelium, the greater the time between the visibility of the choroidal fluorescence and the filling of the retinal vessels. The

lighter pigment presents less interference to choroidal fluorescence, allowing it to be evident earlier in its filling phase. With a more densely pigmented pigment epithelium, the blockage barrier effect is greater. Therefore choroidal fluorescence appears somewhat later because a greater concentration of fluorescein is required to overcome the increased density of the pigment epithelial barrier.

Because no barrier exists in front of the retinal vessels, the patient's pigmentation has no effect on the visibility of the retinal vessels, although the degree of pigmentation does affect the contrast of the angiophotographs. The darker the pigment epithelium is, the less visible the choroidal fluorescence will be and the greater the contrast of the retinal vascular fluorescence (i.e., the better they stand out). The lighter the pigment epithelium is, the more visible the choroidal fluorescence will be and the less the contrast of the fluorescence from the retinal vessels.

After the central retinal artery begins to fill, the fluorescein flows into the retinal arteries, then into the precapillary arterioles, the capillaries, the postcapillary venules, and finally the retinal veins. Because the fluorescein from the venules enters the veins along their walls, the flow of fluorescein in the veins is laminar. Because vascular flow is faster in the center of a lumen (tube) than on the sides, the fluorescein seems to stick to the sides, creating the laminar pattern of retinal venous flow. The dark (nonfluorescent) central lamina is nonfluorescent blood that comes from the periphery, which takes longer to fluoresce because of its more distant location.

In the next 5–10 seconds, fluorescence of the two parallel laminae along the walls of the retinal veins becomes thicker. At the junction of two veins, the inner lamina of each vein may merge. This creates three laminae: one in the center and one on each side of the vein. As fluorescein filling increases in the veins, the laminae eventually enlarge and meet, resulting in complete fluorescence of the retinal veins.

Fluorescence of the disc emanates from the posterior ciliary vascular system, both from the edge of the disc and from the tissue between the center and the circumference of the disc. Filling also comes from the capillaries of the central retinal artery on the surface of the disc. Because healthy disc tissue contains many capillaries,

the disc becomes fairly hyperfluorescent on the angiogram.

The perifoveal capillary net cannot always be seen on the fluorescein angiogram. It can be seen best in young patients with clear ocular media about 20–25 seconds after a rapid fluorescein injection. This is called the “peak” phase of the fluorescein angiogram. The photographer should be aware of this phase and be sure not to miss it by shooting as rapidly as possible as the fluorescein concentration increases and by continuing to shoot rapidly until the concentration of fluorescein begins to decrease.

Approximately 30 seconds after injection, the first high-concentration flush of fluorescein begins to empty from the choroidal and retinal circulations. Recirculation phases follow, during which fluorescein in a lower concentration continues to pass through the circulation of the fundus.

Generally, 3–5 minutes after injection, the choroidal and retinal vasculatures slowly begin to empty of fluorescein and become gray. Vessels of most normal patients almost completely empty of fluorescein in approximately 10 minutes. The large choroidal vessels and the retinal vessels do not leak fluorescein. However, because of large gaps in its endothelium, the choriocapillaris does leak fluorescein. The extravasated fluorescein diffuses through the choroidal tissue, Bruch's membrane, and sclera. Leakage of fluorescein with retention in tissues is designated as staining. In the later phase of the angiogram, staining of Bruch's membrane, the choroid, and especially the sclera may be visible if the pigment epithelium is lightly pigmented. The disc and adjacent visible sclera remain hyperfluorescent because of staining. When the retinal pigment epithelium is especially lightly pigmented, the large choroidal vessels can be seen in silhouette against the fluorescent (fluorescein-stained) sclera. The lamina cribrosa within the disc also remains hyperfluorescent because of staining. This depends on the cup-to-disc ratio and the presence of any visible sclera, such as occurs within a conus adjacent to the disc. The edge of the disc stains from the adjacent choriocapillaris, which normally leaks.

To summarize, the angiogram is initially dark; choroidal and retinal filling is seen 10–15 seconds after fluorescein injection. The retinal and choroidal vasculatures fill maximally about 20–30 seconds after injection. Late angiophotographs show fluorescence

of the choroid and sclera (if the pigment epithelium is light) and fluorescence of the optic cup and the edge of the disc, but otherwise the fundus is dark (nonfluorescent in the late phase).

## **Abnormal Fluorescein Angiogram**

Interpretation of the fluorescein angiogram follows a simple and logical progression. The first step is to recognize areas of abnormal fluorescence and determine if they are hypofluorescent or hyperfluorescent ([Fig. 1.16](#)).

**FIG. 1.16** Flow sheet for abnormal fluorescein angiography. PE window, pigment epithelial window; RPE, retinal pigment epithelium.

## Hypofluorescence

Hypofluorescence is a reduction or absence of normal fluorescence, whereas hyperfluorescence is abnormally excessive fluorescence. A systematic series of decisions follows this initial differentiation to arrive at a proper diagnosis. These decisions relate to (1) the anatomic location of various abnormalities; (2) the quality and quantity of the abnormal fluorescence; and (3) other unique characteristics, as indicated in [Fig. 1.16](#).

Hypofluorescence is any abnormally dark area on the positive print of an angiogram. There are two possible causes of hypofluorescence: blocked fluorescence or a vascular filling defect.

Blocked fluorescence is sometimes referred to as masked, obscured, or negative fluorescence or transmission decrease. Each of these terms indicates a reduction or absence of normal retinal or choroidal fluorescence because of a tissue or fluid barrier located anterior to the respective retinal or choroidal circulation. For example, blood in the vitreous or a layer of blood in front of the retina obscures the view of the retinal and choroidal circulations and therefore blocks fundus fluorescence from these tissues. Hemorrhage that lies under the retina or retinal pigment epithelium, but in front of the choroidal circulation, does not obstruct visibility of the retinal circulation but does block the view of the choroidal circulation. Therefore the approximate histologic location of blocking material can be determined by the presence or absence of visibility of one or both fundus circulations.

Fluorescein is present but cannot be seen in blocked fluorescence. With vascular filling defects, however, fluorescein cannot be seen because it is not present.

The key to differentiating blocked fluorescence from a vascular filling defect is to correlate the hypofluorescence on the angiogram with the ophthalmoscopic view. If there is material visible ophthalmoscopically that corresponds in size, shape, and location to the hypofluorescence on the angiogram, then blocked fluorescence is present. If there is no corresponding material on the color photograph, then it must be assumed that fluorescein has not perfused the vessels and that the hypofluorescence is caused by a vascular filling defect.

Hypofluorescence resulting from a vascular filling defect occurs

when either of the two fundus circulations is not perfusing normally. This is caused by an absence of the vascular tissue or by a complete or partial obstruction of the particular vessels. In these situations an absence or delay of fluorescence of the involved vessels will occur. This type of hypofluorescence has a pattern that follows the geographic distribution of the vessels involved. Although the ophthalmoscopic picture will demonstrate the material blocking fluorescence, it may show nothing if the hypofluorescence is the result of a vascular filling defect.

To summarize, after an area of hypofluorescence is recognized, one must refer to the ophthalmoscopic photograph to determine the cause. If material is visible ophthalmoscopically and corresponds to the area of hypofluorescence, this is blocked fluorescence. If no corresponding blocking material exists, the hypofluorescence is therefore a vascular filling defect.

### **Anatomic Location of Hypofluorescence**

After determining the cause of the hypofluorescence, the next step is (1) to determine the anatomic location of the material that is blocking fluorescence or (2) to determine which of the two fundus circulations is involved in the filling defect. Blocking material affects the retinal and choroidal circulations if it is located in front of the retina. The material blocks only the choroidal circulation if it is located beneath the retinal circulation and in front of the choroid. Similarly, vascular filling defects occur in either the retinal or the choroidal vasculature or in the vessels of the optic nerve head.

### **Blocked Retinal Fluorescence**

Blocked retinal vascular hypofluorescence is caused by anything that reduces media clarity. An opacification in front of the retinal vessels involving the cornea, anterior chamber, iris, lens, vitreous, or the most anterior portion of the retina or disc produces hypofluorescence.

The further the opacification is in front of the fundus, the less it will block fluorescence and the more it will affect the overall quality of the photographs. The closer the material is to the fundus, the more it will block, causing hypofluorescent images on the angiogram. Any material that blocks retinal vascular fluorescence

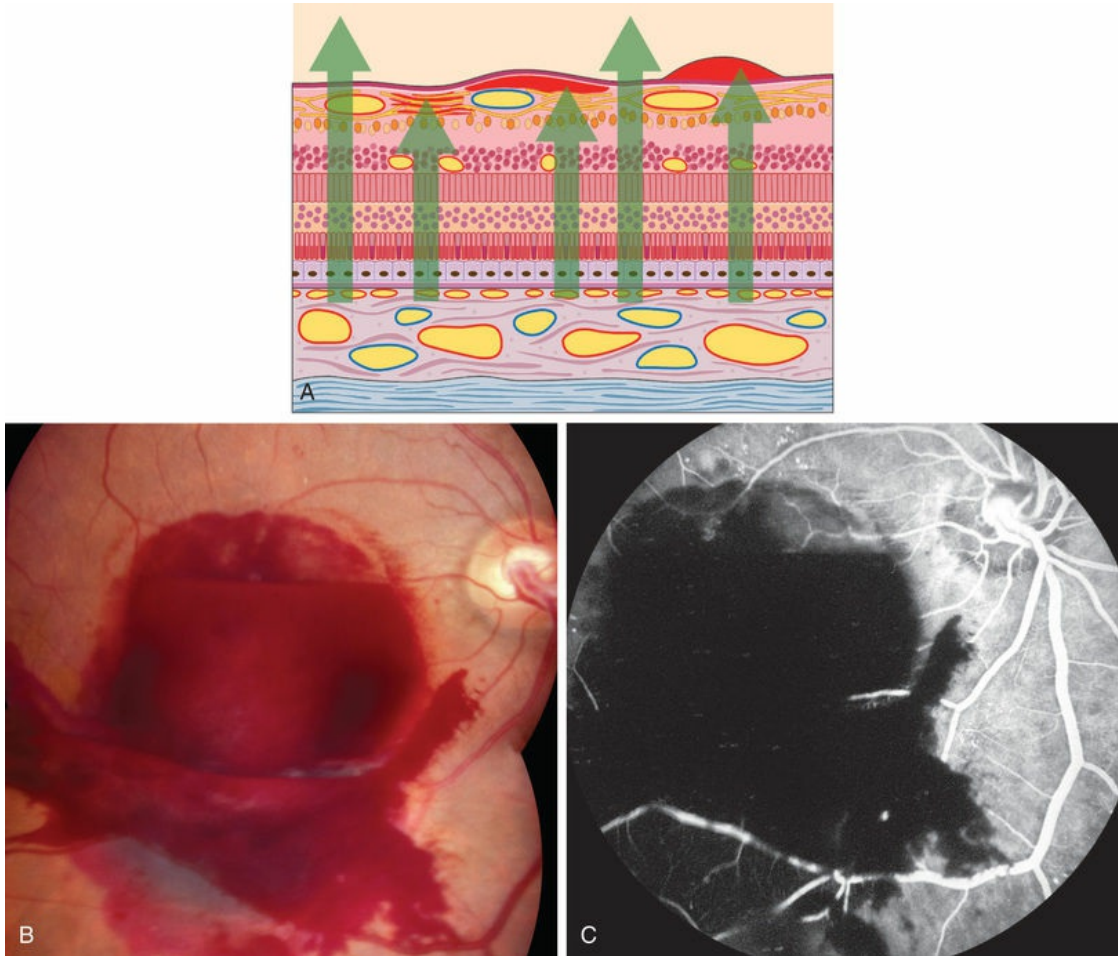

will, of course, block choroidal fluorescence as well.

Any anterior-segment material, such as a corneal opacity, anterior-chamber haziness, or lens opacity, obscuring the view of the ocular fundus will result in an angiogram of reduced brilliance, contrast, and resolution. This affects the quality of the angiogram and is, in a sense, a type of blocked fluorescence.

Many conditions of the vitreous produce a hazy medium that prevents visualizing fundus detail. The most common vitreous opacity to cause blockage is hemorrhage. Whether diffusely dispersed in the vitreous gel or more densely accumulated, vitreous hemorrhage reduces or completely blocks fundus fluorescence. In addition to hemorrhage, media haze may be caused by a variety of opacifications, including asteroid hyalosis, vitreous condensation resulting from vitreous degenerative disease, inflammatory debris, vitreous membranes, or opacification secondary to amyloidosis. When anterior-segment and vitreous opacities are present, the angiogram may be of higher resolution and quality than the color photograph because the light scattered from the nonfluorescing opacities is not transmitted through the barrier filter and therefore has no effect on the angiographic photograph.

Any translucent or opacified material in the retina or in the nerve fiber layer blocks fluorescence from both planes of retinal vessels, as well as from the choroidal vessels. The large retinal vessels and precapillary arterioles are located in the nerve fiber layer in the anterior plane of the retina. The capillaries and postcapillary venules are located deeper in the retina, in the inner nuclear layer. If a blocking material lies in front of the nerve fiber layer, it blocks both planes of retinal vessels (Fig. 1.17). However, if the material lies beneath the nerve fiber layer but within or in front of the inner nuclear layer (where the smaller retinal vessels are located), it blocks only the retinal capillaries (and choroidal vessels), leaving the view of the large retinal vessels unobstructed. If a blocking material lies deeper than the retinal vascular structures, deep to the inner nuclear layer, it does not block the vessels but will block the choroidal vascular fluorescence. In other words, deep intraretinal blocking material, such as hemorrhage or exudate, does not obstruct retinal vascular fluorescence, since the retinal vessels are located in the inner half of the retina (Fig. 1.18).

**FIG. 1.17** Preretinal hemorrhage causing hypofluorescent blockage of all retinal and choroidal fluorescence. (A) Schematic drawing of subhyaloid (right), subinternal limiting membrane (central), and nerve fiber layer (left) hemorrhages. Each hemorrhage lies in front of the retinal, and therefore choroidal, vasculature, causing hypofluorescence-blocked fluorescence. (B) Color photograph of the right disc showing substantial preretinal hemorrhage. (C) Fluorescein angiogram of the right disc showing hypofluorescence caused by blockage as a result of the preretinal hemorrhage. Comment: All fluorescence of the fundus is blocked because the hemorrhage lies in front of the retinal vasculature.

**FIG. 1.18** Intraretinal hemorrhages causing hypofluorescent blockage. (A) Schematic of retina showing hemorrhages located in most of the layers of the retina from the internal limiting membrane to the outer nuclear layer. (B) Color photograph of left macula shows dot-and-blot, as well as flame-shaped hemorrhages just above the fovea. This is a case of branch vein occlusion. (C) Fluorescein angiogram of left macula shows that the hemorrhage causes irregular hypofluorescent blockage. The flame-shaped hemorrhage located in the nerve fiber layer blocks all the retinal vasculature. The dot-and-blot hemorrhages do not block the large retinal vessels and therefore can be localized deeper in the retina. The hemorrhages that do not block retinal capillary fluorescence can be located deeper to the capillary layer, which is in the inner nuclear layer. Comment: Once hypofluorescent blockage is determined, an anatomic localization of the blocking material can be made by determining which normally fluorescent structures can be seen and which are being blocked.

Therefore one can determine the location of a retinal abnormality, such as hemorrhage, by the vessels that are blocked by it and by the fluorescence of the vessels that are not blocked.

The most common cause of blocked retinal vascular fluorescence is hemorrhage. Subinternal limiting membrane hemorrhage blocks fluorescence of all underlying retinal vessels and choroidal vasculature. Nerve fiber layer hemorrhage, which usually is flame-shaped, blocks the smaller retinal vessels lying deeper in the retina but only partially blocks the larger retinal vessels in the nerve fiber layer. Blockage from hemorrhage is usually complete, as opposed to the partial blockage caused by the myelinated nerve fibers.

Various retinal vascular (arteriolar) occlusive diseases may cause white ischemic thickening (nerve fiber edema), which results in some opacification of the retina and blockage of the remaining retinal vascular and choroidal fluorescence. Conditions such as arterial occlusion in hypertension or Purtscher retinopathy cause enough intracellular “cloudy” swelling and opacification to block fluorescence. It should be noted that, because there is occlusion in this type of hypofluorescence, the hypofluorescence is caused partly by the vascular filling defect. However, the opacified ischemic retina effectively blocks fluorescence from underlying retinal and choroidal vasculature.

In summary, when the retinal vessels do not fluoresce, the ophthalmoscopic view should be studied to determine if blocking material is located in front of the retinal vessels. If blocking material is present, the next step is to determine its anatomic location.

### **Blocked Choroidal Fluorescence**

Hypofluorescence caused by blocked choroidal vasculature occurs when fluid, exudate, hemorrhage, pigment, scar, inflammatory material, or the like accumulates in front of the choroidal vasculature and deep to the retinal vasculature (Fig. 1.19).

**FIG. 1.19** Subretinal hemorrhage causing hypofluorescence, specifically, blockage of choroidal fluorescence. (A) Schematic of retina with subretinal hemorrhage (blood located between photoreceptors and pigment epithelium). (B) Color photograph of right macula of an eye with angioid streaks showing large scattered areas of subretinal hemorrhage. (C) Fluorescein angiogram of right macula shows marked hypofluorescence caused by blocked choroidal fluorescence (the retinal vessels are visible) that is due to the subretinal hemorrhage. Comment: The subretinal hemorrhage completely obscures fluorescence from the choroid. The retinal vessels are clearly seen overlying the subretinal hemorrhage.

### Deep Retinal Material.

Materials deposited in the deep retina that cause blockage of choroidal fluorescence are fluid, hard exudate, hemorrhage, and pigment.

Fluid that accumulates in the deep retina has a predilection for the tissue of least resistance, the outer plexiform layer. Deposition of edema fluid, originating from leaking retinal vessels or migrating from subretinal space into the retina, most frequently occurs in the outer plexiform layer. After reaching a certain volume, the fluid tends to form spaces, or pockets, between compressed nerve and Müller fibers, which are pushed aside in the process. This pattern of fluid accumulation in the outer plexiform layer is called cystoid retinal edema. Noncystoid retinal edema occurs when the volume of extracellular fluid is insufficient to produce pockets, or spaces, in the outer plexiform layer or other layers of the retina. A significant amount of retinal edema, whether cystoid or noncystoid, especially if turbid or containing lipid-laden macrophages, partially blocks choroidal fluorescence in the early phase of the fluorescein angiogram. Later in the angiogram, retinal edema fluoresces. Intraretinal hard exudates and lipid-laden macrophages, usually located in the outer plexiform layer, partially block choroidal fluorescence. When retinal vessels bleed, the blood can be deposited anywhere in the retina. When located deep to the retinal vessels beneath the inner nuclear layer, retinal vascular fluorescence is visible, whereas choroidal fluorescence is blocked.

### **Subretinal Material.**

Any opaque or translucent substance located beneath the retina but in front of the choroid blocks fluorescence of the choroidal vasculature but does not block retinal vascular fluorescence (Fig. 1.19). Blood located under the retina causes complete blockage of choroidal fluorescence, with the retinal fluorescence showing through normally. Subretinal hemorrhage appears red, and subpigment epithelial hemorrhage is dark. Subretinal hemorrhage is generally scalloped with somewhat irregular margins, whereas subpigment epithelial hemorrhage is often quite round and well demarcated (Fig. 1.19).

Accumulated pigment (melanin and lipofuscin) from diseased retinal pigment epithelium causes blocked choroidal fluorescence (Fig. 1.20). Any hyperpigmentation of the pigment epithelium causes blocked choroidal fluorescence. Xanthophyll, the pigment present in the outer layers of the fovea, blocks choroidal

fluorescence by selectively absorbing the blue exciting light, which results in less fluorescence. Finally, a choroidal nevus may block much of the choroidal fluorescence (Fig. 1.21) and especially blocks the later hyperfluorescent staining of the sclera. The choriocapillaris may be seen normally over the nevus.

**FIG. 1.20** Hypertrophy of the retinal pigment epithelium. (A) Schematic showing hypertrophic pigment epithelial cells. (B) Color photograph of the macula shows a well-demarcated hyperpigmented lesion. (C) Fluorescein angiogram of the same area shows marked hypofluorescence of the choroid resulting from blocked fluorescence. Comment: This patient had marked hypertrophy of the retinal pigment epithelium, which allowed normal retinal fluorescence; it completely blocked choroidal fluorescence.

**FIG. 1.21** Choroidal nevus hypofluorescent blockage. (A) Schematic drawing of retina showing choroidal nevus. Note that the choriocapillaris is intact. (B) Color photograph of nevus. (C) Arteriovenous phase of fluorescein angiogram shows hypofluorescence corresponding to the area of the nevus. (D) Later arteriovenous phase of fluorescein angiogram shows that the nevus is still hypofluorescent, although the choriocapillaris ground-glass fluorescence can be seen surrounding.

To summarize, various materials located in the deep retinal layers, or beneath the retina, block choroidal fluorescence and are evident ophthalmoscopically. These materials result from a variety of disease processes.

### **Vascular Filling Defect.**

The second cause of abnormal hypofluorescence is vascular filling defect. With blocked fluorescence, the fluorescein is present in the circulations of the fundus but is not visible because a tissue or fluid

barrier conceals it. With vascular filling defect, fluorescein cannot be seen because it is not present. Since fluorescein reaches the retina and choroid by way of vessels, lack of the fluorescein dye in either vascular system indicates an obstructive problem or a lack of vessels (i.e., a vascular filling defect).

As previously indicated, when a hypofluorescent area is seen on an angiogram, the best way to differentiate blocked fluorescence from a vascular filling defect is to compare the angiogram with the ophthalmoscopic picture. When blood, pigment, or exudate can be seen ophthalmoscopically corresponding to the area of hypofluorescence, the material is causing blocked fluorescence. When no material is visible ophthalmoscopically (on the color photograph), one must assume that fluorescein has not perfused the vessels and that the abnormal hypofluorescence is caused by a vascular filling defect. In some instances both forms of hypofluorescent mechanisms play a role simultaneously, as with retinal arteriolar occlusion, when the retina is not only not perfused (vascular filling defect) but is ischemic and therefore white and opaque, causing blocked fluorescence.

Vascular filling defects result from vascular obstruction, atrophy, or absence (congenital or otherwise) of vessels. Any of these conditions can be total or partial. When the obstruction is complete (occlusion) or the vascular tissue is atrophied completely, the hypofluorescence is complete and lasts throughout the angiogram. When the obstruction is only partial or the vascular tissue is not entirely atrophied, the vascular fluorescein filling is delayed or reduced relative to corresponding areas that fill normally. Whatever the cause of a partial vascular filling defect, hypofluorescence will be seen in the early phases of the angiogram but may not persist throughout the entire angiogram. Some vascular filling, although delayed or reduced, will eventually occur.

Once it is determined that a vascular filling defect is the cause of an area of hypofluorescence, the next step is to determine which of the retinal, disc, or choroidal vessels are involved. A vascular filling defect of the disc is easy to discern angiographically. Determining whether a vascular filling defect is retinal or choroidal can be more difficult. Since retinal vessels are normally present, however, the absence of retinal vessels is usually readily apparent. If, on the

other hand, a vascular filling defect is found but the retinal vessels are full and visible, the hypofluorescence must be choroidal in origin.

### **Retinal Vascular Filling Defect.**

If a retinal vascular filling defect is present, the clinician then considers whether the defect results from obstruction of a retinal artery or vein, capillary bed, or any combination of these. Distinguishing the cause of the obstruction is not difficult because the fluorescein angiographic process is dynamic and timed. When nonfilling of a specific retinal vessel occurs, it is easy to differentiate an arterial occlusion from a venous occlusion because the retinal arteries fill first, then the retinal capillary bed, followed by the retinal veins. In addition, retinal vascular filling defects can be localized by tracing the course of a particular vessel; these defects correspond anatomically to the normal distribution of the retinal vasculature (Figs. 1.22 and 1.23). Thus retinal vascular filling defects result from a variety of disease processes, but most are commonly associated with atherosclerosis and diabetes.

**FIG. 1.22** Branch retinal artery occlusion. (A) Color photograph showing areas of retinal whitening inferior to the macula. An intraarterial embolus is seen proximal to the whitened retina. (B) Earliest arterial filling. An area of hypofluorescence is located inferior to the macula. A small retinal artery feeding this area is occluded at the site of the embolus previously identified on panel (A). (C) Midarterial venous filling with a small area of intraarterial hyperfluorescence distal to the site of embolic obstruction. (D) Late

arteriovenous phase of fluorescein angiogram shows that the occluded artery is still mostly hypofluorescent. (E) Portions of the area did fill with fluorescein due to retrograde filling from surrounding areas. There is some mild staining of the occluded retinal artery.

**FIG. 1.23** Retinal branch vein occlusion. (A) Color photograph of the right macula and disc. There are areas of retinal hemorrhage, retinal whitening, and cotton-wool spots. (B) The fluorescein angiogram of the right disc and macula shows normal fluorescence of the superior portion of the macula. The inferior portion shows substantial hypofluorescence due to retinal capillary nonperfusion. The very bright hyperfluorescent areas are due to neovascularization.

Comment: This patient had a very ischemic inferotemporal branch retinal vein occlusion of the right eye. This was a severe occlusion, as evidenced by closure of large areas of the capillary bed. The hypofluorescence was caused not only by vascular filling defect but also by the nonperfused retina, which becomes partially opaque and caused hypofluorescence of the choroid. (In other words, there was blockage of choroidal fluorescence by the opaque retina, which was caused by the retinal capillary nonperfusion.)

## Vascular Filling Defects of the Disc.

Vascular filling defects of the disc occur because of the failure of the capillaries of the optic nerve head to fill. This failure can be caused by (1) congenital absence of disc tissue, as in an optic pit or optic nerve head coloboma (Fig. 1.24); (2) atrophy of the disc tissue and its vasculature, as in optic atrophy; or (3) vascular occlusion, as in an ischemic optic neuropathy. Each condition is characterized by early hypofluorescence caused by nonfilling and late hyperfluorescence resulting from staining of the involved tissue.

**FIG. 1.24** Optic pit and sensory macula detachment. (A) Color photograph of left macula. Note the dark area of the optic pit (*arrows*). Cystic edema is present in the macula secondary to the macular schisis detachment from the optic pit. (B) Early arteriovenous phase of fluorescein angiogram shows hypofluorescence of the disc in the area of the pit due to absence of tissue and vessels. (C) In the late arteriovenous phase fluorescein angiogram, the hypofluorescent area of the pit is evident.

## Choroidal Vascular Filling Defect.

The normal choroidal vasculature is usually difficult to document with fluorescein angiography because of the pigment epithelial barrier. If chronic choroidal vascular filling defects exist, the pigment epithelium is often secondarily depigmented or atrophied. In these cases the hypofluorescence caused by a vascular filling abnormality of the choroid and choriocapillaris can be documented angiographically.

When choroidal vessels do not fill, dark patches of hypofluorescence beneath the retina appear early in the angiogram. The distribution and morphology of the hypofluorescence vary according to the disease process. Because the choroidal circulation is completely separate from the retinal circulation, choroidal vascular filling defects do not correlate with the retinal vascular distribution. If the choriocapillaris is absent and the large choroidal vessels are still present, the choroidal and retinal vessels fluoresce, but hypofluorescent gaps appear because of the loss of the diffuse "ground-glass" fluorescence from the choriocapillaris (Fig. 1.25). When the choroidal vasculature does not fill, as in total occlusion or in atrophy, hypofluorescence occurs early in the angiogram. The hypofluorescence remains throughout the late stages of the procedure, although leakage from surrounding areas of normal choriocapillaris extends into the occluded area. When sufficient leakage occurs, the sclera retains fluorescein (stains) late in the angiogram. When the involved area is large and the leakage is minimal, the hypofluorescence remains throughout the later stages.

**FIG. 1.25** Choroideremia: total loss of retinal pigment epithelium (RPE) and choriocapillaris with much of the large choroidal vasculature remaining. (A) Color photograph of the left disc and macula. The large choroidal vasculature can be seen as pale, irregular lines. Dark patches of pigment are located in the macula and around the disc. (B) Late venous phase of fluorescein angiogram of the left disc and macula. The large choroidal vessels can be seen filling, as can the retinal arteries. The choriocapillaris is not seen. (C) Recirculation phase of fluorescein angiogram. The large choroidal vessels and retinal vessels can be seen, but the choriocapillaris (usually seen as ground-glass fluorescence) is not seen except in the far edges of the view. Comment: This patient had a total loss of RPE and choriocapillaris in most areas of the fundus. The ground-glass choroidal fluorescence was absent from most areas. The large choroidal vessels could be seen. The large choroidal vessels do not leak fluorescein, and therefore the sclera did not stain in these areas. The RPE and choriocapillaris were partially intact in a few areas. These can be seen at the far extremes, where there is some mild ground-glass appearance.

A normal physiologic condition exists in many patients in which the choroid fills in a patchy manner. Areas adjacent to the foci that are filling show early hypofluorescence but eventually fill normally, usually 2–5 seconds later. This has been termed patchy choroidal filling, and it is the most common form of choroidal vascular filling defect. This form of filling follows a pattern in which the short posterior ciliary arteries enter the eye perpendicularly through the sclera. These vessels then feed the choriocapillaris lobules.

The prechoriocapillaris arterioles and lobules are end, or terminal, vessels demonstrating no anastomoses with adjacent choriocapillaris arterioles or lobules. Each choriocapillaris lobule is connected to adjacent lobules on the venous, or emptying, side of the circulation. Fluorescence in each choriocapillaris segment or lobule is in the form of a round, irregular, or hexagonal patch. When some of the channels fill late, a heterogeneous filling pattern results. The choriocapillaris fills most areas, whereas dark hypofluorescent patches are present in other areas. These dark areas are lobules from separate end channels that are not filled simultaneously with adjacent choriocapillaris lobules. They are filled in a delayed fashion by the single feeder choroidal arteriole.

In general, vascular filling defects of the choroid are caused by obstructive disorders or absence of tissue with the following FA characteristics: (1) normal retinal vascular flow; (2) depigmentation of the pigment epithelium; (3) reduction of choroidal blood flow; and (4) hypofluorescence in the early phases of angiography caused by loss of the normal ground-glass choriocapillaris fluorescence. In some conditions the large choroidal vessels are also absent, resulting in total early hypofluorescence in the affected area, with scleral staining only on the circumference of the lesion because of the adjacent patent choriocapillaris. Choroidal vascular defects result from a variety of disease processes ([Figs. 1.26](#) and [1.27](#)).

**FIG. 1.26** Choroidal atrophy, with some remaining islands of choriocapillaris, due to choroideremia. (A) Schematic of retina shows loss of pigment epithelium and choriocapillaris and some of the outer retina (especially photoreceptors). (B) Color photograph of left superior retina showing areas of severe atrophy and more intact areas of retinal pigment epithelium (RPE) peripherally. Arrows delineate margins between normal RPE and RPE atrophy producing window defect. (C) The arteriovenous phase of fluorescein angiogram shows normal fluorescence of the retinal arteries. The large choroidal vessels can be seen temporally on the right side of the photograph. The ground-glass fluorescence of the choriocapillaris can be seen more peripherally on the left side of the angiogram, where the RPE and choriocapillaris are more intact. Comment: This patient had severe atrophy of the RPE and choriocapillaris. Large choroidal vessels could be seen causing hypofluorescence in relationship to absence of ground-glass choroidal fluorescence. Some areas of choriocapillaris remained and showed normal hyperfluorescence (perhaps increased hyperfluorescence caused by loss of overlying RPE).

**FIG. 1.27** Choroidal hypoperfusion caused by photodynamic therapy with verteporfin. (A) Left macula. Color photograph shows widespread retinal pigment epithelial alterations and drusen secondary to an occult choroidal neovascular membrane secondary to age-related macular degeneration. This treatment was considered standard therapy prior to the advent of intraocular antivascular endothelial growth factor medications. (B) The late arteriovenous phase of the fluorescein angiogram of the left macula shows hypofluorescence of the macula and a large area temporally. Larger choroidal vessels are perfused. The macular hypofluorescence corresponds to the laser treated area. The large area of hypofluorescence temporally represents an area of choroidal nonperfusion caused by selective choriocapillaris occlusion from photodynamic therapy. (C) Later phase of the fluorescein angiogram shows continued hypofluorescence of the area temporal to the macula despite relative restoration of perfusion to choriocapillaris temporal to macula.

## Hyperfluorescence

Hyperfluorescence is any abnormally light area on the positive print of an angiogram, that is, an area showing fluorescence in excess of what would be expected on a normal angiogram. There are four possible causes of abnormal hyperfluorescence: (1) preinjection fluorescence; (2) transmitted fluorescence; (3) abnormal vessels; and (4) leakage. The appearance of fluorescence depends in part on the relationship of its appearance to the timing of the

fluorescein injection.

Preinjection fluorescence is hyperfluorescence that can be seen before fluorescein is injected and is caused by structures that naturally fluoresce (autofluorescence) or by poorly matched filters (pseudofluorescence).

Transmitted fluorescence and abnormal vascular fluorescence occur in the early, or vascular, stage of the angiogram, when fluorescein fills patent blood vessels. Transmitted fluorescence appears when fluorescein fills the normal choriocapillaris, but it is more noticeable when there is reduced pigment in the pigment epithelium or loss of retinal pigment epithelium. This is designated pigment epithelial window defect.

When abnormal retinal, disc, or choroidal vessels are present and fill with fluorescein, hyperfluorescence occurs. This type of hyperfluorescence, abnormal vascular fluorescence, is also seen in the early, or vascular, phase of the angiography.

Hyperfluorescence caused by leakage is seen predominantly in the later, or extravascular, phase of angiography. In this phase, fluorescein has emptied from normal and abnormal vessels. Any significant fluorescein that remains in the eye is fluorescein that has escaped or leaked from vascular or tissue barriers and is thus extravascular.

Therefore, to ascertain the type of hyperfluorescence, one must determine the time at which the hyperfluorescence appears in relation to when the fluorescein was injected. Once the hyperfluorescence is determined to be caused by preinjection fluorescence, transmitted fluorescence, the presence of abnormal vessels, or by leakage, the next step is to determine the anatomic location of the hyperfluorescence. Abnormal blood vessels may come from the retina and disc or from the choroid. Leakage can occur in the vitreous, disc, retina, or choroid.

## **Preinjection Fluorescence**

Each angiographic study should include one photograph of the fundus taken with the fluorescein filters in place and before fluorescein is injected. This exposure is called the preinjection, or control, fluorescein photograph. In normal situations this photograph is totally dark; it is completely hypofluorescent. When

the photograph is not dark, autofluorescence or pseudofluorescence is present. The conditions that cause autofluorescence occur infrequently, and the filter problems that produce pseudofluorescence have in recent years been minimized by the development of more precisely matched filter systems.

## Autofluorescence

Autofluorescence is the emission of fluorescent light from ocular structures in the absence of sodium fluorescein. Conditions that cause autofluorescence are optic nerve head drusen and astrocytic hamartoma (Fig. 1.28).

**FIG. 1.28** Autofluorescence of optic nerve drusen. (A) Right disc and macula show a blurred disc margin with nonhyperemic vessels. Blurring of the central optic nerve is consistent with disc edema noted on stereophotos. (B) Preinjection or “control” photos are performed with filters in place, prior to any injection of fluorescein. This allowed for the identification of optic nerve drusen, which autofluoresce.

Pseudofluorescence occurs when the blue exciter and green barrier filters overlap. The blue filter overlaps into the green range, allowing the passage of green light, or the green barrier filter overlaps into the blue range, allowing the passage of blue light (Fig. 1.2). The overlapping light passes through the system, reflects off highly reflective surfaces (light-colored or white structures), and

stimulates the film. This reflected nonfluorescent light is called pseudofluorescence.

Conditions that tend to produce pseudofluorescence include any light-colored or white (reflective) fundus change (e.g., sclera, exudate, scar tissue, myelinated nerve fibers, foreign body).

Currently, fluorescein angiographic filters are usually very well matched; overlap is minimal, so pseudofluorescence is faint and rarely a major problem. However, filters do tend to get thin with time. The frequent flashes of light from the fundus camera wear them down, and most filter pairs eventually allow pseudofluorescence. Therefore, depending on frequency of use, fluorescein filters must be changed occasionally. Our experience indicates that change is required approximately every 5 years.

### **Transmitted Fluorescence (Pigment Epithelial Window Defect)**

This fluorescence is an accentuation of the visibility of normal choroidal fluorescence. Transmitted fluorescence occurs when fluorescence from the choroidal vasculature appears to be increased because of the absence of pigment in the pigment epithelium, which normally forms a visual barrier to choroidal fluorescence. The major cause of pigment epithelial window defect is atrophy of the pigment epithelium (Figs. 1.29–1.32).

**FIG. 1.29** Pigment epithelial window defect. This schematic of the retina shows that the pigment epithelium in the center of the section is less pigmented than the normal pigment epithelium. This allows the normal choroidal and choriocapillaris fluorescence to show through; that is, this pathologic condition would create a typical pigment epithelial window defect.

**FIG. 1.30** An eye with drusen demonstrating pigment epithelial window defects. (A) Color photograph: right macula shows multiple drusen temporally. (B) Late arteriovenous phase of fluorescein angiogram shows marked hyperfluorescence in the areas of the drusen. (C) Late recirculation phase of fluorescein angiogram shows fading of fluorescence. Comment: Note the degree of fluorescence of the entire fundus vasculature. This is typical of a pigment epithelial window defect, which is a type of vascular fluorescence. The drusen allow a better view to the choriocapillaris because of the thinning of the pigment epithelium overlying them.

**FIG. 1.31** Pigment epithelial window defect: choroidal folds. (A) Montage color photograph of right disc and macula. Note the pale lines (choroidal folds) scattered throughout the posterior pole. (B) Arteriovenous phase of fluorescein angiogram of the disc and macula.

Hyperfluorescent lines correspond to the folds, and adjacent hypofluorescent lines are present throughout the macula and surrounding the disc. Comment: This patient had pigment epithelial folds caused by prolonged hypotony from a filtering bleb. The hyperfluorescent lines are thought to be the hills of the folds, in the apices of which the pigment epithelium is thinned, allowing hyperfluorescence in the early phases of the fluorescein angiogram (pigment epithelial window defect). The dark lines are thought to be the valleys of the folds, with an increase in pigmentation causing blockage of choroidal fluorescence. The later phases of fluorescein angiograms often show fading of fluorescence. Choroidal folds represent a type of pigment epithelial window defect with early vascular fluorescence and late fading of fluorescence.

**FIG. 1.32** Pigment epithelial window defect: macular hole. (A) Schematic drawing of macula showing loss of entire central foveal tissue. (B) Color photograph of the left macula. This patient has a macular hole. Note a corona of lighter detached, swollen retinal tissue surrounding the foveal center where the hole is located. (C) Late phase of fluorescein angiogram shows hyperfluorescence within the macular hole. (D) Later phase of the fluorescein angiogram shows some fading of the hyperfluorescence within the macular hole. Comment: The choriocapillaris was intact. Therefore the angiogram showed normal fluorescence of the choriocapillaris (early hyperfluorescence within the center of the fovea) and fading in the late phase of the angiogram.

When the pigment epithelium is dense, choroidal fluorescence is not clearly visible because the pigment blocks the view of the choroid and acts as a barrier to fluorescein. The density of the pigment determines the degree to which transmission of the normal

choroidal fluorescence is blocked. The visibility of choroidal fluorescence is inversely proportional to the concentration of pigment in the pigment epithelium. If the pigment epithelium contains less than the normal amount of pigment or is defective, the choriocapillaris appears to fluoresce more brightly. The presence of hyperfluorescence caused by a defect in the pigment epithelium depends on the state of both the pigment epithelium and the choriocapillaris. The choriocapillaris must be intact for a depigmented area of the pigment epithelium to be apparent. If the choriocapillaris does not fill, a depigmented area of the pigment epithelium does not fluoresce.

Transmitted fluorescence has the following four basic characteristics:

1. It appears early in angiography, coincidental with choroidal filling.
2. It increases in intensity as dye concentration increases in the choroid.
3. It does not increase in size or shape during the later phases of angiography.
4. It tends to fade and sometimes disappear as the choroid empties of dye at the end of angiography.

In short, transmitted fluorescence appears, peaks early, and fades late without changing size or shape, as would any normal vascular fluorescence. When pigment epithelial depigmentation is extensive, late fluorescein staining of the choroid and sclera may be visible, although it is less intense than the fluorescence of the window defect.

### **Abnormal Retinal and Disc Vessels.**

Abnormal vascular fluorescence occurs when abnormal vessels are present. Such pathologic vessels may be in the retina, on the disc, or at the level of the choroid. Normal and abnormal retinal and disc vessels are clearly visible on the angiogram because no barrier obscures them from view. Gross abnormalities of the retinal and

disc vasculature and subtle microvascular changes that cannot be appreciated adequately by ophthalmoscopic examination will be well defined and easily distinguished by FA. These changes in the retinal vasculature can be classified into six morphologic categories: (1) tortuosity and dilation (Figs. 1.33 and 1.34); (2) telangiectasis (Figs. 1.35 and 1.36); (3) neovascularization (Fig. 1.37); (4) anastomosis (Fig. 1.34); (5) aneurysms (Figs. 1.34 and 1.35); and (6) tumor vessels (Figs. 1.38 and 1.39).

**FIG. 1.33** Abnormal retinal vessels, tortuosity, and dilation: internal limiting membrane contraction. (A) Color photograph of right macula shows a pale membrane overlying the right macula, producing contraction of the retina and tortuosity of the retinal vessels. (B) Arteriovenous phase of fluorescein angiogram shows marked irregularity and tortuosity of the retinal vessels in association with the preretinal membrane (macular pucker). (C) Late phase of fluorescein angiogram shows a small amount of vascular leakage due to contraction of the membrane and pulling on the retinal vessels. Comment: This is tortuosity and dilation, a type of abnormal retinal vascular fluorescence. It is caused by the mechanical traction of an epiretinal membrane.

**FIG. 1.34** Abnormal retinal vascular fluorescence: retinal vascular microaneurysms, telangiectasis, and anastomoses. (A) Color photography of right eye shows numerous telangiectatic retinal vessels due to a superotemporal branch-vein occlusion. (B) Arteriovenous-phase fluorescein angiogram shows multiple areas of smaller and larger microaneurysms and telangiectasis. Several small venous–venous anastomoses can be seen just temporal to the macula. The venous system of the occluded area has collateralized with patent vessels in uninvolved areas.

**FIG. 1.35** Retinal telangiectasis and microaneurysms secondary to diabetic retinopathy. (A) Color photograph of right macula showing retinal exudate, retinal striae, and irregularly dilated retinal vessels (telangiectasis). (B) Arteriovenous-phase fluorescein angiogram shows extensive hyperfluorescence from the numerous microaneurysms, and telangiectatic retinal vessels. (C) Later arteriovenous-phase fluorescein angiogram of right macula showing leakage from many of these vessels. (D) Late-phase fluorescein angiogram of right macula shows multiple circular areas of hyperfluorescence due to accumulation of dye in extensive cystoid spaces.  
Comment: This patient had significant retinal microvascular changes due to diabetic retinopathy.

**FIG. 1.36** Abnormal retinal vessels: telangiectasis. (A) Color montage photograph demonstrating severe areas of exudation, as well as dilated and telangiectatic vessels. The retina is very edematous. (B) Arteriovenous phase of fluorescein angiogram shows marked irregularity of the retinal vasculature. There are areas of capillary nonperfusion, telangiectasis, and tortuosity. Comment: This patient had Coats disease with a markedly abnormal retinal capillary bed, including telangiectasis and dilated vessels.

**FIG. 1.37** Abnormal retinal vessels: retinal neovascularization due to proliferative diabetic retinopathy. (A) Montage color photograph of the posterior pole of the right eye. Extensive irregular

tortuous vessels extend from the optic nerve along the vascular arcades and nasally. These vessels lie on the surface of the retina. (B) Later arteriovenous phase of fluorescein angiogram montage shows increasing hyperfluorescence of the retinal neovascularization.

Comment: This patient had severe proliferative diabetic retinopathy with extensive neovascularization of the right disc. The vessels fluoresced early (vascular fluorescence) and leaked late. This is very typical of retinal or disc neovascularization.

**FIG. 1.38** Abnormal retinal vessels: tumor–retinal angioma as part of von Hippel's disease. (A) Color photograph of right macula and disc shows exudate temporal and inferior to the disc. A very vascular, slightly elevated mass was noted on the temporal border of the disc. Ophthalmoscopy showed that it has a reddish appearance. A large full-thickness macular hole is also observed. (B) Early arterial phase of the fluorescein angiogram shows marked fluorescence of the mass. (C) Midarteriovenous phase of the fluorescein angiogram shows an increased fluorescence of the mass. (D) Late phase of the fluorescein angiogram shows leakage of fluorescein

within the mass. Comment: This patient had a peripapillary retinal angioma. It was very vascular and showed early fluorescence and extensive late leakage.

**FIG. 1.39** Arteriovenous malformation: Wyburn–Mason type. (A) Color montage photograph of right macula and temporal retina showing enlarged, dilated retinal artery, with direct connection to an engorged draining vein. There is no intervening capillary bed. (B) Fluorescein angiogram showing marked hyperfluorescence of the abnormal, dilated retinal artery and vein. Two smaller arteriovenous malformations appear to be present, one just above the macula, and the other just below.

These aforementioned changes can be viewed in the early (vascular) phases of angiography. Later, as the vessels empty, some of these vascular abnormalities leak fluorescein, whereas others do not.

Vascular abnormalities of the retina and disc are readily apparent on the fluorescein angiogram. The changes are characterized by early vascular-appearing hyperfluorescence. Each of the six morphologic types indicates specific disease processes that aid the clinician in making a diagnosis, determining the degree of the distinct pathologic process, and understanding the pathophysiology of retinal vascular disease.

### **Abnormal Choroidal Vessels.**

Abnormal vessels that may be present under the retina and originate from the choroid are subretinal neovascularization and vessels within a tumor. When subretinal neovascularization is

present, the early angiogram often shows a lacy, irregular, and nodular hyperfluorescence (Figs. 1.40 and 1.41). With a choroidal tumor, the abnormal hyperfluorescence is a similar, early vascular-type fluorescence, although it may be coarser, as seen in choroidal hemangioma (Fig. 1.42) and malignant melanoma (Fig. 1.43).

**FIG. 1.40** Abnormal choroidal vessels: subretinal neovascularization. (A) Schematic view of the retina shows a small break in Bruch's membrane, with a fine proliferation of capillaries through the break dissecting under and lifting up the pigment epithelium. There is a shallow sensory retinal detachment. (B) Color photograph of the left macula. There is a dirty-gray membrane involving the central macula. Note the small area of subretinal hemorrhage. There is a shallow sensory retinal detachment. (C) The arteriovenous phase of fluorescein angiogram shows fine, lacy, irregular hyperfluorescence corresponding to a small, fine patch of subretinal neovascularization. (D) Late

phase of fluorescein angiogram shows leakage of these vessels into the subpigment epithelial and subretinal spaces. Comment: This patient had a small patch of subretinal neovascularization involving the central fovea. The angiogram shows typical, early vascular fluorescence (in a nodular, irregular, lacelike fashion) and late hyperfluorescent leakage.

**FIG. 1.41** Abnormal choroidal vessels: subretinal neovascularization. (A) Schematic drawing of retina shows vascular proliferation from the choriocapillaris dissecting under the pigment epithelium, with associated fibrous tissue. The pigment epithelium has become thinned and the sensory retina detached. The outer plexiform layer of the sensory retina shows cystic spaces. (B) Red-free photograph of left macula shows some hemorrhage and exudate. On the color

photograph and slit-lamp biomicroscopy, a dirty-gray membrane was noted in the inferotemporal portion of the macula. This is seen as a slightly pale lesion in the inferotemporal macula. (C) Early arteriovenous phase of fluorescein angiogram shows a lacy, irregular, nodular area of hyperfluorescence in the inferotemporal macula. This is a flat patch of vessels that has proliferated from the choriocapillaris under the pigment epithelium. (D) Late phase of the fluorescein angiogram shows leakage from the patch of subretinal neovascularization. Most of the fluorescence is pooling of fluorescein under the sensory retinal detachment, although there is some cystic change in the fovea.

Comment: This patient had a patch of subretinal neovascularization that was nearly 4 disc diameters in size. It fluoresced early with the vascular phase of the angiogram (typical for subretinal neovascularization) and leaked late. Actually, “subretinal neovascularization” is a misnomer because the new vessels are initially located in the subpigment epithelial space.

**FIG. 1.42** Abnormal choroidal vessels in a patient with choroidal hemangioma. (A) Color photos of left macula and disc with elevated choroidal hemangioma. (B) Arteriovenous phase of the fluorescein angiogram shows prominent hyperfluorescence in this area demonstrating the tumor vessels. (C) Late phase of the fluorescein angiogram shows marked leakage in this area. Comment: This patient had a choroidal hemangioma, which is a very vascularized choroidal mass. The vascularity in this mass causes the marked hyperfluorescence and leakage.

**FIG. 1.43** Abnormal choroidal vascular fluorescence due to malignant melanoma. (A) Color photograph of left eye. Note the darkly pigmented mass nasal to the optic nerve. There is some orange lipofuscin pigment overlying the surface of this as well. (B) Arteriovenous phase of fluorescein angiogram of the mass shows hyperfluorescence over the surface of the tumor. This patient also had some macular drusen, which show some early hyperfluorescence in the macula. (C) Late phase of the fluorescein angiogram shows leakage from the mass. There are multiple “hot spots” overlying the tumor. Comment: This patient had a choroidal malignant melanoma. This was a medium-sized tumor that showed the typical early fluorescence that is seen in a medium-sized melanoma.

### Leakage.

Fluorescence of the retinal and choroidal vessels begins to diminish about 40–60 seconds after injection. Fluorescein empties almost completely from the retinal and choroidal vasculature about 10–15

minutes after injection. Any fluorescence that remains in the fundus after the retinal and choroidal vessels have emptied of fluorescein is extravascular fluorescence and represents leakage.

Four types of late extravascular hyperfluorescent leakage occur in the normal eye: (1) fluorescence of the disc margins from the surrounding choriocapillaris; (2) fluorescence of the lamina cribrosa; (3) fluorescence of the sclera at the disc margin if the retinal pigment epithelium terminates away from the disc, as in an optic crescent; and (4) fluorescence of the sclera when the pigment epithelium is lightly pigmented. These are the only forms of late hyperfluorescence or leakage that can be considered "normal." Any other hyperfluorescence observed 15 minutes after the fluorescein injection represents extravascular fluorescein and is referred to as leakage.

Either or both of the two vascular systems of the fundus can produce abnormal late hyperfluorescence (leakage) if defects are present in their respective barriers to fluorescein. The barrier to fluorescein leakage from the retinal vessels is the retinal vascular endothelium. The barrier to leakage from the choroidal circulation is the pigment epithelium. An abnormality of the retinal vascular endothelium can result in permeability to fluorescein and leakage of fluorescein into the retinal tissue. Similarly, an abnormality of the pigment epithelium can result in permeability to fluorescein, and fluorescein will leak from the choroidal tissue through the pigment epithelium. Abnormal late hyperfluorescence of the choroid, however, can occur without damage to the pigment epithelium, as in cellular infiltrates of the choroid that occur in choroidal inflammation or tumor.

There are two other types of late abnormal fluorescence: one occurs when fluorescein enters the vitreous, and the other when fluorescein leaks into the optic nerve head.

### **Vitreous Leakage.**

Leakage of fluorescein into the vitreous creates a diffuse, white haze in the late phase of the fluorescein angiogram. In some instances the haze is generalized and evenly dispersed, and in other cases the white haze is localized.

Leakage of fluorescein into the vitreous is due to three major

causes: (1) neovascularization growing from the retinal vessels on to the surface of the retina or disc or into the vitreous cavity; (2) intraocular inflammation; and (3) intraocular tumors.

Vitreous hyperfluorescence secondary to retinal neovascularization is usually localized and appears as a cotton-ball type of fluorescence surrounding the neovascularization (Fig. 1.37B). The vitreous fluorescence secondary to intraocular inflammation is often generalized, giving a diffuse, white haze to the vitreous because of generalized leakage of fluorescein from the iris and ciliary body. The vitreous fluorescence secondary to tumors is most often localized over the tumor.

### **Disc Leakage.**

The optic nerve head normally has some fluorescein leakage (late hyperfluorescence) as a result of staining of the lamina cribrosa and the surrounding margins of the disc (from the normally leaking peripapillary choriocapillaris). The difference between normal and abnormal leakage at the disc may be subtle.

### **Papilledema and Optic Disc Edema.**

Papilledema is swelling of the optic nerve head as a result of increased intracranial pressure. Edema of the optic disc is defined as swelling of the optic nerve head secondary to local or systemic causes (Fig. 1.44). The angiogram is similar in each case, demonstrating leakage associated with swelling of the optic nerve head. In the early phases of the angiogram, dilation of the capillaries on the optic nerve head may be seen; in the late angiogram, the dilated vessels leak, resulting in a fuzzy fluorescence of the disc margin.

**FIG. 1.44** Disc leakage. (A) Color photograph of right optic nerve. Note the dilation of the disc capillaries. (B) The arteriovenous-phase angiogram of the right disc and macula shows the hyperfluorescence due to these dilated disc capillaries. (C) The late phase of the angiogram shows significant leakage from these dilated optic disc capillaries. Comment: This patient had a papillopathy related to diabetes. This produced significant dilation of the disc capillaries. The leakage from this abnormal disc is quite obvious.

### **Retinal Leakage.**

In the late stages of the normal angiogram, the retinal vessels have emptied of fluorescein and the retina is dark. Any late retinal hyperfluorescence is abnormal and indicates leakage of retinal vessels. When the leakage is severe, the extracellular fluid may flow into cystic pockets, and the angiogram shows fluorescence of the cystic spaces. Fluorescein flows out of the patent retinal vessels to lie in pools in the cystoid spaces or stains the edematous (noncystic) retinal tissue. Cystoid retinal edema is apparent as the fluorescein pools in small loculated pockets. In the macula, cystoid edema takes on a stellate or petalloid appearance ([Fig. 1.45](#)); elsewhere in the retina, it has a honeycombed appearance ([Fig. 1.46](#)). Fluorescent staining of noncystoid edema is diffuse, irregular, and not confined to well-demarcated spaces ([Figs. 1.47](#) and [1.48](#)).

**FIG. 1.45** Retinal leak: cystoid macular edema. (A) Schematic drawing of the macula shows large cystic spaces in the outer plexiform layer. There are some cystic spaces in the inner nuclear layer. (B) Color photograph of left macula. Careful inspection of the retina is often necessary on biomicroscopy to detect intraretinal cystoid. (C) Arteriovenous phase of fluorescein angiogram shows some dilation of the fine capillary network around the fovea. (D) Late phase of fluorescein angiogram shows hyperfluorescence from the accumulation of dye filling the cystic spaces. Note the stellate appearance of the cystoid macular edema. Comment: This patient had late hyperfluorescence (i.e., leakage) into the retina that was severe enough to create cystic spaces. This is a typical example of cystoid macular edema.

**FIG. 1.46** Retinal leakage: cystoid retinal edema. (A) Color photograph of the right macula. Large central cystoid cavity is seen corresponding to fovea. (B) Arteriovenous phase of fluorescein angiogram shows well-defined telangiectatic retinal vessels. (C) Late phase of fluorescein angiogram shows leakage from these vessels. In the center of the macula, the leakage is in stellate cystic pockets, and just outside the macula, temporally, the leakage has taken a honeycomb form. Comment: This patient had leakage of telangiectatic vessels into the retina, and the leakage formed cystoid spaces. Cystoid edema in the center of the macula takes on a stellate form because of the oblique nature of the outer plexiform layer. The cystic spaces take on a honeycomb form in nonmacular areas of the retina because of the perpendicular nature of the fibers of the outer plexiform layer.

**FIG. 1.47** Retinal leakage, severe noncystoid edema. Branch vein occlusion. (A) Color photograph of right macula shows multiple retinal hemorrhages inferotemporally due to a retinal branch vein occlusion. (B) Arteriovenous phase of fluorescein angiogram

shows the vascular abnormalities associated with the branch vein occlusion. Hypofluorescence corresponds to areas previously treated with grid pattern laser photocoagulation. (C) Late phase of fluorescein angiogram shows diffuse leakage of the fluorescein dye. Comment: This patient had generalized leakage of the retinal vascular bed in the distribution of the blocked branch vein. The leakage was not yet severe enough, however, to form clearly defined cystic spaces. Late hyperfluorescence indicates leakage, and this fluorescence is located in the retina; thus this was retinal edema.

**FIG. 1.48** Late hyperfluorescence, retinal leakage: severe epiretinal membrane contraction. (A) Color photograph of right macula showing thick epiretinal membrane overlying the macula and producing severe traction and contraction of the retina and vessels. (B) Arteriovenous phase of fluorescein angiogram shows that the retinal vasculature is tortuous and irregular. (C) Late arteriovenous phase of fluorescein angiogram shows leakage from the retinal vessels. Comment: The marked preretinal membrane caused sufficient traction on the retina, resulting in marked retinal vascular leakage.

The amount of fluorescein leakage depends on the dysfunction of the retinal vascular endothelium (Fig. 1.48). When leakage is not pronounced, the cystoid spaces fill slowly and become visible only late in angiography. When this occurs, the area of cystoid retinal edema may be somewhat hypofluorescent early in the angiogram because the fluid in these spaces acts as a barrier and blocks the

underlying choroidal fluorescence. When there is heavy fluorescein leakage, the cystoid spaces fill rapidly, in some cases within a minute after injection. The large confluent cysts seen with severe cystoid macular edema may fill late in the angiogram. The large retinal vessels can also leak. This is called perivascular staining and is seen in three distinct situations: inflammation (indicating a perivasculitis), traction (severe pulling on a large retinal vessel, [Fig. 1.48](#)), and occlusion. When a large retinal vessel leak is partially occluded, or when it traverses an area of occlusion (and capillary nonperfusion), it will leak ([Fig. 1.49](#)).

**FIG. 1.49** Retinal leakage: perivascular staining. (A) In this late arteriovenous-phase fluorescein angiogram, note the beading of the large retinal veins. There is also associated leakage from these vessels. (B) Later phase of fluorescein angiogram shows perivascular staining (leakage) from the large retinal vessels that are traversing large zones of capillary nonperfusion. Comment: Typically, when a large retinal vessel (artery or vein) is perfused but traverses an area of capillary nonperfusion, ischemic retinal factors will act adversely on the endothelium of the large vessel and cause it to leak. This is called perivascular staining. Perivascular staining also occurs with traction or inflammation.

### Choroidal Leakage.

Late hyperfluorescence under the retina can be classified as either pooling or staining (Fig. 1.50). Pooling is defined as leakage of fluorescein into a distinct anatomic space; staining is leakage of fluorescein diffused into tissue.

**FIG. 1.50** Late hyperfluorescence, subretinal pooling: central serous chorioretinopathy. (A) Schematic drawing of retina shows a sensory retinal detachment. There is a break in the pigment epithelium. Fluorescein flows from the choriocapillaris through Bruch's membrane, through the break in the pigment epithelium, and into the subretinal space, under the detached retina. (B) Color photograph of left macula shows a shallow sensory detachment (*arrows*). Just superonasal to the fovea is a small white area with a gray center. The fluorescein angiogram will reveal that this is the area of the leak. (C) Arteriovenous phase of fluorescein angiogram shows a hyperfluorescent spot that was seen on stereoangiography to be leakage of

fluorescein coming from the pigment epithelium. (D) Late phase of fluorescein angiogram shows that the spot of pigment epithelial leakage has enlarged and become fuzzy. This is the release of fluorescein molecules into the fluid under the detached sensory retina. Comment: This patient had central serous chorioretinopathy. There was a break in the pigment epithelium that allowed leakage of fluorescein through it and into the subretinal space. Late hyperfluorescence means leakage, and in this case, there is pooling of fluorescein under the detached retina.

Fluorescein pools in the spaces created by detachment of the sensory retina from the pigment epithelium or in the space created by detachment of the pigment epithelium from Bruch's membrane. The posterior layer of the sensory retina is made up of rods and cones that are loosely attached to the pigment epithelium. When a sensory retinal detachment occurs, the detached segment separates with little force, forming a very gradual angle at the point of attachment to the pigment epithelium. Because of this narrow angle, the exact limits of a sensory retinal detachment are difficult to locate ophthalmoscopically or by slit-lamp biomicroscopy.

Depending on the specific disease, the late angiogram may or may not portray the full fluorescent filling of the subretinal fluid. For example, in central serous chorioretinopathy the leakage is gradual, and fluorescence of the subsensory retinal fluid will not be complete. In other conditions, such as subretinal neovascularization, fluorescein leakage is profuse, and the subsensory fluid often completely fluoresces ([Fig. 1.51](#)).

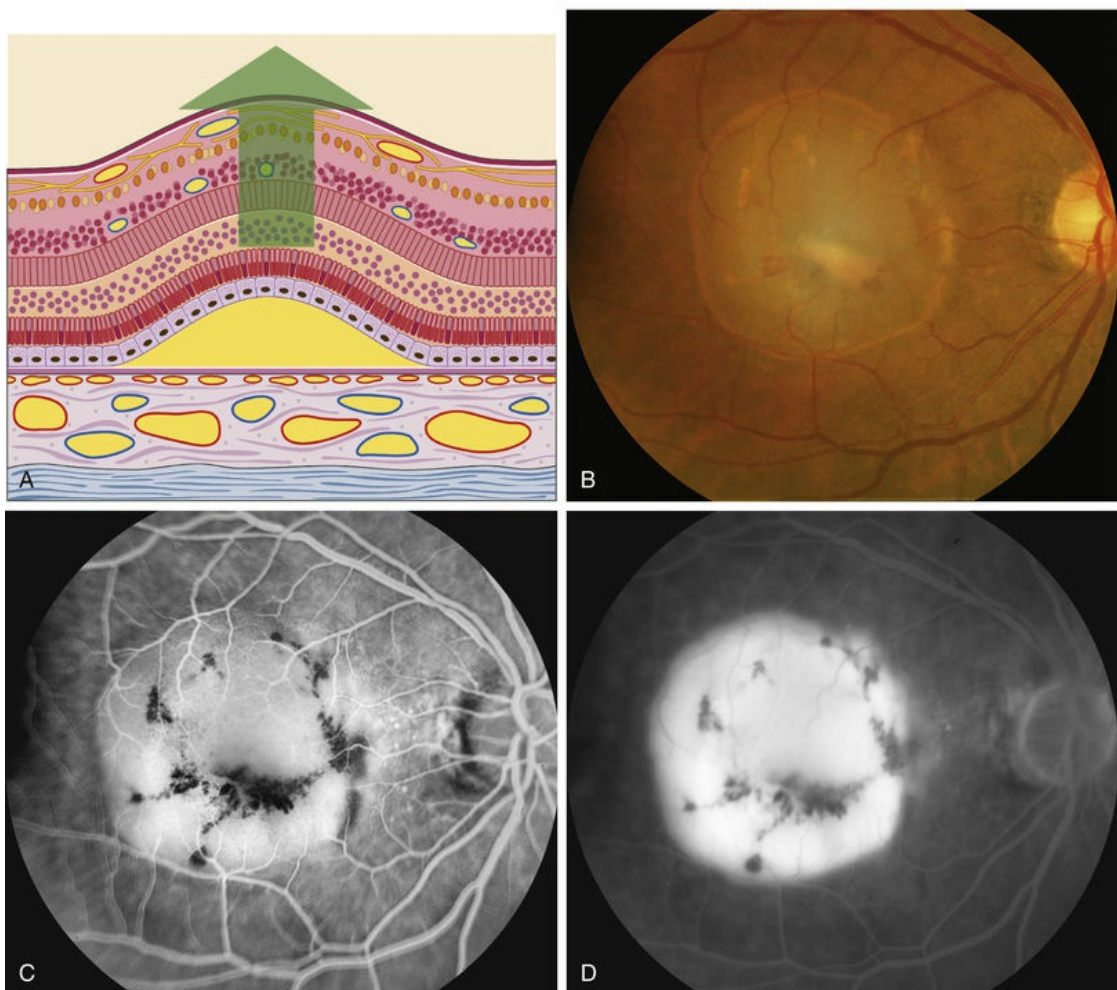

**FIG. 1.51** Late hyperfluorescence, leakage, and pooling under the sensory retina caused by subretinal neovascularization, resulting in a sensory retinal detachment. (A) Schematic of the retina showing that it has detached (photoreceptors are separated from pigment epithelium). Vessels have proliferated from the choriocapillaris through Bruch's membrane. There is a fibrovascular scar involving the pigment epithelium. The sensory retina is detached. (B) Color photograph of left macula shows a pale gray lesion in the inferior portion of the macula with some associated hemorrhage. (C) Arteriovenous phase of fluorescein angiogram shows a patch of subretinal neovascularization inferior to the fovea; this is evidenced by the lacy, irregular hyperfluorescence in this area. (D) Late phase of fluorescein angiogram shows fuzzy fluorescence. There is pooling of fluorescein under the detached retina and some staining of the fibrous tissue associated with the subretinal neovascularization. Comment: This patient

had a patch of subretinal neovascularization with a great deal of leakage, causing a sensory detachment.

The early-phase angiogram showed the vascular nature of the lesion, and the late-phase angiogram showed the leakage and pooling in the subretinal space.

In contrast to the attachment of the sensory retina, the basement membrane of the pigment epithelium adheres firmly to the collagenous fibers of Bruch's membrane. The firm adhesion and wide angle of detachment make it easy to discern a pigment epithelial detachment ophthalmoscopically. Occasionally a light-orange ring appears around the periphery of a pigment epithelial detachment, further facilitating identification (Fig. 1.52).

**FIG. 1.52** Late hyperfluorescent pooling under the retinal pigment epithelium (pigment epithelial

detachment). (A) Schematic diagram illustrating detachment and elevation of the pigment epithelium; the pigment epithelium is separated from Bruch's membrane. Because the attachment of the pigment epithelium to Bruch's membrane is quite firm, the angle of detachment is quite large. (B) Color photography of right macula shows a round detachment of the pigment epithelium. (C) Early arteriovenous phase of fluorescein angiogram shows early fluorescence from the area of detachment pigment epithelium. (D) Late-phase angiogram of right macula shows well-demarcated hyperfluorescent pooling of fluorescein under the detached pigment epithelium. Comment: Fluorescein flows freely through Bruch's membrane and stops at the pigment epithelium. When the pigment epithelium is detached, the fluorescein flows right through Bruch's membrane into the space made by the detached pigment epithelium. Therefore a pigment epithelial detachment fluoresces evenly and slowly (like a light bulb on a rheostat) and shows intense hyperfluorescent pooling that is well demarcated (indicating its well-defined angle of attachment) late in the angiogram.

The differences in the adherence and the angle of detachment between a sensory retinal detachment and a pigment epithelial detachment result in specific differences in fluorescent pooling patterns. The hyperfluorescent pooling of a sensory retinal detachment tends to fade gradually toward the site where the sensory retina is attached. This makes fluorescein angiographic determination of the extent of a sensory retinal detachment difficult. In contrast, the hyperfluorescent pooling under a pigment epithelial detachment extends to the edges of the detachment, making the entire detachment and its margins hyperfluorescent and clearly discernible.

Pooling of fluorescein under a sensory retinal detachment in central serous retinopathy takes place slowly, since the dye passes through one or more points of leakage in the defective pigment epithelium (Fig. 1.50). When leakage comes from subretinal neovascularization (Fig. 1.51) or a tumor (Fig. 1.43), it is more rapid and complete. When the pigment epithelium is detached from

Bruch's membrane, fluorescein passes freely and rapidly through Bruch's membrane from the choriocapillaris into the subpigment epithelial space (Fig. 1.52).

In some cases of central serous chorioretinopathy, there is an associated pigment epithelial detachment, and pooling under each (sensory retinal detachment and the pigment epithelial detachment) is evident. Occasionally, the edge of a pigment epithelial detachment may tear, or rip, and allow fluorescein dye to pass freely into the subretinal space (Fig. 1.53). Drusen may also show late hyperfluorescence similar to that seen with a pigment epithelial detachment (Fig. 1.54). In some cases of pigment epithelial detachment, especially in older patients, subretinal neovascularization is also present. This combination of subretinal neovascularization and pigment epithelial detachment results in an interesting angiogram that can be challenging to interpret (Fig. 1.55).

**FIG. 1.53** Late hyperfluorescence under the retina – leakage from the choroid due to a retinal pigment epithelial (RPE) rip. (A) Schematic of a pigment epithelial detachment that has developed a tear along one edge. The barrier function of the pigment epithelium is lost and fluorescein dye can diffuse easily and rapidly in the subretinal space. (B) Color photography of right macula showing a round dark area under the fovea, and light (depigmented area) area extending temporally. In the inferior portion of the macula, some subretinal hemorrhage is seen. (C) Early arteriovenous-phase fluorescein angiogram shows bright hyperfluorescence of the depigmented area temporally, and hypofluorescence under the fovea as well as inferiorly in the area of the subretinal blood. (D) Late-phase fluorescein angiogram shows pooling of fluorescein under the retina where the dye has been able to diffuse freely through Bruch's membrane in the sensory retinal detachment.

Comment: This patient developed a tear of the pigment epithelial detachment. The dark area under the fovea is where the pigment epithelium has rolled up after tearing away from the area temporally. The area temporal to the macula appears light due to absence of the RPE in this area. Since the RPE barrier is absent in this area, the dye diffuses readily and rapidly into overlying sensory retinal detachment, producing late pooling of fluorescein.

**FIG. 1.54** Late hyperfluorescent pooling (or staining) of large drusen. (A) Schematic section of retina shows progressively larger detachments of pigment epithelium. Drusen deposit between the pigment epithelium and Bruch's membrane and lift the pigment epithelium up, forming small or large pigment epithelial detachments, depending on the size of the drusen. (B) Color photograph of right macula shows multiple, pale,

round, and variably sized drusen. (C) Arteriovenous phase of fluorescein angiogram shows some early hyperfluorescence of the areas of the drusen. (D) Late phase of fluorescein angiogram shows marked hyperfluorescence of the drusen. The larger drusen take longer for the hyperfluorescence to develop. Comment: The larger the drusen, the more similar they are to pigment epithelial detachments, and therefore the more likely it is that they will show pooling of fluorescein (or staining of the drusen material).

**FIG. 1.55** Pigment epithelial detachment with associated (suspicious) subretinal neovascularization. (A) Color photograph of right macula. Note the pigment epithelial detachment temporally and sensory retinal detachment. (B) Arteriovenous-phase fluorescein

angiogram shows early hyperfluorescence of the superotemporal pigment epithelial detachment. (C) Late-phase fluorescein angiogram of left macula shows that the fluorescence of the pigment epithelial detachment temporally has increased significantly. Comment: This patient had an irregularly shaped pigment epithelial detachment, which is a sign of possible choroidal neovascularization. The irregular, fuzzy hyperfluorescence is due to likely occult choroidal neovascularization.

In summary, late hyperfluorescence beneath the retina should first be distinguished as pooling of fluorescein into a space or as tissue staining with fluorescein. When pooling is present, one must determine whether a sensory retinal or a pigment epithelial detachment is present. Similarly, if staining is present, one must find out whether the tissue involved is the retinal pigment epithelium and Bruch's membrane, choroid, or sclera. From this anatomic determination a more specific diagnosis can be determined.

## **Staining**

Staining refers to leakage of fluorescein into tissue or material and is contrasted with pooling of the fluorescein into an anatomic space. Many abnormal subretinal structures and materials can retain fluorescein and demonstrate later hyperfluorescent staining.

## **Drusen.**

The most common form of staining occurs with drusen. Most drusen hyperfluoresce early in the angiogram because choroidal fluorescence is transmitted through defects in the pigment epithelium overlying the drusen (Fig. 1.30). Fluorescence from most small drusen diminishes as the dye leaves the choroidal circulation. However, some larger drusen display later hyperfluorescence or staining (Fig. 1.54). The larger the drusen, the more likely they will retain fluorescein and staining will occur. When drusen are large and have smooth edges, the late staining on the angiogram is similar in appearance to that of pooling of fluorescein under a pigment epithelial detachment. In many cases it is difficult, if not

impossible, to differentiate large drusen from small pigment epithelial detachments: they have a similar ophthalmoscopic, fluorescein angiographic, and even microscopic appearance.

### **Scar.**

Scar tissue retains fluorescein and usually demonstrates well-demarcated hyperfluorescence because little, if any, fluid surrounds the scar. Later in the healing process, when only a few vessels remain, the early angiogram is hypofluorescent because of the paucity of vessels and blockage by the scar tissue. The most commonly seen scar tissue is the disciform scar, which is the endstage of subretinal neovascularization. Scarring is also seen following numerous other insults to the pigment epithelium and choroid, especially inflammation ([Fig. 1.56](#)).

**FIG. 1.56** Late hyperfluorescence and leakage – staining in geographic helicoid peripapillary choroidopathy (GHPC). (A) Color montage of left disc and macula shows large geographic areas of atrophy of pigment epithelium and choriocapillaris. There is some hyperplasia of the pigment epithelium noted as hyperpigmentation (especially in the macula and papillomacular bundle). Some fibrous scar tissue is present. (B) Arteriovenous-phase fluorescein angiogram shows that the geographic lesions are mostly hypofluorescent; they are caused by loss of pigment epithelium and choriocapillaris. Note that the large choroidal vessels can be seen within these

lesions, indicating that the pigment epithelium and choriocapillaris are both gone. There is some hyperfluorescence along the edges of the geographic lesions. The pigment epithelial hyperplasia causes blocked fluorescence. (C) Late fluorescein angiogram of left macula shows hyperfluorescent staining along the edges of the geographic lesion. Comment: This patient had GHPC; inflammation of choroid and pigment epithelium resulted in a loss of the pigment epithelium and choriocapillaris and some of the choroid. The angiogram showed that only large choroidal vessels remained within these lesions. The choriocapillaris was intact, however, in the normal tissue adjacent to the geographic atrophic tissue. The normal choriocapillaris leaked into the atrophic area in a horizontal fashion, causing late hyperfluorescence of areas of scar tissue and some scleral staining.

## Sclera.

In several situations the sclera is visible ophthalmoscopically and exhibits late hyperfluorescent staining on fluorescein angiography. Scleral staining is best seen when the retinal pigment epithelium is very pale (as in a blonde patient) or when the choriocapillaris is fully intact. When the choriocapillaris is not intact, fluorescein staining of the sclera can occur from the edges of the atrophic area where fluorescein leaks from the intact choriocapillaris inward toward the atrophy (Fig. 1.56).

In conditions such as physiologically light-colored (blonde) fundus or in myopia, the choriocapillaris is usually sufficient to stain the sclera completely. After the choroidal vessels have emptied of fluorescein in the later phases of angiography, the large hypofluorescent choroidal vessels appear as dark lines in silhouette against the stained sclera.

When a loss of choroid and choriocapillaris has occurred, there is a consequent diminution of fluorescein flow in the choroid. When this occurs, the sclera stains with fluorescein only from adjacent normal patent choriocapillaris vasculature. These vessels stain the sclera on the borders of the lesion because the dye tends to diffuse toward the center of the lesion. The entire lesion may not stain if the

distance from the edge of the sclera is more than 1 mm. When the choriocapillaris is intact or the lesion is not expansive, the sclera will stain completely.

In summary, late hyperfluorescence beneath the retina should first be distinguished as pooling of fluorescein into a space or as tissue stained with fluorescein. When pooling is present, it must be determined whether a sensory retinal or a pigment epithelium detachment is present. Similarly, if staining is present, it must be determined whether the tissue involved is the retinal pigment epithelium and Bruch's membrane, choroid, or sclera. From this anatomic differentiation, a more specific diagnosis can be determined.

## Acknowledgments

This work was supported by the San Francisco Retina Foundation. The authors would like to thank Ryan Terribilini, head of photography at West Coast Retina Medical Group, for his assistance in acquiring many of the images used in this text.

## Introduction

Intravenous fluorescein angiography (FA) provides excellent spatial and temporal resolution of the retinal circulation, with a high degree of fluorescence efficiency and minimal penetration of the retinal pigment epithelium (RPE). Unfortunately, imaging of the choroidal circulation is prevented by secondary poor transmission of fluorescence through ocular media opacities, pathologic manifestations such as serosanguineous fluid or lipid exudation

and fundus pigmentation, including that from the RPE layer.

In medicine a core principle for diagnostic imaging is the selection of a technique that best visualizes the disease undergoing investigation. Indocyanine green (ICG) has several advantages over sodium fluorescein in imaging the choroidal vasculature. Its physical characteristics allow for visualization of the dye through overlying melanin, xanthophyll pigment, serosanguineous fluid, or lipid exudates. The use of high-resolution infrared digital fundus cameras and confocal scanning laser ophthalmoscopes (SLOs), specifically designed for ICG angiography (ICGA), has reflected a growing awareness and interest in choroidal vascular lesions, and has facilitated the rapid diffusion of ICGA in the ophthalmic community.

Even in the era of anti-vascular endothelial growth factor (VEGF) intravitreal injections, a therapy for which accurate localization of the choroidal neovascular membrane is not as critical, ICGA, among other imaging techniques, is still extremely useful in clinical practice.<sup>1</sup>

## History

ICG was developed by Kodak Research Laboratories,<sup>2</sup> on request by cardiologists, to be used as an indicator of cardiac output, which was not influenced by variations in blood oxygen saturation.<sup>3,4</sup> Hepatologists subsequently began to use ICGA to evaluate hepatic blood flow<sup>5</sup> and hepatocellular function.<sup>6</sup>

In 1969 Kogure and Choromokos first used ICGA for studying the cerebral circulation in a dog.<sup>7</sup> The following year Kogure et al. reported on intraarterial ICG absorption of the choroid in monkeys.<sup>8</sup> The first human ICG angiogram was of the carotid artery.<sup>9</sup> In 1971 Hochheimer modified the system for ICGA by changing the color film that had been used previously to black-and-white infrared film.<sup>10</sup>

In 1972 Flower and Hochheimer performed the first intravenous ICGA to image the human choroid.<sup>11</sup> In the following years Flower and coworkers evaluated the potential utility of ICGA in the investigation of the normal and pathologic eye.<sup>11,12</sup> The relatively poor fluorescence efficiency of the ICG molecule and its limited

ability to produce high-resolution images on infrared film initially restricted its angiographic application. The resolution of ICGA was improved in the mid-1980s by Hayashi and coworkers, who developed improved filter combinations with sufficient sensitivity for near-infrared wavelengths.<sup>13</sup> They were also instrumental in the transition from still-frame to dynamic imaging by introducing videoangiography.<sup>14,15</sup>

Although the sensitivity of the initial video camera system was a vast improvement over previous techniques, its inability to study individual images and the potential light toxicity using a 300-watt halogen bulb restricted the duration and quality of the technique. In 1989 Destro and Puliafito performed ICGA using a system very similar to that described by Hayashi.<sup>16</sup> In the same year, the use of the SLO for ICG videoangiography was introduced by Scheider and Schroedel.<sup>17</sup> In 1992, Guyer introduced the use of a 1024 × 1024 line digital imaging system to produce high-resolution ICGA.<sup>18</sup> However, this system lacked flash synchronization with the video camera.

Finally, Yannuzzi and coworkers described a 1024-line resolution system, which was synthesized with the appropriate flash synchronization and image storage capability, permitting high-resolution, long-duration ICGA.<sup>19</sup>

## Chemical and Pharmacokinetics

ICG is a tricarbo-cyanine, anionic dye. Its structural formula is 2,2'-indo-6,7,6',7'-dibenzocarbocyanine sodium salt<sup>20</sup> with a molecular weight of 774.96 D.<sup>2</sup> ICG is soluble in highly distilled water,<sup>21</sup> even though in protein-free buffer it is difficult to obtain stable and simple ICG solutions, because of the formation of reversible dimers/polymers.<sup>2</sup> Binding to albumin or plasma proteins improves the stability of ICG solutions.<sup>2</sup> ICG is supplied with a solvent consisting of sterile water at pH 5.5–6.5. The final product contains 5–9.5% sodium iodine.<sup>22</sup> to prevent recrystallization.<sup>23</sup>

ICG absorbs light in the near-infrared region of the spectrum. The maximum absorption is at 790 nm,<sup>23</sup> while the maximum emission occurs at approximately 835 nm.<sup>24</sup> These optical properties allow the penetration through macular pigment, melanin<sup>25</sup> blood and

pigment.

About 98% of ICG is bound to plasma protein, in particular to globulins, such as A1-lipoproteins.<sup>22</sup> In pig plasma, lipoprotein HDL3 is the major binding protein.<sup>2</sup> ICG is excreted by the liver,<sup>5,26</sup> with negligible extrahepatic removal.<sup>5,27</sup> The presumed mechanism is active<sup>27</sup> and depends both on liver blood flow and hepatocellular function.<sup>28</sup> ICG is excreted into the bile without metabolic process or enters the enteropathic circulation<sup>27</sup> through three steps: uptake over the hepatocyte sinusoidal (basolateral) membrane (Na<sup>+</sup> mediated); passage through the cell, with some role of the microfilaments and vesicular transport;<sup>2</sup> and excretion over the canalicular (apical) membrane.<sup>2</sup> Rate of ICG disappearance from vascular compartment is 18–24% per minute, and after 20 minutes no more than 4% remains in the plasma.<sup>29</sup> The plasma decay curve is initially exponential, then decelerates.<sup>26</sup> No peripheral uptake has been described in the kidney,<sup>26</sup> lungs, or placenta.<sup>30</sup>

The high molecular weight of ICG, in combination with the high percentage of dye bound to plasma proteins, reduces the amount of dye that exits from fenestrations in choroid vessels. This feature and its optical properties make ICG suitable for choroidal vascular network visualization. Although it has been reported that ICG can diffuse through the choroid and can accumulate in RPE cells, no dye should remain in the late phases (30–40 minutes) of the angiogram.<sup>29</sup>

## Toxicity

ICG is considered a safe and well-tolerated dye. Its LD<sub>50</sub> is 60 mg/kg in mice.<sup>20</sup> Constant infusions over a 3-hour period with dosages as high as 50 mg/kg of body weight were well tolerated.<sup>27</sup>

Subcutaneous extravasation also does not produce significant local effects.<sup>26,31</sup> Overall, the side-effect rate is low: 0.15% with mild events (nausea, vomiting, sneezing, pruritus), 0.2% with moderate events (urticaria, syncope, pyrexia, nerve palsy), 0.05% with severe events (bronchospasm, laryngospasm, anaphylaxis).<sup>31</sup>

The mechanism of these various adverse side-effects is uncertain. For some, a dose-dependent pseudoallergic mechanism has been proposed,<sup>32</sup> though there does not appear to be correlation with

iodide or shellfish intolerance, suggesting that the sodium iodide component is of little significance.<sup>22,33</sup> Nevertheless patients with a history of definite iodine allergy should not be given the dye, because of concerns for possible anaphylaxis.<sup>31</sup> Caution should also be observed in patients affected by liver diseases<sup>29</sup> and kidney diseases, since a 9.3% incidence of adverse reactions has been reported in dialysis patients.<sup>22,34</sup>

ICG was extensively used as a chromodiagnostic agent in the evaluation of hemodynamic changes during pregnancy.<sup>35</sup> Nevertheless there are concerns among ophthalmologists, since the FDA has classified ICG as a pregnancy category C drug, meaning that adequate studies of safety have not been conducted.<sup>30</sup>

## Instrument Comparison

There are several instruments at present that can be used to perform ICGA. All of them can be divided into two main categories: digital flash fundus cameras and SLOs.

At the time of writing of this chapter, the flash camera group includes the TRC-50DX ICG (Topcon, Tokyo, Japan), the FF 450plus (Carl Zeiss Meditec, Inc., Dublin, CA, United States), and the VX-10i (Kowa, Tokyo, Japan). ICG-capable SLO systems include the Spectralis HRA (Heidelberg Engineering, Heidelberg, Germany), the F10 (Nidek, Gamagori, Japan), and the Optos California (Optos plc, Dunfermline, Scotland).

The differences between these instruments are largely related to the acquisition modality (Fig. 2.1). The light source for a digital camera is a white light with an excitation filter (640–780 nm) and a barrier filter (820–900 nm). In an SLO a laser monochromatic light is used to excite (785–790 nm) with a barrier filter at 805 nm. The laser light for an SLO system is moved on the fundus by two rotating mirrors and the image is acquired point by point. For a typical 30° image, this takes approximately from 60 to 200 msec. The presence of a confocal aperture in SLO systems allows selective acquisition of light from a particular tissue layer (from the focal plane) and blocks the light that is coming from the surrounding tissue.<sup>36,37</sup> Flash systems, in contrast, do not use a confocal aperture, and thus the fluorescent light returning to the camera will emanate from

multiple layers. However, even for clinical confocal SLO ICG systems, the confocal aperture is much larger than one would choose for optimum z-resolution imaging. The reason for this is that fluorescence light from different depth planes (i.e., from the choroid and from the retinal vessel) needs to be imaged simultaneously for many clinical applications.

**FIG. 2.1** Schematic representation of the differences between digital flash fundus cameras (A), scanning laser ophthalmoscopes (SLOs) (B), and confocal SLO instruments (C). In digital flash fundus cameras, white light (with or without excitation/barrier filters) is used. In SLO systems the light source is a monochromatic laser. In SLO confocal systems a pinhole aperture blocks the reflected or fluorescent light from areas outside the focal plane.

These characteristics are important to recognize to understand the different appearance of ICGA images obtained by different instruments (Fig. 2.2). Another difference is the number of images acquired per second. With SLO systems the frame rate may reach 12 images per second, thus permitting dynamic ICGA (Fig. 2.2). With

digital fundus cameras the maximum rate is one frame per second.

**FIG. 2.2** Comparison of dynamic (6 frames per second) and conventional indocyanine green angiography of a stage II retinal angiomatous proliferation lesion. A feeding retinal arteriole (A, *arrow*), filling of the vascular lesion, and a draining retinal vein are all characteristic features visible in the dynamic sequences (A–C). The filling sequence is missed during the first two images captured with a conventional flash fundus camera system (D,E).

## Injection Technique

The concentration and preparation for intravenous injection of ICG vary with the instrument used. For fundus cameras the standard concentration is 25 mg of ICG dissolved in 5 mL solvent.<sup>38</sup> The dosage may be increased to 50 mg in patients with poorly dilated pupils and heavy pigmentation.<sup>39</sup> For SLOs the standard dosage is 25 mg of ICG dissolved in 3 mL, and 1 mL of the solution is injected. The solvent may be either saline alone or fluorescein sodium solution at 10–20–25% concentrations, for combined FA and ICGA. Intravenous ICG injection should be rapid and immediately

followed by a 5 mL saline flush.

In patients with iodine allergy, infracyanine green is available, which is the iodine-free formula of indocyanine green. The technique of injection is equivalent, but a glucosate solvent should be used for preparation. As a result, combined fluorescein angiography and infracyanine green angiography is not possible.

## Indocyanine Green Angiography Interpretation

### Normal Eye

To understand the manifestations of disease on ICGA, a recognition of the normal appearance of ICGA in normal subjects is essential.

Since ICGA is a dynamic examination, the characteristic findings may vary depending on the time after dye injection or the “phase” of the angiogram. It is well known that FA has an arterial retinal phase, an arteriovenous, and a venous phase. Similarly for ICGA, one can recognize an early phase when the retinal artery is not yet filled, a mid phase where both arteries and veins are filled, and a late or recirculation phase after more than 10 minutes after injection.

In ICGA the early filling phase may best be correlated with the filling of different layers of the choroid. The first choroidal vessels to be filled are the ones of the deeper Haller's layer, followed by the intermediate Sattler's layer (Fig. 2.3). The choriocapillaris is the last layer to be filled (therefore the sequence progresses from the biggest and outermost to the smallest and innermost vessels). However, the choriocapillaris is typically quite difficult to visualize, since the resolution of the cameras is insufficient to resolve the size of its small lobular morphology. Therefore the choriocapillaris is visualized as a diffuse indistinct haze, more evident in the posterior pole and less evident in the peripheral retina (Fig. 2.3).

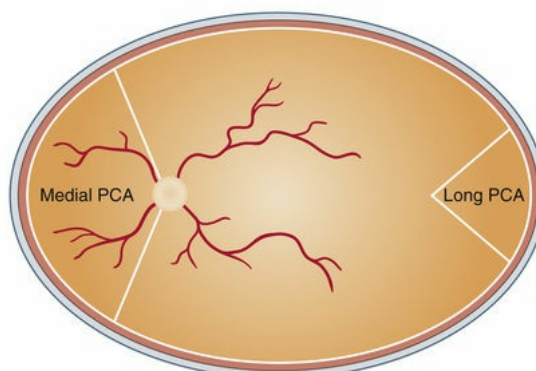

**FIG. 2.3** The filling of vessels during an indocyanine

green angiogram follows a precise sequence. The first layer to be filled is Haller's layer (A,B), followed by Sattler's layer (C,D), and then the choriocapillaris (E,F). Simultaneous dynamic fluorescein and indocyanine green angiography (A,C,E) permits the different phases to be resolved. The choriocapillaris may be better appreciated when there are adjacent areas of focal loss, as in this example of geographic atrophy (G,H).

Choroidal vessels are usually first observed emanating from the posterior ciliary arteries. A well-defined watershed zone is present between the medial and lateral posterior ciliary artery (Fig. 2.4).<sup>40</sup> Compared to fluorescein, the watershed zone is more difficult to visualize, since there is less contrast between perfused and nonperfused choroid.

**FIG. 2.4** A case of occlusion of the medial long posterior ciliary artery (PCA). Indocyanine green

angiography (ICGA) allows one to appreciate the different territories supplied by this artery and the lateral long PCA (A). Venous phase of ICGA shows the filling of the lateral vortex veins (B). In the upper left area, the vortex vein is partially filled due to drainage from the iris (B, *arrow*). (C) Schematic representation of the different vascular territories of the two arteries.

(Panel C modified from Hayreh SS. Physiological anatomy of the choroidal vascular bed. *Int Ophthalmol* 1983;6:85–93.)

Choroidal vortex veins are visible in the late phase of ICGA and are usually four in number (Fig. 2.5). They drain the corresponding segment of the iris, ciliary body, and choroid. Sometimes, especially in the myopic eye, a vein may be seen passing from the choroid through the sclera closely adjacent to the optic nerve head and draining into the venous plexus of the pial sheath of the optic nerve (choriovaginal vein) (Fig. 2.5).<sup>40</sup>

**FIG. 2.5** Indocyanine green angiography allows visualization of the four vortex veins (A), and the choriovaginal vessels (B, *arrow*).

In case of a thin sclera, such as in the setting of a choroidal staphyloma, extrabulbar vessels may be visualized. These can be distinguished from normal choroidal vessels because they pulsate in accordance with the heartbeat. Moreover, they change shape and position with eye movements.<sup>41,42</sup>

## Exudative Age-Related Macular Degeneration

Exudative age-related macular degeneration is generally classified based upon the axial location of the choroidal neovascularization (CNV). A type 1 CNV is a neovascular membrane that is located under the RPE, whereas a type 2 CNV has passed through the RPE and lies under the neurosensory retina.<sup>43</sup> According to the Macular Photocoagulation Study, type 1 CNV is generally considered to correspond with “occult” CNV on FA (as defined by the Macular Photocoagulation Study), and type 2 CNV generally corresponds with “classic” CNV.<sup>44,45</sup> More recently, type 3 CNV has been defined to be CNV with a definite intraretinal component.<sup>46</sup>

The fact that occult CNV accounts for the vast majority of the exudative complications in age-related macular degeneration (AMD)<sup>47</sup> explains in part why ICGA, with its ability to delineate occult CNV, has become part of standard care in exudative AMD for many clinicians.<sup>19,48,49</sup> Nonetheless, in peer-reviewed journals the number of articles published whose title included the terms “indocyanine green angiography (or videoangiography)” decreased between 1995 and 2010.<sup>1</sup> One likely explanation might be the advent of anti-VEGF therapy which inaugurated a new era in the management of exudative AMD: it was the first therapy to improve the mean visual acuity of eyes treated with monthly injections of ranibizumab, regardless of whether the CNV lesion was predominantly classic<sup>50</sup> or occult.<sup>51</sup> Thus, the management of CNV has changed from the use of therapy for which accurate localization of the membrane was crucial (i.e., laser photocoagulation, photodynamic therapy) to the nonspecific intravitreal delivery of active and highly effective biologic drugs. Nonetheless, we would still argue that the gold-standard diagnostic procedure should be the one that best visualizes the disease (CNV) under investigation.

### Type 1 Choroidal Neovascularization

This type of choroidal neovascularization is by definition under the RPE, and corresponds to the occult neovascular network on FA. The Macular Photocoagulation Study recognized two forms of occult CNV: a fibrovascular pigment epithelial detachment (PED)

and a late-phase leakage of an undetermined source (LLUS).<sup>44</sup> As for the fibrovascular PED, its prevalence may vary from 22% to 50%<sup>47–49,52</sup> of occult CNV lesions; dynamic ICGA may delineate the presence of a neovascular network usually located along the edges of the PED<sup>49,53,54</sup> (Fig. 2.6). Moreover, dynamic ICGA may reveal a feeder vessel that can be successfully treated with laser photocoagulation, when it is located outside the foveal region<sup>55,56</sup> (Fig. 2.7). In case of LLUS, which may represent 36–78% of occult CNV,<sup>47,48,52</sup> dynamic ICGA may differentiate an occult form of CNV from retinal angiomatous proliferation<sup>52</sup> (Fig. 2.8). Considering that one-fourth of patients with a LLUS do have a retinal angiomatous proliferation,<sup>52</sup> and that an early diagnosis of these lesions is crucial for the functional prognosis,<sup>57</sup> the importance of an ICG evaluation for these cases becomes readily apparent.

**FIG. 2.6** A pigment epithelium detachment (PED) (A, fluorescein angiography) with a well-delineated neovascular network located along the edges of the PED (B, indocyanine green angiography).

**FIG. 2.7** Fibrovascular pigment epithelium detachment (PED). Fluorescein angiography demonstrates occult choroidal neovascularization with PED (A). In the early phases of indocyanine green angiography (ICGA) a feeder vessel originating in the juxtapapillary area is clearly delineated (B, *asterisk*). Feeder vessel and draining vein are indistinguishable in the late phases of ICGA (C).

**FIG. 2.8** Late leakage of undetermined source (A,C). Indocyanine green angiography may clearly differentiate a subtype of occult choroidal neovascularization (B) from retinal angiomatous proliferation (D).

In conclusion, ICG facilitates a better and more complete classification of occult CNV subtypes, compared to FA. Of note, Yannuzzi<sup>19</sup> found that 39% of lesions classified as poorly demarcated occult lesions by FA were well defined by ICGA.

## **Type 2 Choroidal Neovascularization**

In classic CNV, ICGA improves visualization of the fine structure of the neovascular network<sup>1</sup> (Fig. 2.9), allowing the choroidal and retinal circulation to be distinguished. This high spatial and temporal resolution permits identification of choroidal vessels that

feed into the CNV.<sup>58</sup> In early phases, ICG shows a dark rim which corresponds to a whitish ring on infrared imaging,<sup>59</sup> and a discreet neovascular network surrounded by a hypocyanescent margin which is more visible after 15 minutes.<sup>60</sup> Watzke et al.<sup>54</sup> showed that 87% of eyes with classic choroidal neovascular membranes were hypercyanescent with distinct edges.

**FIG. 2.9** A case of type 2 choroidal neovascularization. In fluorescein angiography images (A), the leakage of the dye from the lesions is evident and obscures the boundaries of the neovascular network. In indocyanine green angiography (ICGA) (B), the limits of the neovascularization are much more visible. Moreover, ICGA allows the visualization of a central feeder vessel, with a surrounding net of smaller neovessels.

This ability to provide a clear delineation of the neovascular network may confer an important advantage in the era of anti-VEGF therapy. It has been reported that VEGF inhibitors were more effective in controlling immature vessels, whereas a VEGF inhibitor along with a platelet-derived growth factor (PDGF) inhibitor appeared to show a synergistic effect for controlling the growth of mature vessels.<sup>61</sup> This is likely because pericyte recruitment is part of the maturation process in blood vessel development. Once the pericyte cell population is well established, the effectiveness of anti-VEGF agents is greatly reduced. PDGF-B is a key requirement for

the recruitment of pericytes to the newly formed vessels. Mature, larger choroidal vessels may be readily differentiated from immature choroidal capillaries on ICGA ([Fig. 2.10](#)). Thus, in patients with chronic AMD or those who did not benefit from previous treatments with anti-VEGF, ICGA might better delineate a more mature stage of CNV. This has potential implications for therapeutic decision-making.

**FIG. 2.10** Red-free image showing intraretinal blood within a central atrophic area. A small subretinal hemorrhage is also present inferiorly (A). Corresponding fluorescein angiogram demonstrating late leakage of undetermined source along the inferior

edge of the atrophic area (B). Simultaneous early phase indocyanine green angiography (C) reveals mature, large choroidal vessel (C, *asterisk*) feeding the large net of neovascularization along the inferior edge of central atrophy. A real chorioretinal anastomosis (C, *arrow*) is also present. Four minutes after injection (D), the draining choroidal veins are well visualized as is the neovascular network inferiorly (D, *open circles*). Red-free image after a 3-month-loading-phase with ranibizumab (E) shows an increase in size of the central retinal hemorrhage despite loading phase with anti-VEGF.

### **Type 3 Choroidal Neovascularization**

During the past decade, retinal angiomatous proliferation (RAP) has been labeled with a number of different terms, including “retinal vascular anomalous complex,” “retinal choroidal anastomosis,” “retinal anastomosis to the lesion,” and “chorioretinal anastomosis.” In a comprehensive article<sup>62</sup> on this entity, Yannuzzi provided evidence to support the original concept of capillaries arising within the inner half of the retina, or “retinal angiomatous proliferation,” thus suggesting the acronym of RAP as the appropriate descriptor for the disease. Subsequently, Gass<sup>63</sup> suggested a possible choroidal origin for these vessels, emanating from occult choroidal neovascularization and developing into an occult chorioretinal anastomosis. The new category, type 3 neovascularization, has been recently proposed<sup>45</sup> to harmonize these conflicting theories. Type 3 lesions would encompass the following disease manifestations: (1) focal neovascular proliferation arising from the deep retinal capillary plexus (the original RAP concept); (2) intraretinal neovascular extension from an underlying occult/type I CNV; and (3) de novo breaks in Bruch's membrane with neovascular infiltration into the retina.

Whatever the origin or initial location might be, our understanding of the importance of RAP as a component of neovascular AMD has been enhanced by ICGA. The fluorescein angiographic study generally shows manifestations of occult CNV, either fibrovascular PED (Fig. 2.11) or LLUS (Fig. 2.12) without a characteristic feature to identify and delineate the angiomatous

process in the retina (indistinct zone of staining within and beyond the retina). By contrast, ICGA may clearly delineate the vascular structure of the lesion. When associated with PED, the RAP is usually well within the area of detachment and not at the edges, as is typically the case with CNV, which vascularizes a serous PED (so called “notched PED” configuration on FA). As previously reported, RAP may be present in up to one-fourth of eyes thought to have occult CNV with LLUS.<sup>52</sup> Dynamic ICGA (d-ICGA) has further expanded our capability for an early diagnosis. By definition, a diagnosis of RAP is based upon the temporal evidence of “dye filling of at least one retinal arteriole descending into the deep retinal space to a vascular communication and at least one draining retinal vein.”<sup>64</sup> In conventional angiography, images are usually captured at 1 frame per second. This makes it virtually impossible to visualize the progression of the dye through the vascular complex, even though images are taken at very early phases. By contrast, d-ICGA takes up to 12 frames per second and captures the progressive filling of the lesion, allowing detection of very small and recent onset cases of RAP (Fig. 2.2). The possibility of repeated viewing of the dynamic sequence of progression on ICG may further increase our chances of an early diagnosis of RAP (Fig. 2.13). In a recent series of RAP diagnosed using d-ICGA,<sup>52</sup> the incidence of stage 1 RAP (64.9%) and the mean distance of the lesions from the fovea ( $682 \pm 304 \mu\text{m}$ ) were both consistent with an early-stage disease process, supporting the utility of this imaging procedure.

**FIG. 2.11** Late-phase fluorescein angiography (A) shows a pigment epithelium detachment (PED) with a "hot spot." Indocyanine green angiography (B) reveals the presence of retinal angiomatous proliferation (RAP) overlying the PED. Feeding retinal arteriole (*arrow*) and draining retinal venule (*arrowhead*) are clearly visualized.

**FIG. 2.12** Indocyanine green angiography (A) and fluorescein angiography (B) demonstrating an extrafoveal stage II retinal angiomatous proliferation (RAP). One feeding first-order macular arteriole (A, *arrow*) shunts blood flow from the vascular arcade (A, *asterisk*) to the RAP and to one draining retinal vein (A, *V*). Cystoid macular edema is evident in late

fluorescein phases.

**FIG. 2.13** Mid-phase fluorescein angiography (A) showing a small area of progressive extrafoveal staining at 6 o'clock. Dynamic indocyanine green angiography (B) reveals a well-delineated stage I retinal angiomatous proliferation with a feeding retinal arteriole (B, A) and a draining retinal vein (B, V).

Early and accurate diagnosis of RAP is important for at least two reasons. First, RAP lesions are thought to be more aggressive,<sup>65</sup> with a treatment response that is likely to diminish with more advanced disease stages.<sup>57</sup> Second, recent data from the literature suggest that successful anatomic and functional results with RAP may be achieved more consistently with combined treatments (i.e., intravitreal injection of steroid or anti-VEGF + photodynamic therapy) rather than with intravitreal injection of anti-VEGF therapy alone.<sup>66,67</sup> Dynamic ICGA is also extremely useful for monitoring the therapeutic effect: a complete remodeling of the vascular structure may be achieved after successful closure and it is clearly highlighted in d-ICGA (Fig. 2.14).<sup>68</sup>

**FIG. 2.14** Baseline fluorescein angiography (FA) (A) and dynamic indocyanine green angiography (ICGA) (B) shows a stage II extrafoveal retinal angiomatous proliferation (RAP) located inferotemporal to the fovea.

One feeding first-order macular arteriole (B, *arrowhead*) shunts blood flow from the vascular arcade to the RAP and to the draining retinal vein (B, *arrow*). Two months after one combined treatment (intravitreal triamcinolone acetonide + photodynamic therapy), the RAP is no longer detectable by either FA (C) or ICGA (D). There is an evident reduction in size of both the first-order macular arteriole and the draining retinal vein (barely visible) (C,D).

## Polypoidal Choroidal Vasculopathy

Polypoidal choroidal vasculopathy (PCV) is a primary abnormality of the choroidal circulation characterized by an inner choroidal vascular network of vessels ending in an aneurysmal bulge or outward projection, visible clinically as a reddish-orange, spheroid, polyp-like structure.<sup>69</sup> It was first described in the peripapillary area<sup>69,70</sup> (Fig. 2.15) but it may affect the macula<sup>71</sup> (Fig. 2.16), and also extramacular areas (Fig. 2.17).

**FIG. 2.15** Late phase fluorescein angiography (A) shows a neurosensory detachment with multiple juxtapapillary “hot spots.” Early (B) and late (C) indocyanine green angiography reveals the presence of juxtapapillary polypoidal choroidal vasculopathy.

**FIG. 2.16** Late phase fluorescein angiographic image revealing type 1 occult choroidal neovascularization with a subfoveal pigment epithelium detachment (PED) (A). Early (B) and late (C) indocyanine green angiography demonstrate a distinct network of vessels within the macular choroid ending with two hyperfluorescent "polyps." One of the two is located within the PED.

**FIG. 2.17** Early (A) and late (B) indocyanine green angiography showing extramacular polypoidal choroidal vasculopathy with a pigment epithelium detachment.

The disorder is associated with multiple, recurrent, serosanguineous detachments of the RPE and neurosensory retina secondary to leakage and bleeding from the peculiar choroidal vascular abnormality. It has been reported that 85% of patients with serosanguineous detachments of the RPE have evidence of PCV.<sup>72</sup> ICGA has been used to detect and characterize the PCV abnormality with enhanced sensitivity and specificity.<sup>1,71</sup> The early phase of the ICG angiogram shows a distinct network of vessels within the choroid (Fig. 2.16B). In patients with juxtapapillary lesions, the vascular channels may follow a radial, arching pattern. In PCV limited to the macula, a vascular network often arises in the macula and follows an oval distribution pattern.<sup>73</sup> Larger choroidal vessels of the PCV network begin to fill before retinal vessels, and the PCV network fills also at a slower rate than retinal vessels. Shortly after the network can be identified by the ICG angiogram, small hyperfluorescent “polyps” become visible (Fig. 2.16C). These polypoidal structures correspond to the reddish-orange choroidal excrescence seen clinically. They appear to leak slowly as the surrounding hypofluorescent area becomes increasingly hyperfluorescent. In the later phase of the angiogram there is uniform disappearance of dye (“washout”) from the bulging polypoidal lesions.

PCV is often misdiagnosed or confused with chronic central serous chorioretinopathy<sup>74,75</sup> and with exudative age-related

maculopathy,<sup>71,76</sup> and may represent a transitional condition between the two pathologies.<sup>1</sup> Moreover, the treatment strategies for PCV differ from exudative AMD. The use of anti-VEGF agents is controversial in PCV,<sup>1</sup> while verteporfin photodynamic therapy, alone or in combination with bevacizumab,<sup>77</sup> as well as selective laser photocoagulation have been shown to be effective treatments.<sup>78</sup>

Given the facts that ICGA is the most sensitive and specific tool for PCV identification and the treatment for PCV may differ from other diseases for which it is frequently confused, it would seem apparent that ICGA is an important tool in the evaluation of all cases of exudative lesions suspected of harboring PCV.

## Central Serous Chorioretinopathy

Central serous chorioretinopathy (CSC) is characterized by multifocal areas of choroidal hyperpermeability on ICG,<sup>79-81</sup> visible in the mid- and late phases of the angiogram<sup>82</sup> (Fig. 2.18). These areas surround the active retinal pigment epithelial leaks but can also be found in areas apparently unaffected by leakage or abnormal fluorescence on FA, even in the fellow eyes.<sup>79</sup> Zones of choroidal hyperpermeability tend to persist in cases of severe and chronic CSC<sup>83</sup> (Fig. 2.19), and are of value for distinguishing CSC from age-related macular degeneration in older patients with suspected occult neovascularization.<sup>80,84</sup>

**FIG. 2.18** A case of central serous chorioretinopathy. In the fluorescein angiographic image (A) it is possible to visualize three distinct serous detachments of the pigment epithelium, and one point of leakage. Another hyperfluorescent area is visible (A, *arrow*), but it is not clear if it corresponds to another point of leakage or represents an additional detachment. Indocyanine green angiographic images (B,C) allow one to clearly distinguish points of leakage as hyperfluorescent areas, with marked leakage in the late phases (C, *arrow*). The uncertain area noted on fluorescein angiography is another leaky point.

**FIG. 2.19** A case of central serous chorioretinopathy. Fluorescein angiographic image (A) shows only an area of pigment epithelium disturbance. Indocyanine green angiography (B) reveals a more extensive alteration of the choriocapillaris, with multiple areas of hyperfluorescence.

Moreover, ICG assessment of the location of these areas of hyperpermeability may be useful when considering treatment with verteporfin photodynamic therapy (PDT), using normal<sup>80</sup> or half-fluence laser energy.<sup>85</sup> The treatment focused on these areas showed rapid reduction of fluid and improvement in visual acuity,<sup>80</sup> possibly by leading to hypoperfusion of choriocapillaris and vascular remodeling.<sup>86</sup> In these studies, verteporfin PDT success rate seemed to be dependent on the degree of hyperpermeability, as the treatment was less effective or had more frequent recurrence of CSC in eyes without intense hyperfluorescence.<sup>87</sup>

Other findings in CSC using ICGA include multiple “occult” serous PED,<sup>79</sup> punctate hyperfluorescent spots,<sup>88</sup> delays in arterial filling of the choroidal arteries and choriocapillaris,<sup>89,90</sup> and venous congestion.<sup>90</sup> ICG is also useful in differentiating CSC from polypoidal choroidal vasculopathy.<sup>75</sup>

## Choroidal Tumors

### Choroidal Hemangioma

Unlike diffuse choroidal hemangiomas, which are usually evident

at birth and typically occur as part of neuro-oculocutaneous hemangiomatosis or Sturge–Weber syndrome, circumscribed choroidal hemangioma may be more difficult to diagnose.

Circumscribed choroidal hemangiomas are benign hamartomas that typically present from the second to fourth decades of life.<sup>91</sup> They usually occur sporadically in the absence of systemic disease. Histopathology reveals that the tumor is composed by vascular channels lined with endothelium. It involves the full thickness of the choroid with secondary changes of the overlying RPE and the retina.<sup>92</sup> Although commonly asymptomatic, choroidal hemangiomas can be associated with exudative retinal detachment resulting in reduced visual function, metamorphopsia, and photopsia.

On ophthalmoscopic examination, a circumscribed choroidal hemangioma appears as an orange choroidal mass with indistinct margins that blend with the surrounding choroid. They are frequently located in the macular region of the posterior pole, and are not usually thicker than 6 mm.<sup>93</sup> Surrounding subretinal fluid leading to exudative retinal detachment with macular involvement is common in symptomatic cases. Retinal hard exudates are minimal or absent.

Angiographic studies such as fluorescein and ICG can be helpful in establishing the diagnosis and differentiating these benign lesions from other tumors, namely amelanotic malignant melanoma and choroidal metastases. Fluorescein angiography demonstrates a hyperfluorescent mass with a fine lacy vascular network of intrinsic vessels in the early choroidal filling phase. The hyperfluorescence increases throughout the angiogram, and there is variable leakage in late views<sup>94</sup> (Fig. 2.20A-B). ICGA is the most useful study for demonstrating the intrinsic vascular pattern of circumscribed choroidal hemangioma.<sup>95</sup> The advantage of ICG dye over sodium fluorescein dye is that it diffuses much more slowly out of fenestrated small choroidal vessels than does sodium fluorescein. Within 30 seconds of injection of the ICG dye, the tumor's intrinsic vascular pattern becomes apparent. By 1 minute, choroidal hemangiomas completely fill with the dye showing brilliant hyperfluorescence. This 1-minute stage of intense hyperfluorescence seen with choroidal hemangiomas is brighter

than any other tumor, and it is very suggestive of the diagnosis. In the following phases (6–10 minutes), the hyperfluorescence can persist or begin to wane (Figs. 2.20C–E). In the late phases of the ICG angiogram (30 minutes), a “washout” effect with reduction of the initial hyperfluorescence is observed secondary to the outflow of dye from the hemangioma (Fig. 2.20F).<sup>95</sup> The low-resistance, high-flow properties of the tumor allow rapid flow of the dye into and out of the tumor. The resulting final effect is that the tumor empties sooner than the normal surrounding choroid and thus appears hypofluorescent in comparison. This “washout” sign is very helpful in differentiating choroidal hemangiomas from amelanotic malignant melanoma and choroidal metastases.

**FIG. 2.20** Fluorescein angiography demonstrating a hyperfluorescent mass along the inferior vascular arcade (A). The hyperfluorescence increases progressively throughout the angiogram with variable leakage in late views (B). Early-phase indocyanine green angiography (ICGA) (49 seconds) revealing a fine lacy vascular network of intrinsic vessels (C). Increasing hyperfluorescence is detected at 2 min (D) and 5 minutes (E) after injection. Of note, the margins of the tumor appear scalloped. Late-phase ICGA study demonstrating hypofluorescence within the tumor (washout effect) (F). A halo of minimal hyperfluorescence surrounds the tumor. This may result from staining of the retinal pigment epithelium or leakage of indocyanine green into the subneurosensory retinal space.

## Choroidal Melanoma

Indocyanine green angiography findings in uveal melanoma are variable.<sup>96</sup> No study revealed any pathognomonic sign with ICG to identify choroidal melanoma.<sup>23,97</sup>

Nevertheless ICGA was found to be capable of identifying tumor vessels (Fig. 2.21),<sup>98,99</sup> which are usually irregularly tortuous, with anarchic branching,<sup>97</sup> dilated with a parallel course,<sup>98</sup> and characterized by vasculogenic mimicry patterns.<sup>100</sup> ICGA was demonstrated to be superior to FA in detecting both tumor borders and vasculature.<sup>97,101</sup>

**FIG. 2.21** A case of choroidal melanoma. Indocyanine green angiography (A) allows visualization of the tumor's intrinsic vasculature with irregular tortuosity and anarchic branching. Note the strong fluorescence within the large choroidal vessels around the lesion, a possible sign of increased flow due to the presence of the tumor. Melanoma intrinsic vessels are leaky by fluorescein angiography (B), and therefore they cannot be identified with this diagnostic tool. In fluorescein angiographic images (B), in the inferior quadrant it is possible to visualize damage to retinal vessels with associated exudative detachment.

Mueller et al. found that different patterns of the microcirculation within the tumor may be useful in the prognosis of the disease.<sup>101</sup> The evidence of microcirculation patterns characterized by networks and a parallel course with cross-linking may be associated with a higher risk of metastatic disease.<sup>101</sup> Other studies reported the possible role of ICGA in evaluating the outcome of brachytherapy,<sup>102</sup> proton beam irradiation,<sup>103</sup> and transpupillary thermotherapy.<sup>104</sup>

### **Peripheral Exudative Hemorrhagic Chorioretinopathy**

Peripheral exudative hemorrhagic chorioretinopathy (PEHCR) is a bilateral peripheral exudative-hemorrhagic retinal degenerative process of the eye.<sup>105,106</sup> The condition is characterized by blood in the subretinal or subretinal pigment epithelial space. PEHCR is most often found in older Caucasian patients and may simulate a

vitreous hemorrhage with suspicion of underlying retinal detachment or break, intraocular inflammatory process, retinal artery macroaneurysm, or choroidal melanoma.<sup>105</sup> In fact, PEHCR often appears as a visible intraocular elevated mass with a mean basal dimension of 10 mm and a mean thickness of 3 mm, consistent with the size of a small to medium-sized melanoma.<sup>106</sup> The lesion is most often located temporally (77%) between the equator and the ora serrata (89%) and involves 1 (46%) or 2 (46%) quadrants.<sup>106</sup> In comparison, eyes with uveal melanoma show tumor location in the macula (5%), between the macula and the equator (78%), and between the equator and the ora serrata (17%).<sup>106</sup>

Many eyes with PEHCR have features of macular or extramacular (peripheral) degeneration such as drusen, RPE alterations, or choroidal neovascularization.<sup>106</sup> The majority of PEHCR lesions spontaneously resolve, leaving RPE atrophy, hyperplasia, and fibrosis. These features imply a bilateral generalized aging process within the eye and are consistent with the degenerative nature of the disease. Although almost half of patients may be asymptomatic, a decrease in visual acuity related to PEHCR may occur in up to 20% of cases.<sup>106</sup> Both for this reason and for the fact that the acute hemorrhagic form is typically mistaken for melanoma, PEHCR deserves an early and proper clinical diagnosis. Fluorescein angiography is of little help because choroidal neovascular lesions are visible in only 3% of cases.<sup>106</sup> This is due to the blockage of choroidal fluorescence related to subretinal hemorrhage, sub-RPE hemorrhage, or RPE hyperplasia. Diffuse peripheral changes consistent with variable degrees of RPE hyperplasia or atrophy are also common FA features.

By contrast, ICGA may clearly delineate the choroidal neovascular process, which is often located at the edges of the blood pool, even in the far periphery. Photodynamic therapy or laser photocoagulation applied to the choroidal new vessels may further accelerate the reabsorption of subretinal blood with decreased risk of subsequent visual acuity loss (Figs. 2.22 and 2.23).

**FIG. 2.22** A case of a midperipheral inferotemporal subretinal hemorrhage. Mid-phase fluorescein angiography showing a hyperfluorescent leaking spot within the hemorrhage (A). To be noted are the diffuse peripheral changes consistent with variable degrees of RPE hyperplasia or atrophy. Indocyanine green angiography (ICGA) 31 seconds after injection (B): the choroidal neovascularization (CNV) is clearly outlined (B, *asterisk*). Six months after laser photocoagulation of the CNV: fluorescein (C) and ICGA reveal fibrosis of the CNV with late staining and no leakage.

**FIG. 2.23** Infrared image of a peripheral temporal subretinal hemorrhage (A). Mid-phase fluorescein angiography showing diffuse peripheral changes consistent with variable degrees of retinal pigment epithelium hyperplasia or atrophy. Typical features of choroidal neovascularization (CNV) are absent (B). Corresponding indocyanine green angiography (ICGA) 2 minutes after injection (C): CNV is clearly visible (*asterisk*) while a second choroidal new vessel is suspected (*circle*). Six minutes after injection, ICGA shows progressive leakage (D). Infrared image 3 months after photodynamic therapy on the two leaking spots: the reabsorption of the subretinal hemorrhage is almost complete (E). Corresponding fluorescein (F) and indocyanine green (G) angiograms reveal persistent obliteration of CNV with no late leakage.

## Varix of the Vortex Vein Ampulla

Varix of the vortex vein ampulla is a rare, benign, asymptomatic condition, which may be confused with a choroidal nevus or melanoma.<sup>107</sup> The choroidal veins drain into an average of four vortex veins, which exit the globe through scleral canals.<sup>108</sup> About half of the vortex veins show dilatations of varying sizes and shapes, and are referred to as vortex vein ampullae. The varix of the vortex vein ampulla is an unusually large dilatation of the vortex vein. The cause remains unclear. The gaze-dependent dynamic nature of the lesion suggested gaze-evoked kinking of the extrascleral vortex vein or narrowing of the scleral canal to be considered as the possible cause.<sup>109</sup> The varix may be enlarged also by factors that increase ocular venous pressure, such as the Valsalva maneuver, head-down positioning, and jugular vein compression.<sup>109</sup> Biomicroscopically, the lesion appears as a smooth red-brown elevation in the equatorial region, usually in the nasal quadrants.<sup>107</sup> It is usually a single lesion but may be bilateral.<sup>109</sup> A proper diagnosis may be achieved by pressure on the globe that readily collapses the varix (Fig. 2.24).<sup>109</sup> ICGA<sup>96,97,110</sup> is particularly useful because it demonstrates the relationship of the varix to the choroidal vasculature and also allows visualization of the pressure and gaze-dependent changes. Relatively early maximum fluorescence and a homogeneous filling pattern may further help differentiate the varix from other choroidal masses.<sup>107</sup>

**FIG. 2.24** Indocyanine green angiography in a case of

varix of the vortex vein in the nasal equatorial region (A). Application of sufficient pressure on the globe readily collapses the varix (B).

## Choroidal Inflammation and White Dot Syndromes

### Multiple Evanescent White Dot Syndrome

Multiple evanescent white dot syndrome (MEWDS) is a unilateral acute disease that affects young women, presenting with a transient, self-limiting visual loss. The disease involves the choroid and the outer retina.<sup>111,112</sup> ICGA shows a pattern of multiple hypofluorescent areas at the posterior pole and peripheral retina. These spots become visible in the mid-late phases, range in size between 50 and 1000  $\mu\text{m}$ ,<sup>112</sup> and are more apparent in ICGA images than by fundus examination and FA<sup>1,112</sup> (Fig. 2.25). In addition, ICGA may show hypofluorescence surrounding the disc area.<sup>111</sup> The hypofluorescent spots disappear at the recovery stage of the disease, and sometimes are more persistent with ICGA.<sup>113</sup>

**FIG. 2.25** A case of multiple evanescent white dot syndrome. Late phases of the fluorescein angiogram reveal only mild alterations at the level of the outer retina and retinal pigment epithelium (A). Early phases of indocyanine green angiography (B) begin to reveal areas of hypofluorescence, which become much more evident in the mid–late phases of the angiogram (C).

## **Multifocal Choroiditis**

In multifocal choroiditis the white lesions are visualized as hypofluorescent spots in ICGA images. These lesions may be followed up with ICGA both in the natural course of the pathology and in the response to treatment with oral prednisone.<sup>114</sup> A reduction in size and number of hypofluorescent spots is observed after successful treatment. Other findings visible on ICGA are hyperfluorescent spots, which usually do not correspond with the hyperfluorescent foci seen on FA, and a large hypofluorescent area surrounding the optic nerve.

## **Birdshot Chorioretinopathy**

This disease is characterized by deep cream-colored dots scattered

diffusely throughout both fundi. The lesions appear as round–oval, hypofluorescent, symmetric dots on ICGA.<sup>115</sup> These lesions are typically not seen by FA, and therefore ICGA may detect birdshot lesions more rapidly than FA.<sup>116</sup> Other findings on ICGA include diffuse ICG hyperfluorescence, predominantly found in the posterior pole in the late phase of angiography, and an alteration of the vascular pattern of the choroid, with choroidal vessels appearing fuzzy and indistinct in the intermediate phase of angiography.<sup>115</sup> In the chronic phase of the disease the hypofluorescent dots persist in the late phases of the angiogram and correspond to RPE atrophy or choroidal granulomas.<sup>1,117</sup>

### **Acute Multifocal Placoid Pigment Epitheliopathy**

ICGA of acute posterior multifocal placoid pigment epitheliopathy (AMPPE) shows areas of hypofluorescence in both early and late phases that correlate with the placoid lesions. These lesions may be caused by choroidal hypoperfusion, secondary to occlusive vasculitis,<sup>118</sup> and ICGA often shows partial or complete resolution throughout the time-course of the disease.<sup>119</sup> New, active and healed, inactive lesions in AMPPE can both be imaged and differentiated using ICG angiography.<sup>120</sup>

### **Serpiginous Choroidopathy**

ICGA allows better staging and identification of active lesions in serpiginous chorioretinopathy.<sup>121</sup> The active phase of the pathology is characterized by hypofluorescent areas with poorly defined margins (Fig. 2.26). These findings can predict the active lesions observed by FA. The presence of late hyperfluorescence in ICGA images represents a sign of choroidal hyperpermeability and may be associated with a more aggressive evolution of the disease. The healed lesions appear hypofluorescent with well-defined margins. The atrophy of the RPE and choriocapillaris allows better identification of large and medium-size choroidal vessels.

**FIG. 2.26** A case of serpiginous chorioretinopathy. The lesion observed by indocyanine green angiography (ICGA) (A) occupies a greater extent than is evident on fluorescein angiography (B). This may indicate a progression of the pathology that can be anticipated or predicted using ICGA.

### **Punctate Inner Chorioretinopathy**

The subretinal lesions observed in punctate inner chorioretinopathy are visualized by ICGA as hypofluorescent areas throughout all the phases of the angiogram.<sup>122</sup> These areas may correspond to localized choroidal hypoperfusion<sup>123</sup> and are greater in number compared to FA.<sup>124</sup> Another finding in ICGA images is the presence of hyperfluorescent points situated close to the vessel wall, representing a possible sign of vasculitis.<sup>123</sup>

### **Acute Zonal Occult Outer Retinopathy**

In acute zonal occult outer retinopathy, ICGA shows a variety of pattern of presentations. Spaide reported that the peripapillary drusenoid material blocks the choroidal fluorescence in ICGA and therefore the involved areas appear hypofluorescent.<sup>125</sup> The secondary atrophy of the choriocapillaris produces hypofluorescence as well, which does not affect the fluorescence from the underlying larger choroidal vessels.<sup>125</sup> In some cases though, ICGA may show an increase of the fluorescence from the affected areas, due to the lack of photoreceptor outer segments and

the minor blocking effect from this layer (Fig. 2.27).

**FIG. 2.27** A case of acute zonal occult outer retinopathy. Autofluorescence shows the typical features of this disorder, with hyperautofluorescent areas around the optic disc. Simultaneous spectral domain optical coherence tomography suggests that these areas (A, *black arrows*) correspond to zones with loss of the outer segments of the photoreceptors (A, *white arrows*), thus resulting in less blockage of the autofluorescence originating from the retinal pigment epithelium. Fluorescein angiography shows increased fluorescence corresponding to these areas (B). Early phase of indocyanine green angiography does not reveal alterations (C), while the late phase of the angiogram allows the affected areas to be distinguished by increased fluorescence (D).

## Chorioretinal Atrophy

ICGA may be of help in the evaluation of the choriocapillaris in different stages of chorioretinal atrophy. The presence of hypocyancence in the late phases of the examination suggests a complete absence of choriocapillaris. This condition, also called “dark atrophy,” is more frequent in Stargardt disease as compared

with nonexudative AMD (Fig. 2.28).<sup>126</sup> In the former there is a complete loss of the choriocapillaris layer whereas in AMD there may be residual areas of patent choriocapillaris in areas otherwise deemed to be atrophic. The presence of residual choriocapillaris in atrophic AMD has been demonstrated by McLeod et al.<sup>127</sup> and Bhutto and Luty.<sup>128</sup> Different pathogenetic mechanisms may be responsible for the distinct ICG appearance in the two diseases but the “dark atrophy” sign is of great help in the differential diagnosis between late-onset Stargardt disease and geographic atrophy.

**FIG. 2.28** Differences apparent on indocyanine green angiography (ICGA) in two cases of chorioretinal atrophy associated with Stargardt disease (SD) (A,B) and nonexudative age-related macular degeneration

(AMD) (C,D). In SD, areas of atrophy visible by fundus autofluorescence (A) appear hypocyanescent in late phases ICGA (B). In AMD areas of atrophy revealed by fundus autofluorescence (C) appear isocyanescent in late-phase ICGA (D).

In summary, despite the changing landscape of retinal disease therapeutics with an increased emphasis on pharmacotherapies and the rise in prominence of noninvasive diagnostic technologies such as optical coherence tomography, indocyanine green angiography remains an important tool in the diagnosis and management of a variety of retinal disorders.

## **Physical Principles of Optical**

# Coherence Tomography

During the past two and a half decades, optical coherence tomography (OCT) has evolved to become an essential tool in ophthalmology. Its ability to noninvasively image detailed ocular structures and associated microvasculature in vivo with high resolution has revolutionized patient care.<sup>1,2</sup> OCT technology is based on the principle of low-coherence interferometry, where a low-coherence (high-bandwidth) light beam is directed on to the target tissue and the scattered back-reflected light is combined with a second beam (reference beam), which was split off from the original light beam. The resulting interference patterns are used to reconstruct an axial A-scan, which represents the scattering properties of the tissue along the beam path. Moving the beam of light along the tissue in a line results in a compilation of A-scans with each A-scan having a different incidence point. From all these A-scans, a two-dimensional cross-sectional image of the target tissue can be reconstructed and this is known as a B-scan. If these B-scans are repeated at multiple adjacent positions using a raster scan pattern, then a three-dimensional volume of structural and flow information can be compiled.

Typically, spectral domain OCT instruments use an infrared light source centered at a wavelength of about 840 nm. For a given wavelength, the axial resolution is dictated by the bandwidth of the light source. The latest commercial instruments typically have an axial resolution of approximately 5  $\mu\text{m}$ , while research instruments have been built with a resolution as high as approximately 2  $\mu\text{m}$ .<sup>1</sup> The lateral resolution is limited by the diffraction caused by the pupil and it is normally about 20  $\mu\text{m}$ . For clinical purposes, the image acquisition time is limited by the patient's ability to avoid eye movements, the availability of scanning techniques to adjust for movements, and the availability of tracking software that adjusts for eye movements. The instrument's scanning speed (number of A-scans acquired per second) is then the crucial parameter determining the amount of data available for a single OCT volumetric dataset.

The early OCT instruments, known as time domain OCT (TD-OCT), used a single photon detector, and an A-scan was created by

moving a mirror to change the optical path of the reference beam in order to match different axial depths in the target tissue. This setup limited the scanning speed to a few thousand A-scans per second. Another more recent technique, known as spectral domain OCT (SD-OCT), Fourier domain OCT (FD-OCT), or high-definition OCT (HD-OCT), is able to acquire an entire A-scan by using an array of detectors instead of using multiple reference beams from a moving mirror. Scanning speeds with SD-OCT instruments can exceed 100,000 A-scans per second, about 200 times faster than TD-OCT. Currently available SD-OCT commercial systems operate at a scanning rates of approximately 27,000–70,000 A-scans per second.<sup>1</sup> A newer OCT imaging technique that had been available only for research, but is now commercially available, is known as swept source OCT (SS-OCT).<sup>3</sup> In SS-OCT, the broadband superluminescent diode light source found in the SD-OCT is replaced with a swept source tunable laser with a center wavelength of about 1050 nm, and the spectrometer from the SD-OCT is replaced with a single detector. The advantages of SS-OCT include faster scanning speeds at 100,000–400,000 A-scans per second and the longer wavelength that provides better visualization of structures and flow beneath the retinal pigment epithelium with less sensitivity roll-off.

The scanning pattern used in the commercial TD-OCT instrument (Stratus OCT, Carl Zeiss Meditec, Dublin, CA) incorporated six radial, concentric, 6-mm-long B-scans centered on the fovea. With the development of high-speed SD-OCT systems, several novel and important imaging strategies have been introduced based on acquiring three-dimensional datasets and B-scan averaging (Fig. 3.1). Three-dimensional datasets are obtained using a dense two-dimensional raster array over a defined retinal region. The resulting datasets can be rendered as a volume image in three dimensions and can be analyzed by showing two-dimensional slices (i.e., sequences of parallel B-scans). Three-dimensional datasets give detailed information about the retinal structure over large areas. In addition, it is possible to generate en face fundus-like images directly from the OCT datasets. These OCT fundus images (OFIs) provide an accurate spatial colocalization of retinal features observed on the en face and cross-sectional images. Therefore, exact

correlations can be achieved between the retinal cross-sectional geometry seen on the OCT B-scans and the retinal landmarks seen on en face images, known as the OFI. The potential exists for registration between several SD-OCT datasets of the same eye and images obtained using other imaging modalities, such as color fundus photography, fluorescein angiography, and fundus autofluorescence imaging. This holds the promise for an unprecedented ability to describe and monitor changes in the local geometry of the retina.<sup>4</sup> In addition to the OFI generated by a full OCT dataset, partial OFIs (or slabs) can be generated to produce en face renderings that correspond to particular retinal layers or features.<sup>5,6</sup> These slabs can be very useful to visualize and quantify specific pathologies (Fig. 3.2). In addition to imaging geographic atrophy, en face imaging of the outer retina has been shown to be useful for predicting the progression of geographic atrophy and for diagnosing and following the progression of macular telangiectasia type 2 and subretinal drusenoid deposits.<sup>7-11</sup>

**FIG. 3.1** Three-dimensional dataset. (Courtesy of Cirrus HD-OCT, Carl Zeiss Meditec, Dublin, CA.)

**FIG. 3.2** (A) Color fundus image of a patient with geographic atrophy secondary to age-related macular degeneration. (B) Optical coherence tomography (OCT) fundus image, which is the en face image from the reflected light from each A-scan, of the same patient obtained with a scan pattern of  $200 \times 200$  A-scans in the Cirrus high-definition OCT instrument. (C) Registration of the color fundus image with the OCT fundus image. Since the area of the OCT fundus image is known to be  $6 \times 6$  mm, it is possible to quantify lesion area and calibrate the fundus camera to use this technique.

The scanning speed of SD-OCT can also be used to produce very high-quality individual B-scan images through a combination of high sampling density and image averaging. One of the main factors affecting the perceived quality of OCT images is noise, in particular the speckle noise which is responsible for the characteristic “granular” appearance of OCT. Noise can be reduced through the acquisition, registration, and averaging of a number of B-scans at approximately the same retinal position (Fig. 3.3).

**FIG. 3.3** Averaging process. (A) Multiple B-scans acquired through the foveal center of a normal patient. (B) The registration and averaging of these B-scans can reduce the speckled noise and improve the image

quality. In these examples the image was averaged 20 times using the Cirrus high-definition optical coherence tomograph.

Although en face registration and B-scan averaging strategies can be implemented in many ways, a particularly powerful and flexible solution is the use of a separate built-in laser eye-tracking system. The main limitation of this approach is that the necessary acquisition times can become very long and sometimes unmanageable, particularly for large raster scans and for subjects with poor fixation. Newer techniques use the image obtained from the scanning laser ophthalmoscopic image that is obtained as part of the routine scanning technique.

Recently, different companies have invested in research in the field of retinal imaging, especially in the development and improvement of SD-OCT. It is not an objective of this section to discuss the differences between each of the currently available instruments since these instruments are continuously evolving. [Table 3.1](#) lists currently available instruments.

**TABLE 3.1**  
**Commercially Available Spectral Domain Optical Coherence Tomography (OCT) Instruments**

Device (Manufacturer)	Axial Resolution; Scanning Rate	Special Characteristics
3D-OCT 2000 (Topcon, Tokyo, Japan)	5 $\mu\text{m}$ ; 27 kHz	Fundus camera
Bioptigen SD-OCT (Bioptigen, Research Triangle Park, NC)	4 $\mu\text{m}$ ; 20 kHz	Designed for research applications, handheld use and intraoperative use
Cirrus HD-OCT (Carl Zeiss Meditec, Dublin, CA)	5 $\mu\text{m}$ ; 27 kHz	Automated en face analysis software with drusen volume and area of geographic atrophy; OCT angiography module available with eye tracking
RTVue-100 (Optovue, Fremont, CA)	5 $\mu\text{m}$ ; 26 kHz	OCT angiography module available with automated retinal vessel density measurements
SOCT Copernicus (Canon, Tokyo, Japan)	6 $\mu\text{m}$ ; 27 kHz	B-scans with color overlay, 3D retinal imaging with anterior segment module
Spectral/Optos OCT SLO	6 $\mu\text{m}$ ; 27 kHz	SLO and microperimetry

(Optos, Dunfermline, UK)		
Spectralis OCT (Heidelberg Engineering, Heidelberg, Germany)	8 $\mu\text{m}$ ; 40 kHz	Eye-tracking, fluorescein angiography, ICGA, autofluorescence
Nidek SD-OCT (Nidek Co Ltd, Maehama Hiroishi Gamagori Japan)	4 $\mu\text{m}$ ; 53 kHz	Eye tracking, SLO

3D, three-dimensional; HD, high-definition; ICGA, indocyanine green angiography; SD, spectral domain; SLO, scanning laser ophthalmoscope; SOCT, spectral optical coherence tomography.

## Quantitative Analysis of OCT Datasets

A crucial step towards a clinically useful, quantitative understanding of the retinal anatomy is the development of accurate, robust, reproducible segmentation algorithms that can automatically identify the boundaries between specific retinal layers and/or other retinal features. The currently available SD-OCT instruments have several advantages over the previous generation of TD-OCT instruments. SD-OCT instruments generally have a higher axial resolution and can produce B-scans with better image quality by increasing the A-scan density and through averaging techniques. Much more importantly, the higher scanning speed made possible by the SD-OCT technology reduces the effect of artifacts associated with eye motion and produces images that provide a true picture of the retinal geometry. The large, dense raster scans make it possible to obtain detailed surfaces of individual retina layers over large areas, resulting in segmentation maps. These maps allow for an unprecedented visualization and quantitative evaluation of the corresponding retinal structures.

Several commercially available SD-OCT instruments offer some level of quantitative analysis using different, proprietary segmentation algorithms. The various segmentation algorithms make different design choices and have been shown to have very different performance profiles in terms of accuracy, reproducibility, and robustness.<sup>12-15</sup> Care should be exercised when comparing measurements obtained from different OCT instruments.

The most commonly used quantitative parameter derived from OCT datasets is retinal thickness, obtained by segmenting the internal limiting membrane (ILM) and a boundary representing the retinal pigment epithelium (RPE). This information can be used to generate surface maps of the ILM and the RPE as well as two-dimensional and three-dimensional retinal thickness maps. These maps can be very useful in identifying and describing deviations from the normal anatomy and changes over time. Registering OCT datasets acquired over time can give very precise information about the dynamics of disease progression and response to treatment based on changes in retinal anatomy (Fig. 3.4).

**FIG. 3.4** Segmentation process. (A) B-scan through the foveal center of a normal patient with a yellow line identifying the internal limiting membrane (ILM) and a red line corresponding to the retinal pigment epithelium (RPE). Three-dimensional map of the ILM (B), RPE (C), and the retinal thickness map (D) acquired with a  $200 \times 200$  scan pattern with the Cirrus high-definition optical coherence tomography instrument.

It is important to keep in mind that there is some confusion in the definition of the outer retinal boundary. In a normal eye, the bright reflective band at the external aspect of the retina, often referred to

as the RPE complex, can be resolved in ultrahigh-resolution images, and occasionally in images acquired with a commercially available SD-OCT instrument, consisting of three individual layers.<sup>16</sup> Different segmentation algorithms from different instruments tend to follow different borders and therefore result in different measurements. For example, the Spectralis SD-OCT instrument typically follows the posterior surface of the RPE complex, the Stratus TD-OCT instrument typically follows Band #2, also known as the ellipsoid zone or inner segment–outer segment (IS/OS) junction, which is anterior to the RPE complex, and the Cirrus SD-OCT instrument typically follows the anterior edge of the RPE layer (Fig. 3.5). This situation becomes even more complicated and sometimes inconsistent when the normal retinal structure is deformed by the presence of pathology.<sup>17</sup>

**FIG. 3.5** Differences in segmentation and retinal thickness maps between instruments. The B-scan identifying the internal limiting membrane (yellow line), and the retinal pigment epithelium (red line), and the retinal thickness map acquired with the Cirrus high-definition optical coherence tomograph (A–C) and the Spectralis (D–F). Note that, using the Cirrus instrument, the segmentation algorithm identifies the actual retinal pigment epithelium (B) and using the Spectralis the segmentation algorithm identifies Bruch's membrane. This subtle difference in the segmentation algorithm between each instrument can be responsible for different retinal thickness measurements.

In addition to total retinal thickness, a number of other quantitative parameters have been proposed. For example, it is

possible to obtain measurements of particular retinal layers, such as the thickness of the ganglion cell layer or the thickness of the photoreceptors' outer segments, as well as measurements of retinal lesions, like the area of geographic atrophy (GA).<sup>16,18-20</sup>

An area of particular promise is the measurement of RPE deformations associated with drusen.<sup>21-23</sup> These measurements are obtained by comparing the actual RPE geometry with the geometry of a virtual RPE free of deformations. Parameters like drusen area and volume can be generated in a fully automated manner and have been shown to be quite robust and reproducible (Fig. 3.6).

**FIG. 3.6** Retinal pigment epithelium (RPE) deformation algorithm. (A) Color fundus image of a patient with drusen. A 6×6-mm white box was superimposed on the image to represent the scan area. (B) B-scan from the spectral domain optical coherence tomography dataset that corresponds to the central line on the color fundus image. (C) B-scan with a yellow line representing the RPE segmentation and a red line showing the RPE floor (virtual map of the RPE free of deformations). (D) En face image of the 6×6-mm scan pattern (optical coherence tomography fundus image). (E) Three-

dimensional RPE map delineating the drusen conformation. (F) RPE elevation map with drusen area (1.41 mm<sup>2</sup>) and volume (0.08 mm<sup>3</sup>).

The amount of information provided by each dataset, together with the possibility for image registration and longitudinal studies, makes SD-OCT a valuable tool for the quantitative study of retinal pathologies. Despite the advantages of SD-OCT, segmentation algorithms can produce artifacts, particularly in the presence of macular disorders with complex morphology like neovascular age-related macular degeneration (AMD).<sup>24-28</sup> Therefore, it is important to be vigilant and monitor the quality of the segmentation in order to eliminate artifacts arising from flawed segmentation and associated measurements.

## Normal Macular Anatomy

The OCT image closely approximates the histologic appearance of the macula and, for this reason, it has been referred to as an *in vivo* optical biopsy. With the increase in the axial resolution of the new SD-OCT instruments (5–8 μm) and the ultrahigh-resolution OCT (2 μm), it has become possible to correlate OCT images accurately with histologic features of the retina.<sup>29</sup> However, care must be taken when making assumptions about these correlations because histologic sections require fixation and exogenous staining to produce contrast within tissue, and this can introduce artifacts, while OCT relies on intrinsic differences in tissue optical properties to produce image contrast.<sup>30</sup> When light travels through the retinal tissue it can be reflected, scattered, or absorbed, and this creates the multilayered pattern of the retina. The angle of incidence of the light, motion artifacts, speckled noise, and image contrast can affect the axial resolution of the retinal imaging. Therefore, one-to-one correspondence of histology with OCT images cannot be expected.<sup>2,30</sup>

Although the interpretation of features of the retina, which can be defined for our purpose to span from the ILM to the outer segments of the photoreceptors appears to correlate well with histology, the OCT features of the outer retina are less well understood and

remain a topic of discussion (Fig. 3.7)<sup>16,31-34</sup>

**FIG. 3.7** Spectral domain optical coherence tomography (Spectralis, Heidelberg) image of a normal individual. The multilayered retinal architecture can be observed and each retinal layer can be identified.

(Reproduced with permission from Staurengi G, Sadda S, Chakravarthy U, Spaide RF, International Nomenclature for Optical Coherence Tomography P. Proposed lexicon for anatomic landmarks in normal posterior segment spectral-domain optical coherence tomography: the IN\*OCT consensus. *Ophthalmology* 2014 Aug;121(8):1572-8)

The first detected layer in most OCT scans is the ILM that appears as a hyperreflective layer at the vitreoretinal interface. In some patients, the posterior hyaloid can be seen above the ILM as a hyperreflective layer. Within the retina, the retinal nerve fiber layer and the plexiform layers (both inner and outer) are seen as hyperreflective while the ganglion cell layer and the nuclear layers (both inner and outer) are relatively hyporefective. A recent study demonstrated that the incidence of the light beam could affect the appearance of Henle fiber layer by OCT, resulting in a thin hyperreflective layer corresponding to the photoreceptor synapses or a thicker hyperreflective layer corresponding to photoreceptor

axonal extensions enveloped by the outer cytoplasm of Müller cells (Fig. 3.8).<sup>35</sup> The retinal vessels may sometimes be seen on OCT images as circular hyperreflective structures located in the inner retina, with a vertical shadow or reduced reflectivity extending into deeper layers.

**FIG. 3.8** Spectral domain optical coherence tomography of the same patient using a different light incidence. This results in a thin hyperreflective layer that corresponds to the photoreceptor synapses (*white arrow*) or a thicker hyperreflective layer corresponding to photoreceptor axonal extensions enveloped by the outer cytoplasm of Müller cells (*white asterisk*).

Outside the central fovea, commercially available SD-OCT instruments typically resolve four bands in the outer retina. There is discordance between different authors regarding which anatomic structure correlates with each band.<sup>29,30,36</sup> The innermost band has been attributed to the external limiting membrane (ELM). This band is typically thinner and fainter than the others. The nomenclature for the middle two bands has much less supportive evidence. The second of the four bands has been commonly ascribed to the boundary between the IS/OS photoreceptors, but a recent consensus meeting suggested that this band correlates with the inner segment ellipsoid zone (EZ), although this interpretation is not universally accepted.<sup>33,34</sup> The third band is referred to as either the OS tips or as Verhoeff membrane.<sup>16,37</sup> This third band appears to correspond to the contact cylinder between the RPE apical process and the external portion of the cone outer segment, and has been suggested

to be called the interdigitation zone by the recent consensus meeting.<sup>33</sup> This band typically merges with the fourth band in the central fovea, and this is explained by a greater height of the contact cylinder of the cones and RPE outside the fovea.<sup>36</sup> The fourth hyperreflective outer retinal band is attributed to the RPE, with potential contribution from Bruch's membrane and choriocapillaris, with abundant experimental and clinical evidence supporting this designation.<sup>16,31,38</sup>

Although the current SD-OCT uses a short wavelength of approximately 840 nm, which results in light scattering at the level of the RPE and a lower signal from the deep choroidal tissue, it is also possible to image the choroid and extract quantitative information (Fig. 3.9).<sup>39-42</sup> Choroidal thickness may be influenced by age, axial length, and perhaps refractive abnormalities.<sup>43</sup> It also varies in different retinal regions within the same normal subject, being thickest beneath the fovea,<sup>42</sup> or in the superior outer macula (Early Treatment Diabetic Retinopathy Study (ETDRS) subfield), with the thinnest choroid being located in the nasal outer ETDRS subfield.<sup>44</sup> When centering the optic nerve head as a reference point, the choroid appears thin in the peripapillary region and increases in thickness with eccentricity in all directions, up to a certain point, except inferiorly.<sup>44</sup> This is the embryonic location of the optic fissure closure and thus may be responsible for the localized thinning.<sup>44,45</sup> OCT that uses a light source with a wavelength around 1050 nm can better visualize the posterior choroid and sclera than currently available SD-OCT instruments.<sup>41,45,46</sup>

**FIG. 3.9** Enhanced-depth spectral domain optical

coherence tomography image (Spectralis, Heidelberg)  
of a normal subject showing the boundaries of the  
choroid (*arrowheads*).

The high axial resolution and the different scan patterns offered by SD-OCT provide comprehensive structural information that can be used to map retinal layer thicknesses and perform volumetric analyses. Using different SD-OCT instruments, several authors have reported an approximate central retinal thickness of 265  $\mu\text{m}$  in normal subjects.<sup>47</sup> However, caution is required, as errors in automated measurements may occur and are more often found in macular disorders with complex morphology like neovascular AMD, which alters the ability of segmentation algorithms to detect normal boundaries.<sup>24-28</sup> Therefore, care must be taken that high-quality and artifact-free scans are obtained before running the retinal thickness algorithm.

It is essential to consider the following points when analyzing OCT images: location, shape, and reflectivity of the structure, along with its histologic correlation. It is also important to remember that the alignment of the instrument with the pupil can generate signals that may lead to a misinterpretation of the exam.

Characteristic OCT findings in several common retinal disorders, which are frequently studied using OCT, are discussed below. For OCT findings in other disorders, such as retinal degenerations, the reader is directed to the specific chapters describing these diseases.

## **SD-OCT in Retinal Disorders**

### **Vitreoretinal Interface Disorders**

Abnormalities of the vitreoretinal interface are involved in the pathogenesis of several macular conditions. In idiopathic epiretinal membranes (ERMs), a layer of fibrotic tissue develops on the surface of the retina, usually after a posterior vitreous detachment. Contraction of this membrane can result in retinal distortion, leading to vision loss. In other conditions, such as vitreomacular traction (VMT) syndrome or idiopathic macular hole, there are abnormal attachments between the vitreous and the retina. The resulting traction exerted on the retina causes anatomical alteration

and subsequent visual loss.

## Vitreomacular Adhesion

Vitreomacular adhesion (VMA) syndrome results from persistent vitreoretinal attachments in the setting of a partial posterior vitreous detachment.<sup>48</sup> In normal eyes, as the vitreous liquefies due to age, it detaches from the macula. This natural progression has been demonstrated using OCT.<sup>49</sup> In some people, an unusually strong adhesion is present between the vitreous and macula, and as the vitreous detaches peripherally, it continues to pull on areas of the macula. The vitreoretinal adhesions transmit tractional forces to the retina from the vitreous body, having the potential to cause tensile deformation, foveal cavitations, cystoid macular edema (CME), limited macular detachment, or a macular hole.<sup>50,51</sup> Patients can present with visual loss and metamorphopsia.

Diagnosis of VMA by biomicroscopy may be challenging, particularly when the area of vitreoretinal attachment is broad. OCT better defines the vitreoretinal relationships in eyes with VMA and also documents concomitant ERM and macular edema.<sup>52-56</sup> With OCT imaging, the abnormal VMA bands from the prominent posterior hyaloid are well delineated as reflective lines from the perifoveal area into the vitreous cavity, distorting the macular contour with or without accumulation of intraretinal or subretinal fluid (Fig. 3.10).

**FIG. 3.10** Vitreomacular traction syndrome: color fundus image of the left eye of a 71-year-old woman superimposed with the retinal thickness map (A) showing an increase in the retinal thickness (red areas). The B-scan of the macular region shows an increase in the retinal thickness and the presence of subretinal fluid and intraretinal cysts due to vitreomacular traction and an epiretinal membrane (B). A three-dimensional spectral domain optical coherence tomography is presented in panel (C) (courtesy of Cirrus, Carl Zeiss Meditec). The patient underwent surgery and, 2 months after pars plana vitrectomy, the retinal thickness decreased, with resolution of the intraretinal cysts (D–F).

In recent years, OCT has been most beneficial in diagnosing VMA and subsequently directing treatment of this condition. In fact, vitreomacular abnormalities, including vitreomacular adhesion, traction, and macular holes, have recently been reclassified primarily on the basis of OCT.<sup>57</sup> This current scheme includes OCT-based assessment of vitreous traction, measurement of the size of the hole and whether the hole is primary or secondary, all of which are related to the medical and surgical prognosis. According to this International Classification System, VMA is defined on OCT as “perifoveal vitreous separation with remaining vitreomacular attachment and unperturbed foveal morphologic features.” Vitreomacular traction, on the other hand, is defined by “anomalous posterior vitreous detachment *accompanied by anatomic distortion of the fovea.*” Pseudocysts, cystoid macular edema, macular schisis, and subretinal fluid are typical findings of VMT. Both VMA and VMT can be further subclassified as having focal (1500  $\mu\text{m}$  or less) or broad (more than 1500  $\mu\text{m}$ ) vitreoretinal attachment. Generally, pharmacologic vitreolysis may be indicated for focal but not broad VMT.

OCT also allows detailed assessment of structural changes in the retina associated with vitreomacular adhesion or traction. This allows for a more accurate visual prognosis, obtained by the tomographic integrity of the photoreceptor layer, specifically the inner/outer photoreceptor cell junction/ellipsoid zone, as well as the integrity of the external limiting membrane.

In some cases, spontaneous resolution can occur with separation of the vitreous from the macula, leading to subsequent resolution of the intraretinal and subretinal fluid and restoration of normal vision.<sup>58,59</sup> However, in most eyes, VMA leading to VMT persists and vitrectomy or ocriplasmin may be effective treatment options for patients with symptomatic VMT.<sup>52,60–62</sup> Consequently, OCT is useful in monitoring subtle changes in the retinal architecture and in assisting with the treatment decision-making process.

## Macular Hole

Idiopathic macular holes typically occur in the sixth to seventh decade of life with a 2 : 1 female preponderance. Symptoms include decreased visual acuity, metamorphopsia, and central scotoma. Bilateral involvement occurs in 15–20% of patients.<sup>30</sup>

A full-thickness defect in the neural retina as seen with OCT can differentiate a true macular hole from a pseudohole seen clinically. Pseudoholes are seen in the presence of a dense sheet of ERM with a central defect that overlies the foveal center, giving the ophthalmoscopic appearance of a true macular hole.<sup>30,63</sup>

Gass described the stages of macular hole formation based on biomicroscopic findings, and this traditional staging system is still widely used in clinics and in the literature.<sup>64</sup> A stage 1 impending hole is characterized by a foveal detachment seen as a yellow spot (1A) or ring (1B) in the fovea (Fig. 3.11A). Spontaneous resolution will occur in approximately 50% of these cases. In stages 2–4, there is a full-thickness retinal defect, with a complete absence of neural retinal tissue overlying the foveal center. What differentiates these stages is the size of the retinal defect (<400  $\mu\text{m}$  in stage 2 and >400  $\mu\text{m}$  in stage 3) or the presence of a complete posterior vitreous detachment regardless of the hole size (stage 4) (Fig. 3.11B).

**FIG. 3.11** Macular hole. (A) Stage 1 macular hole in a 63-year-old woman with a 3-month history of decreased visual acuity (20/60). An outer retinal defect can be observed in the B-scan (*arrow*). (B) A full-thickness retinal defect developed after 2 months of follow-up with worsening in the visual acuity (20/80). The posterior vitreous remains adhered to the edge of the macular hole. (C) One month after surgery, the macular hole was closed and the visual acuity improved to 20/50, but a persistent foveal outer defect could be observed (*arrowhead*).

OCT has enhanced our understanding of the pathogenesis of macular holes, the healing process after surgical repair, and helped in identifying pre- and postoperative features that are related to visual outcome. The anatomic changes identified on OCT have been correlated with the various stages of macular hole. In stage 1A, patients usually present with a localized foveolar detachment, which can resolve spontaneously after posterior vitreous detachment with resolution of the yellow foveal spot, or it can

progress to stage 1B with a development of a pseudocyst with loss of the outer retinal layers and later develop into a full-thickness macular hole.<sup>65,66</sup> Generally, the retinal defect is accompanied by a variable amount of intraretinal fluid appearing as cysts and a variable amount of subretinal fluid at the edge of the hole. The edge of the hole can appear elevated, as a result of the significant intraretinal fluid accumulation or due to persistent vitreofoveal traction. In a stage 4 macular hole, OCT can demonstrate complete hyaloid separation and occasionally a retinal operculum can be seen floating above the foveal center.

The changes noted on OCT have become the basis for a new classification system of macular holes proposed by the International Vitreomacular Traction Study Group.<sup>57</sup> This classification divides macular holes based on the cause, size of the hole, and the presence or absence of vitreomacular adhesion. Full-thickness macular holes can be either primary (if caused by VMT) or secondary (if caused by other conditions unrelated to abnormal vitreoretinal traction), and can be further subclassified by the size of the hole measured on SD-OCT. Based on the minimum horizontal aperture size (hole width), macular holes are divided as follows: small holes measure 250  $\mu\text{m}$  or less; medium size holes are between 250  $\mu\text{m}$  and 400  $\mu\text{m}$ , and large holes are larger than 400  $\mu\text{m}$ . Holes are also further subclassified by presence or absence of vitreomacular adhesion. This classification is of clinical importance because it determines the management and prognosis of macular holes.

According to the OCT-based classification, Gass Stage 0 macular hole corresponds to vitreomacular adhesion in the setting of a history of full-thickness macular hole in the contralateral eye. A Stage 1 macular hole corresponds to vitreomacular traction, a stage 2 or 3 macular hole corresponds to a small, medium, or large hole on the OCT-based classification with vitreomacular adhesion present, and a stage 4 macular hole corresponds to a small, medium or large-sized macular hole with release of the vitreomacular adhesion.

Vitrectomy has become the standard treatment for macular hole with anatomic success rates of 85–100%.<sup>67,68</sup> OCT can be used to confirm complete macular hole closure and restoration of the normal foveal contour.<sup>69–72</sup> In cases with suboptimal postoperative

visual outcomes, OCT can visualize persistent retinal abnormalities despite anatomically successful macular hole surgery (Fig. 3.11C). Restoration of the ELM and the so-called junction of the inner and outer segment of photoreceptors may reflect the morphologic and functional recovery of the photoreceptors in surgically closed macular holes.<sup>71-74</sup> A residual small defect in the ELM is often still evident in closed holes, particularly in those that are spontaneously healed. The ability to perform OCT imaging in eyes filled with gas or silicone oil has also been useful as an adjunct to determine the extension of the face-down position in patients following vitrectomy for macular hole.<sup>75-77</sup>

## **Epi-retinal Membrane**

ERM occurs in approximately 6% of patients over the age of 60, with incidence increasing with age.<sup>78,79</sup> ERMs can be classified as idiopathic or secondary to an initiating event. Most idiopathic ERMs are thought to result from fibroglial proliferation on the inner surface of the retina secondary to a break in ILM occurring during posterior vitreous detachment.<sup>80,81</sup> Secondary ERMs result from an already-existing ocular pathology such as central or branch retinal vein occlusion, diabetic retinopathy, uveitis, and retinal breaks with or without detachment.<sup>82</sup> Glial cells, RPE cells, and myofibroblasts are shown to be mostly involved in ERM formation.<sup>80,81</sup> ERM may lead to loss of normal retinal anatomy, with the patient experiencing metamorphopsia, micropsia, monocular diplopia, and decreased visual acuity. These symptoms vary in severity depending on the location, density, and contraction of the membrane.

On slit-lamp biomicroscopy, a mild ERM appears as a glistening layer on the retinal surface. Denser membranes may be seen as a gray sheet overlying the retina and causing distortion in the macular vascular architecture. Occasionally, ERMs can evolve into macular pseudoholes and ERMs are often seen in conjunction with idiopathic full-thickness macular holes.<sup>50</sup> Fluorescein angiography may demonstrate macular leakage, which can be variable from case to case.

OCT provides qualitative and quantitative information about the retinal anatomy, which can identify factors contributing to vision

loss in patients with ERM. On OCT, ERMs are seen as a highly reflective layer on the inner retinal surface (Fig. 3.12). In most eyes, the membrane is globally adherent to the retina but, in some cases, it can be separated from the inner aspect of the retina, which enhances its visibility by OCT. In this situation, it is usually distinguishable from a detached posterior hyaloid. Secondary effects of the membrane include loss of the normal foveal contour, increased retinal thickness, and the presence of cystoid changes – these features may be observed in more advanced membranes. OCT is useful for monitoring changes in cases that are being observed and for documenting the response to treatment in patients undergoing pars plana vitrectomy with membrane peeling.

**FIG. 3.12** Epiretinal membrane – color fundus image of the left eye of a 65-year-old man with grayish tissue over the retina (A). Cross-sectional optical coherence tomography image showing a hyperreflective tissue overlying the retina, resulting in increased retinal thickness and cysts in the retina (B and C).

## Age-Related Macular Degeneration

AMD is a common cause of irreversible vision loss among the elderly worldwide. It is estimated that approximately 30% of adults older than 75 years have some sign of AMD and that approximately 10% of these patients have advanced stages of the disease.<sup>83–86</sup> AMD can be classified in two forms: non-neovascular (dry) and neovascular (wet or exudative). The non-neovascular form accounts for 80–90% of cases while the neovascular form accounts for 10–20% of cases, but was responsible for the majority of severe vision loss (80–90%) prior to the widespread use of vascular endothelial growth factor (VEGF) inhibitors.<sup>85,87</sup>

## Non-Neovascular Age-Related Macular Degeneration

Non-neovascular (dry) AMD is characterized by abnormalities of the RPE, Bruch's membrane, and choriocapillaris (see [Chapter 68](#), Age-related macular degeneration: non-neovascular early AMD, intermediate AMD, and geographic atrophy). These abnormalities may be asymptomatic or accompanied by compromised vision, and are considered to be the precursors of GA and choroidal neovascularization (CNV).<sup>88,89</sup>

### Early Non-Neovascular AMD: Drusen and Pigmentary Changes.

Drusen appear clinically as focal white–yellow excrescences deep to the retina. They vary in number, size, shape, and distribution. Several strategies have been developed to grade drusen using color fundus imaging.<sup>90,91</sup> Although color fundus imaging is useful for assessing the appearance of drusen, these images only provide two-dimensional area information on the geometry of the drusen and cannot be used to measure quantitative properties such as drusen volume. Until the advent of high-speed spectral domain technology, evaluation of drusen with OCT was often difficult as motion artifacts commonly resulted in apparent undulation of the RPE, mimicking the appearance of drusen.<sup>92,93</sup> SD-OCT can provide a three-dimensional, geometric assessment of drusen.

The high-definition B-scans obtained with SD-OCT are useful to assess the ultrastructure of drusen and to evaluate for evidence of disruption of adjacent retinal layers. Drusen are seen as discrete areas of RPE elevation with variable reflectivity, which is consistent with the variable composition of the underlying material ([Fig. 3.13](#)).<sup>94,95</sup> In larger drusen or drusenoid retinal pigment epithelial detachments (PEDs), the RPE has a greater elevation with a dome-shaped configuration.<sup>96</sup> Larger drusen may often become confluent and can sometimes be accompanied by fluid accumulation under the retina in the absence of CNV ([Fig. 3.14](#)).<sup>94</sup> Recognition of this feature may avoid unnecessary treatment with anti-VEGF drugs. SD-OCT imaging has the resolution to evaluate the retinal layers overlying drusen. A thinning in the photoreceptor layer can be observed in up to 97% of cases, with average photoreceptor layer thickness reduced by 27% compared to age-matched control eyes.

The inner retinal layers usually remain unchanged. These findings demonstrate a degenerative process, with photoreceptor loss leading to visual impairment.<sup>97</sup>

**FIG. 3.13** Early non-neovascular age-related macular degeneration. (A) Color fundus image of the right eye of a 61-year-old man with drusen and pigmentary changes in the macula. (B) Foveal B-scan showing the drusen as elevations of the retinal pigment epithelium (RPE). The inner and outer segment junction of the photoreceptors adjacent to the drusen appears disrupted (*arrow*). (C) Fundus autofluorescence illustrating that drusen cannot be reliably identified by this imaging modality. (D) RPE segmentation map showing drusen in a unique three-dimensional perspective. (E) RPE elevation map providing the drusen area ( $1.37 \text{ mm}^2$ ) and volume ( $0.063 \text{ mm}^3$ ).

**FIG. 3.14** Drusenoid retinal pigment epithelium detachment (DPED). (A) Color fundus image of the right eye of a 66-year-old man with a DPED and pigmentary changes in the macula. (B) Foveal B-scan showing the confluent drusenoid material as a large elevation of the retinal pigment epithelium (RPE). Intraretinal pigment migration can be observed (*arrow*). (C) Fundus autofluorescence image (Heidelberg retina angiograph, Heidelberg). (D) RPE segmentation map showing the DPED in a three-dimensional perspective. (E) RPE elevation map providing the DPED area ( $3.87 \text{ mm}^2$ ) and volume ( $0.508 \text{ mm}^3$ ).

The acquisition of dense raster scans comprised of a large number of lower-density B-scans combined with the use of segmentation algorithms results in the ability to generate maps of the RPE, which provides information on RPE geometry and therefore a unique perspective of drusen. A novel algorithm developed to identify RPE deformations such as drusen has been shown to be highly reproducible in the measurement of drusen area and volume.<sup>21</sup> The algorithm creates a drusen map from a scan pattern of 40,000 uniformly spaced A-scans organized as 200 A-scans in each B-scan and 200 horizontal B-scans, covering an area of  $6 \times 6 \text{ mm}$  centered in the fovea. The algorithm uses the actual RPE geometry and compares this RPE map to a virtual map of the RPE free of any deformations (RPE floor). The algorithm creates a

difference map from these two maps, which permits reproducible measurements of drusen area and volume (Fig. 3.6). This algorithm was used to study the natural history of drusen in AMD.<sup>22</sup> Drusen were shown to undergo three different growth patterns. In most eyes, drusen were found to increase in volume and area. Drusen could also remain stable or they could dramatically decrease over time. When these drusen decreased, they could evolve into GA or neovascular AMD, or they could decrease with in no apparent residual anatomic defect in the macula.

The RPE cells are capable of hypertrophy and proliferation in response to different stimuli and in many cases an intraretinal pigment migration may occur (Fig. 3.14B). The Age-Related Eye Disease Study research group reported a severity scale defining large drusen ( $\geq 125 \mu\text{m}$ ) and pigment abnormality in the macula as being a risk factor for disease progression in patients with intermediate AMD.<sup>98,99</sup> This pigmentary abnormality can be observed on OCT imaging as small discrete hyperreflective lesions within the neurosensory retina, usually within the outer nuclear layer.<sup>100</sup> Recently, these hyperreflective lesions were noted to precede the development of retinal angiomatous proliferation.<sup>101</sup>

Typical drusen in AMD are seen as deposits between the RPE and the inner collagenous layer of Bruch's membrane. OCT imaging is also useful for the assessment of a variety of conditions characterized by variant forms of drusen. These deposits can also be seen on top of the RPE and are known as "subretinal drusenoid deposits."<sup>102,103</sup> They appear on OCT imaging as granular hyperreflective material between the RPE and the IS/OS junction and are also well visualized on blue-light reflectance imaging and autofluorescence imaging (Fig. 3.15).

**FIG. 3.15** Subretinal drusenoid deposits. (A) Color fundus image of a 76-year-old woman shows multiple yellowish, small, and round lesions. (B) Fundus autofluorescence clearly shows these deposits as small and multiple hyperautofluorescent spots. (C) On optical coherence tomography, these lesions appear as multiple areas of granular hyperreflectivity between the retinal pigment epithelium and the inner/outer-segment junction (*arrows*).

Another form of drusen, known as “cuticular drusen,” appears as numerous, uniform, round, yellow–white punctuate accumulations under the RPE. Cuticular drusen are usually seen on OCT imaging as elevations of the RPE with occasional disruption of the overlying IS/OS junction and ELM.<sup>95</sup> Although cuticular drusen, subretinal drusenoid deposits, and soft drusen are composed of common components, they are distinguishable by multimodal imaging because of differences in location, morphology, and the optical properties of the drusenoid material and the RPE.

### Late Non-Neovascular AMD: Geographic Atrophy.

The natural history of GA has been described as a progressive condition that evolves through stages with loss of vision occurring over many years.<sup>104-106</sup> Multiple imaging modalities have been used to document and quantify the area of GA. Until recently, color fundus photography was used as the standard method to image GA; however, the use of color photos can be challenging due to the reported difficulty in detecting and accurately delineating GA.<sup>106,107</sup> Other imaging modalities such as fluorescein angiography, fundus autofluorescence, and SD-OCT imaging are now used to evaluate and quantify GA (Fig. 3.16). Although these imaging modalities provide different information, none has been shown to be superior to the other.

**FIG. 3.16** Geographic atrophy (GA). (A) Color fundus image of the left eye of a 74-year-old male with central GA secondary to age-related macular degeneration. (B) Fundus autofluorescence (Spectralis, Heidelberg) showing a central area of hypoautofluorescence corresponding to the GA seen on the color image. (C) Late-phase fluorescein angiography showing a central window defect corresponding to the GA. (D) Horizontal B-scan through the foveal center demonstrating retinal

thinning, loss of the retinal pigment epithelium (RPE), and photoreceptors. The loss of photoreceptors (*yellow arrows*) often extends beyond the margins of the RPE loss (*white arrows*). Observe the increased light penetration in the areas where the RPE is absent (*bracket*) and thin choroid (*arrowhead*). (E) Optical coherence tomography fundus image (courtesy of Cirrus, Carl Zeiss Meditec), showing the GA as a bright area.

GA is seen clinically as one or more well-demarcated areas of hypopigmentation or depigmentation due to the absence or severe attenuation of the underlying RPE. The larger, deeper choroidal vessels are more readily visualized through the atrophic areas, and are accompanied by varying degrees of photoreceptor and choriocapillaris loss. Associated retinal atrophy is seen as thinning or loss of the outer nuclear layer and the absence of ELM and IS/OS junctions.<sup>108,109</sup> The loss of photoreceptors often extends beyond the margins of GA, with the ELM and IS/OS junctions disappearing while bridging across the GA margin.<sup>110</sup> Evaluation of these junctional zones may provide information about the pathogenesis of GA, and the role of RPE, photoreceptor, and choriocapillaris loss in the initiation and propagation of this condition.<sup>110</sup> SD-OCT has been shown to be useful in detecting some of these morphologic alterations ([Fig. 3.16D](#)).

With the use of SD-OCT enhanced-depth imaging (EDI) protocols, it is now possible to visualize the structure of the choroid in greater detail.<sup>40</sup> EDI demonstrated that subfoveal choroidal thickness decreases with age and axial length.<sup>42</sup> In a subset of elderly patients complaining of unexplained vision loss, abnormal choroidal thinning was identified, and this condition was named “age-related choroidal atrophy.”<sup>111</sup> Future studies are necessary to confirm if this represents a new clinical entity or a subtype of AMD. In contrast, the choroidal thickness appears to be unaffected in early non-neovascular AMD patients.<sup>112</sup>

SD-OCT can also be used to quantify the areas of GA and monitor the progression of the disease. GA is currently imaged with SD-OCT by using the OFI, which represents a virtual fundus image resulting from the en face summation of the reflected light from

each A-scan. This en face OCT fundus image identifies GA as a bright area due to the increased penetration of light into the choroid where atrophy has occurred in the macula. The absence of the RPE and choriocapillaris is responsible for this increased penetration of light associated with GA. The OFI was shown to correlate well with the GA seen on clinical examination, color fundus imaging, and autofluorescence imaging (Fig. 3.16E).<sup>19,113,114</sup> More recently, a newer algorithm provides an enhanced (partial) OFI, which is the summation of the reflected light from beneath the RPE (Fig. 3.17). In addition, this new algorithm is able to quantify the area of GA automatically. The enhanced OFI has advantages over the conventional OFI because the area of GA appears brighter than in the conventional OFI due to a better contrast at the boundaries of the lesions and there is less interference from other macular pathologies such as ERMs.

**FIG. 3.17** Geographic atrophy (GA). (A) Horizontal B-scan through the foveal center of a 73-year-old man with GA showing increased light penetration in the areas where the retinal pigment epithelium (RPE) is absent. *White arrow* shows the junction where the RPE is present and absent. (B) Optical coherence tomography (OCT) fundus image represents a virtual fundus image resulting from the en face summation of the reflected light from each A-scan. GA lesions are identified as a bright area due to the increased penetration of light into the choroid where atrophy has occurred. (C) Enhanced OCT fundus image (courtesy of Cirrus, Carl Zeiss Meditec), which represents the summation of the reflected light from beneath the RPE (*red lines and arrows* in panel A).

## Neovascular AMD

The neovascular (wet) form of AMD is characterized by the overproduction of VEGF and the growth of abnormal vessels in the macular region (see [Chapter 69](#), Neovascular (exudative or “wet”) age-related macular degeneration). These vessels may arise from the choroidal circulation and penetrate Bruch's membrane to form a fibrovascular tissue beneath or above the RPE, or these vessels may arise primarily from the retinal circulation. In either case, the presence of VEGF and abnormal vessels leads to structural changes in the retina and choroid with the accumulation of fluid within the retina, in the subretinal space, or under the RPE. Furthermore, this neovascular invasion may lead to significant disorganization and remodeling of the retina, resulting in the loss of the RPE and photoreceptors with the formation of a disciform scar.<sup>115,116</sup>

## Intraretinal and Subretinal Fluid

In cases suspicious for exudative changes, OCT imaging can be extremely useful in detecting intraretinal, subretinal, or sub-RPE fluid. In cases with active neovascular AMD, OCT imaging can be used to establish baseline retinal thickness and volume, and determine the extent of neovascularization, fluid involvement, and other lesion components (blood, fluid, pigment, and fibrosis).

The growth of neovascularization is often accompanied by VEGF-

dependent leakage from both the mature vessels and the growing immature vessels. Intraretinal edema can range from mild retinal thickening of the outer nuclear layer to large and diffuse cystoid edema, seen as round or oval hyporeflective areas (Fig. 3.18).<sup>30</sup> Lipid exudation can also be present in patients with profuse intraretinal edema and appear as small hyperreflective dots in the outer retina. The fluid may also accumulate in the space between the RPE and the neurosensory retina. The subretinal fluid appears on OCT imaging as homogeneous hyporeflective spaces when the fluid exudation is serous, or may be separated by fibrinous membranes when profuse proteinaceous exudation is present.<sup>117</sup> Usually, neovascular lesions growing in the subretinal space are associated with a larger volume of subretinal fluid compared with sub-RPE lesions.<sup>118</sup>

**FIG. 3.18** Neovascular age-related macular degeneration. (A) Color fundus image of the right eye of an 81-year-old man with a 1-month history of vision loss. Visual acuity was 20/100. (B) Horizontal B-scan through the foveal center showing retinal thickening and the presence of intraretinal fluid with large cysts. (C) Retinal thickness map (courtesy of Cirrus, Carl Zeiss Meditec) showing the increase in retinal thickness (*red areas*). After three intravitreal injections of anti-vascular endothelial growth factor, the intraretinal fluid was reabsorbed (D). This is better observed in the B-scan and retinal thickness map (E,F).

## Retinal Pigment Epithelium Detachment

In wet AMD, a retinal PED is formed by the separation of the RPE from Bruch's membrane due to the presence of sub-RPE fluid, blood, or fibrovascular tissue. A serous PED is defined as an area of smooth, sharply demarcated dome-shaped elevation of the RPE, often yellow–orange in color with a reddish halo of subretinal fluid. On fluorescein angiography, serous PEDs are associated with early hyperfluorescence with a well-defined border, which increases gradually throughout the study and classically demonstrates a pooling of dye rather than leakage.<sup>119,120</sup> Serous PEDs can be categorized as vascular or avascular.<sup>121</sup> On OCT imaging, serous PEDs appear as a dome-shaped elevation of the RPE typically seen overlying a homogeneously hyporeflective space, bound inferiorly by a visible Bruch's membrane, which is seen as a thin hyperreflective line at the outer aspect of the PED (Fig. 3.19).<sup>122,123</sup> The appearance of vascularized serous PEDs is similar. However, in some cases, the apparent fibrovascular proliferation can be seen adjacent to the PED and even adherent to the outer surface of the RPE.

**FIG. 3.19** Vascularized serous retinal pigmented epithelium detachment (PED). (A) Color fundus image of the left eye of a 77-year-old woman with pigmentary changes in the macula associated with an elevation of the macula. (B) Horizontal B-scan through the fovea showing a dome-shaped retinal pigment epithelium (RPE) elevation overlying a homogeneous hyporeflective space. Observe the presence of subretinal fluid above the PED. (C) RPE segmentation map showing a three-dimensional perspective of the PED. (D) RPE elevation map showing the area (5.84 mm<sup>2</sup>) and volume (0.83 mm<sup>3</sup>) measurements of the PED.

The fibrovascular PED usually produces an irregularly elevated lesion visible on clinical examination and can be associated with RPE hyperpigmentation, subretinal hemorrhage, subretinal lipid exudation, and intra- or subretinal fluid collection.<sup>124</sup> The elevation is often low and the borders are ill defined. The detailed structural characteristics and precise mechanism of PED formation have not been completely resolved. Recent studies using SD-OCT imaging revealed that many of the fibrovascular PEDs appear to be filled with solid layers of material of medium reflectivity, separated by hyporeflective clefts (Fig. 3.20).<sup>125</sup>

**FIG. 3.20** Fibrovascular retinal pigmented epithelium detachment (PED). Cross-sectional B-scan of the right eye of an 87-year-old woman with a fibrovascular PED.

The space below the retinal pigment epithelium is filled with solid layers of medium reflectivity separated by hyporeflective clefts. A small amount of subretinal fluid can be identified over the PED (*arrow*).

Hemorrhagic PEDs occur when a CNV membrane bleeds into the sub-RPE space or as a result of an RPE tear. The hemorrhage can invade the subretinal space, with the sub-RPE blood having a typically darker appearance than subretinal blood. OCT demonstrates a dome-shaped lesion, similar to serous PEDs, although the slope of the elevation is more acute and the blood under the RPE appears hyperreflective, attenuating the signal from deeper structures, with the loss of choroidal detail (Fig. 3.21).<sup>122,124,126</sup>

**FIG. 3.21** Hemorrhagic retinal pigmented epithelium detachment (PED). (A) Color fundus image of the right eye of a 65-year-old woman with a large subretinal pigment epithelium (RPE) hemorrhage secondary to neovascular age-related macular degeneration. (B) Optical coherence tomography demonstrates a dome-shaped lesion, similar to serous PEDs. The blood under the RPE appears hyperreflective, attenuating the signal from deeper structures. Subretinal fluid can be observed as hyporeflective spaces above the RPE (*arrows*).

In addition, the same algorithm used to measure drusen can be used to measure PEDs, since both involve the deformation of the RPE. This algorithm is able to measure both the area and volume of PEDs (Fig. 3.19D). In addition, algorithms may be developed to characterize the internal architecture of the PEDs automatically.<sup>127</sup>

The qualitative appearance of the B-scans and the qualitative and quantitative changes in the retinal thickness maps and RPE elevation map can be used to appreciate better the natural history of the disease and to monitor the effect of anti-VEGF therapy in patients with PEDs associated with wet AMD.

## **Tear of the Retinal Pigment Epithelium**

RPE tears are most commonly seen in association with CNV secondary to AMD, especially when a PED is present.<sup>128,129</sup> RPE tears may also be associated with central serous chorioretinopathy (CSC), trauma, as well as other causes of CNV.<sup>130,131</sup> Although RPE tears can occur spontaneously in AMD patients, they have also been related temporally to various treatments for AMD, such as verteporfin photodynamic therapy and intravitreal injection of anti-VEGF agents.<sup>132-136</sup> Hemodynamic factors play a role in the pathogenesis of the tear. The RPE layer is put on stretch as a result of accumulating sub-RPE fluid, and this stress leads to a tear in the RPE. A sheet of RPE cells then contracts and scrolls up upon itself in a radial fashion, leaving an area of retina without underlying RPE.<sup>129,137</sup> Subretinal and sub-RPE hemorrhages frequently accompany an RPE tear, which appears ophthalmoscopically as an area of well-demarcated hyperpigmentation immediately adjacent to an area of relative hypopigmentation.

On OCT imaging, an area of discontinuity in a large PED is often seen, with the free edge of the RPE often curled under the PED. Adjacent to the tear, there is increased reflectivity from the choroid vessels, due to the absence of the RPE. The overlying retina is typically intact, but may be separated from the area of atrophy by subretinal fluid.<sup>129</sup> The tear tends to occur at the base of the PED, near or at the intersection of attached and detached retina (Fig. 3.22).<sup>128</sup> During anti-VEGF therapy, the height of the PED and the irregular surface contour may help in predicting the risk for RPE tear, which may also occur without treatment as part of normal disease progression.<sup>138,139</sup> The visual outcome in patients with RPE tears is generally poor when the fovea is involved.

**FIG. 3.22** Retinal pigment epithelium (RPE) tear. (A) Color image of the right eye of an 81-year-old man with an area of relative hypopigmentation that corresponds to the RPE tear. (B) Heidelberg fundus autofluorescence showing hypoautofluorescence in the area where the RPE is absent. (C) On the B-scan there is an area of discontinuity of the RPE near the base of the pigmented epithelium detachment with the free edge of the RPE curled under the pigmented epithelium detachment (*arrow*).

### Disciform Scarring

Disciform scarring and subretinal fibrosis mark the endstage of CNV. The vascular components of CNV typically regress as the lesion becomes less active, and the fibrous components typically increase, resulting in disciform scar formation. Clinically the scar appears as smooth, elevated white or gray tissue in the subretinal

space, and on OCT imaging the scar corresponds to a highly reflective outer retinal or subretinal lesion (Fig. 3.23).<sup>30</sup> Scar formation may be associated with loss of the overlying photoreceptor layer and irreversible reduction in visual acuity. This may be observed on OCT imaging as a disruption of the IS/OS junction and ELM.<sup>140,141</sup> In this stage of the disease, the OCT is very helpful in identifying the presence of subretinal fluid or intraretinal cysts that are associated with the neovascular activity of the lesion, and may help in making the retreatment decision.

**FIG. 3.23** Disciform scar. (A) Color fundus image of the left eye of an 80-year-old woman with a white-grayish tissue involving the macula. (B) Horizontal B-scan with a large hyperreflective lesion under the retina (*arrow*).

## Retinal Angiomatous Proliferation

The term “retinal angiomatous proliferation” was introduced by Yannuzzi and coworkers to describe a form of neovascularization in AMD patients, which arises from within the retina with possible formation of a retinochoroidal anastomosis as the disease progresses.<sup>142</sup> Whether the development of the retinochoroidal anastomosis is a result of a primary intraretinal neovascularization or a sub-RPE lesion remains controversial.<sup>142,143</sup> Recently, studies with SD-OCT imaging concluded that the initial neovascular process could originate from either the retinal or choroidal circulation; however, histopathologic studies suggest that all the neovascularization is within the retina.<sup>144,145</sup> On OCT imaging, the most common feature is the presence of a serous PED with CME

overlying the PED (Fig. 3.24).<sup>144,146,147</sup> An intraretinal hyperreflective angiomatous complex consistent with the intraretinal neovascularization and subretinal fluid may also be seen.<sup>142</sup> A recent analysis of the natural evolution of RAP lesions (also termed Type 3 neovascularization), revealed that pigment migration typically precedes the development of RAP, leading to the hypothesis that elaboration of angiogenic factors from migrated RPE may be important in the initiation of these lesions.<sup>101</sup>

**FIG. 3.24** Retinal angiomatous proliferation. (A) Color fundus image of the right eye of a 90-year-old woman with a history of blurred vision and metamorphopsia for 2 weeks. Visual acuity was 20/40. Fundus examination revealed multiple drusen, pigmentary changes, and hemorrhage inferior to the fovea with a subtle elevation of the retina. (B) Fundus autofluorescence demonstrates hypoautofluorescence in the area corresponding to the hemorrhage. (C) Fluorescein angiography demonstrates a focal area of leakage inferior to the fovea. (D) Late-phase indocyanine green angiography reveals a hot spot. (E) B-scan through the lesion reveals a retinal pigment epithelium detachment (*arrow*) with cystoid macular edema overlying the pigmented epithelium detachment.

## Polypoidal Choroidal Vasculopathy

Polypoidal choroidal vasculopathy is considered a variant form of CNV characterized by the presence of multiple vascular saccular dilations (polyps) in the choroidal circulation that manifests clinically with variably sized serous and serosanguineous detachments of the neurosensory retina and RPE, usually around the optic nerve or in the central macula.<sup>148</sup> Indocyanine green angiography (ICGA) is particularly useful in imaging the polypoidal abnormalities seen in polypoidal choroidal vasculopathy, with a branching vascular network of vessels ending in polyp-like structures.<sup>149</sup> SD-OCT images can demonstrate the polypoidal structure beneath the RPE, which remains adherent to the RPE, even with increased exudation. It is especially useful to detect the abnormalities surrounding the polypoidal lesions such as intraretinal, subretinal, and sub-RPE fluid.<sup>150,151</sup>

## Choroidal Neovascularization: Response to Treatment

The combination of clinical examination, fluorescein angiography, OCT images, and, less frequently, ICGA is usually required to diagnose neovascular AMD and exclude other macular conditions that can mimic the features of neovascular AMD.<sup>152</sup> With the use of anti-VEGF drugs the ideal strategy for following eyes with wet AMD has evolved from monthly injections to OCT imaging to determine whether the treatment is effective in resolving the macular fluid.<sup>153,154</sup> Many alternative treatment regimens have used OCT-guided strategies, with good visual and anatomical results with fewer intravitreal injections compared with monthly dosing.<sup>155-159</sup> The macular fluid can be identified by examining the B-scans and reviewing the retinal thickness maps, which calculate the retinal thickness between the ILM and the RPE segmentation maps. The effect of anti-VEGF therapy can then be assessed based on the qualitative appearance of the B-scans and the qualitative, as well as quantitative, changes in the retinal thickness maps (Figs. 3.18 and 3.25). The presence or recurrence of intraretinal or subretinal fluid has to be differentiated from the appearance of “outer retinal tubulation” since the latter represents a

rearrangement of photoreceptors in response to injury and RPE loss and is usually present in patients with chronic and advanced neovascular AMD (Fig. 3.26). Importantly, this tubulation does not respond to anti-VEGF therapy.<sup>160</sup> In patients with PEDs, the area and volume of the lesion can be assessed and used to monitor the effect of anti-VEGF therapy in patients with wet AMD associated with PEDs, and an increase in the area and volume of PEDs could be used to indicate when retreatment is necessary.

**FIG. 3.25** Neovascular age-related macular degeneration (response to treatment). Color fundus image, horizontal B-scan, and retinal thickness map of the right eye of a 65-year-old man with wet age-related macular degeneration before (A–C) and after (D–F) a single treatment with intravitreal anti-vascular endothelial growth factor. Observe the improvement of the intraretinal fluid and cysts in the B-scans (B,E) and the decrease in retinal thickness (C,F).

**FIG. 3.26** Outer retinal tubulation: a 67-year-old woman with wet age-related macular degeneration who has received 13 intravitreal injections over the last 2 years. The foveal horizontal B-scans before (A) and after the last (B) treatment are presented. The larger intraretinal cyst present in the image before treatment (*arrowhead*) disappeared after treatment. The small cyst (*arrow*) showed no response to the intravitreal injection of anti-vascular endothelial growth factor. This smaller cyst corresponds to an outer retinal tubulation which is frequently present in patients with chronic and advanced neovascular age-related macular degeneration.

## Central Serous Chorioretinopathy

CSC is an idiopathic syndrome that typically affects young to middle-aged males and is characterized by serous detachment of the neurosensory retina. Focal and multifocal areas of leakage secondary to increased permeability of the choroidal vessels and a barrier defect at the level of the RPE have been described in the pathogenesis of this disorder.<sup>161-163</sup>

Presenting symptoms include central vision loss, a decrease in vision that can be corrected with an increased hyperopic correction, metamorphopsia, central scotoma, and decreased color saturation. The symptoms are usually self-limited but can recur in the same or the opposite eye. In most cases, CSC resolves spontaneously within 6 months, with a good visual prognosis. However, prolonged and recurrent macular detachment in some cases may cause degenerative changes in the subfoveal RPE and neurosensory retina with poor visual outcome.<sup>164,165</sup>

The primary pathology of acute CSC is thought to begin with disruption of the choroidal circulation. The RPE then decompensates, and exudation from the choroidal vasculature passes into the subretinal space. These hypotheses were based on fluorescein angiography and ICGA findings.<sup>162,166-169</sup> The development of OCT imaging has provided a better understanding of CSC, especially the abnormalities in the RPE layer.<sup>170-174</sup>

There are two forms of the disease, acute and chronic. Acute CSC (Fig. 3.27) is classically unilateral and characterized by one or more focal leaks at the level of the RPE on fluorescein angiography. The chronic form (Fig. 3.28) is believed to be due to diffuse RPE disease and is usually bilateral. It presents with diffuse RPE atrophic changes, varying degree of subretinal fluid, RPE alterations, and RPE tracks. It is characterized by diffuse RPE leakage on fluorescein angiography.

**FIG. 3.27** Acute central serous chorioretinopathy. (A) Color photo shows a well-defined, circular area of retinal elevation. (B) Fluorescein angiography shows an area of hyperfluorescence with “smokestack” leakage. (C) Retinal thickness map shows elevation of the retina. (D) Spectral domain optical coherence tomography (OCT), horizontal, acquired through the fovea, shows serous detachment of the neurosensory retina above an optically clear, fluid-filled cavity, associated with a pigment epithelial detachment. The retinal pigment epithelium detachment corresponds to the area of hyperfluorescence seen on the angiogram. (E–H) Follow-up visit 1 month later. (E) Color photo shows resolution of the retinal elevation in the area of the fovea but illustrates a well-defined, circular area of retinal elevation inferior to the fovea (*small arrow*). (F) Fundus autofluorescence shows a well-defined, circular area of retinal elevation inferior to the fovea involving the inferior arcade (*small arrow*). (G) Retinal thickness map shows decrease in the thickness of the retina in the fovea. (H) Spectral domain OCT, horizontal B-scan acquired through the fovea, shows decrease in the amount of subretinal fluid.

**FIG. 3.28** Central serous chorioretinopathy. (A) Color photo shows a well-defined, circular area of retinal elevation: white line represents the location of the B-scan. (B) Fundus autofluorescence shows an area of hyperfluorescence. (C,D) Fluorescein angiography shows an inkblot appearance that leaks later. (E) Spectral domain optical coherence tomography shows serous detachment of the neurosensory retina associated with an irregular, granulated retinal pigment epithelial layer and sagging/dipping of the posterior layer of the neurosensory retina (*asterisk*).

OCT imaging is helpful in diagnosing and managing patients with CSC. OCT imaging can noninvasively identify the presence and extent of subretinal fluid and PEDs. OCT imaging is also useful for assessing the resolution of subretinal fluid and the morphologic retinal changes during normal disease progression. OCT is more sensitive than clinical exam and fluorescein angiography in identifying small amounts of subretinal fluid.<sup>175</sup> OCT is useful in predicting the recovery of visual acuity and explaining poor visual outcomes even after the resolution of the fluid. With SD-OCT imaging, topographic changes in CSC can be visualized with two- and three-dimensional reconstructions. SD-OCT also offers the ability of exact localization of the pathology and accurate volumetric measurements.<sup>176</sup>

OCT features of acute CSC include thickening of the neurosensory retina within the area of retinal detachment, PED, the presence of fibrinous exudates in the subretinal space, and the

shaggy outer segments of the neurosensory retina above the leakage site. OCT features of the chronic form include foveal atrophy, retinal thinning, and cystoid degenerative changes.<sup>171,172,177-181</sup> OCT can also visualize the subretinal yellow deposits as highly reflective material. Precipitates are not only on the posterior surface of the detached retina but also in the detached neurosensory retina. Photoreceptor segment morphologic changes along the detached retina show elongation of the photoreceptor outer segments and decreased thickness of the outer nuclear layer.<sup>182</sup> Accumulation of abnormal outer segments in the neurosensory retina is related to clinical manifestation on OCT as a granulated shaggy profile of the outer surface of the detached retina.<sup>183</sup>

En face OCT imaging has been found to detect alterations of the RPE in the form of a PED or a small defect in the RPE. Most alterations of RPE are associated with choroidal abnormalities.<sup>174</sup> OCT imaging has been found to detect morphologic changes at the point of dye leakage in eyes with CSC. Transverse images (C-scans) have shown serous retinal detachments and irregular lesions of the RPE. These findings, along with other findings on B-scans and segmentation maps, are consistent with location of lesions in areas of fluorescein angiographic leakage.<sup>184,185</sup>

Visual prognosis in patients with CSC can be linked to retinal morphologic changes by OCT.<sup>186,187</sup> Mastsumoto et al. correlated the visual outcome with the preservation of outer nuclear layer thickness and continuity of photoreceptor IS/OS in resolved CSC. The outer nuclear layer thickness was positively correlated with visual acuity. Discontinuity of the IS/OS line was prevalent in eyes with thinner outer nuclear layer and lower visual acuity.<sup>187</sup> Ojima et al.<sup>186</sup> reported that microstructural changes occur in the photoreceptor layer of the detached retina and the visualization of the ELM and the photoreceptor layer correlates with visual function. Foveal thickness can be a predictor of visual outcome in patients with CSC.<sup>178</sup> Both foveal thickness and visual acuity have been observed to be proportional to the duration of symptoms, Foveal attenuation, and atrophy, which may be a consequence of prolonged absence of contact between photoreceptor and RPE cells.<sup>175</sup>

## Enhanced-Depth Imaging OCT in CSC

Conventional SD-OCT has a limited ability to image the choroid because of scattering by the pigment granules within the RPE and by the pigment and blood within the choroid, and because of a depth-dependent roll-off in sensitivity of SD-OCT instruments in general.<sup>40</sup> A method to improve imaging of the choroid, known as EDI OCT, showed that eyes with CSC had a much thicker choroid compared with normal eyes (Fig. 3.29).<sup>188</sup> Fellow eyes of patients with CSC were also found to have thicker choroids compared with age-matched normal eyes.<sup>189</sup> Maruko et al. reported a thickened choroid in CSC and the association with choroidal vascular hyperpermeability on ICG angiography.<sup>190</sup>

**FIG. 3.29** Central serous chorioretinopathy. (A) Color photo of the right eye shows area of retinal elevation with pigmentary changes; white line represents the position of B-scan. (B) Fundus autofluorescence shows an area of hyperfluorescence and hypofluorescence. (C) Spectral domain optical coherence tomography (SD-OCT), enhanced depth imaging, shows serous detachment of the neurosensory retina along with pigmented epithelium detachment, retinal pigment epithelial alterations, granulated posterior detached retina, and thick choroid (*arrowheads* represent the outer boundary of the choroid). (D) Color photo of the left eye shows pigmentary changes without retinal elevation; white line represents location of B-scan. (E) Fundus autofluorescence shows an area of hyperfluorescence and hypofluorescence. (F) SD-OCT, enhanced depth imaging, demonstrates a thick choroid (*arrowheads*

represent the boundary of the choroid) without serous detachment of the neurosensory retina.

Verteporfin photodynamic therapy is one of the therapies used to treat leakage and subretinal fluid in eyes with CSC. Maruko et al.<sup>190</sup> reported that eyes treated with focal laser showed no alteration in choroidal thickness even though there was fluid reabsorption, but eyes treated with verteporfin photodynamic therapy showed a decrease in choroidal thickness by SD-OCT imaging and a decrease in choroidal hyperpermeability seen during ICG angiography. The changes occurring in the choroid after photodynamic therapy may reflect a more normalized choroidal permeability.

## Cystoid Macular Edema

CME is an important cause of reduced visual acuity in a wide variety of retinal diseases such as diabetic retinopathy, retinal vein occlusion, CNV, retinal dystrophies, uveitis, and following intraocular surgery. Regardless of the underlying etiology, CME appears as retinal thickening with intraretinal cavities of reduced reflectivity on OCT (Fig. 3.30).

**FIG. 3.30** Cystoid macular edema. Left eye of a 64-year-old man 30 days after phacoemulsification. The visual acuity was 20/50. (A) Color fundus image with some cystic changes: white line represents where the B-scan was acquired. (B,C) Fluorescein angiography showing the classic petaloid leakage pattern. (D) B-scan showing the intraretinal cysts as hyporeflective spaces within the retina. (E) Retinal thickness map showing increased retinal thickness due to the presence of cysts. (F,G) Same patient after 45 days of treatment with topical nonsteroid anti-inflammatory medication. The retinal thickness decreased and the intraretinal cysts disappeared. ILM, internal limiting membrane; RPE, retinal pigment epithelium.

Clinically significant pseudophakic CME is estimated to occur in 1–2% of patients undergoing cataract extraction.<sup>191,192</sup> Inflammatory

components induced by surgery along with mechanical forces induced by a modified vitreous are responsible for the macular changes in these patients.<sup>193,194</sup> The diagnosis based only on fundus examination can be challenging, and usually fluorescein angiographic imaging, which shows a classic petaloid pattern of leakage, or OCT imaging is needed for confirmation. OCT has the advantage of being a faster and noninvasive imaging technique, which can also provide quantitative assessment of the macular thickness that can be used to monitor the clinical course and to make therapeutic decisions.

## Diabetic Retinopathy

Diabetic retinopathy is the leading cause of blindness in individuals under 65 years of age in the United States, with diabetic macular edema (DME) being the principal cause of vision loss in these patients.<sup>195,196</sup> Diabetic retinopathy can be classified into nonproliferative diabetic retinopathy (NPDR) and proliferative diabetic retinopathy (PDR).

### Nonproliferative Diabetic Retinopathy and Diabetic Macular Edema

The important role of OCT in DME management involves the evaluation of retinal pathology, including retinal thickness, CME, intraretinal exudates, vitreomacular interface abnormalities, subretinal fluid, and photoreceptor IS/OS junction abnormalities. OCT is also important in monitoring the response to treatment of DME by laser, intravitreal pharmacotherapies, and vitreoretinal surgery.

Diagnosis of macular edema can be difficult with biomicroscopy or color fundus imaging, especially when the edema is mild.<sup>197-199</sup> It has been suggested that OCT measurements may be a more sensitive and reproducible indicator of true change in retinal thickness than color fundus imaging, supporting the use of OCT as the principal method for documenting retinal thickness. However, OCT is less suitable than fundus imaging for documenting the location and severity of other morphologic features of diabetic retinopathy, such as hard exudates, retinal hemorrhages,

microaneurysms, and vascular abnormalities. Furthermore, OCT cannot provide information on overall retinopathy severity, for which color photographs remain the gold standard.<sup>200–203</sup>

OCT can be used to distinguish patients with normal retinal contour and thickness despite extensive angiopathy from those with early retinal edema. In general, the DME can be classified into several categories: diffuse retinal thickening, CME, serous retinal detachment or subretinal fluid, and vitreomacular interface abnormality.<sup>204–206</sup> Diffuse retinal thickening is usually defined as a sponge-like swelling of the retina with a generalized, heterogeneous, mild hyporeflectivity compared with normal retina. CME is characterized by the presence of intraretinal cystoid areas of low reflectivity, which are typically separated by highly reflective septa (Fig. 3.31). Serous retinal detachment is defined on OCT as a focal elevation of neurosensory retina overlying a hyporeflective, dome-shaped space. The posterior border of the detached retina is usually highly reflective, which helps to differentiate subretinal from intraretinal fluid. Vitreomacular interface abnormalities include the presence of ERMs, VMT, or both. Intraretinal focal hyperreflections that correspond clinically to retinal exudates are a frequent finding in all the patterns described above.

**FIG. 3.31** Diabetic macular edema. Right eye of a 43-year-old woman with type 2 diabetes and moderate nonproliferative diabetic retinopathy. (A) B-scan and

(B) retinal thickness map showing diffuse macular edema and the presence of intraretinal cysts with an increased retinal thickness. (C) B-scan and (D) retinal thickness map of the same patient after 3 months of intensive blood sugar control and focal laser therapy.

The intraretinal cysts disappeared and the retinal thickness map shows an important decrease in the retinal thickness.

OCT has become widely accepted in monitoring progression and treatment response in patients with DME. Prior to OCT imaging, precision in central retinal thickness monitoring was not possible. The ETDRS provided guidelines for laser management of patients with DME.<sup>207-209</sup> Although OCT was not available for use in this study, quantitative retinal thickness maps can be used to direct laser therapy and may be better than using biomicroscopy alone. In the era of pharmacotherapy, many agents like triamcinolone and anti-VEGF agents (ranibizumab and bevacizumab) have been studied to treat DME. In these studies, OCT played an important role in determining the retinal thickness and the treatment response.<sup>210,211</sup> The treatment response of each OCT pattern of DME has been shown to be different.<sup>212</sup> Patients with diffuse retinal thickening may achieve a greater reduction in retinal thickness and a greater improvement in visual acuity compared with patients exhibiting CME, subretinal fluid, or vitreomacular interface abnormality.<sup>212,213</sup>

Macular traction has become increasingly recognized in patients with DME, especially in eyes with persistent edema after focal laser or pharmacologic treatment. These patients often show the clinical appearance of a thick posterior hyaloid with diffuse fluorescein leakage. Recognition of this condition can be difficult using the clinical exam alone. This is readily recognized on OCT imaging as diffuse cystoid retinal thickening, a flat-appearing foveal contour, and a thickened hyperreflective linear vitreoretinal interface. Focal vitreoretinal adhesions that cannot be identified on clinical exam are also often evident on OCT.<sup>214,215</sup> These findings can direct the decision as to whether to proceed with pars plana vitrectomy and membrane peeling.<sup>216</sup>

Furthermore, the improvement in axial resolution with SD-OCT

has enhanced the ability to evaluate foveal microstructural abnormalities, including the photoreceptor IS/OS junction or EZ, which may reveal damage to macular photoreceptors. Several studies have demonstrated that an intact IS/OS junction or EZ is predictive of a better visual acuity in patients after treatment for DME.<sup>217-219</sup>

## Proliferative Diabetic Retinopathy

PDR can be visualized with OCT imaging as highly reflective preretinal bands anterior to the retinal surface consistent with preretinal fibrovascular or fibroglial proliferation. Diffuse retinal thickening, distortion, and irregularity of the retinal contour can also occur as a result of the contraction of these preretinal membranes. An associated traction retinal detachment may be observed as well. OCT imaging is valuable in determining the extent of the tractional component as well as the presence of foveal involvement, assisting in the decision to intervene surgically (Fig. 3.32).<sup>30</sup> The decision for surgery typically hinges on the progressive nature of the traction and the degree to which the macula is affected by the traction.

**FIG. 3.32** Diabetic retinal tractional detachment. (A) Color fundus image of the right eye of a 72-year-old woman with proliferative diabetic retinopathy. (B) Foveal B-scan of the same patient showing a thick posterior hyaloid distorting the retinal architecture with traction and accumulation of fluid under the retina.

## Retinal Vein Occlusion

Retinal vein occlusions have been defined as retinal vascular disorders characterized by engorgement and dilatation of the retinal veins with secondary, mostly intraretinal, hemorrhages and mostly intraretinal (and partially subretinal) fluid, retinal ischemia, including cotton-wool spots, and retinal exudates.<sup>220</sup> Retinal vein occlusions are commonly divided into central retinal vein occlusion and branch retinal vein occlusion, and as soon as the foveal region is involved with macular edema, central visual acuity may be affected.

In retinal vein occlusions, OCT can display intraretinal cysts responsible for the increase in retinal thickness often associated with serous detachment of the neurosensory retina. Retinal cysts can be numerous and confluent, forming large central cystoid spaces. Associated findings can be observed, such as vitreous macular adherence, ERM, and hyperreflectivity of the posterior layer corresponding to atrophy or fibrosis of the RPE, subretinal accumulation of material, subretinal fibrosis, lamellar macular hole formation, intraretinal lipid exudates, and intraretinal hemorrhage (Fig. 3.33).

**FIG. 3.33** Central retinal vein occlusion. (A) Color

photo of the right eye shows optic nerve head edema, dilated tortuous retinal veins, scattered intraretinal hemorrhages in all quadrants, and macular edema: white line represents the location of the B-scan. (B) Spectral domain optical coherence tomography (SD-OCT) obtained through the fovea illustrates loss of normal foveal contour and marked and diffuse retinal thickening. Large areas of low intraretinal reflectivity consistent with cystic fluid accumulation and edema were seen. A detachment of the neurosensory retina with subretinal fluid was observed below the fovea. (C) Color photo of the right eye 1 month after bevacizumab injection shows dilated tortuous retinal veins and scattered intraretinal hemorrhages in all quadrants: white line represents area of B-scan. (D) SD-OCT, 1 month after bevacizumab injection obtained through the fovea, shows that macular edema almost completely disappeared with a small amount of residual subretinal fluid. Improvement in the normal foveal contour and decrease in the retinal thickening and edema. Areas of high intraretinal reflectivity consistent with the hemorrhages.

Ota et al. reported that, in branch retinal vein occlusion, visual function and recovery of vision are correlated with thickness of the central macula, and that is correlated with the integrity of the inner and outer segments of the photoreceptors in the fovea.<sup>221</sup> SD-OCT imaging helps to quantify the amount of CME. The accumulation of fluid can be located mostly within the retinal layers or additionally in the subretinal space.<sup>222</sup> Anti-VEGF therapy is increasingly used to treat macular edema in patients with retinal vein occlusions. Nevertheless, a significant proportion of eyes retain poor visual acuity despite treatment. Several studies have shown that low visual acuity has been associated with a poor functional outcome after treatment or during the natural course (Fig. 3.34). SD-OCT can help predict visual acuity based on the integrity of the neurosensory retina.

**FIG. 3.34** Branch retinal vein occlusion. (A) Color photo of the right eye shows dilated tortuous retinal veins, flame-shaped hemorrhages in an arcuate configuration in the distribution of inferotemporal branch retinal vein occlusion, and macular edema. (B) Retinal thickness map showing increase in retinal thickness. (C,D) Spectral domain optical coherence tomography (SD-OCT) horizontal and vertical scan respectively obtained through the fovea revealed that marked retinal thickening, areas of low intraretinal reflectivity consistent with cystic fluid accumulation, and edema were identified, especially in the outer plexiform layer. High reflectivity is noted in the inner layers from intraretinal hemorrhage. (E) Retinal thickness map 1 month after bevacizumab injection, showing decrease in retinal thickness. (F,G) SD-OCT horizontal and vertical scan respectively, 1 month after bevacizumab injection, obtained through the fovea showed complete resolution of macular edema, improvement in foveal contour, and decrease in retinal thickening.

## Central Retinal Artery Occlusion

Central retinal artery occlusion shows a distinct pattern on OCT images. In the acute phase, OCT images demonstrate the increased reflectivity and thickness of the inner retina and a corresponding decrease of reflectivity in the outer layer of the retina and RPE/choriocapillaris layer. Follow-up OCT images demonstrate a decrease in the reflectivity and thickness of the inner retinal layers and a corresponding increase of reflectivity in the outer retina and RPE/choriocapillaris layer compared with the baseline OCT image, suggesting a generalized atrophy of the neurosensory retina as a late finding. Therefore, the use of OCT may help facilitate prompt

recognition of acute and chronic central retinal artery occlusion. In patients with central retinal artery occlusion, OCT images closely correspond with known histopathologic changes. Histology following acute central retinal artery occlusion shows retinal changes limited to the nerve fiber and ganglion cell layers. There are profound losses of ganglion cells and diffuse edema of the inner retinal layers with little change seen in the deeper retinal layers supplied by choroidal vessels. OCT images provide an in vivo view of the retinal structure following central retinal artery occlusion. Increased reflectivity of the inner retina, presumably because of opacification of the ganglion cell and nerve fiber layers, corresponds to previously described histologic findings of “cloudy swelling” of these layers. Attenuation of reflectivity in the outer layer of the retina and the RPE/choriocapillaris layer is due to the ganglion cell and nerve fiber changes allowing less light reflected back from the outer portions of the retina. Further evidence of this phenomenon is at the foveal depression where the ganglion cell layer is absent. As more light is allowed through the fovea, the RPE/choriocapillaris layer directly beneath the fovea shows a relative increase in reflectivity compared with the other regions of the RPE/choriocapillaris. An additional finding on OCT imaging is the thinning and atrophy in the affected area of the retina, which occurs after a period of time (Fig. 3.35).<sup>223</sup>

**FIG. 3.35** Central retinal artery occlusion. (A) Color photo of the left eye shows cherry-red spot appearance, retinal opacity of posterior fundus, most marked in the parafoveal region, and a small area of normal retina temporal to the optic disc corresponding to the patent cilioretinal retinal artery. (B) Spectral

domain optical coherence tomography horizontal scan through the fovea illustrates increased thickness and hyperreflectivity of the inner retinal layers, denoting the presence of intracellular edema, with decreased reflectivity of photoreceptor and retinal pigment epithelial layers because of the shadowing effect.

## Branch Retinal Artery Occlusion

Branch retinal artery occlusions are usually embolic in nature. The embolic source is either a carotid artery atheroma or myocardial thrombus. The embolus usually lodges at the bifurcation of the central retinal artery into the branch retinal artery.

Histopathologically, acute branch retinal artery occlusions reveal ischemia in the corresponding retinal quadrant marked by inner retinal edema at the initial stage followed by atrophy in longstanding cases. SD-OCT imaging shows the edematous inner retina, comprising the inner nuclear layer, inner plexiform layer, and ganglion cell layer, as a hyperintense band with increased thickness, which is contrasted by the normal reflectivity and thickness of the corresponding layers of the unaffected macular regions. Prolonged ischemia results in consecutive atrophy of these layers with each layer exhibiting differential sensitivity to the underlying hypoxia. Animal experiments have revealed retinal ganglion cells to be relatively resistant to the ischemia compared to the other retinal neurons.<sup>224</sup> Similar findings in vivo using SD-OCT imaging revealed the relative preservation of ganglion cell layer as opposed to the thinning of the inner plexiform and nuclear layers (Fig. 3.36).<sup>225</sup>

**FIG. 3.36** Branch retinal artery occlusion. (A) Color photo of the right eye shows area of whitening in the distribution of an inferotemporal retinal arteriole: white vertical line represents location of B-scan; square

dotted line represents area of embolus in arteriole which is magnified. (B) Embolus was appreciated in the inferior retinal arteriole next to the optic nerve. (C) Spectral domain optical coherence tomography (OCT) vertical scan through the fovea illustrates increased thickness and hyperreflectivity of the inner retinal layers in the inferior perifoveolar area, denoting the presence of intracellular edema, with decreased reflectivity of photoreceptor and retinal pigment epithelial layers. The asymmetry of optical reflectivity in perifoveal region is an important finding; OCT findings in the superior perifoveolar area are normal. (D) Retinal thickness map shows increased thickness in the inferior perifoveal area.

## **Paracentral Acute Middle Maculopathy**

More recently, Sarraf and colleagues described the manifestations of selective ischemia involving the deep retinal plexus capillary, which can lead to a local infarct of the middle retina layers, in particular at the level of the inner nuclear layer.<sup>226</sup> This entity, termed paracentral acute middle maculopathy (PAMM), may be associated with various retinal vascular and systemic diseases, with patients often presenting with an acute scotoma. OCT-imaging in the acute stage reveals a region of increased reflectivity in the inner nuclear layer, with subsequent thinning of this layer over time – much like what is observed in the inner retina with nerve fiber layer infarct or cotton-wool spot.

## **OCT Angiography**

OCT angiography (OCTA) is a method of visualizing the movement of red blood cells by analyzing the changes in the intensity and/or phase signal that arises from repeated B-scans performed in the same location. Other names, which essentially refer to the various approaches to OCTA, include OCT microangiography (OMAG) or split-spectrum amplitude decorrelation angiography (SSADA).<sup>227,228</sup> OCTA does not require dye injection and is noninvasive. In general, OCTA systems can be

divided into spectral domain-based (SD-OCT) and swept-source (SS-OCT) systems. The first SD-OCT system approved by the US Food and Drug Administration is the ZEISS Angioplex™ OCT angiography instrument, while the first system approved for use outside of the United States is the Optovue Angiovue system. However, OCTA instruments will become commercially available from multiple vendors within the next few years. The faster scanning rates and deeper choroidal penetration of the SS-OCT systems should allow larger scan areas and better visualization of the choroidal microvasculature compared with SD-OCT systems.

OCTA discriminates between the scattering signals from stationary and moving tissues to image microvascular blood flow in the retina and choroid. Light scattering from stationary tissues is stable over time, whereas light scattering from moving particles such as erythrocytes will vary randomly over time. OCTA assesses intensity and/or phase changes that result from the movement of these erythrocytes over multiple B-scans performed at the same position.

OCTA can resolve layer-specific microvascular details from within the retina and choroid.<sup>229–231</sup> High-resolution images of normal capillary networks within the retina and choroid are shown in Figs. 3.37 and 3.38. OCTA images demonstrate capillary detail that approaches the resolution of histologic studies. In addition, the variation in normal retinal capillary density between the central macula, temporal macula, and peripapillary retina was described in the living human eye without dye injection for the first time using OCTA. Estimates of retinal vascular density in the superficial and deep capillary plexi using OCTA are also consistent with human cadaver histology studies, demonstrating the high spatial resolution of OCTA. A comparison of the radial peripapillary network using OCTA and fluorescein angiography (FA) in normal human patients showed that the peripapillary capillary network was visualized better in the OCTA images than in FA images. OCTA has also been used to evaluate changes in blood flow upon stimulation of the healthy human retina by flickering light.<sup>232</sup> This may be useful in assessing functional deficits in patients with diabetes and glaucoma, as these conditions have a known abnormal vascular response to flickering light.

## OCTA in Retinal Vascular Disease

The most common retinal vascular disease for the application of OCTA is to assess the microvascular pathology in diabetic retinopathy (Fig. 3.39).<sup>231,233</sup> It has been shown by epidemiologic studies that the clinically visible signs of diabetic retinopathy take many years to manifest, and this is reviewed in detail in another chapter of this text. However, it is very likely that subclinical changes are occurring long before the well-known clinical manifestations. These microscopic changes are not visible on standard ophthalmoscopy or fundus photography. In the vast majority of cases, fluorescein angiography is not clinically indicated in the assessment of subclinical disease with normal visual acuity. In addition, fluorescein angiography is not adequate for resolution of the deep capillary plexus and significantly underestimates capillary density under the best of circumstances.<sup>234</sup> Therefore, one of the main barriers to detection of early changes in diabetic retinopathy is the lack of appropriate imaging methods. OCTA has excellent spatial resolution, which allows consistent and clear imaging of the finest capillary detail in the retina, often comparable to histology.<sup>233</sup> Due to this excellent spatial resolution, OCTA has the potential to detect novel subclinical microvascular changes in diabetic retinopathy.

**FIG. 3.39** Diabetic retinal en face flow images from a Zeiss Cirrus HD-OCT Angioplex optical coherence tomography (OCT) angiography instrument: 3×3-mm and 6×6-mm en face total retina color-coded depth flow map, total retina intensity map, superficial retinal layer flow images, and deep retinal layer flow images.

(A) 3-mm horizontal B-scan through fovea corresponding to B. (B) 3×3-mm total retina color-coded depth flow map. (C) 6-mm horizontal B-scan scan through fovea corresponding to D. (D): 6×6-mm scan total retina color-coded depth flow map. (E) 3-mm horizontal B-scan through fovea with segmentation lines outlining the total retinal intensity layer shown in panel F. (F) 3×3-mm total retinal intensity image. (G) 6-mm horizontal B-scan through fovea with segmentation lines outlining the total retinal intensity layer shown in panel H. (H) 6×6-mm total retinal intensity image. (I) 3-mm horizontal B-scan through fovea with segmentation lines outlining the superficial retinal layer shown in panel J. (J) 3×3-mm superficial retinal layer flow image. (K) 6-mm horizontal B-scan through fovea with segmentation lines outlining the superficial retinal layer shown in panel L. (L) 6×6-mm superficial retinal layer flow image. (M) 3-mm horizontal B-scan through fovea

with segmentation lines outlining the deep retinal layer shown in panel N. (N) 3×3-mm deep retinal layer flow image. (O) 6-mm horizontal B-scan through fovea with segmentation lines outlining the deep retinal layer shown in panel P. (P) 6×6-mm deep retinal layer flow image.

OCTA can be used to characterize typical changes associated with diabetic retinopathy.<sup>231,233,235–238</sup> For example, OCTA can detect many of the key features of diabetic maculopathy, including areas of impaired capillary perfusion, cotton-wool spots, intraretinal microaneurysmal anomalies, and neovascularization. OCTA-based capillary density measurements also correlate closely with clinical staging of diabetic retinopathy and will likely offer a quantitative grading scheme in the near future. Future advances in quantitative OCTA may be used to better characterize the area of impaired capillary perfusion, activity of neovascularization or may be used to detect early findings of diabetic retinopathy such as size of the foveal avascular zone.<sup>235,236</sup> The clinical utility of these findings has yet to be determined but it is likely that OCTA will allow clinicians to detect subtle microvascular changes earlier than conventional clinical examination and fluorescein angiography.

In much the same way that OCTA can help characterize and improve the accuracy of microvascular changes in diabetic retinopathy, it will likely find a role in other retinal vascular diseases such as retinal venous occlusion and retinal arterial occlusion.<sup>239</sup> For example, OCTA can detect many of the key features of retinal venous occlusion, including areas of impaired capillary perfusion, vascular shunting, and some types of intraretinal edema (Fig. 3.40). Quantification of these clinical findings could allow for better clinical assessments of disease progression and may help with disease management, but that remains to be shown. In addition, OCTA images allow detailed localization of findings in a layer specific manner that has not been possible in the past. For example, OCTA images of “twig” retinal venous occlusions demonstrate that the intraretinal hemorrhage occurs largely in the mid-retinal capillary plexus.<sup>239</sup> This finding corroborates earlier histopathologic findings and demonstrates the sensitivity of OCTA as a *in vivo* optical biopsy.

**FIG. 3.40** Branch retinal venous occlusion retinal en face flow images from a Zeiss Cirrus HD-OCT Angioplex optical coherence tomography (OCT) angiography instrument: 3×3-mm and 6×6-mm en face total retina color-coded depth flow map, total retina intensity map, superficial retinal layer flow images, and deep retinal layer flow images. (A) 3-mm horizontal B-scan through fovea corresponding to panel B. (B) 3×3-mm total retina color-coded depth flow map. (C) 6-mm horizontal B-scan through fovea corresponding to panel D. (D) 6×6-mm scan total retina color-coded depth flow map. (E) 3-mm horizontal B-scan through fovea with segmentation lines outlining the total retinal intensity layer shown in panel F. (F) 3×3-mm total retinal intensity image. (G) 6-mm horizontal B-scan through fovea with segmentation lines outlining the total retinal intensity layer shown in panel H. (H) 6×6-mm total retinal intensity image. (I) 3-mm horizontal B-scan through fovea with segmentation lines outlining the superficial retinal layer shown in panel J. (J) 3×3-mm superficial retinal layer flow image. (K) 6-mm horizontal B-scan through fovea with segmentation lines outlining the superficial retinal layer shown in

panel L. (L) 6×6-mm superficial retinal layer flow image. (M) 3-mm horizontal B-scan through fovea with segmentation lines outlining the deep retinal layer shown in panel N. (N) 3×3-mm deep retinal layer flow image. (O) 6-mm horizontal B-scan through fovea with segmentation lines outlining the deep retinal layer shown in panel P. (P) 6×6-mm deep retinal layer flow image.

A less common retinal vascular disease, but one that is ideal for OCTA imaging, is macular telangiectasia type 2 ([Fig. 3.41](#))<sup>240,241</sup> This disease is ideal because it is contained within the central 3×3-mm scan area of the macula where the high scanning density allows for the best image quality. Moreover, the disease involves microvascular changes in all the perifoveal retinal layers and progresses to subretinal and choroidal neovascularization late in the late proliferative stages. The first microvascular changes occur in the deep temporal capillary plexus and then spread to the superficial capillary plexus and then circumferentially around the fovea. As abnormal anastomoses form between the retinal capillary layers, the retina undergoes atrophy and the microvasculature becomes prominent in the avascular outer retina. In the late stage of MacTel2, neovascularization arises in the outer retina and communicates with both the retinal and choroidal circulations.

**FIG. 3.41** Macular telangiectasia type 2 retinal en face flow images from a Zeiss Cirrus HD-OCT Angioplex optical coherence tomography (OCT) angiography instrument: en face total retina color-coded depth flow

image, superficial retinal layer flow image, deep retinal layer flow image, and avascular retinal layer flow image (3×3-mm scans). (A,C,E,G) B-scans with segmentation lines outlining the layer. (B) En face total retina color-coded depth flow image. (D) Superficial retinal layer flow image. (F) Deep retinal layer flow image. (H) Avascular retinal layer flow map.

One of the drawbacks of OCT is its limited field of view. An increase in the scanning field results in either an unacceptably long scanning time or a lower scan density and resulting lower resolution. However, with the availability of eye-tracking and the ability to montage multiple 3×3-mm or 6×6-mm images, wider fields of view can be obtained that may be especially useful in retinal vascular disease. With the introduction of machines with higher scanning speed, wider fields of view may be available.<sup>242</sup>

Other important limitations of OCTA include motion artifact, segmentation errors, and inconsistencies particularly in the setting of disease, and projection artifact from overlying retinal vascular structures. These artifacts can present significant challenges in the accurate interpretation of OCTA images, though simultaneous viewing of the en face OCTA and the OCT flow B-scan can be of some help. It is hoped that future advances in OCTA processing algorithms can address these limitations.

## OCTA in Age-Related Macular Degeneration

OCTA provides us with a unique ability to monitor the vasculature in patients with AMD over time. Traditional intensity-based SD-OCT has provided images of anatomic details of the photoreceptors and RPE, and has shown us the structural changes that precede the formation of GA. However, with increasing focus on the pathogenesis of AMD, one of the fundamental debates is whether AMD is a primary disease of the photoreceptors, the RPE, or the choriocapillaris or whether it is a disease that results from the choreographed dysfunction between all three layers with specific layers playing a more dominant role in different patients depending on their genetics, environment, and overall health. While structural OCT provides us with exquisite detail on the

anatomic features of AMD, it has not provided us with a way to evaluate the choriocapillaris. Thus an incomplete picture of disease progression in AMD results. For example, we do not know if photoreceptor loss is primary, or secondary to RPE dysfunction. Moreover, if RPE dysfunction precedes photoreceptor loss, is it a primary RPE abnormality or secondary to the loss of the choriocapillaris. Up until now, we have been unable to untangle the web of interdependence between these three layers because we can only measure anatomic and functional changes in the photoreceptors and the RPE in vivo, but have been unable to visualize the choriocapillaris changes in vivo and have to rely on extrapolating from in vitro specimens. To help unravel the mystery of disease progression, we need to understand the temporal sequence of anatomic and functional changes in the macula. OCT angiography may bring clarity to the role of the choriocapillaris in disease progression. With the advent of OCT angiography (OCTA), it is now also possible to visualize the vascular changes that occur in dry AMD.<sup>243-245</sup>

OCTA provides a three-dimensional, depth-resolved image of the vasculature in the retina and choroid, which enables us to evaluate independently the vasculature of the inner and outer retina and the choriocapillaris and to correlate the vascular changes with the structural changes noted on cross-registered OCT scans. Moreover, the application of SS-OCT technology allows better visualization of the choriocapillaris as it has a lower sensitivity roll-off with depth and longer wavelength which enables better image penetration below the RPE.<sup>246-250</sup> SS-OCT also can support faster A-scan acquisition rates compared with SD-OCT. The faster acquisition speeds in SS-OCT are especially important because OCTA relies on decorrelation between sequentially acquired OCT B-scans in the eye,<sup>251,252</sup> therefore acquisition speed forces trade-offs between imaging time, retinal coverage, and pixel density in the OCTA data sets. Higher acquisition speeds also support OCTA protocols with multiple repeated B-scan and the use of techniques that can detect flow impairment, such as variable interscan time (VISTA), explained in greater detail below.<sup>253,254</sup>

## **Early AMD**

Early and intermediate AMD are characterized by drusen and pigmentary abnormalities, but it is unknown whether changes in the choriocapillaris occur at these stages. Drusen and RPE changes can be visualized on structural OCT images.<sup>255</sup> With the advent of OCTA, it is now possible to visualize the microvasculature of the retina and choriocapillaris in vivo and to correlate microvascular alterations to structural changes in the retina and RPE.<sup>229,243</sup>

As expected, there are no significant changes noted in the retinal vasculature in early AMD. However, OCTA of the choriocapillaris shows changes beyond what would be expected to be seen due to aging alone. OCTA imaging of the choriocapillaris in normal eyes shows a dense homogenous network, with a fine pattern in the macula, which is near the transverse resolution limit of OCT imaging. More peripheral OCTA images of the choriocapillaris exhibit lobular architecture, consistent with the known morphology from vascular casting studies. These patterns are observed using SD-OCT, centered at 840 nm wavelength as well as SS-OCT, centered at longer 1050 nm wavelength. With age, the density of the choriocapillaris is likely to be reduced, with, however, a homogenous and regular pattern of vasculature still present.

OCTA images of early non-neovascular AMD eyes suggest that there is generalized reduced choriocapillaris density compared to age-matched normal controls, with some focal areas of choriocapillaris loss or flow impairment. The dark patches at the level of the choriocapillaris that correspond to choriocapillaris loss may sometimes be accompanied by displacement of the larger choroidal vessels into the space previously occupied by the choriocapillaris. These changes become more marked in more severe cases. This is in agreement with histopathologic studies which have noted that drusen form over areas devoid of capillary lumens and extend into the intercapillary pillars.<sup>256-258</sup> Increased drusen density in histopathologic studies has been shown to correspond to decreased vascular density of the choriocapillaris.<sup>258</sup> Analysis of en face structural OCT-B images of early AMD has also shown reduced visible choriocapillaris compared with normal eyes, but with a reduction in the OCT signal intensity underlying the drusen, it can be challenging to distinguish between loss of signal and loss of the choriocapillaris.<sup>259</sup>

Although these changes in the choriocapillaris density are visible in both SD-OCT and SS-OCT images, SS-OCT systems have better penetration into the choroid and therefore enable more reliable visualization of the choriocapillaris. In SD-OCT systems, drusen and RPE changes are more likely to cause signal attenuation shadowing. Strong structural OCT signals are required in order to obtain OCTA images, and shadowing causes dark areas on the en face OCTA at the level of the choriocapillaris that are the result of poor signal, rather than lack of blood flow. These areas of shadowing (as opposed to decreased perfusion) can be identified by concurrently looking at an en face OCT intensity image at the level of the choriocapillaris and the OCTA and by examining the cross-sectional OCT image in the area of suspected choriocapillaris pathology. Areas of shadowing will appear dark on both the OCT intensity image as well as the angiographic image, whereas areas of decreased blood flow will appear normal on the intensity image but will appear dark on the en face OCTA image. Because areas of shadowing are so much more prevalent in SD-OCT images than in SS-OCT, it is much easier to assess loss of choriocapillaris flow on the SS-OCTA images than on the SD-OCTA images.

### **Late Dry AMD**

In patients with GA, OCTA shows loss of choriocapillaris flow under the regions of GA. In these areas of choriocapillaris alteration, larger choroidal vessels may be displaced into the area ordinarily occupied by the choriocapillaris and may be seen on the en face OCTA image at the depth level where the choriocapillaris is ordinarily seen. Although the larger choroidal vasculature ordinarily appears dark on SD-OCTA images because of the reduced depth penetration of the SD-OCT signal, in this situation where the larger choroidal vessels are displaced, they may appear as large bright vessels showing flow decorrelation. [Fig. 3.42](#) shows SS-OCTA images from a patient with GA with corresponding red-free ([Fig. 3.42A](#)) and fundus autofluorescence images ([Fig. 3.42B](#)). In this patient, there were no changes in the retinal vasculature, as visible on OCTA segmented at the level of the retinal vasculature in [Fig. 3.41C](#). In many cases, the areas of choriocapillaris alterations extend beyond the margins of the GA in an asymmetric pattern

(Figs. 3.42D–E). These alterations outside the margins of the GA may be quite extensive, or may be very limited and subtle. In a smaller number of cases, the choriocapillaris alterations may be limited to the area of the GA and not extend beyond that area. The changes underlying the area of GA are usually well visualized on both the spectral domain and the swept source OCTA systems, since the RPE in these areas is missing and therefore does not attenuate the SD-OCT signal. However, especially at the margins of the GA where the RPE is still intact, it may be more difficult to visualize the changes in the choriocapillaris with SD-OCT.

**FIG. 3.42** Fundus autofluorescence (FAF), optical coherence tomography (OCT) and optical coherence tomography angiography (OCTA) in a 75-year-old patient with nonexudative age-related macular degeneration (AMD) with geographic atrophy (GA). The FAF (A) and the mean en face projection of the entire OCT volume (B) clearly show the region of GA, outlined by the yellow dashed contour in (B). The GA region appears lighter due to increased light penetration into the choroid caused by RPE atrophy. Panel (C) shows a mean en face projection of the OCTA volume through the depths spanned by the

retinal vasculature; the vasculature appears normal.

Panel D shows a 4.4  $\mu\text{m}$  thick en face OCTA choriocapillaris (CC) slab corresponding to a  $\sim 1.5$  ms interscan time. The yellow dashed contour from (B) is superimposed, and severe CC alteration appears within it. Severe CC alteration is also evident outside the GA margin. Panel E shows the same 4.4- $\mu\text{m}$  thick en face OCTA choriocapillaris (CC) slab as in (D), but corresponding to a  $\sim 3.0$  ms interscan time. Note how some areas with low decorrelation signal in (D) have increased decorrelation in (E), suggesting flow impairment, not atrophy. Enlarged views of the solid orange and green boxes of (D) and (E) are shown in (F) and (G), respectively. Note that some choroidal vessels that are not visible in (F) become visible in (G). Enlarged views of the dashed orange and green boxes of (D) and (E) are shown in (H) and (I), respectively. Note that some of the regions with low decorrelation signal in (H) have a higher decorrelation signal in (I), suggesting flow impairment along the GA margin. OCT (top) and OCTA (bottom) B-scans through the red, blue, and purple horizontal dashed lines in (D) are shown in (J), (K), and (L), respectively. All scale bars are 1 mm. (Courtesy of Eric M Moulton, MIT).

One of the debates in the visualization of choriocapillaris alterations in patients with GA is whether they truly represent absence of flow or merely reduced flow. OCTA creates flow images by comparing the differences between consecutive OCT B-scan images. If the velocity of flow in the vessels is very slow, OCTA may not be able to detect this slow flow. In addition, if flow is fast, then the OCTA image saturates (fast flows appear white) and variations in flow cannot be differentiated.

Thus, OCTA machines have a “slowest detectable flow” or sensitivity threshold below which they cannot detect flow at slow speeds, as well as a “fastest distinguishable flow” or saturation limit above which different flow speeds appear the same. The slowest detectable flow depends on the time between repeated B-scans, with longer interscan times producing a lower slowest detectable flow, because erythrocytes have more time to move between B-scans. In addition, a longer interscan time also reduces

the fastest distinguishable flow. The interscan time of current SD-OCT machines is ~5 ms while the interscan time of the SS-OCTA prototype instrument reported here is ~1.5 ms. The SD-OCT and SS-OCT instruments have acquisition speeds of 70,000 and 400,000 A-scans per second, respectively. The faster scanning speed allows SS-OCT to acquire larger numbers of repeated B-scans for the OCTA scan protocol in the same amount of time as SD-OCT. This allows OCTA data to be generated between B-scans with longer versus shorter interscan times. Looking at the same areas using OCTA from consecutive B-scans (Fig. 3.42D) versus every second B-scan scan (Fig. 3.42E) helps us identify areas of flow impairment, which may not be distinguishable using instruments with slower acquisition speeds and OCTA with long interscan times. Using SS-OCTA with variable interscan time analysis (VISTA) in order to vary the slowest detectable flow and fastest discernible flow, we can show that choriocapillaris alterations within the borders of GA tend to have slow flows and may be primarily atrophic, while choriocapillaris alterations beyond the borders of GA have flow impairment. The images in Figs. 3.42F and 3.42G are magnified images that correspond to a region within the borders of the GA when analyzed with varying interscan time OCTA. In Fig. 3.42G, we are better able to visualize slow flow in some vessels in this region of atrophy. However, as is clear when comparing to the surrounding choriocapillaris, there are considerable areas of absent flow or reduced flow underlying this area of geographic atrophy. The images in Figs. 3.42H and 3.42I correspond to a region at the margin of GA when analyzed with varying interscan time. Fig. 3.42H shows an OCTA with 1.5 ms interscan time, while Fig. 3.42I corresponds to a 3.0 ms interscan time. With increased interscan time, we are able to better visualize that most of the areas of choriocapillaris alteration in this region represent slow flow rather than a complete loss of flow. Conversely, if OCTA was performed using only a longer interscan time (which would be typical for SD-OCT instruments) it would not be possible to distinguish areas of flow impairment.

It is still unclear as to why these choriocapillaris flow changes take place in patients with GA. However, these changes in the choriocapillaris clearly seem to precede the obvious detectable

atrophic structural changes in the RPE and retina of these patients when imaged with conventional structural OCT. These results suggest that microstructural changes detectable by OCTA are present before they become detectable using conventional intensity-based OCT. Additional longitudinal studies are needed to better characterize the progression of these choriocapillaris alterations. In response to the debate about whether the primary site of pathogenesis of GA is the choriocapillaris or the RPE, these OCTA findings that choriocapillaris alterations appear to be at least the size of the GA, and often greater, appear to support the hypothesis that choriocapillaris loss may precede RPE changes. However, it has also been reported that there are changes in the RPE and the outer retina lying outside the areas of geographic atrophy and there is not enough information as yet to conclusively determine the site of primary alteration in AMD, and additional studies using high-resolution SD-OCT may be needed to confirm these findings.

In summary, OCTA can be used to visualize alterations in the choriocapillaris of patients with dry age-related macular degeneration. These changes seem to be present in all stages of the disease. The use of high-speed, long wavelength SS-OCT for angiography, with its better penetration into the choroid and high acquisition speeds, enable variable interscan time analysis OCTA. Scaling the slowest detectable flow and fastest distinguishable flow will enable us to better investigate changes in the choriocapillaris of patients with dry AMD. The ability to image choriocapillaris structure and flow impairment may be a useful future tool for detecting and monitoring progression in dry AMD and for monitoring treatment responses in clinical trials for therapies that target disease progression in dry AMD.

## **Neovascular AMD**

Perhaps one of the most interesting applications of OCTA has been in neovascular or wet AMD, since treatment with anti-VEGF agents leads to rapid changes in the vasculature in wet AMD that can be sequentially visualized on OCTA.<sup>260,261</sup> CNV on OCTA can be visualized by both SS and SD-OCTA systems as a network of abnormal, dilated, often tortuous vessels detected in the normally avascular outer retina (type 2 CNV) or lying under the RPE (type 1

CNV)<sup>262</sup> (Figs. 3.43 and 3.44). The CNV may be seen as a medusa-like or seafan-like pattern, often with larger feeder vessel trunks and fine arborizing vessels. Appropriate segmentation of the layer containing the CNV results in improved visualization of the neovascularization (Fig. 3.43). OCT angiography has been shown to have a high sensitivity and specificity in the detection of CNV and has been shown to have a high level of correspondence to traditional multimodal imaging; however, the presence of large amounts of intraretinal or subretinal hemorrhage can interfere with visualization of the CNV.<sup>263,264</sup> Moreover, OCTA can be used in quantitative evaluation of CNV, by measuring the area of the CNV.

**FIG. 3.43** Neovascular age-related macular degeneration: En face choriocapillaris layer flow images and custom map flow image en face flow images from a Zeiss Cirrus HD-OCT Angioplex optical

coherence tomography (OCT) angiography instrument. (A–D) 3×3-mm scans. (E–H) 6×6 mm scans. (A,C,E,G) B-scans with segmentation lines outlining the layer. (B,F) Choriocapillaris layer flow image. (D,H) Custom segmentation flow image with the RPE contour as the inner boundary and the RPE-Fit line (Bruch's membrane) as the contour of the outer boundary.

**FIG. 3.44** Pre (A) and post (B) treatment with bevacizumab image of choroidal neovascularization. The posttreatment image shows a pruning of the smaller vessels at the margins of the choroidal neovascularization, with a decrease in the overall size of the membrane. Note that the larger trunks at the center of the choroidal neovascularization do not show regression.

OCTA can also be used to follow CNV over time and with treatment. Treatment-naive CNV shows numerous fine, arborizing vessels (Fig. 3.44A). On treatment with anti-VEGF agents, the size

of the CNV can be seen to decrease and regression is seen especially of the fine vessels of the CNV (Fig. 3.44B). Interestingly, follow up of patients with multiple anti-VEGF injections has shown that the vascular diameter of the vessels in the CNV appeared large even in small lesions, with few branch points and many vascular anastomotic connections among larger vessels. In these “chronically treated” CNVs, there was a paucity of capillaries visualized within the lesions. It has therefore been hypothesized that anti-VEGF agents cause regression and pruning of the smaller abnormal vessels in CNV, without causing regression of the larger trunks that have already acquired an endothelial lining.

OCTA may sometimes allow detection of CNV before it is detected as leakage on fluorescein and accumulation of subretinal fluid on structural OCT (Fig. 3.45). Moreover, in patients who have previously been treated with anti-VEGF agents, quiescent, non-leaking CNV may sometimes be visualized as an abnormal pattern of tangled vasculature lying under the RPE. Moreover, it has also been noted that CNV overlies areas of severe choriocapillaris alterations.<sup>265</sup> The significance of these changes in terms of risk of recurrence and frequency of treatment are just beginning to be investigated. However, needless to say, this ushers in an exciting era where in-vivo visualization of vasculature allows us to follow responses to therapy and to better understand the variety of responses observed to treatment in different individuals.

**FIG. 3.45** (A) Color fundus photograph, (B) fluorescein angiogram (FA), and (C) indocyanine green angiogram (ICGA) of a patient who was suspected of having choroidal neovascularization (CNV). No clear evidence of CNV is seen on the FA and ICGA, nor on the optical coherence tomography angiogram (OCTA) segmented at the level of the outer retina (E). The 6×6-mm OCTA (D) and the 3×3-mm OCTA (F) segmented at the level of the choriocapillaris show abnormal vascular trunks (outlined in yellow). Panel (G) shows an OCT B-scan acquired through the area of interest.

## Future Directions

The recent advances in OCT technology have clearly revolutionized the assessment of patients with retinal disorders. Although SD-OCT

has changed the way we image macular diseases, the future of OCT holds even more promise with the use of longer-wavelength light sources, faster scan times, higher image resolution, and noninvasive angiography.

Current commercially available SD-OCT instruments allow dense scanning of the macula with high axial resolution (approximately 5–8  $\mu\text{m}$ ). Ultrahigh-resolution OCT may achieve axial image resolution of 2–3  $\mu\text{m}$  enabling better visualization of retinal structures. However, the price-versus-performance tradeoff remains, limiting the use of this technology to research applications.<sup>2</sup> The use of adaptive optics to correct the ocular aberrations may increase not only the axial resolution, but also the transverse resolution of OCT systems and provide cellular level detail.<sup>266</sup> However, the use of SS-OCT for structural imaging and OCTA should be commercially available in the near future.

SS-OCT systems allow significant increases in imaging sensitivity and speed (100,000–400 000 A-scans per second), through the use of a tunable laser and a photodetector, and faster scan times combined with improved motion-correction strategies should yield larger scan areas that contain few, if any, motion artifacts,. While swept-source OCT can achieve extremely high imaging speeds, the axial image resolution is slightly less than that achieved using SD-OCT.<sup>2,3,267</sup>

Clinically available SD-OCT instruments operate with a light source of approximately 840 nm. This wavelength is highly scattered and absorbed by the melanin in the RPE and choroid, reducing the light penetration into deeper tissues. Imaging the retina with a wavelength of 1050 nm enables greater light penetration and thus a better visualization of choroidal structures.<sup>268,269</sup> The use of this wavelength also has the advantage of less interference by media opacities such as cataract.<sup>270</sup>

In the field of functional OCT, OCT angiography systems are already able to detect retinal and choroidal blood flow, but the role of OCTA in patient management is still being defined. Polarization-sensitive OCT uses tissue birefringence properties to detect the health of different retinal layers.<sup>271</sup> The combination of birefringence and thickness measurements may provide a more sensitive diagnostic tool than either alone.<sup>272–274</sup>

Much has been learned since the development of the first OCT instrument, and OCT holds the promise for continuing advances in fundamental research and improvements in clinical care.

## Disclosures

Drs. Garcia Filho and Rosenfeld received research support from Carl Zeiss Meditec. The University of Miami co-owns a patent that is licensed to Carl Zeiss Meditec. Dr. Rosenfeld and Dr. Kashani have received honoraria for lectures from Carl Zeiss Meditec. Dr. Kashani serves as a consultant for Carl Zeiss Meditec. Dr. Waheed has received honoraria for lectures from Carl Zeiss Meditec Nidek and Optovue. Dr. Duker serves as a consultant to Carl Zeiss Meditec and Optovue.

## Acknowledgments

We appreciate the contributions by the previous authors of this chapter in the 5th edition of this textbook: Zohar Yehoshua, Giovanni Gregori, and Carmen A. Puliafito. We are also grateful to Karen Schaal, Andrew Miller, Fang Zheng, Gillian Robbins, Eric M. Moulton, and Eduardo Novais for their help in assembling the figures.

Abnormalities**

## Basic Principles

### Fundus Autofluorescence

Fundus autofluorescence (FAF) imaging is a noninvasive imaging method for in vivo mapping of naturally or pathologically occurring fluorophores of the ocular fundus (Fig. 4.1 and Fig. 4.5B). The dominant sources are fluorophores accumulating in lipofuscin (LF) granules in postmitotic retinal pigment epithelium (RPE) cells.<sup>1</sup> In the absence of RPE cells, minor fluorophores including collagen and elastin, e.g., in choroidal blood vessel walls, may also become visible. Bleaching phenomena and loss of photopigment may result in increased FAF by reduced absorbance anterior to the RPE level.

**FIG. 4.1** Normal fundus autofluorescence image obtained with a Nidek F-10 scanning laser ophthalmoscope.

## Retinal Pigment Epithelium and Lipofuscin

The RPE constitutes a polygonal monolayer between the neurosensory retina and the choroid. Given multiple essential physiologic functions of the RPE, it is not surprising that RPE dysfunction has been implicated in a variety of retinal diseases (reviewed by Schmitz-Valckenberg et al.<sup>2</sup>).

A hallmark of aging is the gradual accumulation of LF granules in the cytoplasm of RPE cells. It is thought that progressive LF accumulation is mainly a byproduct of the constant phagocytosis of shed photoreceptor outer-segment discs.<sup>3-5</sup> Several lines of evidence indicate that adverse effects of excessive LF accumulation represent a common downstream pathogenetic mechanism in various monogenic macular and retinal dystrophies, as well as in multifactorial complex retinal disease entities, including age-related macular degeneration (AMD).<sup>3,4,6-8</sup>

Apparently, once formed, the RPE cell has no means of either degrading or transporting LF material and granules into the extracellular space via exocytosis. Subsequently, these granules are trapped in the cytoplasmic space of the postmitotic RPE cells. Previous studies have shown that various LF components such as

A2-E (*N*-retinylidene-*N*-retinylethanol-amine), a dominant fluorophore, possess toxic properties that may interfere with normal cell function via various molecular mechanisms, including impairment of lysosomal degradation due to inhibition of the lysosomal adenosine triphosphate-dependent proton pump.<sup>9-12</sup> Other components of LF include precursors of A2-E, molecules formed by the mixture of oxygen-containing moieties within photo-oxidized A2-E, reactions between retinoids and other constituents other than ethanolamine, and peroxidation products of proteins and lipids.<sup>13,14</sup> The molecular composition of LF may possibly be dependent on specific underlying molecular mechanisms. Zhou and associates demonstrated with an *in vitro* assay a link between inflammation, activation of the complement system, oxidative damage, drusen, and RPE LF.<sup>15</sup> They suggested that products of the photo-oxidation of RPE LF components could serve as a trigger for the complement system which could predispose the macular area to a chronic, low-grade inflammatory process over time. A recent study demonstrated that accumulation of lipofuscin-like material *in vitro* renders RPE cells susceptible to phototoxic destabilization of lysosomes, resulting in inflammasome activation and secretion of inflammatory cytokines. This new mechanism of inflammasome activation links photo-oxidative damage and innate immune activation in RPE pathology.<sup>16</sup>

Detection of LF and its constituents is facilitated by its autofluorescent properties. When stimulated with light in the blue range, LF granules typically emit a green–yellow fluorescence.<sup>17,18</sup> The distribution of LF in postmitotic human RPE cells and its accumulation with age have been extensively studied *in vitro*, applying fluorescence microscopic techniques.<sup>5,6,8</sup>

## Near-Infrared Autofluorescence

Near-infrared autofluorescence (NIR-AF) images can also be obtained *in vivo*, most commonly and easily by using the indocyanine green angiography (ICGA) mode of the scanning laser ophthalmoscope (SLO), *i.e.*, without dye injection (Fig. 4.2).<sup>19,20</sup> Due to the excitation and emission in the red end of the spectrum, the topographic distribution of fluorophores other than LF may be

studied by this technique. It has been suggested that the NIR-AF signal is largely melanin-derived.<sup>19-21</sup> As such, Keilhauer and Delori<sup>19</sup> further speculated that, to varying degrees, choroidal sources contributed to this signal. Gibbs et al.<sup>22</sup> investigated NIR-AF in humans and mice and suggested that melanosomes in the RPE and choroid were likely the dominant origin of the signal. Except for measurements in cell cultures at low magnification, their analyses were limited to excitation at 633 nm, in contrast to in vivo NIR-AF, which is generated at 795 nm. Using a customized magnification lens attached to the front of the confocal SLO (cSLO), Schmitz-Valckenberg and coworkers studied the distribution of the NIR-AF signal in retinal cross-sections of a human donor eye and correlated ex vivo autofluorescence measurements to in vivo findings in a rat animal model.<sup>23</sup> They observed that the NIR-AF signal was spatially confined to the RPE monolayer and melanin in the choroid.

**FIG. 4.2** Confocal scanning laser ophthalmoscopy fundus autofluorescence imaging with an excitation of 488 nm (left image) and near-infrared autofluorescence obtained by using the indocyanine green angiography mode (right image) of the scanning laser ophthalmoscope in an eye with geographic atrophy with 'foveal sparing'.

## Macular Pigment Imaging

Macular pigment, consisting of lutein and zeaxanthin, extensively accumulates along the axons of the cone photoreceptors in the central retina.<sup>24-26</sup> As has been reported, a number of functions have been proposed for macular pigment,<sup>25,26</sup> including filtration of blue light which may reduce photo damage and glare, minimization of the effects of chromatic aberration on visual acuity, improvement in fine-detail discrimination, and enhancement of contrast sensitivity. Neutralization of reactive oxygen species by macular pigment may have a protective effect on the neurosensory retina. Although there may be a large variation with regard to the concentration of macular pigment, the pattern of distribution is relatively uniform in the normal population. It generally shows a peak concentration at the foveal center and rapidly decreases with eccentricity, with very little present at about 8° of eccentricity.

Peak absorption of luteal pigment is at 460 nm. These absorption properties can be readily recorded in vivo by blue-light autofluorescence imaging.<sup>27</sup> Therefore, blue FAF imaging can also be used to determine the topographic distribution of macular pigment. Compared to other methods, including heterochromatic flicker photometry, the advantage of FAF imaging is its objective acquisition technique which is not dependent on psychophysical cooperation by the examined individual.

## Techniques of Fundus Autofluorescence Imaging

Recording of autofluorescence images is noninvasive and requires relatively little time.

The intensity of naturally occurring fluorescence of the ocular fundus is about two orders of magnitude lower than the background of a fluorescein angiogram at the most intense part of the dye transit.<sup>1</sup> Absorption of light with reduction of the fluorescence signal, or excitation and emission of light with an increase in the fluorescence signal by anatomical structures anterior to the retina, may further complicate or interfere with the detection of the FAF signal. In the eye, the principal barrier is the crystalline

lens, which has highly fluorescent properties in the short-wavelength range (excitation between 400 and 600 nm results in peak emission at c. 520 nm). With increasing age and particularly the development of nuclear lens opacities, the fluorescence of the lens becomes even more prominent.

Pioneering work on the spectral analysis of the origin of the autofluorescence signal was performed by Delori and coworkers<sup>1</sup> using a fundus spectrometer. In parallel, von Rückmann et al., in their landmark paper, described the use of cSLO for FAF imaging.<sup>28</sup>

## Fundus Spectrophotometer

The fundus spectrophotometer by Delori and coworkers<sup>1</sup> was designed to systematically analyze the excitation and emission spectra of the autofluorescence signals originating from small retinal areas (2° diameter) of the fundus. By incorporating an image intensifier diode array as a detector, a beam separation in the pupil, and confocal detection to minimize contribution of autofluorescence from the crystalline lens, this device allowed the absolute measurements of autofluorescence. These authors showed that fundus fluorescence is emitted across a broad band from 500 to 800 nm. Both at the center of the fovea and at 7° temporally, optimal excitation occurred at 510 nm, with peak emission at approximately 630 nm, indicating the predominance of a fluorophore at these excitation and emission spectra. There was a significant increase with age and the recording along a horizontal line through the fovea showed a minimum fluorescence at the fovea, a maximum intensity at 7–15° from the fovea, and a decrease toward the periphery, most likely reflecting the concomitant distribution of macular pigment and melanin interfering with the emission of the dominant fluorophore. The optic disc was characterized by a less intense signal. The relationship with age and the topographic distribution of the dominant fundus fluorophore were consistent with those of RPE LF as measured in the RPE of human donor eyes.<sup>3,5</sup>

Along with autofluorescence recordings in patients with several pathologic conditions, the initial work by Delori et al.<sup>1</sup> demonstrated that LF is the dominant source of intrinsic

fluorescence of the ocular fundus. However, the small area sampled by the fundus spectrometer as well as the customized relatively complex instrumentation and techniques were not practical for recording FAF from patients in a clinical setting.

## Scanning Laser Ophthalmoscopy

Confocal SLO acquisition optimally addresses the limitations of the low intensity of the autofluorescence signal and the interference of the crystalline lens. It was used initially by von Rückmann and coworkers in a clinical imaging system.<sup>28</sup> The cSLO projects a low-power laser beam on the retina which is swept across the fundus in a raster pattern.<sup>29</sup> The intensity of the reflected light at each point, after passing through the confocal pinhole, is registered by means of a detector, and a two-dimensional image is subsequently generated. Confocal optics ensure that out-of-focus light (i.e., light originating outside the adjusted focal plane, but within the light beam) is suppressed and, thus, the image contrast is enhanced. This suppression increases with the distance from the focal plane and signals from sources anterior to the retina, i.e., the lens or the cornea, are effectively reduced.

In contrast to the 2° retinal field of the fundus spectrophotometer, the cSLO allows imaging over larger retinal areas. To reduce background noise and to enhance image contrast, a series of several single images is usually recorded (reviewed by Schmitz-Valckenberg et al.<sup>2</sup>). For the final FAF image, a number of these frames (usually out of 4–32) are averaged and pixel values are normalized. Given the high sensitivity of the cSLO and the high frame rate of up to 16 frames per second, FAF imaging can be performed within seconds and at low excitation energies which are well below the maximum retinal irradiance limits of lasers established by the American National Standards Institute and other international standards.

With cSLO FAF imaging, excitation is usually induced in the blue range ( $\lambda = 488 \text{ nm}$ ), and an emission filter between 500 and 700 nm is used to detect emission of the autofluorescence signal.

At this excitation wavelength – compared to an excitation in the green range – there is reduced FAF intensity in the central retina

due to absorption by macular pigment.

The most widely used cSLO system for FAF imaging is the Heidelberg retina angiograph/Heidelberg Spectralis. One key advantage of the Spectralis system is the simultaneous acquisition of optical coherence tomography (OCT) recordings that allows for both averaging of several OCT B-scans in order to enhance the signal-to-noise ratio and the synchronous topographic alignment of FAF features with OCT findings. Other previous systems, such as the Rodenstock cSLO and the Zeiss prototype SM 30 4024 for FAF imaging, are no longer commercially available. Nidek has introduced the F-10 cSLO platform that also allows for FAF imaging with a variety of confocal pinholes (see [Fig. 4.1](#)).

## Fundus Camera

The relatively weak FAF signal, absorption effects of the crystalline lens, nonconfocality, and light-scattering effects are important limitations of fundus camera-based systems for FAF recordings. Delori and coworkers described a modified fundus camera for FAF imaging.<sup>30</sup> Their design included the insertion of an aperture in the illumination optics of the camera in order to minimize the loss of contrast caused by light scattering and fluorescence from the crystalline lens. However, the modification also resulted in the restriction of the field of view to a 13° diameter circle; this, together with the complex design, is the likely reason why this configuration has not been further pursued. In 2003, Spaide<sup>31</sup> reported the modification of a commercially available fundus camera system by shifting the excitation and emission wavelengths for FAF imaging towards the red end of the spectrum in order to suppress the fluorescence originating from the lens ([Fig. 4.3](#)). The relatively inexpensive purchase of an additional filter set, together with the broad availability of the flash fundus camera, may make this an attractive alternative. These operate with excitation in the green spectrum and emission is recorded in the yellow–orange spectrum.<sup>32</sup>

**FIG. 4.3** Range of excitation and emission for different camera systems. *cSLO*, confocal scanning laser ophthalmoscopy; *FC*, fundus camera.

In addition to the different excitation light (green versus blue) for FAF recording, other major technical differences between fundus camera systems and the *cSLO* setup must be considered (Table 4.1). In particular, the absence of confocal optics makes the fundus camera prone to light scattering and generation of secondary reflectance light that interferes with the FAF detection. The visualization of subtle FAF alterations is challenging with the modified fundus camera, as shown in one study of patients with geographic atrophy (GA) secondary to AMD.<sup>33</sup>

**TABLE 4.1**

**Summary of Technical Differences Between the Confocal Scanning Laser Ophthalmoscope (*cSLO*) and the Modified Fundus Camera for Fundus Autofluorescence Imaging**

<b>cSLO</b>	<b>Modified Fundus Camera</b>
One excitation wavelength (laser source) Large emission spectrum (cutoff filter)	Bandwidth filters for excitation and emission
Continuous scanning at low light intensities in a raster pattern	One single flash at maximum intensities
Confocal system	Entire cone of light
Laser power fixed by manufacturer, detector sensitivity adjustable	Flash light intensity, gain and gamma of detector adjustable
Imaging processing with averaging of single frames and pixel normalization	Manual contrast and brightness

Aside from qualitative differences, discrepancies in quantitative assessment between different FAF imaging systems must be accounted for. It has recently been demonstrated that inherent image-scaling differences are not restricted to simple pixel-to-millimeter calibration variances, but appear to vary depending on measurement orientation.<sup>34</sup> These factors should be considered

when comparing measurements obtained using different imaging systems, particularly in the context of clinical trials.<sup>34</sup>

## Wide-Field Imaging

The standard image field of the typical cSLO encompasses a retinal field of  $30^\circ \times 30^\circ$ . Additional lenses allow for imaging of a  $55^\circ$  field or, using the composite mode, imaging over even larger retinal areas. Using the fundus camera, so-called montage images can be manually generated using image analysis software on the basis of a seven-field panorama survey.

Peripheral FAF images can also be recorded with a wide-field scanning laser ophthalmoscope (P200Tx, Optos). This system allows for FAF acquisition in less than 2 seconds by using green light excitation (532 nm). FAF imaging beyond the vascular arcades is helpful for assessment of the peripheral extension of retinal diseases.<sup>35-37</sup> Therefore, wide-field FAF scanning laser ophthalmoscopy is also useful to evaluate longitudinal variations of diseases affecting the peripheral retina (Fig. 4.4).<sup>38</sup>

**FIG. 4.4** Patient with geographic atrophy due to age-related macular degeneration. The image was recorded by a wide-field scanning laser ophthalmoscope (P200Tx, Optos). This system allows for fundus autofluorescence acquisition in less than 2 seconds by using green light excitation (532 nm). Marked atrophic areas are already present at baseline in peripheral retinal areas that show progression – in addition to the typical findings within the central atrophic lesions – over time. (Reproduced from Duisdieker V, Fleckenstein M, Zilkens KM, et al. Long-term follow-up of fundus autofluorescence imaging using wide-field scanning laser ophthalmoscopy. *Ophthalmologica* 2015;234:218-2. Copyright Karger Publishers.)

## Interpretation of Fundus Autofluorescence Images

The FAF image shows the spatial distribution of the intensity of the FAF signal for each pixel in gray values (arbitrary values from 0 to 255). Per definition, low pixel values (dark) illustrate low intensities and high pixel values (bright) denote high intensities. The topographical distribution of FAF in normal eyes demonstrates a consistent pattern, as illustrated in [Fig. 4.5](#).<sup>28</sup> A diffuse FAF signal over the posterior pole can be seen, while retinal vessels (due to an absorption phenomenon by blood contents, i.e., hemoglobin) and the optic nerve head (absence of autofluorescent material) are characterized by a very low signal and appear dark. Showing a high degree of interindividual variability, decreased FAF intensities at the macular area with a minimum in the fovea are observed; these are caused by absorption of short-wavelength light due to luteal pigment (lutein and zeaxanthin). Other contributing factors may be an increased accumulation of melanin and a reduced deposition of lipofuscin granules.<sup>1</sup>

**FIG. 4.5** Color fundus photograph (A) and fundus autofluorescence image (B) of the right eye of a normal subject imaged with the confocal scanning laser ophthalmoscope (Heidelberg retina angiograph, HRA 2, Heidelberg Engineering, Heidelberg, Germany). Topographical distribution of fundus autofluorescence intensity shows typical background signal with a dark optic disc (absence of autofluorescent material) and retinal vessels (absorption). Further, intensity is markedly decreased over the fovea due to the absorption of the blue light by yellow macular pigment.

(Reproduced with permission from Schmitz-Valckenberg S, Fleckenstein M, Scholl HP, et al. Fundus autofluorescence and progression of age-related macular degeneration. *Surv Ophthalmol* 2009;54:96–117.)

Using pixel gray values, typical ratios between the intensity of the fovea and perifoveal macula have been established in normal subjects (reviewed by Schmitz-Valckenberg et al.<sup>2</sup>). Based on these findings, qualitative descriptions of localized FAF changes are widely used. Usually, the FAF signal over a certain retinal location is categorized in decreased, normal, or increased intensities in comparison to the background signal of the same image.

In contrast, the quantification of absolute intensities and their comparison between subjects or within longitudinal observation in the same subject are more complicated and remain a challenge in FAF imaging. Of note, as the pixel histogram in the usual available cSLO images is normalized in order to visualize better the topographic distribution of the FAF intensity (see above), the pixel

values are not absolute and these images must not be used for absolute intensity analyses from the outset. Furthermore, when interpreting FAF images, one should take into account that the digital resolution of the detector in current imaging devices exceeds the maximum spatial resolution of ocular media and the optics of the system, mainly due to high-order aberrations. Therefore, single pixel values of a standard FAF image do not reflect the actual anatomical resolution of the image and should not be used to compare intensities between different locations. This also explains why increasing the digital resolution of the detector usually does not improve the resolution of the actual image, but rather results in an artificially high-resolution, posterized image.

When analyzing absolute intensities on averaged but unnormalized FAF images (after ensuring that the normalization of the pixel histogram is turned off), a great variability of the mean gray value for a certain retinal location is usually noted when FAF images are subsequently acquired from the same subject directly one after the other using the same imaging device. A systematic analysis by Lois and coworkers<sup>39</sup> reported good intraobserver and moderate interobserver reproducibility when comparing the absolute mean pixel value of a  $16 \times 16$  pixel square on the retina. In this report, the image resolution is not provided. When assuming an image resolution of  $256 \times 256$  pixels and a  $40^\circ \times 30^\circ$  field (as these settings were published in previous studies using the same cSLO by the same group), the  $16 \times 16$  pixel box would encompass a retinal area of c.  $2^\circ \times 1.9^\circ$ . Hence, moderate interobserver reproducibility would just have been achieved over a rather large retinal area, but was not shown for the anatomical resolution of the imaging system.

Several confounding factors have to be taken into account when comparing absolute FAF intensities between different examinations and different individuals. This not only includes standardization of settings (laser power, detector sensitivity, correction of refractive errors, and image-processing steps, including the number of averaged images), but also eye movements, position of the patient in the chin rest, orientation of the camera, distance between the camera and the cornea, subtle variations in the illumination of the frame, fluctuations of laser power, and short-term dynamic changes in FAF intensities caused by prolonged exposure to the excitation

light or previous dark adaptation (reviewed by Schmitz-Valckenberg et al.<sup>2</sup>).

## Quantitative Autofluorescence Imaging

Delori and coworkers introduced a method for quantitative autofluorescence (qAF) imaging by insertion of an internal FAF reference to account for variable laser power and detector sensitivity.<sup>40</sup> Autofluorescence intensity is calculated by the use of a calibrated reference in the optical pathway. Attaining reliable qAF measurements is critically dependent upon good image quality.<sup>40</sup> The operator must be experienced and skilled and must follow established protocols. Key requirements for images suitable for qAF measurement are uniform and maximal signal intensity, fine-tuned focus, central alignment of the camera with the eye to avoid obstruction by the iris, and exposure within the range of linearity of the detector.<sup>41</sup> Lens and vitreous opacities still represent a challenge, as absorption confounds measured FAF intensity levels originating from the retina/RPE.

Quantitative autofluorescence levels exhibit a significant increase with age (Fig. 4.6). In healthy eyes, qAF increases with increasing eccentricity up to 10–15° from the fovea with highest values superotemporally.<sup>41</sup> Furthermore, qAF values have been shown to be higher in females. Finally, there may be ethnic differences: compared with Hispanics, qAF is significantly higher in whites and lower in blacks and Asians.<sup>41</sup>

**FIG. 4.6** Age-related increase in autofluorescence intensities determined by quantitative autofluorescence imaging. (Courtesy Peter Charbel-Issa, Martin-Gliem.)

Recent studies have demonstrated the potential of qAF to guide clinical diagnosis and genetic testing (see below, “[Macular and Diffuse Retinal Dystrophies](#)”). Furthermore, this approach enhances the understanding of disease processes and may serve as a diagnostic aid, as a more sensitive marker of natural disease progression, and as a tool to monitor the effects of therapeutic interventions targeting LF accumulation.<sup>40</sup>

## Clinical Applications

### Age-Related Macular Degeneration (AMD)

#### Early and Intermediate AMD

Early manifestations of AMD include focal hypo- and hyperpigmentation at the level of the RPE as well as drusen with extracellular material accumulating in the inner aspects of Bruch's membrane.<sup>42</sup> Increased FAF signal adjacent to drusen, which corresponds to focal hyperpigmentation and pigment figures on biomicroscopy, has been attributed to the presence of melanolipofuscin or changes in the metabolic activity of the RPE. Areas of hypopigmentation on color photographs tend to be associated with a corresponding decreased FAF signal, suggesting the absence of RPE cells or degenerating RPE cells with reduced LF

granule content (reviewed by Schmitz-Valckenberg et al.<sup>2</sup>). Drusen by themselves are not necessarily correlated with notable FAF changes.<sup>43</sup> Overall, larger drusen are more frequently associated with significant FAF abnormalities than smaller ones, with the exception of basal laminar drusen. Crystalline drusen typically demonstrate a corresponding decreased FAF signal. The variability of the FAF phenotype of drusen in AMD contrasts with young patients with monogenic disorders in whom the drusen typically autofluoresce brightly, presumably reflecting a distinctly different composition of the accumulating material from age-related drusen.

Delori and coworkers described a pattern of FAF distribution associated with drusen in AMD which consists of decreased FAF in the center of the druse with a surrounding annulus of increased FAF.<sup>30</sup> It has been speculated that this appearance is caused by attenuated RPE at the center and tangential orientation of RPE cells at the edges of the druse. Several authors have consistently reported that confluent drusen and large foveal soft drusen (drusenoid RPE detachments) topographically correspond well with mildly increased FAF using cSLO (reviewed by Schmitz-Valckenberg et al.<sup>2</sup>). With a fundus camera-based system, large soft drusen have a slightly decreased FAF signal at their centers and are surrounded by a faint ring of increased signal.

Applying a multimodal imaging approach including spectral domain optical coherence tomography (SD-OCT) and FAF revealed that focal hyperreflectivity overlying drusen was most frequently spatially confined to increased FAF while outer nuclear layer thinning and choroidal hyperreflectivity were associated with decreased FAF.<sup>44</sup>

## **Reticular Pseudodrusen**

Several lines of evidence indicate that, in addition to drusen and pigmentary changes, reticular pseudodrusen (RPD) seem to confer a high risk for the development of late-stage AMD. This specific phenotypic pattern, which is best recognizable by SD-OCT, cSLO infrared reflectance, and cSLO FAF imaging, can be detected in over 60% of eyes with GA and in 42% of eyes with intermediate AMD.<sup>45,46</sup> Morphologic variations of RPD have been described, with the characteristic reticular pattern<sup>47</sup> further subdivided into “dot,”

“target,” and “ribbon” configurations (Fig. 4.7).<sup>48,49</sup>

**FIG. 4.7** Multimodal imaging of reticular pseudodrusen. The example demonstrates the “ribbon” pattern (*R*), clearly visible in fundus autofluorescence (FAF) (upper middle), color fundus (upper right) and blue reflectance (BR) (lower middle) images. “Targets” (*T*) are well detectable in FAF (upper middle), BR (lower middle) and near-infrared reflectance (IR) (upper left) images. The black line indicates the position of the two corresponding spectral domain optical coherence tomography (SD-OCT) scans (*1* and *2*, lower left). In the IR image, no ribbon pattern but rather coalescence lesions are visible that correspond to waves (*W*) in SD-OCT. Targets are clearly visible in the IR image and correspond to spikes (*S*) in the SD-OCT scan. In the fluorescein angiography image (lower right), “dots” (*D*) are detectable. (Reproduced from Steinberg JS, Göbel AP, Fleckenstein M, et al. Reticular drusen in eyes with high-risk characteristics for progression to late-stage age-related macular degeneration. *Br J Ophthalmol* 2015;99:1289–94. Copyright BMJ Publishing Group.)

The morphologic substrate of RPD is now assumed to be located anterior to the RPE cell monolayer in contrast to the sub-RPE location of “regular” drusen.

Interestingly, RPD are not specific for AMD and have recently been reported to also frequently occur in other retinal diseases,

including Sorsby fundus dystrophy and pseudoxanthoma elasticum (PXE).<sup>50,51</sup> As the latter diseases are characterized by a primary Bruch's membrane pathology, changes in this anatomic layer may play an important role in the pathophysiology of RPD.<sup>51</sup>

## Geographic Atrophy

Areas of GA are associated with RPE cell death as well as with loss or attenuation of adjacent layers, in particular the outer neurosensory retina and the choriocapillaris.<sup>52</sup> With disappearance of the RPE, LF is also lost, resulting in a corresponding marked decrease in FAF intensity (Figs. 4.8 and 4.9).<sup>28</sup> Compared to drusen, which may also exhibit a decreased FAF signal, atrophic areas typically show an even more profound reduction of FAF.<sup>30</sup> The high-contrast difference between atrophic and nonatrophic regions of retina allows more easy and reliable delineation of the area of atrophy than from conventional fundus photographs. These advantages of documenting and studying GA by FAF imaging have been used in natural history studies<sup>53,54,59</sup> (Figs. 4.8 and 4.9).

**FIG. 4.8** In atrophic age-related macular degeneration, geographic atrophy appears as a sharply demarcated area with depigmentation and enhanced visualization of deep choroidal vessels on the color fundus photograph (A). On the corresponding fundus autofluorescence (FAF) image (B), atrophic patches are clearly delineated by decreased intensity and high-

contrast to adjacent nonatrophic retina. Surrounding the atrophy, in the junctional zone, foci and areas of increased FAF intensity are observed which are invisible on fundus photography. These abnormalities tend to precede atrophy over time and may serve as disease markers. (Reproduced with permission from Holz FG, Spaide RF. *Essentials in ophthalmology: Medical retina*. Berlin: Springer; 2007, Fig. 5.3.)

**FIG. 4.9** Monitoring of atrophic progression over time with fundus autofluorescence imaging, showing the natural course of the disease over two years in a 73-year-old male patient.

An even more striking finding of FAF imaging in GA patients is the frequent presence of areas of hyperautofluorescence in the junctional zone surrounding the patch of atrophy.<sup>55</sup> Distinct patterns of abnormal FAF in the junctional zone of atrophy and a high degree of intraindividual symmetry between fellow eyes have been described (reviewed by Schmitz-Valckenberg et al.<sup>2</sup>).

A classification system of FAF patterns in the junctional zone of atrophy in GA patients has been proposed (Fig. 4.10).<sup>56</sup> Studies of retinal sensitivity have underscored the importance of increased FAF surrounding areas of GA and, thus, the pathophysiologic role of increased RPE LF accumulation in such patients. Scholl and coworkers have demonstrated that rod photoreceptor function is more severely affected than cone function over areas with increased FAF using fine matrix mapping.<sup>57</sup> Combining SLO microperimetry and FAF imaging in another study, impaired photopic sensitivity has been observed in areas of abnormal FAF in the junctional zone.<sup>58</sup>

**FIG. 4.10** Classification of fundus autofluorescence (FAF) patterns in the junctional zone in patients with geographic atrophy (GA) due to age-related macular degeneration. Eyes with no apparent increased FAF intensity are graded as “none” (slow progressor). The eyes with increased FAF are divided into two groups depending on the configuration of increased FAF surrounding atrophy. Eyes showing areas with increased FAF directly adjacent to the margin of the atrophic patch(es) and elsewhere are called “diffuse” (rapid progressors) and are subdivided into five groups. From left to right: (top row) fine granular, branching, (bottom row) trickling, reticular, and fine granular with punctuated spots. Eyes with increased FAF only at the margin of GA are divided into three subtypes: focal (slow progressor), banded (rapid progressor), and patchy (no data, occurs rarely) according to their typical FAF pattern around atrophy.

(Reproduced with permission from Schmitz-Valckenberg S, Fleckenstein M, Scholl HP, et al. Fundus autofluorescence and progression of age-related macular degeneration. *Surv Ophthalmol* 2009;54:96–117.)

Outer retinal atrophy in the context of AMD is a dynamic process with gradual enlargement of atrophic areas over time. Initial natural history studies on atrophy progression in GA patients using

FAF imaging demonstrated the occurrence of new atrophic patches and the spread of preexisting atrophy in areas with abnormally high levels of FAF at baseline.<sup>55</sup> Looking at larger patient groups with longer review periods, the significance of increased junctional FAF for foreshadowing atrophy enlargement has been highlighted.<sup>53,54</sup> In accordance with other natural history studies, the FAM (Fundus Autofluorescence Imaging in Age-related Macular Degeneration) study identified a large variability in the rate of atrophy enlargement between patients, which was neither explained by the extent of baseline atrophy nor by any other comorbid factor such as smoking, lens status, or family history. Interestingly, the initial studies using FAF imaging on patients with GA have already reported various patterns of changes in FAF in the junctional zone of GA (reviewed by Schmitz-Valckenberg et al.<sup>2</sup>). These investigators speculated that their observations might reflect heterogeneity of the underlying disease process.

A more detailed analysis of the FAM study of 195 eyes of 129 patients shows that variable rates of progression of GA are dependent on the specific phenotype of abnormal FAF pattern at baseline.<sup>54</sup> Atrophy enlargement was the slowest in eyes with no abnormal FAF pattern (median 0.38 mm<sup>2</sup>/year), followed by eyes with the focal FAF pattern (median 0.81 mm<sup>2</sup>/year), then by eyes with the diffuse FAF pattern (median 1.77 mm<sup>2</sup>/year), and finally, by eyes with the banded FAF pattern (1.81 mm<sup>2</sup>/year). The difference in atrophy progression between the groups of no abnormal and focal FAF patterns and the groups of the diffuse and banded FAF patterns was statistically significant ( $p < .0001$ ). These results have subsequently been confirmed in another large-scale study (the Natural History of Geographic Atrophy Progression (GAP) study).<sup>59</sup> These findings underscore the importance of abnormal FAF intensities around atrophy and the pathophysiologic role of increased RPE LF accumulation in patients with GA due to AMD.

In eyes with GA, the fovea may remain uninvolved by the atrophic process until late in the course of the disease, a phenomenon referred to as “foveal sparing.” Detection of “foveal sparing” in eyes with GA using FAF imaging with an excitation wavelength of 488 nm is challenging due to signal absorption by

macular pigment.<sup>60</sup> Evaluation of the integrity of the “spared” fovea is facilitated by combined analysis of SD-OCT or infrared reflectance with FAF images (Fig. 4.11). The approach combining infrared reflectance with FAF images for quantification of “foveal sparing” in eyes with GA has recently been shown to be feasible.<sup>61</sup> In this study, it has been demonstrated that the atrophic area in eyes with “foveal sparing” progresses 2.8-fold faster towards the periphery than towards the central retina. These findings would seem to support the hypothesis of the presence of local factors that protect the fovea, at least for some time, from degeneration.

**FIG. 4.11** Foveal sparing in geographic atrophy visualized by different imaging modalities. (A) Fundus autofluorescence imaging (excitation wavelength 488 nm); (B) near-infrared reflectance imaging; (C) spectral domain optical coherence tomography (vertical scan).

Directional kinetics of geographic atrophy progression in age-related macular degeneration with foveal sparing. *Ophthalmology* 2015;122:1356-65. Copyright Elsevier.)

## Pigment Epithelium Detachment

FAF imaging in eyes with pigment epithelium detachment (PED) secondary to AMD show variable FAF phenotypes which are not always detectable using conventional imaging techniques such as fundus photography, fluorescein, or ICGA (Fig. 4.12).

**FIG. 4.12** Pigment epithelium detachment classification based on fundus autofluorescence (FAF) characteristics. (A) Increased FAF; (B) decreased FAF; (C) FAF; and (D) cartwheel FAF. *FL-A*, fluorescein angiography; *ICG-A*, indocyanine green angiography. (Reproduced with permission from Roth F, et al. Fundus autofluorescence imaging of pigment epithelial detachments. ARVO Meet Abstracts 2004;45:2962.)

However, a systematic analysis of these FAF alterations with correlation to the underlying causes of PED such as choroidal neovascularization (CNV), retinal angiomatous proliferation, polypoidal vasculopathy, or serous, nonexudative PED is lacking to date. These changes are probably not only caused by increased or decreased amounts of LF, but may derive from other dominant fluorophores with similar excitation and emission spectra, such as extracellular fluid or degraded photoreceptors (Fig. 4.12).

## Choroidal Neovascularization

Theoretical considerations would suggest that FAF imaging may provide important clues to our understanding of CNV secondary to AMD. For example, it may be helpful to assess the integrity of the RPE which may influence the development and behavior of new vascular complexes as well as photoreceptor viability and potential therapeutic success.

Patients with early CNV secondary to AMD tend to have patches of “continuous” or “normal” autofluorescence corresponding with areas of hyperfluorescence on the corresponding fluorescein angiograms, implying that RPE viability is preserved at least initially in CNV development (Fig. 4.13).<sup>62</sup> By contrast, eyes with longstanding CNV typically exhibit more areas of decreased FAF signal, which could be explained by photoreceptor loss and scar formation with increased melanin deposition (Fig. 4.13).

**FIG. 4.13** (A) The right central macula of this 73-year-old woman with a history of blurred vision for 2 weeks (central visual acuity 20/30) showed fresh

hemorrhages, subretinal fluid, and a pigment epithelium detachment. (C,D) Fluorescein angiography reveals an active choroidal neovascular membrane with leakage in the inferior part of the lesion. (B) On the autofluorescence image, the borders (*arrows*) of the subretinal fluid can be seen. Of note, the autofluorescence signal appears to be normal at the site of the active neovascularization, suggesting that the retinal pigment epithelium is still viable. (Reproduced with permission from Schmitz-Valckenberg S, Holz FG, Bird AC, et al. Fundus autofluorescence imaging: review and perspectives. *Retina* 2008;28:385–409.)

Heimes and coworkers analyzed the prognostic value of RPE autofluorescence with respect to the therapeutic outcome of anti-vascular endothelial growth factor therapy in exudative AMD.<sup>63</sup> The analysis of 95 eyes showed a significant difference in visual acuity outcomes in eyes with changes in FAF within the central 500 and 1000  $\mu\text{m}$ .

One other important finding in eyes with CNV is that abnormal FAF intensities typically extend beyond the edge of the angiographically defined lesion, indicating a more widespread involvement than is apparent from conventional imaging studies. Increased FAF signal has also been described around the edge of lesions. It has been speculated that this observation may reflect the proliferation of RPE cells around the CNV.<sup>64</sup> As in other exudative retinal disease, such as central serous chorioretinopathy, areas with increased FAF are commonly found inferior to the leakage on fluorescein angiography, most likely representing gravitational effects of fluid tracking or partial loss of photoreceptor segments resulting in less photopigments. In contrast to fluid, hemorrhages and intraretinal exudates typically show a decreased FAF signal because of light absorption obscuring the underlying retinal details. When retinal hemorrhages undergo organization and evolve into an ocher color on fundoscopy, they may become intensely autofluorescent. Later, with disappearance of the yellowish material seen on biomicroscopy, a large RPE scar and atrophy with decreased autofluorescence may be visible.<sup>65</sup>

Detection of atrophy in eyes with exudative AMD is becoming more important since there is increasing evidence that atrophy development in eyes treated with anti-VEGF is the main cause for

severe visual loss in the long term.<sup>66</sup>

FAF imaging herein represents an important tool,<sup>67</sup> although, delineation of “pure” atrophy by FAF imaging is challenging, since retinal changes associated with exudation also exhibit a decreased FAF signal. Hence, a multimodal imaging approach appears to be most appropriate to detect, evaluate, and quantify atrophy in eyes with exudative AMD.

## Macular and Diffuse Retinal Dystrophies

In macular and diffuse retinal dystrophies, various associated abnormalities in FAF have been described (reviewed by von Rückmann et al.<sup>68</sup>).

The extent and pattern of abnormal FAF may show characteristic abnormal distributions in retinal dystrophy disease entities and therefore aids in the differential diagnosis. In particular, in late-onset macular dystrophies (e.g., late-onset Stargardt disease and central areolar choroidal dystrophy), FAF imaging is an important technique to differentiate such masquerading disease entities from AMD.<sup>69</sup>

It is well established that autofluorescent material excessively accumulates in the RPE in association with various genetically determined retinal diseases. Increased FAF due to excessive LF accumulation in RPE cells may result from abnormally high turnover of photoreceptor outer segments or impaired RPE lysosomal degradation of normal or altered phagocytosed molecular substrates.

The fundoscopically visible pale/yellowish lesions at the level of RPE/Bruch's membrane in Best macular dystrophy (Fig. 4.14), adult vitelliform macular dystrophy, and other pattern dystrophies, as well as Stargardt macular dystrophy/fundus flavimaculatus (Fig. 4.15), are associated with an intense focally increased FAF signal.

**FIG. 4.14** Best macular dystrophy. Vitelliruptive stage. There is prominent increased fundus autofluorescence (FAF) in the lower part of the original vitelliform lesion that is still demarcated by a faint ring of increased FAF.

(Reproduced with permission from De Laey J, Puech B. Color atlas of retinal dystrophy: Springer; 2014.)

**FIG. 4.15** Stargardt macular dystrophy/fundus flavimaculatus. Fundoscopically visible focal flecks show a bright, increased fundus autofluorescence (FAF) signal. Focal areas of decreased FAF seem to correspond with retinal pigment epithelial atrophy.

(Reproduced with permission from Ho AC, Brown GC, McNamara JA, et al. Color atlas and synopsis of clinical ophthalmology: Retina. New York: McGraw Hill;

2003.)

The flecks with increased FAF signal in Stargardt macular dystrophy and fundus flavimaculatus may fade over time, with subsequent atrophy development. This finding is in accordance with histopathologic data which have shown that these flecks represent aggregates of enlarged RPE cells engorged to 10 times their normal size with LF. Interestingly, flecks in recessive Stargardt disease can exhibit increased FAF, while NIR-AF is usually reduced or absent at fleck positions. Sparrow and coworkers further evaluated this incongruous observation, and in 2015 reported that in NIR-AF, flecks are predominantly hypofluorescent and larger,

and that NIR-AF darkening occurs prior to development of a heightened FAF signal. They concluded that these observations indicate that RPE cells associated with flecks in recessive Stargardt disease are considerably changed or lost, and that the bright FAF signal of flecks likely originates from augmented LF formation in degenerating photoreceptor cells impaired by the failure of RPE.<sup>70</sup>

Lorenz and coworkers<sup>71</sup> described absent or minimal FAF intensities in patients with early-onset severe retinal dystrophy associated with mutations on both alleles of *RPE65*. The lack or severe decrease of FAF signal would be consistent with the biochemical defect and could be used as a clinical marker of this genotype. Another study demonstrated that patients with Leber congenital amaurosis having vision reduced to light perception and undetectable electroretinograms (ERGs) may still exhibit normal or minimally decreased FAF intensities.<sup>72</sup> The authors concluded that the RPE–photoreceptor complex is, at least in part, functionally and anatomically intact. This finding would have implications for future treatment, suggesting that photoreceptor function may still be rescuable in such patients.

Discrete, well-defined lines of increased FAF may occur in various forms of retinal dystrophies (Fig. 4.16).<sup>68,73,66</sup> These lines have no prominent correlate on fundus biomicroscopy, although there is evidence that these lines precisely reflect the border of the regions of retinal dysfunction (Figs. 4.17 and 4.18).<sup>73–75</sup> Despite the variable orientation of this line in different entities, e.g., orientation along the retinal veins in pigmented paravenous chorioretinal atrophy (PPCRA) or as a ring-like structure in retinitis pigmentosa (RP) or macular dystrophies (Fig. 4.16), the similar appearance on FAF images and the concordance of functional findings indicate that these lines in heterogeneous diseases share a common underlying pathophysiologic mechanism.<sup>74</sup>

**FIG. 4.16** Arcs and rings of increased fundus autofluorescence (FAF) in patients with various forms of retinal dystrophies. Patients 1–3 (A–C), diagnosed with pigmented paravenous chorioretinal atrophy, demonstrate an arc of increased FAF orienting along the retinal veins. There is a normal FAF signal between this arc and the atrophic areas (i.e., decreased FAF) and in the area that is not circumscribed by the line. In the left eye of patient 1 (A) and the right eye of patient 3 (C), the arc of increased FAF almost merges to a parafoveal ring with a temporal opening. In patient 4 (D) with sector retinitis

pigmentosa, there is an arc with a semicircular configuration in the parafoveal region. In typical retinitis pigmentosa (patient 5, E), there is a ring of increased FAF. Within and outside the ring, there is a normal FAF signal. In patient 6 (F), who is diagnosed with macular dystrophy, there is a parafoveal ring of increased FAF. Centrally, there is reduced FAF corresponding to the fundoscopically visible lesion. On both sides of the ring, there is a normal FAF signal. In patient 7 (G) with another bull's-eye macular dystrophy, a ring of increased FAF directly borders the central lesion. In the very center, there is a spot of preserved FAF. Note that there is no significant correlate of the arc of increased FAF in the conventional color fundus photograph. (Reproduced with permission from Fleckenstein M, Charbel Issa P, Fuchs HA, et al. Discrete arcs of increased fundus autofluorescence in retinal dystrophies and functional correlate on microperimetry. *Eye (Lond)* 2009;23:567–75.)

**FIG. 4.17** Fundus-controlled microperimetric assessment of rings of increased fundus autofluorescence (FAF). The sensitivity map is superimposed on the FAF image. Light increment sensitivity (LIS) varies from 0 to 20 dB (attenuation scale). Hollow red squares indicate testing points where the brightest stimulus was not seen. (A) In the patient with autosomal dominant retinitis pigmentosa, LIS is preserved within the ring; outside, there is severely impaired LIS despite a normal FAF signal. In patients with macular dystrophy exhibiting a ring of increased FAF (B,C), LIS is significantly impaired within the ring independently of a normal or decreased FAF signal; outside, LIS is preserved. These findings are the inverse of the findings in patients diagnosed

with retinitis pigmentosa (A). (Reproduced with permission from Fleckenstein M, Charbel Issa P, Fuchs HA, et al. Discrete arcs of increased fundus autofluorescence in retinal dystrophies and functional correlate on microperimetry.

Eye (Lond) 2009;23:567–75.)

**FIG. 4.18** Fundus-controlled microperimetric assessment in pigmented paravenous chorioretinal atrophy. The sensitivity map is superimposed on the fundus autofluorescence (FAF) image. Light increment sensitivity (LIS) varies from 0 to 20 dB (attenuation scale). Hollow red squares indicate testing points where the brightest stimulus was not seen. In the area that is framed by the arc of increased FAF, LIS is severely impaired independently of a normal or abnormal FAF signal. The arc of increased FAF demarcates the area of preserved LIS. (Reproduced with

permission from Fleckenstein M, Charbel Issa P, Fuchs HA, et al. Discrete arcs of increased fundus autofluorescence in retinal dystrophies and functional correlate on microperimetry. Eye (Lond) 2009;23:567–75.)

Fleckenstein and coworkers<sup>76</sup> first described the SD-OCT correlate of these lines of increased FAF. Specifically, these corresponded with a discrete junctional zone between an area with preserved OCT layers and an area where the outer aspects of the retina are lost and the external limiting membrane band appeared to rest directly on the RPE (Figs. 4.19 and 4.20).

**FIG. 4.19** Simultaneous fundus autofluorescence (FAF) and spectral domain optical coherence tomography imaging. The line of increased FAF corresponds to a junctional zone (within black lines) between involved and preserved retina. *RNFL*, retinal nerve fiber layer; *GCL*, ganglion cell layer; *IPL*, inner plexiform layer; *INL*, inner nuclear layer; *OPL*, outer plexiform layer; *ONL*, outer nuclear layer; *ELM\**, presumed correspondence of the external limiting membrane; *IPRL\**, presumed correspondence of the interface of the inner/outer segments of photoreceptors; *RPE\**, presumed correspondence of the retinal pigment epithelium. (Reproduced with permission from Fleckenstein M, Charbel Issa P, Helb HM, et al. Correlation of lines of increased autofluorescence in macular dystrophy and pigmented paravenous retinochoroidal atrophy by optical coherence tomography. *Arch Ophthalmol* 2008;126:1461–3.)

**FIG. 4.20** Simultaneous fundus autofluorescence (FAF) and spectral domain optical coherence tomography imaging. The line of increased FAF corresponds to a junctional zone (within black lines) between preserved and involved retina. *RNFL*, retinal nerve fiber layer; *GCL*, ganglion cell layer; *IPL*, inner

plexiform layer; *INL*, inner nuclear layer; *OPL*, outer plexiform layer; *ONL*, outer nuclear layer; *ELM\**, presumed correspondence of the external limiting membrane; *IPRL\**, presumed correspondence of the interface of the inner/outer segments of photoreceptors; *RPE\**, presumed correspondence of the retinal pigment epithelium. (Reproduced with permission from Fleckenstein M, Charbel Issa P, Helb HM, et al. Correlation of lines of increased autofluorescence in macular dystrophy and pigmented paravenous retinochoroidal atrophy by optical coherence tomography. *Arch Ophthalmol* 2008;126:1461–3.)

The same SD-OCT correlate has been demonstrated in patients with RP.<sup>77</sup> This junction might be characterized by progressively altered photoreceptor outer and inner segments. While the pathophysiologic mechanism is unknown, it may be hypothesized that the increased FAF signal observed in various retinal dystrophies might result from an increased metabolic burden of corresponding RPE cells and subsequent excessive accumulation of fluorophores in the lysosomal compartment due to phagocytosis of components of severely altered photoreceptors in such junctional zones. Changes in absorption of the FAF signal due to loss of photoreceptor outer segments may also contribute to this phenomenon. In the zone with a normal FAF signal but impaired retinal sensitivity, the structure of the photoreceptors seems to be severely distorted. A normal FAF signal, therefore, does not necessarily reflect an intact photoreceptor–RPE complex, but may rather correspond to a structurally intact-appearing RPE cell monolayer with or without the presence of intact photoreceptors.

Quantitative autofluorescence imaging has been shown to be useful for differential diagnosis in retinal dystrophies, e.g., qAF allows for differentiation between *ABCA4*-associated and non-*ABCA4*-associated retinal disease. Moreover, *PRPH2/RDS*- and *ABCA4*-associated disease exhibiting phenotypic overlap can be discriminated when qAF values are corrected for age and race. In general, *ABCA4* patients have been shown to exhibit higher qAF values than *PRPH2/RDS* patients, while most patients without mutations in *PRPH2/RDS* or *ABCA4* have qAF levels within the normal range.<sup>78</sup>

While high qAF levels represent a hallmark of *ABCA4*-related

disease<sup>78</sup> in the absence of atrophy (Fig. 4.21), patients with mutations in *BEST1* exhibit mean nonlesion qAF values that are within normal limits for age.<sup>79</sup> Therefore, it has been concluded that, based on qAF, mutations in *BEST1* do not cause increased lipofuscin levels outside the yellowish, focal lesions.

**FIG. 4.21** Fundus autofluorescence images of a 28-year-old healthy young female (upper left) and a 30-year-old patient with Stargardt disease (upper right). Quantitative autofluorescence imaging analyses with color-coding (lower panel) showing higher intensities in

the eye affected by Stargardt disease. (Courtesy Peter Charbel-Issa, Martin-Gliem.)

## Macular Telangiectasia

Macular telangiectasia (MacTel) type 2 is a bilateral disease of unknown cause with characteristic alterations of the macular capillary network and progressive retinal cell death (see [Chapter 58](#), Macular telangiectasia).<sup>80–82</sup> The disease typically manifests temporal to the fovea, and may later encompass an oval-shaped area centered on the foveola.

As outlined above, normal eyes show masking of the foveal 488-nm blue-light FAF due to the accumulation of luteal pigment. Reduced macular pigment density in MacTel type 2 affects this masking. Eyes with MacTel type 2 show an abnormally increased signal in the macular area to a variable degree with blue-light FAF imaging ([Figs. 4.22](#) and [4.23](#)).<sup>83</sup> A loss of luteal pigment may initially occur in the area temporal to the foveal center.<sup>83,84</sup> Quantitative analysis confirmed that the loss of luteal pigment was more pronounced in the temporal compared with the nasal parafoveolar area and suggested that zeaxanthin would be more reduced than lutein.<sup>84</sup>

**FIG. 4.22** Fundus autofluorescence image obtained at 488 nm (excitation) of a normal eye (*left*) and of a 59-

year-old woman with type 2 idiopathic macular telangiectasia (right). (Reproduced with permission from Helb HM, Charbel Issa P, van der Veen RLP, et al. Macular pigment density and distribution in patients with type II macular telangiectasia. *Retina* 2008;28:808–16.)

**FIG. 4.23** Fluorescein angiogram frame (left) and fundus autofluorescence (FAF) image obtained at 488 nm (right) of a patient with type 2 idiopathic macular telangiectasia showing an abnormal FAF distribution in the macular area due to depletion of luteal pigment.

(Reproduced with permission from Helb HM, Charbel Issa P, van der Veen RLP, et al. Macular pigment density and distribution in patients with type II macular telangiectasia. *Retina* 2008;28:808–16.)

Further proof for the depletion in macular pigment derived from a postmortem analysis of an eye with MacTel type 2. Macroscopic examination disclosed the absence of the central yellowish spot.<sup>85</sup> A yellow ring of residual macular pigment was present eccentrically in accordance with the in vivo imaging observations. The loss of macular pigment was subsequently divided into three classes based on a cross-sectional analysis of two-wavelength (blue-light and green-light) FAF images:<sup>86</sup> class 1 shows a wedge-shaped loss of macular pigment restricted to an area temporal to the foveal center. In class 2, the area is larger and also involves the foveal center. Class 3 is characterized by loss of luteal pigment within an oval-shaped area centered on the foveola. There was a significant

association of these three classes of macular pigment loss with the consecutive disease stages of MacTel type 2 described by Gass and Blodi.<sup>80</sup> Correlation studies with microperimetric data revealed a trend towards worse retinal function with increasing class of macular pigment changes.

A recent study succeeded in visualizing even earlier pathologic changes in fellow eyes which otherwise did not meet diagnostic standards for mac tel type 2.<sup>87</sup> While no functional deficits were detected, eyes consistently showed a severely reduced directional cone reflectance (Stiles–Crawford effect). An additional consistent minimal disease manifestation was an asymmetric configuration of the foveal pit with focal temporal thinning, which was most pronounced at 1° eccentricity. Topographically related, macular pigment optical density was reduced in a small wedge-shaped temporal paracentral sector, resulting in an increased signal on fluorescein angiography and FAF imaging. These described alterations may be helpful for early identification of patients and affected family members.

## Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum (PXE) is caused by a mutation in the *ABCC6* gene. More than 300 distinct loss-of-function mutations representative of over 1000 mutant alleles in *ABCC6* have been found. Many of the missense mutations occur at locations in the protein involving domain–domain interactions in the *ABCC6* transporter. Even heterozygotes can show manifestations of disease. FAF abnormalities are common in eyes affected by PXE. Typical phenotypic alterations, including angioid streak and drusen of the optic nerve, have autofluorescence correlates. Peau d'orange is hardly detectable on FAF, whereas comet-tail lesions are typically apparent. RPE atrophy can be widespread and heterogeneous, located mostly adjacent to angioid streaks or CNV.<sup>88</sup>

Furthermore, irregular patterns of increased FAF at the posterior pole with an appearance similar to that of pattern dystrophies can be found in eyes with PXE. In these eyes, areas of yellowish deposits and hyperpigmentation on color photography corresponded to areas of increased FAF (Fig. 4.24). Agarwal et al.<sup>89</sup>

suggested the following classification: a fundus appearance similar to a pattern dystrophy of the fundus flavimaculatus, the reticular, the vitelliform and the fundus pulverulentus types, respectively. The pattern dystrophy-like changes in PXE may occur unilaterally or bilaterally.

**FIG. 4.24** Various types of retinal pigment epithelium degenerative patterns of the macula observed in pseudoxanthoma elasticum (first column: fundus autofluorescence; second column: fluorescein angiography; third column: color fundus photograph). (A–C) Fundus changes resembling reticular dystrophy; (D–F) fundus changes resembling fundus flavimaculatus; (G–I) fundus changes resembling

vitelliform dystrophy; (J–L) fundus changes resembling fundus pulverulentus. (Reproduced with permission from Finger RP, Charbel Issa P, Ladewig M, et al. Fundus autofluorescence in pseudoxanthoma elasticum. *Retina* 2009;29:1496–505.)

Abnormalities of the RPE–photoreceptor complex detected by FAF imaging are more diverse and widespread than expected from conventional fundus imaging. Such extensive alteration of the RPE suggests an important role of pathologic RPE changes in the evolution of visual loss in PXE.

Ocular alterations related to PXE typically begin at the central fundus and then spread centrifugally, resulting in the most pronounced phenotype in the papillomacular area with the least abnormalities in the periphery.<sup>90</sup> This process also allows the observation of different disease stages from the periphery to the central fundus. It has recently been shown that peau d'orange, which marks the transition from calcified to uncalcified Bruch's membrane, is localized peripheral to areas of RPD. A similar topographic relationship was identified for the transition zone between normal and centrally reduced late-phase ICGA fluorescence, the latter being a result from reduced indocyanine green staining of altered Bruch's membrane and/or RPE.<sup>90</sup> Thus, specific PXE-related fundus changes appear to be localized eccentric to the RPD and precede their development.<sup>51</sup>

## Central Serous Chorioretinopathy

Central serous chorioretinopathy (CSC) is a condition characterized by idiopathic leaks at the level of the RPE leading to serous pigment epithelial and neurosensory retinal detachments. In the early phases of the disease, the visual acuity may be good despite the presence of the macular detachment, and after resolution the acuity often shows improvement. More chronic forms of CSC are associated with atrophic and degenerative changes of the retina and RPE and consequently with visual acuity decline.<sup>91</sup>

Accordingly, FAF findings in CSC are dependent on the extent of involvement of the RPE and the stage of the disease.<sup>91</sup> Patients with acute leaks imaged within the first month have minimal abnormalities other than a slight increase in autofluorescence in the

area of the serous retinal detachment. Over time, the area of the detachment increasingly exhibits more irregular increased autofluorescence. In some patients, discrete granules with increased intensity within the detachment are observed which correspond with the pinpoint subretinal precipitates seen on fundoscopy. It has been suggested that these dots may represent macrophages engorged with phagocytosed outer segments. Patients with chronic disease have irregular levels of autofluorescence with markedly decreased intensity over areas of atrophy. A typical finding also includes the visualization of fluid tracks in the inferior retina (Fig. 4.25).

**FIG. 4.25** Chronic central serous retinopathy as imaged by confocal scanning laser ophthalmoscopy shows decreased fundus autofluorescence (FAF) in the macula due to atrophy with surrounding increased FAF. Additional FAF abnormalities outside the central

macula, including prominent descending tracts or gutters, are also observed.

The area of the leak also undergoes change in autofluorescence over time. Soon after the development of CSC, little or no change in the autofluorescence pattern in the area around the leak is seen, although the leak site may be somewhat hypoautofluorescent. Patients with more chronic leaks can have decreased autofluorescence surrounding the known leaks. This area of hypoautofluorescence appears to expand in size with increasing chronicity of the leak. Altered FAF in chronic CSC patients has recently been shown to have a functional correlation quantified by microperimetry. This study underlines the impact of FAF changes on retinal sensitivity and their value to reflect the functional impairment in chronic CSC.<sup>92</sup>

## Chloroquine and Hydroxychloroquine Retinopathy

FAF imaging may show distinct alterations due to toxic retinal effects of long-term chloroquine and hydroxychloroquine therapy. Various methods have been proposed to detect early stages of chloroquine retinopathy. Early on, a pericentral ring of increased FAF intensity may occur associated with pericentral reduction in multifocal ERG amplitudes and pericentral interruption of the photoreceptor inner/outer-segment junction on SD-OCT imaging.<sup>93</sup> More advanced stages are associated with a more mottled appearance with increased and decreased FAF intensity in the pericentral macula (Fig. 4.26). While electrophysiologic examination has been thought to represent an adequate tool to diagnose early chloroquine maculopathy, FAF imaging can be used as a highly sensitive tool. However, the current recommendation is to apply a multimodal approach as multifocal ERG, FAF, and SD-OCT can all show damage at a relatively early stage, but it is not possible to predict which test will be most definitive for any given individual.<sup>94</sup>

**FIG. 4.26** Advanced stage of chloroquine retinopathy. There is a mottled appearance with increased and decreased fundus autofluorescence intensity in the pericentral macula.

## Functional Correlates of Fundus Autofluorescence Abnormalities

The relevance of alterations in FAF images can further be addressed by assessing corresponding retinal sensitivity. Severe damage to the RPE such as atrophy, melanin pigment migration, or fibrosis leading to compromised photoreceptor function is confirmed by microperimetry to correspond topographically to areas of decreased autofluorescence.<sup>57,58</sup> In patients with GA secondary to AMD, it has been shown that, in addition to absence of retinal sensitivity over atrophic areas, retinal function is relatively and significantly reduced over areas with increased FAF intensities compared to areas with normal background signal.<sup>58</sup> Localized functional impairment over areas with increased FAF has also been recently confirmed in patients with early AMD. Using fine matrix mapping,

it has been demonstrated that, interestingly, rod function is more severely affected than cone function over areas with increased FAF in patients with AMD.<sup>57</sup> These studies are in accordance with the observation of increased accumulation of autofluorescent material at the level of the RPE prior to the occurrence of cell death. As normal photoreceptor function is dependent on normal RPE function, in particular with regard to the constant phagocytosis of shed distal outer-segment stacks for photoreceptor cell renewal, a negative-feedback mechanism has been proposed, whereby cells with LF-loaded secondary lysosomes would less efficiently phagocytose newly shed photoreceptor outer segments, subsequently leading to impaired retinal sensitivity. This would also be in line with experimental data showing that compounds of LF such as A2-E possess toxic properties and may interfere with normal RPE cell function.<sup>10</sup>

In patients with different retinal dystrophies, lines and rings of increased FAF have been noted (see above).<sup>73</sup> Interestingly, functional testing by microperimetry and electrophysiology indicates that these rings circumscribe areas of preserved photoreceptor function (see [Fig. 4.17A](#)).<sup>73–75</sup>

## Introduction

Retinal imaging continues to undergo significant advances and innovations. One posterior segment imaging modality that continues to evolve is wide-field imaging. Traditional fundus cameras image 30–60° of the ocular fundus. Newer devices are capable of providing up to a 200° view of the posterior pole. The role and clinical utility of wide-field imaging continues to evolve as this imaging modality becomes more widely available and utilized in clinical research, including large clinical trials. This chapter will provide a comprehensive overview of wide-field retinal imaging.

## Historical Perspective and Terms

Early clinical examination of the fundus prior to the development of the ophthalmoscope relied either on postmortem histologic analysis of eyes or rudimentary examination of the gross red reflex observed through the pupil.<sup>1</sup> Development of the ophthalmoscope by Helmholtz in 1851 permitted detailed clinical examination of the fundus, but with a narrow field of view.<sup>2</sup> Luminaries such as Gonin

depended on a modified indirect ophthalmoscope based on Reute's "inverted image instrument,"<sup>3</sup> which offered a superior and more illuminated view, permitting Gonin and Dufour a distinct advantage over their contemporaries to definitively describe the pathogenesis of retinal detachments. Further developments in instrumentation and technology led to the development of the modern binocular indirect ophthalmoscope by Schepens which allowed a wider field of view, transforming examination of the peripheral fundus and operative repair of retinal detachments with scleral buckling. Similarly, modern wide-field imaging is now allowing enhanced examination of the retina beyond the posterior pole.

The Carl Zeiss Company produced the first fundus camera in 1926 capable of providing a 20° field of view,<sup>4</sup> which later increased to the "normal" 30° field of view which is the current "standard" field of view for fundus cameras. Any device with a larger field of view was then variably referred to as "wide-field" or "wide-angle." The actual definition of wide-field imaging in terms of number of degrees of the fundus images was historically not well established.

However, the Diabetic Retinopathy Clinical Research Network (DRCR.net) has recently defined ultrawide-field (UWF) images to have at least a 100° view of the fundus, and protocol AA<sup>5</sup> from this research network is a large ongoing prospective study specifically investigating the role of UWF imaging with results expected in approximately 2020. More recently with results from [DRCR.net](https://www.drcr.net) protocol S supporting the noninferiority of primary intravitreal ranibizumab to panretinal photocoagulation for the treatment of proliferative diabetic retinopathy (PDR),<sup>6</sup> the potential role of wide-field imaging to assess the peripheral retina for pathology including neovascularization is potentially of greater interest.

## Historical Wide-Field Imaging Systems

### Montage With Traditional Fundus Camera

Wide-field imaging may have been first described in 1977 by Lotmar who utilized a traditional fundus camera with a small field

of view, and with the assistance of a fixation lamp and rotatable mirror, was able to acquire up to 19 images to create a 96° montage. This technique is limited by patient and photographer cooperation and requires a large pupil<sup>7</sup> (Fig. 5.1). Furthermore, this method is unable to acquire simultaneous images, which may limit its use for time-dependent or dynamic studies such as fluorescein angiography (FA).

**FIG. 5.1** Posterior polar choroidal annular dystrophy: Zeiss color photographs (A,B) and corresponding color photo montage (C,D).

## Pomerantzeff Camera

In 1975, Pomerantzeff reported on the Equator-plus fundus camera which is a contact lens-based system requiring pupillary dilation and employed fiberoptic transpupillary illumination and scleral

transillumination to obtain images up to 148° degrees of the retina.<sup>8,9</sup> Major limitations of this technique included limited resolution secondary to the location and intensity of the light source.<sup>10</sup>

## Panoret

The Panoret-1000 (Medibell Medical Vision Technologies, Haifa, Israel) is based on the concept used in Pomerantzeff's camera utilizing transscleral illumination, but was handheld, capable of digital image acquisition, and provided a 100° view through an undilated pupil using a contact lens.<sup>11,12</sup> This system allowed image acquisition through miotic pupils and lenticular opacity (i.e., cataract) with limited glare given the transscleral light source. It is unwieldy to obtain images, requiring one hand to hold the camera, the other hand to hold the light and the use of a foot or assistant to capture the image by activating a foot switch. Nevertheless, with a skilled photographer, image acquisition is possible in approximately 3 minutes. One series reported reliable and high-quality imaging in 1500 patients with only six instances of an inability to acquire images due to poor patient cooperation.<sup>12</sup>

## Modern Wide-Field Imaging Systems

### RetCam

The RetCam (Clarity Medical Systems, Inc., Pleasanton, CA), first introduced in 1997, is a contact-based digital imaging system with an external fiberoptic light source that is primarily used to image neonatal and pediatric patients<sup>13-16</sup> (Fig. 5.2). Given that the illumination is performed through the cornea and crystalline lens, even small lenticular opacities may produce poor image quality, limiting its use in the adult population with cataract. The handpiece portion of the system has five interchangeable lenses capable of providing varying degrees of view, the wide-angle lens being able to image 130° degrees of the retina. This imaging system may be outfitted with a commercially available FA module at additional cost, an imaging modality that is becoming increasingly important

in many pediatric vitreoretinal conditions.<sup>17-21</sup> The RetCam is commonly used in telescreening applications for retinopathy of prematurity (ROP) – see [Chapter 65](#), Telescreening for retinopathy of prematurity.

**FIG. 5.2** Crystalline retinopathy in pediatric patient status post renal transplant. Comparison of Zeiss non-wide-angle color fundus photograph, wide-angle RetCam color fundus photographs with 80° and 130° lens along with corresponding 130°-angle fluorescein angiogram and Optos fundus photograph.

## Staurenghi Lens System and Precursors

In 2005, Staurenghi and colleagues reported on the use of a wide-angle contact lens system with a confocal scanning laser ophthalmoscopy (SLO)-based imaging platform (Ocular Staurenghi 230 SLO Retina Lens; Ocular Instruments Inc, Bellevue, WA).<sup>22-24</sup> The integrated, multielement, wide-field system consists of two biconvex aspheric lenses and a two-element convex–concave lens, which is able to image up to 150° degrees of the ocular fundus. Disadvantages of this system include that it requires topical anesthesia given a contact lens must be placed, image quality may be limited by lenticular opacities, and it requires a skilled

photographer to stabilize the lens while simultaneously acquiring the images.

Prior to the development of the Staurenghi lens system, investigators in Japan become interested in wide-angle (up to 70°) indocyanine green angiography (ICGA) to examine the peripheral choroidal circulation and watershed zones.<sup>25</sup> In 1996, this team performed ICGA using a SLO and a handheld 30-diopter lens. Soon after in 1998, Spaide and colleagues reported on the use of a wide-angle contact lens (Volk SuperQuad 160, Volk Optical Inc., Mentor, OH) in combination with a fundus camera to provide a greater view of the peripheral fundus circulation.<sup>26</sup> These systems, like the Staurenghi lens system, have the disadvantage of autofluorescence from the crystalline lens, which degrades image quality.

## Mobile Phone Imaging With Indirect Lenses

In an era of smartphone mobile technology, reports have been published on utilizing the camera light of a smartphone with a conventional indirect condensing lens to acquire digital images of the fundus.<sup>27,28</sup> Low cost software applications may be needed to facilitate image acquisition. Modifications of the technique, including placement of a Koeppel lens on the cornea, can be used to improve image quality and prevent corneal desiccation when imaging is done during exams under anesthesia. Globally, this may prove to be a cost-effective alternative to more expensive systems such as the RetCam, but at the expense of decreased resolution and challenging image acquisition.

## Heidelberg Spectralis Non-Contact Ultrawide-Field Module

Recently, a non-contact lens has been developed that may be attached to the existing Heidelberg Spectralis or HRA2 cSLO (Heidelberg Engineering, Inc., Heidelberg, Germany) to expand the existing 55° maximum field of view available with this system to 105°.<sup>29</sup> Although this adapted system images less area than the other commercially available non-contact UWF system from Optos, it may have the advantage of less lash artifact, resulting in

improved imaging of the superior and inferior periphery in some patients. In a single view, this system is capable of providing real-time, UWF multimodal imaging including simultaneous FA and ICGA.

## Optos

The Optos cSLO UWF imaging system (Optos PLC, Dunfermline, United Kingdom) utilizes an ellipsoid mirror to image up to 200° or approximately 80% of the ocular fundus<sup>30</sup> (Fig. 5.3). It first became commercially available in 2000. It does not require the use of a contact lens and is capable of imaging through a nondilated pupil or other conditions where there is a small optical aperture to the posterior segment such as a permanent keratoprosthesis<sup>31</sup> or implanted telescope in patients with advanced macular degeneration. The image acquisition time is rapid at approximately 0.25 seconds by using two galvanometer mirrors to provide quick two-dimensional scanning. This technical aspect can be particularly useful to acquire images of the posterior pole in patients with nystagmus and photophobia and in children. The ellipsoid mirror of the device has two focal points with the laser of the Optos being directed to one of the focal points and the patient positioned in front of the machine such that the second focal point is within the eye near the pupillary plane thereby creating large scan angles, allowing imaging out to the ora serrata in patients with good compliance and wide pupillary dilation.<sup>30</sup> The Optos platform is capable of pseudocolor fundus photography, green-light fundus autofluorescence (FAF), FA, and ICGA.

Lasers are projected through an optical scanning system. These lasers sweep through a virtual scanning point inside the eye.

**FIG. 5.3** Optics of Optos scanning laser ophthalmoscope with ellipsoidal mirror. (Copyright 2015 Optos. All rights reserved. Optos and optos are registered trademarks and optomap is a trademark of Optos Plc. GA-00244/1.)

Although this platform currently provides the largest single frame view of the posterior pole, there are some disadvantages or limitations. Currently, the SLO only employs a red and green channel SLO that are combined to create a pseudocolor image. The manufacturer may add a blue channel in the future to better simulate the true colors of the posterior segment that are seen with traditional flash fundus photography. Additionally, mapping a three-dimensional structure onto a two-dimensional surface creates a map distortion. Peripheral areas of the ocular fundus are disproportionately imaged by nearly twice that of the posterior pole with the horizontal axis being warped and stretched more so than the vertical axis.<sup>32</sup> These distortions may be mitigated by a stereographic projection/correction that has recently been developed.<sup>33</sup> This stereographic projection maintains the same angular magnification at all eccentricities, allowing reliable measurements to be made. Lastly, UWF images captured with the device provide a lower resolution image of the posterior pole compared with other SLO systems such as the Heidelberg Spectralis. This shortcoming is partially reduced when utilizing the

ResMax™ feature which allows a smaller area to be imaged (i.e., posterior pole) on the same sensor that would be used to image a much larger area of the retina, thereby resulting in a higher resolution image. Additionally, the large depth of focus in this system is useful to maintain the entire ocular fundus in focus despite different anterior and posterior locations and for imaging elevated lesions such as choroidal tumors or depressed areas such as a posterior staphyloma. However, this large depth of field also commonly allows the patient's eyelashes and nose to appear in the image. The eyelash artifact can be diminished by placement of a speculum.<sup>34</sup>

## Overview of Imaging Capabilities and Optical Principles

Traditional fundus cameras produce color fundus photographs by using white light as an illumination source and capturing the image on traditional film or via digital methods. Among UWF devices, this type of imaging or acquisition strategy is employed by the RetCam platform. However, both the Heidelberg and Optos UWF platforms utilize SLO optics. For instance, the Heidelberg Spectralis in a non-wide-field platform is able to produce a multicolor image from infrared (820 nm), green (518 nm), and blue (488 nm) reflectance channels. Similarly, the Optos platform produces color images of the retina by confocal scanning with green (red-free) laser light at 532 nm and also red-light at 633 nm. The images may be viewed together which provides a colored image of the fundus, and a “white-balance” mode may be employed to more closely approximate the true colors of posterior segment pathology. Furthermore, the separate SLO channels may be viewed separately. Green (red-free) highlights the retinal vasculature and anterior retinal structures, and the red channel accentuates deeper retinal structures and the choroidal vasculature. It is important for the clinician to be aware that the SLO derived images are acquired differently than traditional fundus cameras, which employ a full spectrum of white light, therefore the coloration between the two types of systems will be distinct. This has implications for the

assessment of many lesions for which coloration is of significant importance such as with intraocular tumors or areas of retinitis.

For FA, the Optos employs a 488 nm excitation signal through its dichroic beam-splitters and confocal aperture and a 500 nm filter when detecting the fluorescence from the fundus.<sup>35,36</sup> For ICGA with the Optos platform, a 805 nm excitation beam is emitted and the cyanescence returns through a 835 nm filter.<sup>37</sup> Identical excitation and barrier filter wavelengths are used for FA in the Heidelberg Wide-Field Non-Contact System. However, for indocyanine green angiography a diode laser at 790 nm is used together with a barrier filter at 830 nm to separate excitation and cyanescence.

With regard to the spectrums used for wide-field FAF, the Optos system employed the green 532 nm for excitation and a 570–780 nm filter (yellow–orange–red range) to detect fundus autofluorescence. In comparison, the Heidelberg platform most commonly uses a 488 nm to produce short-wavelength autofluorescence images, though the capability for green autofluorescence has also been added to some systems. The Heidelberg system is also capable of producing near-infrared autofluorescence using a 787 nm wavelength. The most striking difference with the near-infrared images of the posterior pole is that there is an area of increased hyperautofluorescence centered on the fovea which likely corresponds to the area with higher retinal pigment epithelial melanin seen in color photographs.<sup>38</sup> Comparing the short-wavelength of the Optos versus Heidelberg SLO systems for fundus autofluorescence (532 nm vs. 488 nm), the slightly longer wavelength of the Optos system may be less affected by absorbance from cataract,<sup>39</sup> but both systems utilize a confocal pinhole which greatly reduces out of focus autofluorescence signal from the lens to limit image quality degradation.<sup>40</sup>

## Clinical Utility of Wide-Field Imaging

Wide-field and more recently ultrawide-field imaging continues to have an evolving role in the diagnosis and management of retinal diseases. Though the majority of published reports utilizing UWF imaging are predominately descriptive and retrospective in nature,

they have led to important observations which have prompted more detailed prospective studies that are in progress.

## Diabetic Retinopathy

The importance of the periphery in diabetes was apparent in early prospective trials such as the Early Treatment of Diabetic Retinopathy Study (ETDRS) where seven standard field 30° images could be combined to create a 75° montage. This 75° assessment became the early standard for diabetic clinical trials.<sup>41</sup> The use of UWF imaging has revealed potentially important clinical findings in the periphery of diabetic eyes beyond the seven standard ETDRS field, and the clinical significance of these findings are continuing to be investigated.

Initial studies utilizing nonmydriatic UWF imaging for screening of diabetic retinopathy found that there was a 94% sensitivity compared to the clinical exam, and follow-up recommendations corresponded to clinical recommendations at a rate of 82%.<sup>30</sup> Subsequent studies have found moderate agreement between slit-lamp examination and review of Optos UWF imaging for the detection of diabetic retinopathy in a real-life setting.<sup>42</sup> Another study comparing nonmydriatic Optos UWF images with dilated ophthalmoscopy reported a sensitivity of 94% and specificity of 100% for detection of diabetic retinopathy worse than mild nonproliferative disease, with moderate to substantial intergrader agreement for retinopathy severity grading using an unweighted kappa statistic.<sup>43</sup> Another study found similar sensitivity and specificity of nonmydriatic UWF imaging compared to single-field and dual-field mydriatic digital retina photography, with sensitivity of 83.6% and specificity of 89.5% for UWF, albeit with a slightly higher technical failure rate with wide-field imaging.<sup>44</sup> More recently, studies have compared the seven standard field ETDRS photographs to UWF imaging and have found substantial agreement in determining disease severity, with UWF also identifying peripheral lesions suggesting more severe disease than observed within the ETDRS fields in 10% of eyes.<sup>45</sup> Telemedicine screening paradigms are now being reported using real-time, point-of-care UWF image acquisition and interpretation by nonphysician

imagers in which <0.1% of referable diabetic retinopathy would be missed.<sup>46–48</sup>

Early reports also noted the benefit of UWF–FA for the diagnosis of PDR<sup>49</sup> (Fig. 5.4) and that this type of wide-field imaging could be particularly useful in the setting of vitreous media opacity such as asteroid hyalosis.<sup>50</sup> A study from Weill Cornell found that UWF–FA compared to the seven standard fields (7SF) FA imaged 3.9 times more nonperfusion, 1.9 times more neovascularization, and prompted 3.8 times more panretinal photocoagulation.<sup>51</sup> This study, in addition to others, also found that in 10% of eyes, UWF–FA demonstrated peripheral nonperfusion and neovascularization not evident on 7SF imaging.

**FIG. 5.4** Optos photograph of proliferative diabetic retinopathy (PDR) (A) and additional cases of PDR on Optos ultrawide-field–fluorescein angiography (UWF–FA).

UWF imaging has also been used to specifically investigate

peripheral nonperfusion and neovascularization and the relationship to macular ischemia and diabetic macular edema.<sup>52</sup> A study of 264 eyes with diabetic retinopathy found that peripheral vascular leakage (PVL) was present in 41% of eyes as frequently as neovascularization, but less commonly than peripheral nonperfusion (54%) or focal or diffuse angiographic macular edema (57%).<sup>53</sup> This study found an association between PVL and peripheral nonperfusion and posterior neovascularization, but not with macular edema. An additional retrospective study found a moderate association between the peripheral ischemic index and increased foveal avascular zone (FAZ).<sup>52</sup> Other studies have found a direct correlation between peripheral retinal ischemia in diabetic retinopathy and diabetic macular edema, reporting a 3.75 increased odds of DME in association with peripheral retinal nonperfusion.<sup>54</sup> Another report investigated the correlation of the ischemic index (ratio of nonperfused fundus area to total fundus area) in patients with recalcitrant DME.<sup>55</sup> Eyes with a greater ischemic index and more severe diabetic retinopathy were found to have more severe DME as measured by number of focal macular laser treatments and less reduction in central macular thickness on SD-OCT. Previous studies utilizing “ischemic index” with Optos imaging should be interpreted with caution given that they did not employ standardized technique for quantification, nor did they account for the distortion and overrepresentation of the peripheral fundus in these UWF images, or the differing metabolic requirements and types of cells present in peripheral areas of the fundus.<sup>56,57</sup>

Naturally, clinicians utilizing UWF imaging including angiography for the evaluation of diabetic retinopathy have investigated its use for delivering angiographic guided therapy including targeted laser photocoagulation (TRP).<sup>58</sup> In contrast to panretinal photocoagulation (PRP), TRP implies viewing the UWF-FA and specifically treating area of retinal nonperfusion along with the intermediate, transition zones between perfused and nonperfused retina. A prospective study of treatment-naïve PDR with a single session 20 msec, 1500-spot pattern scan laser (PASCAL) retinal photocoagulation found that 76% of patients exhibited regression of PDR at 12 weeks.<sup>59</sup> If these results can be replicated, potential benefits of TRP over PRP include decreased

incidence of post-laser macular edema, nyctalopia, and peripheral visual field loss. Future prospective, randomized clinical trials are needed to assess the safety and efficacy of this modified treatment paradigm.

## Retinal Venous Occlusions

Retinal vein occlusion is the most common retinal vascular occlusion and may lead to peripheral retinal ischemia, neovascularization, and macular edema. UWF-FA has been shown to be important for diagnosing central retinal vein occlusion (CRVO) with peripheral nonperfusion and is reliable at detecting macular leakage and ischemia<sup>60</sup> (Fig. 5.5). UWF-FA has been reported in branch and hemiretinal vein occlusion, and it has been shown that untreated peripheral nonperfusion was significantly associated with macular edema and neovascularization<sup>61</sup> (Fig. 5.6).

**FIG. 5.5** Bilateral central retinal vein occlusion in

patient with leukemia: Optos photographs (A,B),  
fluorescein angiography (C,D).

**FIG. 5.6** Optos fluorescein angiogram of superior retinal vein occlusion.

Tsui and colleagues found that treatment-naïve eyes with CRVO and neovascularization on presentation were found to have a significantly larger ischemic index than eyes not presenting with neovascularization (mean 75% vs. 25%), however, the study was not prospective and the time of onset of CRVO to presentation could not be precisely ascertained.<sup>62</sup> Spaide evaluated peripheral nonperfusion on UWF-FA in eyes with CRVO undergoing anti-VEGF therapy and found no correlation between the number of intravitreal injections and peripheral nonperfusion. He did, however, observe an inverse statistically significant correlation between the area of peripheral nonperfusion and visual acuity.<sup>63</sup> In a study of retinal vein occlusions, patients with ischemic index >10% had increased subfoveal macular thickness on SD-OCT and worse visual acuity.<sup>64</sup> Similar to diabetic retinopathy treatment, TRP has been reported in a patient with CRVO and rebound macular edema which resulted in regression of rubeosis and rebound edema.<sup>65</sup> Further studies are needed to better correlate peripheral

nonperfusion on UWF-FA with actual retinal ischemia to better characterize and subgroup retinal vein occlusion phenotypes, which may have important diagnostic, prognostic, and treatment implications (Figs. 5.7 and 5.8). The ongoing SCORE-2 trial, comparing aflibercept and bevacizumab for the treatment of macular edema associated with retinal vein occlusion, is employing Optos wide-field angiography, and should yield additional information in this regard. UWF imaging may also be of clinical benefit in other retinal occlusive disease such as retina arterial occlusion, but few studies have been reported.

**FIG. 5.7** Optos fluorescein angiogram of retinal artery occlusion.

**FIG. 5.8** Nonmydriatic Optos color photograph (A) in a pregnant patient demonstrates cherry-red spot consistent with central retinal artery occlusion and corresponding optical coherence tomography (B) demonstrated inner retinal edema.

## Other Retinal Vascular Conditions

UWF imaging has been utilized in other conditions with posterior segment pathology including sickle cell disease<sup>66</sup> (Fig. 5.9), beta-thalassemia,<sup>67</sup> antiphospholipid antibody syndrome,<sup>68</sup> Takayasu arteritis,<sup>69,70</sup> retinopathy associated with facioscapulohumeral muscular dystrophy,<sup>71</sup> Duchenne muscular dystrophy,<sup>72</sup> Susac syndrome,<sup>73</sup> preeclampsia with HELLP syndrome,<sup>74</sup> and Valsalva retinopathy (Fig. 5.10).

**FIG. 5.9** Sickle cell retinopathy: Optos fluorescein angiography in three distinct cases reveals peripheral nonperfusion and neovascularization in two cases (A,B).

**FIG. 5.10** Optos color photograph of Valsalva retinopathy.

## Uveitis

The use of UWF in various types of intraocular inflammation has provided additional information about the retinal periphery in

these diverse disease entities (Figs. 5.11–5.14). However, the optimal use, clinical impact and utility in dictating therapeutic interventions, and monitoring response to treatment remain controversial among uveitis specialists. Early reports have shown the utility of UWF–FA to assess the extent and severity of retinal disease and progression and response to treatment in intermediate<sup>75</sup> and posterior uveitis (Fig. 5.15) including systemic lupus erythematosus, cytomegalovirus (CMV) retinitis (Figs. 5.16–5.18), idiopathic and acute posterior multifocal placoid pigment epitheliopathy.<sup>76</sup> A study with 12 eyes with CMV retinitis demonstrated that UWF imaged 48.3% greater retinal area and 40.0% more active retinitis area compared to conventional nine-field photography.<sup>77</sup> Importantly, standard field photography missed CMV lesions in two eyes. A patient satisfaction survey indicated a preference for UWF imaging due to increased comfort and decreased image acquisition times. Subsequently a study of 52 eyes of 31 patients, compared Optos UWF imaging to standard nine-field montage and found that Optos UWF–FA captured more retinal vascular pathology in the periphery and posterior pole, but noted the clinical implications of these findings remains to be determined.<sup>78</sup> Another study utilized the Staurenghi lens system in 26 patients with posterior uveitis.<sup>24</sup> The study found UWF imaging assisted in the diagnosis, quantifying the extent of vasculitis and planning treatment (photocoagulation or immunosuppression titration) in 62% and enhanced disease monitoring in 35%. The UWF imaging in this study detected vasculitis that was not clinically evident in 31% of patients.<sup>24</sup> Collectively, these studies support the concept that UWF–FA in uveitis may aid in planning targeted laser photocoagulation to areas with significant nonperfusion with or without neovascularization (Figs. 5.19 and 5.20).

**FIG. 5.11** Ocular syphilis: Optos color photographs (A,B), autofluorescence (C,D), late fluorescein angiogram (E,F).

**FIG. 5.20** Multifocal choroiditis with choroidal neovascular membrane: Optos color photograph (A) and autofluorescence (B).

Although initial studies were primarily descriptive in nature, prospective studies have also been conducted to evaluate the relevance of UWF imaging on management decisions. In a study of 43 eyes with noninfectious posterior uveitis, only 16% had a change in management based on findings evident on a standard posterior pole FA, but this increased to a change in management in 48% of cases when an UWF–FA with visualization of the periphery was available.<sup>79</sup> A similar study from the same group examining the role of UWF in retinal vasculitis found that management was altered in 4% of eyes with the addition of simulated non-wide-field color images, in 14% with the addition of Optos pseudocolor images, and in 51% of eyes with the addition of Optos UWF–FA.<sup>80</sup> A study of wide-field imaging in Beçhet disease associated with retinal vasculitis found that Optos UWF imaging assisted in diagnosis and quantification of the degree of retinal vasculitis in 80% which led to enhanced diseased monitoring in 55% and medical treatment or laser photocoagulation in 65%.<sup>81</sup> These studies support the evolving clinical role of UWF imaging in the diagnosis, therapeutic decision-making, and monitoring of disease activity in the setting of uveitis.

## Pediatric Retina

Wide-field imaging in the pediatric population has several unique considerations including potential challenges related to patient cooperation. Many pediatric vitreoretinal disorders can manifest

with significant peripheral pathology, and some, in particular retinopathy of prematurity (ROP), have lent themselves to telescreening programs. Although binocular indirect ophthalmoscopy remains the gold standard for the diagnosis of conditions such as ROP,<sup>82</sup> it requires a skilled examiner and may result in cardiac or respiratory distress in neonates,<sup>83</sup> which may be lessened with wide-field imaging.<sup>84</sup> The two imaging platforms primarily utilized in the pediatric population include the RetCam and Optos. The main disadvantage of the RetCam system is it requires a cooperative patient or examination under anesthesia given it is a contact-based system. Optos is an alternative, non-contact system that is increasingly being used to diagnose and monitor a variety of pediatric retinal conditions including uveitis, Coats disease, hereditary dystrophies, congenital anomalies such as coloboma (Fig. 5.21), and familial exudative vitreoretinopathy (FEVR) (Fig. 5.22) in the outpatient setting without the need for examination under anesthesia.<sup>85,86</sup> Optos UWF imaging and FA has also led to improved classification and new insights into the pathophysiology and varying phenotypes of disorders such as FEVR.<sup>87,88</sup> Wide-field FA has also provided insights into the normal retinal vascular periphery in children which may include areas of nonperfusion.<sup>89</sup>

**FIG. 5.21** Optos color photograph of inferior coloboma.

**FIG. 5.22** Familial exudative vitreoretinopathy: Optos color photograph demonstrated macular dragging and temporal traction (A) with corresponding fluorescein angiogram showing peripheral nonperfusion (B).

Wide-field imaging has been extensively studied in retinopathy of prematurity, in part related to the growth of telemedicine screening programs.<sup>14,16,20,90-102</sup> This is discussed at length in [Chapter 65](#), Telescreening for retinopathy of prematurity. Multiple studies have evaluated the sensitivity and specificity for detecting ROP compared to the clinical exam,<sup>14,93,94</sup> with generally favorable results, including one study reporting RetCam photography having 82% sensitivity and 94% specificity for detecting any stage of ROP.<sup>14</sup> More recently, several studies have investigated the role of fluorescein angiography for the diagnosis and management of ROP, as FA may improve the ability to detect certain subtypes of ROP, including disease requiring treatment.<sup>20,21</sup> Although the RetCam is the wide-field imaging system most commonly used in neonatal screening for ROP, reports have also been published using the Optos system with a special “flying baby” position to obtain high-resolution UWF images in ROP babies.<sup>103,104</sup>

## Retinal Detachment and Myopia

Wide-field imaging is increasingly being used to preoperatively

document retinal detachments, assist in preoperative planning, and postoperatively monitor the status of the retina. The peripheral documentation capability of UWF imaging is especially important in the era of co-management and the primary retina surgeon practicing at multiple sites<sup>105-107</sup> (Figs. 5.23–5.26). It may be also used to document less common entities such as choroidal detachment.<sup>74,108</sup> Nevertheless, binocular indirect ophthalmoscopy remains the gold standard for the diagnosis of retinal detachments and visualization of pathology in the far periphery.<sup>105,109</sup> One study noted that in patients with acute posterior vitreous detachment, the Staurenghi lens system detected all (100%) peripheral retinal tears.<sup>110</sup> This is in contrast to the Optos system which has satisfactory sensitivity and specificity for the detection of retinal detachments and retinal tears or holes,<sup>109,111</sup> but may not perform as well in the superior and inferior periphery.<sup>105,112</sup> This limitation can be overcome to some extent by good dilation and obtaining additional steered images, where the photographer instructs the patient to gaze toward the desired quadrant prior to image capture.<sup>113</sup>

**FIG. 5.23** Optos color photograph (A) and autofluorescence (B) of retina detachment with areas of patchy hyper- and hypoautofluorescence.

**FIG. 5.24** Optos photograph of subtotal retinal detachment with temporal retinal tear (A) and status post repair with pars plana vitrectomy (B).

**FIG. 5.25** Optos photograph of superior giant retinal tear extending from 10 to 2 o'clock (A) with corresponding red-free channel image (B).

**FIG. 5.26** Optos photograph of retinal detachment (A) and status post pneumatic retinopexy (B) with  $C_3F_8$  gas, note early chorioretinal scarring to retinal breaks superiorly.

Multimodal wide-field imaging including fundus autofluorescence (FAF) has been evaluated in the setting of retinal detachment by Witmer and colleagues.<sup>114</sup> This study found that UWF-FAF is useful for determining the complete extent of the retinal detachment by areas of increased hypoautofluorescence. Additionally, in all but one case they observed a hyperfluorescent leading edge (HLE) preoperatively which resolved in all eyes postoperatively. The study also noted that granular autofluorescent changes were associated with worse preoperative and postoperative visual acuities.<sup>114</sup>

Although UWF imaging is not a substitute for clinical examination, its role currently appears to be as a useful adjunct to binocular indirect ophthalmoscopy, colored fundus drawings, and electronic medical records. For instance, one group has investigated UWF imaging to assess the adequacy of cryotherapy and determining buckle height based upon autofluorescence changes. The study found the ideal amount of cryotherapy was associated with central increased hypoautofluorescence and a ring of increased hyperautofluorescence. Additionally, a higher buckle height was associated with an increase in hyperautofluorescent streaks in the area of imbrication.<sup>115</sup> A study on proliferative vitreoretinopathy-associated detachments revealed that early Optos imaging could document the extent of fibrotic epiretinal and subretinal tissue as

well as anatomic reattachment with inferior retinectomy.<sup>107</sup> A case report has also described the use of UWF to monitor for postoperative complications such as neovascularization and macrocyst associated with chronic rhegmatogenous retinal detachment.<sup>116</sup> A study from our group has also suggested that though Optos UWF was not as good as the clinical exam for evaluating superior and inferior pathology, it was better for documenting the actual, precise clock hours and extent of retinal detachments.<sup>105</sup>

Degenerative high myopia is a risk factor for retinal detachment and is associated with other complications including myopic choroidal neovascularization (CNV). One study reported a sensitivity of 43.8% for detecting retinal breaks and 66.7% for retinal detachments with an overall 90.9% sensitivity for detecting other peripheral lesions, including lattice degeneration and white without pressure.<sup>113</sup> The Optos UWF system can be advantageous for documenting posterior staphyloma, which may extend outside of the traditional 30–50° view and can be well imaged due to the device's large depth of field. One study proposed a new classification for posterior staphyloma and found that multimodal Optos UWF imaging compared to three-dimensional magnetic resonance imaging had a sensitivity of 85% and specificity of 85.7% for detecting the borders and extent of the staphyloma.<sup>117</sup> Another group from Japan has also found that UWF–FAF documents radial tracts emanating from the staphyloma edge in pathologic myopia.<sup>118</sup> UWF–FA has also provided new insights into peripheral retinal circulation of eyes with high myopia, showing that compared with emmetropic eyes which had significant peripheral nonperfusion present in only 4.8%, eyes with high myopia exhibited similar changes at a rate of 82.6%.<sup>119</sup>

## Retinal and Choroidal Dystrophies

UWF imaging, particularly fundus autofluorescence (FAF), can be a useful imaging modality in these disorders for not only aiding in detection and diagnosis, but also in facilitating phenotype–genotype correlations, in conjunction with other definitive testing such as electroretinogram (ERG) or genetic analysis (Figs.

5.27–5.30). Gyrate atrophy and choroidemia were the first dystrophies reported to have UWF fundus photography and fluorescein angiography performed and compared to non-wide-angle imaging.<sup>120</sup>

**FIG. 5.27** Familial dominant drusen: Optos color photograph (A) and corresponding autofluorescence (B).

**FIG. 5.28** Autosomal dominant retinal degeneration:  
Optos color photograph (A,B) and fundus  
autofluorescence (C,D).

**FIG. 5.29** Retinitis pigmentosa: Optos color photograph (A,B) and fundus autofluorescence (C,D).

**FIG. 5.30** Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS): Optos color photograph (A,B) and fundus autofluorescence (C,D).

A study reported on multimodal UWF imaging in a large family with a novel *CHM* mutation resulting in X-linked choroidemia.<sup>121</sup> All males displayed characteristic peripheral chorioretinal atrophy with islands of macular sparing, however, female carriers exhibited a wide range of variability on FAF with more severe changes observed with increasing age. Additionally, studies have been published on retinitis pigmentosa<sup>122</sup> and cone-rod dystrophies.<sup>123</sup> In retinitis pigmentosa, investigators found that the total area of abnormal FAF on UWF imaging correlated with the visual field area measured by Goldmann visual field (GVF) testing.<sup>122</sup> These results in retinitis pigmentosa were also supported by similar results from another group, who also report that UWF-FAF can be important for monitoring disease progression as FAF changes precede loss of retinal function.<sup>124</sup> A similar study conducted by this group found that in cone-rod dystrophies the area of abnormal FAF

on UWF imaging correlated with scotoma measured by GVF I4e isopter testing, amplitude of rod ERG, combined ERG a-wave and b-wave, cone ERG and flicker ERG.<sup>123</sup>

## Ophthalmic Oncology

Many peripheral fundus lesions including choroidal nevi, uveal melanoma (Figs. 5.31 and 5.32), retinoblastoma, choroidal metastases (Fig. 5.33), tumors of the retinal pigment epithelium, retinal hemangioblastomas (Fig. 5.34), choroidal hemangiomas, and vasoproliferative tumors may occur or have secondary effects in the retinal periphery such as exudation and inferior serous retinal detachments. Initial reports utilized the Panoret-1000 imaging platform to image peripheral tumors.<sup>11,12</sup> More recent reports have utilized the Optos UWF imaging system.<sup>125-131</sup> UWF-FAF, available with Optos SLO, may have particular value in lesions with orange pigment, a surrogate for lipofuscin, which is a risk factor for growth and metastasis of melanocytic lesions.<sup>132</sup>

**FIG. 5.31** Optos photograph of choroidal melanoma (A) and early (B) and late (C) fluorescein angiogram.

**FIG. 5.32** Optos photograph of choroidal melanoma with subretinal fluid (A) and Heidelberg autofluorescence (B) illustrating mottled areas of increased hyperautofluorescence corresponding to lesion and increased hyperautofluorescence corresponding to areas of subretinal fluid.

**FIG. 5.33** Choroidal metastasis from metastatic breast cancer: Optos photograph right eye (A) demonstrated multifocal choroidal lesions and left eye (B) shows choroidal lesions with inferior serous retinal detachment.

**FIG. 5.34** Von Hippel–Lindau syndrome: Optos fluorescein angiogram shows small retinal capillary hemangioblastoma along inferotemporal arcade.

Consequently, clinicians have begun to investigate the clinical utility of wide-field imaging for the diagnosis, monitoring, and progression of melanocytic lesions. Studies have also suggested that UWF imaging may be more accurate at determining the true prevalence of choroidal nevi in a healthy population.<sup>133</sup> Basal diameters of tumors determined with Panoret-1000 imaging were found to be larger when compared with measurements obtained by B-scan ultrasonography (US).<sup>11</sup> This discrepancy may be attributable to photography documenting the extent of pigmentation or pigment alteration which extend beyond the area of elevation detectable on the B-scan. A more recent study found good concordance between B-scan US dimensions and Optos UWF but with a slightly greater correlation for transverse versus longitudinal scans.<sup>128</sup> Reports have also assessed the red and green SLO channels on the Optos system independently,<sup>128,129</sup> with one study suggesting on the “green channel separation,” a trend towards a more mixed FAF appearance of melanomas compared to nevi.<sup>129</sup> Another study suggested that melanomas appeared dark on the red channel and bright on the green channel, with this binary characteristic providing relatively high sensitivity and specificity for the correct classification of lesions.<sup>128</sup>

Given the widespread and increasing use of UWF imaging,

particularly UWF–FA, in retinal diseases such as diabetic retinopathy and retinal venous occlusive disease, a similar future area of applicability for wide-field imaging is in the diagnosis, evaluation and management of radiation retinopathy. Radiation retinopathy shares many similarities to diabetic retinopathy, including microvascular angiopathy with peripheral nonperfusion, possible retinal neovascularization, and macular edema.<sup>134–136</sup> UWF imaging may also be important to determine the effects of therapies aimed to reduced radiation retinopathy such as pars plana vitrectomy with placement of silicone oil at the time of plaque brachytherapy.<sup>137</sup>

## Central Serous Chorioretinopathy

With UWF–FAF and the recent addition of UWF indocyanine green angiography (ICGA),<sup>37</sup> new insights into the extent of choroidal vessel hyperpermeability, extent of serous retinal detachments, and pigment epithelial detachments have been appreciated in the periphery of the fundus in central serous chorioretinopathy (CSCR)<sup>138</sup> (Fig. 5.35). A multicenter retrospective study found that dilated choroidal vessels and hyperpermeability on UWF–ICGA corresponded with areas of altered FAF, with 57% of eyes displaying pathology outside the standard 50° field of view. Additionally, in 83.3% of eyes, dilated vessels were associated with one or more congested vortex vein ampullas, suggesting impeded ocular outflow as a novel pathophysiologic contributing factor to CSCR.<sup>138</sup> Another study including 24 eyes with CSCR found peripheral abnormalities on UWF–ICGA in 64.6% of eyes.<sup>37</sup> A report compared the non-wide-field Heidelberg FAF to Optos UWF–FAF and found differences in lesion intensity before and after resolution but similar lesion composite patterns.<sup>139</sup> Future studies are needed to ascertain the ability of UWF imaging to provide further phenotypic differentiation in this disorder, direct treatments such as photodynamic therapy, and better monitor disease activity including recurrence.

**FIG. 5.35** Central serous chorioretinopathy (CSCR): Optos fluorescein angiography demonstrated diffuse multifocal late leakage.

## Age-Related Macular Degeneration

Although the clinical management of macular degeneration hinges upon macular imaging including OCT and FA, wide-field imaging has allowed for monitoring of concurrent peripheral findings in both neovascular and non-neovascular age-related macular degeneration (AMD).<sup>37</sup> The benefits of wide-field imaging apply to related neovascular disorders such as polypoidal choroidal vasculopathy (PCV). Initial reports highlighted the ability of UWF imaging to detect peripheral CNV<sup>140,141</sup> (Fig. 5.36). A study of participants in the Reykjavik Eye Study found that Optos pseudocolor SLO images compared to Zeiss fundus camera 45° images had overall agreement of 96.43% with excellent intergrader agreement ( $\kappa = 0.93$ ).<sup>142</sup> Importantly, a large, multicenter study of multiple disease conditions including AMD and PCV found that Optos UWF imaging was able to provide excellent quality images of the macula as well as the fundus periphery for the detection and diagnosis of vascular changes on ICGA.<sup>37</sup>

**FIG. 5.36** Optos color photographs of several cases of extrafoveal choroidal neovascular membranes which would be incompletely detected by non-wide-field imaging.

Other studies have focused on peripheral FAF findings in AMD.<sup>143–145</sup> A retrospective study of UWF–FAF and UWF pseudocolor images found that among 135 eyes with AMD, 73.9% had peripheral FAF changes and 79.3% of pseudocolor images had peripheral findings outside the central field of view (standard ETDRS Field 2 and Field 1M photographs used in AREDS study).<sup>143</sup> A prospective study of 119 patients (100 with AMD and 19 without AMD) reported peripheral FAF abnormalities in 68.9% of eyes with significant risk factors for peripheral abnormalities including neovascular AMD (OR 12.7, compared to normals), non-neovascular AMD (OR 6.2), older age (OR 6.5), and female sex (OR 4.1).<sup>145</sup> A study found increased peripheral FAF changes with age, but found that age-corrected peripheral FAF irregularity was greater in both treated (anti-VEGF) and untreated eyes with AMD compared to normal controls.<sup>144</sup> More recent studies are proposing new classifications and phenotypes for AMD-like changes in the far periphery even in those without macula-threatening disease<sup>146</sup> (Fig. 5.37).

**FIG. 5.37** Presumed ocular histoplasmosis syndrome (POHS): Optos color photograph (A) and fundus autofluorescence (B).

## Limitations

The most important limitation of wide-field imaging or UWF imaging systems is the inability to image the entire retina ora-to-ora with a single acquisition in most patients.

Traditional fundus cameras image approximately 5–15% of the total retinal surface area, whereas the Optos manufacturer states their system is capable of imaging 82% of the retinal surface based on several assumptions, including a standardized radius of the eye of 11 mm.<sup>106</sup> Likewise, the representation of a three-dimensional image on a two-dimensional surface overrepresents areas of the periphery compared to their true anatomic proportions, which may limit quantitative assessment of UWF images.<sup>63</sup> The optics of the device, combined with the large depth of field (Fig. 5.38), also tend to provide poorer imaging of the superior and inferior quadrants of the retina,<sup>105,112</sup> which may also be limited by lash artifact and other structures anterior to the retina.<sup>147</sup> Reports also suggest that image acquisition with devices such as the Optos have a learning curve, given that it is a SLO acquisition, there is no preview of the image to be acquired such as with traditional fundus photography or the Heidelberg system, which provides an infrared image for the photographer to focus prior to acquisition of OCT or FAF.<sup>148</sup> Finally, many of these systems, including the Optos and RetCam, may be

costly and present a challenge in a era of rising healthcare costs and a desire to keep these costs contained.

**FIG. 5.38** Optos vitreous imaging: Asteroid hyalosis (A), free-floating vitreous cyst (B), dislocated intraocular lens in a patient with pseudoexfoliation (C). The large depth of field of the Optos platform allows relatively focused simultaneous imaging of both the fundus and vitreous cavity.

## Future Directions

The role of wide-field imaging continues to evolve, with an increasing number of initial case reports, followed by retrospective series and now prospective trials incorporating this imaging technology. In an era of increasing numbers of patients with a limited pool of healthcare providers, wide-field imaging will

continue to have a role in screening and telemedicine applications for diseases such as diabetic retinopathy and retinopathy of prematurity.

The Optos platform initially became available as a SLO with pseudocolor imaging capability, and has now evolved into a multimodal imaging device capable of FAF, FA, and ICGA. Newer platforms such as the PanoCam LT (Visunex Medical Systems, Fremont, CA) have recently been approved by the Food and Drug Administration in the United States and provide another option for wide-field imaging (Figs. 5.39 and 5.40). Additional imaging technologies, such as swept source OCT, may be incorporated in the future with advances in optics that may allow for noninvasive wide-field OCT angiography. As UWF imaging continues to allow us to further study the retinal periphery with multimodal imaging, the pathophysiology of different retinal diseases will continue to be studied noninvasively, which may translate into improved disease diagnosis, staging, and treatment.

**FIG. 5.39** PanoCam LT photograph of retinoblastoma.

**FIG. 5.40** PanoCam LT photograph of retinopathy of prematurity.

Additionally, in an era of electronic medical records (EMR), traditional color fundus drawings are becoming a lost art. Cumbersome digital interfaces on EMR, which focus on efficiency and prioritize billing criteria, result in inferior fundus drawings. Wide-field imaging may become a useful adjunct or replacement for documentation of the appearance of the fundus at office visits, which may have numerous positive implications for the physician and patient alike.

## Conclusion

Technologic innovations and the realization that the periphery of the ocular fundus is a key site of primary vitreoretinal pathology and secondary changes has led to the continued use and improvement in wide-field imaging. Current studies with this imaging modality have suggested important clinical applications for numerous retinal diseases, including diabetic retinopathy, retinal vein occlusions, ophthalmic oncology, uveitis, pediatric vitreoretinal disorders, and hereditary retinal degenerations. Ongoing prospective trials will serve to refine and optimize the use of this technology. (Fig. 5.41 online).

## Prospective

The development of pars plana vitreoretinal surgery in the 1970s required a sea change in surgical tools, shifting from operating with loupes, which had been sufficient for open-sky techniques, to the use of an operating microscope as a stable platform to view the vitreous and retina.<sup>1</sup> In the early years of vitreoretinal surgery, the development of novel illumination methods, lens systems, and positioning techniques allowed surgeons to view the target tissues and determine achievement of surgical endpoints. The retinal surgeon in the 21st century has continued to use this conventional optical microscope system to view the illuminated surgical site.

Over the past two decades, optical coherence tomography (OCT) emerged from a bench-top research instrument to a disruptive diagnostic technology, which provided novel information useful for the management of a vast number of vitreoretinal disorders.<sup>2-5</sup> Accompanying this transition in technology was the emergence of new pharmacologic therapeutics that changed our treatment paradigms and management approach to various retinal conditions.<sup>6-8</sup> OCT provided the detailed, morphologic insight into the disease process and disease state that allowed clinicians to make critical judgments on diagnosis, management, and prognosis. During that time, OCT emerged as one of the most commonly ordered diagnostic tests in medicine.

Although the interpretation of OCT images transformed our clinical assessment of the microanatomy before and after surgery in diseases such as macular hole, vitreomacular traction, epiretinal membrane, myopic schisis, and retinal detachment, the application of this technology to real-time surgical management lagged behind. Numerous barriers existed, hindering the adoption of intraoperative OCT. Integrative solutions, high-speed imaging, OCT-compatible surgical instrumentation, novel software analysis systems, and optimal surgeon feedback systems were all lacking. This chapter will review the current state-of-the-art of intraoperative OCT, a technology that continues to evolve at a rapid rate.

## OCT in the Operating Room: Integrative Advances

The initial transition from imaging in the clinic to imaging in the operating room was based on modifications to available tabletop OCT systems. In an early attempt to utilize perioperative OCT imaging, infants with retinopathy of prematurity were positioned on their side while under general anesthesia, for tabletop time domain OCT system (with the headrest removed) imaging prior to vitreoretinal surgery.<sup>9</sup> Another approach modified the clinical system to reposition the tabletop component which then allowed for imaging of supine patients. This was used to examine infants with retinopathy of prematurity outside of the surgical suite.<sup>10</sup> However, this approach had significant limitations for portability and practical use in a sterile operating room field. One of the first major breakthroughs in intraoperative imaging technology was the development of a compact, light, handheld OCT scan head and the introduction of this technology to the surgical suite (Fig. 6.1).<sup>11-14</sup> This smaller scan head no longer rested on a tabletop over the OCT engine and computer system, creating significantly improved flexibility for intraoperative imaging of the supine patient. The two most common systems for intraoperative use featuring a portable scan head are the handheld Bioptigen SDOIS/Envisu portable system (Bioptigen, Research Triangle Park, NC) and the stand-mounted Optovue IVue (Optovue, Fremont, CA) system.<sup>12,13,15-22</sup>

**FIG. 6.1** Research use of an early version of the Bioptigen handheld portable spectral domain optical coherence tomography system in surgery. (Left) At a pause in surgery, the surgeon captures and views the macular B-scan. (Right upper) A scan prior to release of vitreomacular traction and removal of epiretinal membrane. (Right lower) Imaging in the same region after completion of the surgical maneuvers. The epiretinal membrane is absent and inner retinal surface irregularity is present, while on the left side of the scan the interdigitation zone (presumed outer border of photoreceptors) is now separated from the retinal pigment epithelium by a thin hyporeflective band. (See

Video 6.1.)

Initial approaches to acquiring images with these systems utilized either handheld imaging or external mounting systems. Handheld imaging has both advantages and limitations. There is tremendous flexibility of scanhead orientation and the ability to dynamically alter the position of the scan during acquisition (Fig. 6.1, Video 6.1 online). However, there may be significant challenges with surgeon learning curves, reproducibility of scan location, and optimal targeting to the area of interest. To address some of the challenges of handheld imaging, microscope-mounting systems have been developed to tether the portable scanhead to the microscope (Fig. 6.2, Video 6.1 online).<sup>15-18,22,23</sup> This allows the user

to control lateral and vertical translation of the system utilizing the joystick and focus control of the microscope foot pedal. Microscope-mounting portable systems provides increased stability and precision, while potentially improving learning curves for users and increasing scan efficiency. The microscope mount maintains the OCT scan head on the side of the microscope and the system remains nearby throughout the case, while the handheld system offers the convenience of being able to introduce or remove the system from the surgical area as needed. An alternate OCT system, IVue, utilizes a supporting armature on a stand to provide similar stability and precision for a larger scan head not connected to the operating microscope.

**FIG. 6.2** Microscope-mounted portable spectral domain optical coherence tomography system. Scan head is tethered to a microscope that allows foot-pedal control of X–Y–Z translation utilizing a combination of the joystick and focus controls. (See Video 6.1.)

Though a major step forward, these systems still lacked true microscope-integration, and this results in multiple limitations, including the need to halt the surgical procedure to perform imaging, lack of “real-time” video-rate imaging, the need for additional space in the operating room to position the system, and limited opportunities for integrated surgeon feedback. These

systems did, however, provide the surgeon with rapid feedback on the impact of surgical maneuvers on the tissues, often with excellent visualization of tissue details and subclinical alterations.<sup>13,15,19,21,22</sup> However, given the need to stop surgery to perform the scan, none of these systems allow for the actual OCT-based visualization of tissue-instrument interaction.

To address many of these limitations, researchers and engineers began to develop microscope-integrated OCT systems. Early iterations on these systems included novel OCT scan heads that were adapted to the various microscopes and then utilized a commercial OCT engine. One example was the research adaptation of the Bioptigen portable spectral domain optical coherence tomography (SD-OCT) system into a novel scanner head that was integrated into a Leica operating microscope (Fig. 6.3).<sup>24,25</sup> Another example was the adaptation of the Zeiss SD-OCT system into a Zeiss surgical microscope (Carl Zeiss Meditec, Oberkochen, Germany)(Fig. 6.3).<sup>26</sup> The development of these systems represented a major advance in intraoperative OCT and for the first time allowed true “real-time” intraoperative OCT with visualization of surgical motion.<sup>26–30</sup> Utilizing a combined optical pathway, in each case, the OCT would be able to be parfocal with the surgeon view.<sup>24</sup> System enhancements to these early generation platforms allowed for targeting and tracking the OCT scan beam, tunable focus, optimized visualization of surgical motion, and heads-up display of the OCT data stream, all of which improved the interface with the surgeon (Fig. 6.3).<sup>27,30–32</sup> Building on this momentum, commercial integrated systems are now available worldwide, including from Haag–Streit (Haag–Streit, Koeniz, Switzerland) Leica, and Zeiss.<sup>33–36</sup> Leica, which recently acquired Bioptigen, has developed the EnFocus system which is a microscope-integrated OCT platform. Microscope-integrated OCT system that can be introduced as an add-on for a standard surgical microscope.<sup>36</sup> The Haag–Streit system, the *i*OCT, is powered by an OPMedT (OPMedT, Lubeck, Germany) OCT engine and utilizes a microscope side-port for integration.<sup>35</sup> The Rescan 700 is built on the Lumera 700 microscope platform allowing the form factor of the microscope head to remain undisturbed (Fig. 6.3).<sup>33,34</sup>

**FIG. 6.3** Microscope-integrated optical coherence tomography systems. (Left) The research prototype system (*yellow arrows*) developed at Duke University by Dr. Joseph Izatt and Dr. Yuankai Tao and used for either spectral domain (SD) or swept source (SS) OCT imaging with heads-up three-dimensional stereo display (*red arrow*) to both oculars of the surgeon. (Center) A more recent microscope-integrated research scanner (*yellow arrow*) developed at the Cleveland Clinic for use with SD-OCT or SS-OCT. (Right) The Zeiss Rescan system with integrated SD-OCT scanner (*white arrow*) and heads-up display projected into one ocular of the surgeon.

Research and active development is underway for the next generation of intraoperative OCT systems. Key areas of need include enhanced image quality, faster acquisition speed, automated tracking, and advanced software analysis. Emerging OCT technology may provide unique opportunities for intrasurgical solutions.<sup>37,38</sup> Spectrometers that provide enhanced range may increase the flexibility of visualization of pathology.<sup>36</sup> Swept source OCT acquisition represents a potential opportunity to further enhance the capabilities of intraoperative OCT (Fig. 6.4, Video 6.2 online).<sup>39</sup> Swept source microscope-integrated intraoperative OCT systems have demonstrated the ability to not only capture instrument–tissue interaction, but to also capture the three-dimensional motion and interaction that occurs during surgery (Fig. 6.5, Video 6.3 online).<sup>39</sup> The tremendous increased speed provides the opportunity to perform real-time volumetric scanning at near video rates.<sup>39</sup> High-speed image processing methods have been integral to the intraoperative visualization of

instrument-tissue interaction (Figs. 6.4 and 6.5) and will continue to evolve.<sup>40</sup>

**FIG. 6.4** Three-dimensional view which is possible in real time because of the high speed of the research microscope integrated swept source optical coherence tomography system. (See Video 6.2.)

**FIG. 6.5** Three frames of microscope integrated swept source optical coherence tomography three-dimensional images taken from the streaming video visible to the surgeon in a stereo heads-up display, and a B-scan across the middle frame of the series. The surgeon is peeling the scrolled internal limiting membrane from right to left and the tips of the 25-gauge forceps are visible grasping the center of the scrolled edge and pulling to the left. Note the shadow in the retina in the first two frames and on the B-scan from the metallic forceps. (See Video 6.3.)

## Surgeon Feedback Platform Enhancements

Bringing OCT technology to the operating room requires unique features to maximize integration, including automated aiming, OCT-compatible instrumentation, heads-up display systems, and software analysis. Current systems utilize surgeon or assistant-directed control of the aiming beam of the OCT to the area of interest.<sup>30,31,33,34,36</sup> Control systems include mouse-based, manual control screen operation, and foot-pedal control. Although these control capabilities are significant improvements over external systems, they are still limited by the need for surgeon input and lack of automation. Integrated automated aiming or region-of-interest tracking could enhance visualization of surgical maneuvers and improving imaging workflow.<sup>38</sup> There are numerous potential approaches to improved aiming to the area of interest. One option is to augment the surgical instrument to allow it to provide feedback regarding location or position to the OCT scanner.<sup>38</sup> An additional option is to utilize an image processing approach to analyze dynamic changes to the image that result from surgical motion and direct the OCT to that area of interest.<sup>41,42</sup> An additional option is to place the OCT scanner within the instrument so that the OCT is always directed to the tissue immediately proximal to the instrument being used.<sup>43</sup>

The information to the surgeon related to the OCT can be presented in numerous ways, including as an external display screen or ocular-injected heads-up display.<sup>31,33,34,39,44</sup> Multiple research systems and commercial systems have featured heads-up display systems (Fig. 6.6).<sup>31,33,34,39</sup> Optimizing the surgeon's heads-up visualization is an area of active development and a variety of novel approaches are being explored.<sup>45</sup> Providing surgeon-critical information in an optimal format is vital to maximizing the effectiveness of these system. Customized visualization with ocular selection, data type display, and data formatting will all be important to maximizing surgeon comfort.

**FIG. 6.6** (Left) Heads-up display of the horizontal and vertical spectral domain optical coherence tomography (OCT) B-scans viewed through the right eyepiece in the Zeiss Rescan microscope (image courtesy Zeiss). The location of scanning is changeable and the display can be turned on and off during surgery. (Right) In a model eye in the research lab, the surgeon turns off the fiberoptic light and peels membranes using either (a) real-time stereoscopic three-dimensional (3D) OCT volumes projected into the oculars via the heads-up display (*red arrow*) or (b) as shown here, displayed on a 3D video screen and viewed by the surgeon wearing 3D glasses while she operates. (See Videos 6.3 and 6.4.)

Current generation metallic surgical instruments and other surgical materials result in absolute shadowing on OCT imaging and limit visualization of the tissue–instrument interaction (Figs. 6.5 and 6.7, Videos 6.3 and 6.4 online).<sup>24</sup> To maximize real-time visualization of surgical maneuvers, compensatory techniques will need to be introduced to minimize the disruption to visualization caused by shadowing. One potential approach relies on advances in image processing. Utilizing a variety of methods, such as spatial compounding, the impact of shadowing can be minimized and surgical visualization can be enhanced.<sup>27</sup> An alternate approach is to change the material composition of the surgical instruments.<sup>31</sup> Identifying materials that provide both the optical properties needed for OCT visualization and material properties needed for surgical precision and reliability is critical for the success of this approach. Prototypes of OCT-compatible instrumentation have been developed and appear to enhance visualization of both the surgical instrument and the tissue–instrument interaction.<sup>31,44</sup>

**FIG. 6.7** Research microscope integrated spectral domain optical coherence tomography imaging (upper frames) of an epiretinal membrane before (left) and during (right) removal of an epiretinal membrane and internal limiting membrane stained with indocyanine green. During surgery, there are shadows from both the forceps (*white arrows*) and scrolled indocyanine green-stained membrane (*green arrows*). In the research microscope integrated swept source optical coherence tomography (SS-OCT) B-scan (lower left) from the three-dimensional (3D) real-time volume (lower right), the reflective diamond-dusted instrument tip casts a shadow (*blue arrow*), as does the suspended debris (*white arrow*), but not the silicone tube between these. The diamond-dusted tip similarly shows up well dragging the membrane across the retinal surface, however the silicone behind the tip is nearly invisible on the SS-OCT 3D volume. (See Videos 6.3 and 6.4.)

Lastly, alterations to the tissue conformation change rapidly and potentially dramatically during surgery (Figs. 6.5 and 6.7).<sup>13,17,18,22,46,47</sup> New software packages will be needed to help facilitate surgeon

decision-making and provide immediate assessment of clinically relevant alterations in tissue architecture. Automated assessment of changes in inner and outer retinal features, macular hole geometry, and fluid interfaces may all have potential impact on anatomic and visual outcomes following surgery.<sup>18,47-50</sup> Optimally integrating this information into new systems will be a key element in the next evolution of OCT-guided surgery.

## **Surgical Findings With Intraoperative OCT in Vitreoretinal Conditions**

### **Membrane Peeling in Vitreoretinal Interface Disorders**

Disorders of the vitreoretinal interface (e.g., macular hole [MH], epiretinal membrane [ERM], and vitreomacular traction [VMT]) may be one of the optimal applications of intraoperative OCT. Numerous studies have described the ability of intraoperative OCT to visualize residual membranes and potentially alter surgical decision-making.<sup>13,15,17,18,22,33,47,51</sup> Visualizing tissue alterations with OCT is a common application, and it is clear that surgical manipulations impact tissue conformation and relationships.<sup>17,18,47,52</sup>

Intraoperative OCT may be particularly helpful during surgical procedures for membrane peeling. Multiple subclinical alterations have been reported with intraoperative OCT following membrane peeling, including residual membranes, perturbations to the inner retinal architecture, and full-thickness retinal elevations (Fig. 6.8).<sup>11,13,17,18,22,26,47,52</sup> Intraoperative OCT appears to impact surgical decision-making in membrane peeling procedures in 15–30% of cases, including the identification of membranes that need additional peeling or alternatively confirming successful attainment of surgical objectives prior to surgeon realization through conventional visualization.<sup>13,15,33</sup> Additional changes have been described at the macro (e.g., full-thickness retinal elevation) and micro (e.g., diffuse subtle alterations in retinal layer thickness) level of the retinal architecture.<sup>52</sup> Common microarchitectural alterations after membrane peeling include the expansion of the distance

between the ellipsoid zone and the retinal pigment epithelium, and alterations to the inner retinal surface (Fig. 6.1, lower right).<sup>15,22,47,52</sup> In one report, for example, inner retinal projections (e.g., connecting strands) to the internal limiting membrane (ILM) were visible on the inner retinal surface immediately following ILM peeling, and subsequently resolved postoperatively without significant nerve fiber layer alterations.<sup>47</sup> The macroarchitectural alterations appear to be frequently related to direct tissue–instrument interaction.<sup>52</sup> One report identified with video/intraoperative OCT correlation that the alterations appeared to be more common with forceps application compared with the diamond-dusted membrane scraper.<sup>52</sup> The overall clinical significance of these retinal alterations remains unknown. Intraoperative OCT may also impact our utilization of vital dyes and stains. Indocyanine green and triamcinolone and other steroid suspensions have significant impact on intraoperative OCT-based visualization of tissues (Fig. 6.7).<sup>53–55</sup> Additionally, OCT-guided membrane peeling has the potential to reduce the need for utilization of these stains, which may reduce surgical time and minimize potential pharmacotoxicity to the retina.<sup>56</sup>

**FIG. 6.8** Intraoperative optical coherence tomography (OCT) during macular hole repair. (A) Preincision scan reveals full-thickness macular hole with associated vitreomacular traction (*arrowhead*). (B) Partial peel scan revealing residual membrane (*arrow*) and area of retina where peel has been completed (*arrowhead*). (C) Following completed peel, OCT identifies changes in macular hole architecture. (See Video 6.5.)

In MH cases, peeling of the ILM results in variable changes in MH configuration (Fig. 6.8, Video 6.5 online).<sup>13,18,19,22</sup> These configuration changes include alterations in MH volume, base area, and height. Focal areas of inner retinal elevation or full-thickness retinal elevation have also been described following surgical

manipulation. Similar to ERM peeling, more diffuse changes in the outer retina have also been identified.<sup>15,18,22,46,52</sup> In particular, an increase in the ellipsoid zone to retinal pigment epithelium distance appears to occur following ILM peeling. These changes have been associated with the rate of visual recovery following MH surgery and architectural normalization rate.<sup>46</sup>

Vitreomacular traction syndrome is an additional condition that may benefit from image-guided feedback with intraoperative OCT (Figs. 6.1 and 6.4).<sup>13,15,17,33</sup> Intraoperative OCT can identify subclinical full-thickness macular holes or unroofed cysts following hyaloid elevation. These findings can directly impact surgical decision-making, such as choice of gas tamponade or peeling of the ILM.<sup>15,17,33</sup>

## Retinal Detachment and Other Vitreoretinal Conditions

Although membrane peeling procedures are an intuitive use for intraoperative OCT, the potential benefit of intraoperative OCT feedback for retinal detachment repair may not be immediately apparent. However, multiple reports have identified potentially important novel OCT-identified features evident during the course of retinal detachment repair.<sup>15,23,33</sup> In fact, the foveal microarchitecture visualized under perfluorocarbon liquid tamponade has been linked to visual acuity outcomes.<sup>23</sup>

Additionally, nearly all eyes under perfluorocarbon liquid have some degree of subretinal fluid.<sup>15,23,33</sup> In other reports, intraoperative OCT has been used to confirm the absence of fluid in peripheral areas of white without pressure and to identify optimal locations for drainage of subretinal fluid.<sup>33</sup>

Other conditions that have been impacted by intraoperative OCT include optic pit-associated maculopathy and proliferative diabetic retinopathy.<sup>33,57,58</sup> In one publication, intraoperative OCT was able to confirm collapse of the nasal schisis in the macula following aspiration over the area of the pit. This potentially confirmed a direct connection between the vitreous cavity and the area of schisis.<sup>58</sup> In complex vitreoretinal pathology, such as proliferative diabetic retinopathy, intraoperative OCT may facilitate

identification of tractional membranes, candidate dissection planes, and areas of retinal detachment. This can provide rapid feedback to the surgeon and help inform appropriate surgical maneuvers.<sup>33</sup>

The delivery of subretinal therapeutics, such as tissue plasminogen activator, may also be facilitated by intraoperative OCT technology. Visualization of subretinal injections and retinal perturbations following injection has been successfully documented with intraoperative OCT.<sup>16</sup> The objective assessment of volumetric delivery may prove critical to an emerging field of novel therapeutics, such as with gene therapy and stem cells.

Additional immediate surgeon feedback and guidance has been described during the removal of subretinal perfluorocarbon liquid.<sup>59</sup> In these challenging cases, optimally and completely removing the subretinal perfluorocarbon liquid can be quite difficult. Intraoperative OCT provides immediate feedback to the surgeon regarding the successful completion of these objectives.<sup>59</sup>

## Pediatric Vitreoretinal Surgery

Because infants and children may not readily cooperate for OCT imaging in the clinical setting, OCT imaging may be useful in the preoperative setting during examination under anesthesia. OCT imaging under anesthesia has revealed the extent of retinal detachment and retinoschisis in retinopathy of prematurity, macular holes or pseudoholes in the setting of shaken baby, and the configuration of epiretinal membranes and the underlying retina in a wide range of pediatric vitreoretinal diseases (Figs. 6.1 and 6.9).<sup>11,12,51,60</sup> In other vitreoretinal conditions such as childhood tumors, imaging under anesthesia has been useful in monitoring response to treatment.<sup>61</sup> As with adult surgery, and perhaps more so since postoperative evaluation may again be hampered by an inability to cooperate, intraoperative imaging after surgical maneuvers may be especially useful in determining the anatomical results (Figs. 6.1 and 6.9).<sup>11,51</sup> As the technology evolves and is applied in pediatric vitreoretinal surgeries, intraoperative OCT imaging is likely to inform the pediatric surgeon and be applicable to a wide range of pediatric retinal diseases.

**FIG. 6.9** In a young child with familial exudative vitreoretinopathy and tractional membranes across the macula, the preoperative and postoperative assessment in clinic may be limited. Intraoperative handheld spectral domain optical coherence tomography imaging before surgery (upper frames) demonstrates the deep retinal folds and thickness of preretinal membranes. After membrane removal (lower frames), a scroll of inner limiting membrane is visible above the folded inner retinal surface, the pronounced distortion and thickening of retinal layers is evident, and the presence of the ellipsoid zone across the area of peel points to an absence of subretinal fluid at this location.

## Conclusion

Though still an emerging field, research in intraoperative OCT has made tremendous progress over the last several years and is likely to enable new procedures not achievable with conventional retinal visualization. Numerous clinical studies and reports emphasize the

potential role for intraoperative OCT in image-guided surgery as well as the potential impact on patient outcomes and surgical decision-making. Technologic advances in integrated OCT systems, surgical instruments, and software have made these initial steps possible. However, hurdles remain in maximizing these integrative approaches, enhancing surgeon feedback systems, and improving our ability to seamlessly incorporate this technology into our surgical procedures. As capabilities improve, establishing specific parameters or procedures where intraoperative OCT adds value and enhances outcomes will also be critical to facilitate its widespread adoption.

## **Introduction: Retinal Imaging to Date**

Assessment of chorioretinal disease is dependent on the ability to visualize pathologic changes occurring in the posterior segment of the eye using optical instruments, termed ophthalmoscopy (Fig. 7.1A).<sup>1</sup> Ophthalmoscopy, in turn, has been greatly enhanced by the development of techniques that allow recording of these changes.<sup>2</sup>

By the end of the 19th century the first images of the living human retina had been obtained (Fig. 7.1B) and, by the 1950s, with the advent of electronic flashes and 35 mm cameras, the field of modern retinal/fundal imaging had been born.<sup>3</sup>

**FIG. 7.1** Early attempts at retinal visualization and image capture. (A) Early model of the Helmholtz ophthalmoscope, 1851. (B) The first published human fundus photograph involved this apparatus, an albcarbon burner, and a  $2\frac{1}{2}$ -minute exposure. Blood vessels cannot be defined, but the optic disc can be seen as a white area superiorly, while inferiorly, the larger light area is an artifact (Panel A reproduced with permission from Alcon Laboratories Museum of Ophthalmology, The Sherman Collection, Fort Worth, TX, USA. Historical image: Helmholtz ophthalmoscope, 1851. Ophthalmology. 2002; 109(4):729. Panel B reproduced with permission from Same PJ. Landmarks in the historical development of fluorescein angiography. J

As well as documenting pathology, fundal imaging facilitates the identification of morphologic features not visible to the clinician on biomicroscopy. For example, from an early stage in its development, fundus photography has incorporated angiographic methodologies for the visualization of blood vessels.<sup>1,4</sup> In the 1960s, the assessment of retinal disease was revolutionized by the introduction of fluorescein angiography (Fig. 7.2A). In the 1970s, evaluation of the choroidal circulation was also improved through the use of indocyanine green dye. The development of these angiographic techniques has also led, at least in part, to the discovery that certain fundal structures fluoresce in the absence of contrast – the subsequent evolution of fundus autofluorescence imaging has greatly extended our ability to evaluate retinal degenerative and other disorders.<sup>2</sup>

**FIG. 7.2** Fluorescein angiography, scanning laser ophthalmoscopy, and optical coherence tomography (OCT). (A) Early attempt at fundus fluorescein angiography in a normal subject. (B) A single frame from a fluorescein angiogram taken with a confocal scanning laser ophthalmoscope (cSLO) showing a choroidal neovascular membrane. (C) Early attempt at OCT imaging of the human retina and optic nerve, obtained in vitro. *BV*, blood vessel; *RPE*, retinal pigment epithelium; *SRF*, subretinal fluid. Panel B reproduced with permission from Bennett PJ, Barry CJ. Ophthalmic imaging today: an ophthalmic photographer's viewpoint – a review. *Clin Exp Ophthalmol* 2009;37(1):2-13. Panel C reproduced with permission from Huang D,

Since the 1990s, fundus photographic systems have also made the transition from “analog” image capture using film, to digital image capture using charge-coupled devices (CCDs), allowing for improved image processing and analysis.<sup>2</sup> In parallel with this, new image capture technologies have emerged, such as scanning laser ophthalmoscopy (SLO) and optical coherence tomography (OCT) (Fig. 7.2B–C). In particular, the widespread adoption of OCT in recent years has greatly extended our knowledge of chorioretinal disease pathophysiology, and proven important for the provision of new pharmacotherapeutics.<sup>1</sup>

Despite the unprecedented advances of recent years, considerable deficiencies exist in our retinal imaging capability. While angiographic techniques provide exquisite detail of vascular structures, our ability to quantify chorioretinal blood flow and subsequent oxygen saturations – in a noninvasive manner – remains inadequate. While OCT provides cross-sectional images of the neurosensory retina (and more recently the choroid) with high axial resolution, its transverse resolution is limited, and our ability to assess many retinal cell types remains poor (e.g., Müller cells, microglia, astrocytes, and individual neuronal elements). Furthermore, many advances in microscopic techniques that permit “molecular” imaging in basic science research have yet to make the transition to human clinical studies.

In this chapter we discuss the attempts that are underway to address the shortcomings of current retinal imaging technologies. We begin by describing the recent introduction of smartphone ophthalmoscopy, an advance that may usher in the demise of the direct ophthalmoscope and, in turn, change the way in which ocular examination is performed by nonophthalmologists. We next describe the use of adaptive optics to provide cellular-level image resolution, before moving on to describe Doppler and spectral imaging techniques for the assessment of retinal blood flow and oxygenation. We then describe a number of technologies with the potential for assessment of novel functional parameters, such as photoacoustic and magnetic resonance imaging. We conclude by introducing the emerging field of “molecular imaging,” an area

where the continued discovery of retinal molecular biomarkers is combined with advances in ocular imaging technologies. Throughout the chapter, we focus on emerging imaging techniques that, for the most part, are not yet commercially available, or are not yet in widespread clinical use (detailed descriptions of fundus angiography, autofluorescence, ultrasonography, and OCT, are provided elsewhere in the text).

## Smartphone Ophthalmoscopy – Replacing the Direct Ophthalmoscope?

### Basic Principles

Since its widespread introduction in the 1960s, ophthalmic fundus photography has relied on expensive and bulky tabletop devices, operated by skilled medical photographers in a hospital or eye clinic setting. In 2007 the introduction of the iPhone (Apple Inc., California) heralded a new era of “smartphone” technology. As most clinicians now carry a smartphone, and as these smartphones typically incorporate sophisticated cameras, the opportunity has arisen to make fundus cameras cheaper, more robust, and easier to use. Due to their portability, wireless connectivity, and data storage capability, smartphone ophthalmoscopy has the potential to enter widespread clinical usage.

### Technology

A number of smartphone fundus cameras are now available.<sup>5</sup> Welch Allyn (Skaneateles Falls, New York) has developed a PanOptic™ Ophthalmoscope that uses a halogen lamp for illumination and provides ×5 zoom image acquisition through an undilated pupil. The Welch Allyn “iExaminer” turns this ophthalmoscope into a mobile imaging device by aligning its optical axis to the visual axis of a smartphone. An associated iExaminer application allows storage and printing of images.

“Ocular Cellscope” is another form of smartphone fundus

camera currently under development.<sup>6</sup> It comprises a mobile phone, a housing that contains the illuminating and collecting optics, and an integrated smartphone holder that ensures alignment with the smartphone camera. Both the optical components and the smartphone are integrated within a polymer casing, and a single 54 D ophthalmic lens is used for focusing and capturing reflected light.

A number of cheaper and potentially more portable devices have more recently been developed. The D-EYE system (D-EYE, Pasadena, California) works on the principles of direct ophthalmoscopy and exploits the autofocus capabilities of smartphone cameras to account for a patient's refractive error (this allows for compensation of refractive error from  $-12.00$  to  $+6.00$  diopters).<sup>7</sup> The D-EYE system consists of a small optical device, which is attached magnetically to the back of a smartphone. The light emitted by the “flash” of the smartphone camera is conveyed into the eye by a mirror and a beamsplitter, in the same manner as a direct ophthalmoscope. Image acquisition with this device is similar to direct ophthalmoscopy with the device being held at a distance of  $\sim 10$  mm from the patient's eye. Unlike direct ophthalmoscopy, the device is targeted using the screen of the smartphone so that the examiner has no need to lean towards the patient's face and can work from a comfortable position. For a patient with a dilated pupil, the system captures a field-of-view of  $\sim 20^\circ$ , for a single fundus image at a distance of  $\sim 10$  mm from the patient's eye. This field-of-view is much wider than that obtained with conventional direct ophthalmoscopes (typically  $5\text{--}8^\circ$ ) and is comparable to that of the iExaminer. In 2015 the D-EYE system was evaluated in patients with diabetic retinopathy in a hospital eye clinic – grading of diabetic retinopathy using the system was found to be comparable to that of dilated slit-lamp biomicroscopy.<sup>8</sup> The D-EYE system is now commercially available for approximately \$400 ([www.d-eyecare.com](http://www.d-eyecare.com)).

“PEEK (Portable Eye Examination Kit)” is a smartphone-based system for comprehensive eye examinations ([www.peakvision.org](http://www.peakvision.org)).<sup>9,10</sup> PEEK consists of a plastic clip that covers the smartphone camera and flash with a prism assembly. The prism deflects light from the flash to match the illumination path with the field of view of the camera. This allows acquisition of fundus

images. Similar to D-EYE, PEEK allows the smartphone to be held in front of and close to the patient's eye for image capture. PEEK also allows other ophthalmic testing to be performed, for example visual acuity measurements. PEEK is undergoing extensive clinical validation studies as part of the Nakuru Eye Disease Project in Kenya. These studies have demonstrated that PEEK provides accurate and repeatable measurements of visual acuity,<sup>10</sup> and that images of the optic nerve head can be obtained comparable with those from digital retinal cameras.<sup>9</sup> Of note, in both cases, PEEK testing was performed by nonhealthcare personnel.

## Conclusion

The development of smartphone ophthalmoscopy is likely to have profound benefits for general ophthalmic examination in the developing world, as well as greatly improving eye examination in pediatric settings and by nonophthalmic-trained physicians in the developed world. In 2016 the widespread availability of devices like PEEK and D-EYE may signal the end of conventional direct ophthalmoscopy for many nonophthalmologists.

## Adaptive Optics: Imaging of Single Cells in the Retina

### Basic Principles

Our ability to obtain high-resolution images of the human retina is limited by the presence of defects, or aberrations, in the optical system of the eye (i.e., the cornea and lens).<sup>11</sup> In addition to exhibiting lower-order monochromatic aberrations such as defocus and astigmatism, normal eyes also exhibit higher-order monochromatic aberrations such as coma, trefoil, and spherical aberration. The combined effects of these aberrations limit the quality of images obtainable for the diagnosis and management of retinal disease. Until the early 1990s there existed no effective way to obtain rapid, precise measurements of the human eye's optical aberrations. However, wavefront sensors based on the Hartmann–Shack principle, originally developed for astronomical purposes,

have now been adapted for use in the human eye. These sensors consist of an array of lenses, each having the same focal length, which can be used to approximate the whole wavelength of incident light. Once measured, the detected aberrations can then be corrected (i.e., rendered flat) using one or more deformable mirrors (mirrors have large numbers of small electronically controlled actuators on their rear surface that can push and pull the mirror within a range of  $\pm 2 \mu\text{m}$ , allowing it to adopt any desired configuration) (Fig. 7.3). By incorporating wavefront sensing and correction into existing optical imaging platforms – “adaptive optics” – it is now possible to acquire images of the retina with cellular-level resolution, and in a noninvasive fashion.<sup>11,12</sup>

**FIG. 7.3** Schematic representation of a typical adaptive optics system. (Courtesy of Joseph Carroll, Williams Laboratory, University of Rochester).

## Technology

The adaptive optics devices first developed for ophthalmic use were conventional fundus cameras modified to incorporate wavefront sensing and correction.<sup>13,14</sup> These systems typically focus a laser beam on the retina at a location of interest. The light reflected from the retina is then distorted by the optical system of the eye before returning to the wavefront sensor. Information obtained from the wavefront sensor is then used to alter the shape of the deformable mirrors and compensate for the aberration. This process continues in a closed loop until the ocular aberrations have been reduced to near diffraction-limited levels; at this point, a flash from a separate incoherent light source is triggered by the wavefront sensor, illuminating the retina as an image is captured by the digital fundus camera. Adaptive optics “flood-illuminated” fundus cameras are now commercially available and approved for use in clinical settings (e.g., “rtx1 Adaptive Optics Retinal Camera”, Imagine Eyes, France). The rtx1 system uses a light source with a wavelength of 840 nm to provide a near-infrared reflectance image that is particularly well suited to deep retinal structures (see above). While these devices offer greatly improved transverse resolution, their field of view is still limited (e.g.,  $4^\circ \times 4^\circ$ ).

Adaptive optics components have also been incorporated into confocal SLO systems, offering the advantage of increased contrast, cross-sectional imaging, and the measurement of dynamic changes such as blood flow.<sup>11,15</sup> In an adaptive optics SLO, light returning from the retina is split into a light detection path and a wavefront-sensing path. Again, deformable mirrors are used to provide closed-loop dynamic compensation for ocular aberrations. In contrast to flood-illuminated adaptive optics devices, the adaptive optics SLO uses the same source of light for the wavefront sensor as for the retinal illumination – as a result, the wavefront sensor is able to measure aberrations from the entire scanned area of the retina. When imaging the retina, SLO devices provide a transverse resolution of approximately 15  $\mu\text{m}$  but are limited to an axial resolution of approximately 300  $\mu\text{m}$ . With the addition of adaptive optics correction to an SLO, the transverse resolution may be

increased to less than 3  $\mu\text{m}$  while the axial resolution may be improved to 40  $\mu\text{m}$ . Adaptive optics SLO systems are not yet commercially available, although a prototype system has recently been developed by Canon Medical Imaging.

Adaptive optics devices have also been incorporated into prototype OCT systems.<sup>16,17</sup> The axial resolution achievable using OCT is many orders of magnitude greater than that achievable using an SLO device, with commercially available devices commonly achieving axial resolutions of approximately 5  $\mu\text{m}$ . However, the transverse resolution of OCT systems is determined by the size of the laser spot that can be focused on the retina – a factor limited by ocular aberrations. A successful combination of OCT and adaptive optics could potentially demonstrate, therefore, the narrowest point-spread function of all in vivo retinal imaging techniques (Fig. 7.4). However, a number of technical challenges remain, in particular, the reductions in image quality that occur as a result of chromatic aberrations when large bandwidth light sources are used.<sup>18,19</sup> Nevertheless, recent use of a prototype adaptive optics OCT device has reopened the debate about the identity of the outer retinal hyperreflective lines on OCT, in particular whether the 2nd hyperreflective band constitutes the photoreceptor inner segment ellipsoid zone or inner/outer-segment junction.<sup>20</sup>

**FIG. 7.4** Adaptive optics optical coherence tomography (AO-OCT) volume acquired over a  $1^\circ$  retinal region located temporal of the fovea, as illustrated by the rectangle in the fundus photograph. The images on the right are en face views of particular retinal layers extracted from the AO-OCT volume. Retinal layers from top to bottom are nerve fiber layer (NFL), ganglion cell layer (GCL), outer plexiform layer (OPL), and outer segment layer of photoreceptors (OS) (Reproduced with permission from Miller DT, Kocaoglu OP, Wang Q, Lee S. Adaptive optics and the eye (super resolution OCT). *Eye* 2011; 25(3):321–330.)

Finally, adaptive optics may be useful for the performance of fundus perimetry (“microperimetry”) in the study of macular disease.<sup>1</sup> In current microperimetry systems, macular light sensitivity is measured using a stimulus size that covers an area containing in excess of 150 cones at the foveal center. As with the

imaging modalities described above, further reductions in stimulus size are hindered by aberrations of the optical systems in the human eye, a shortcoming that may be overcome through the incorporation of adaptive optics.<sup>21</sup> In addition, by analyzing the warping that occurs both within individual SLO frames, and between frames, adaptive optics can be used to resolve the effects of eye movements at a fine spatial scale. As a consequence, in adaptive optics microperimetry, real-time stabilization of the retinal image is possible, allowing for targeted delivery of the small visual stimulus to the retina.<sup>22,23</sup>

## Visualization of Retinal Structures

Cone photoreceptors are the dominant feature seen with both flood-illuminated and SLO devices (Fig. 7.5A).<sup>12,24</sup> Light projected into the eye from these devices passes through the cone outer segment and is reflected by the retinal pigment epithelium (RPE), the most highly reflective surface in the retina. As light is reflected out of the eye, it is guided toward a small area of the pupil by the cone inner segments (in this respect cones act as “optical fibers,” rejecting stray light in the retina and maximizing efficiency in light collection). As a result, the cones appear as hyperreflective dots (recently referred to as a “positive” mosaic). However, when adaptive optics is used to examine the peripheral retina of healthy eyes, cones often appear as hyporeflexive dots (a “negative” mosaic). This finding has only recently been recognized and it is likely to represent a physiologic manifestation of the optical Stiles–Crawford effect.<sup>25</sup> Numerous studies have evaluated the reproducibility of both manual and automated approaches to cone density quantification using adaptive optics.<sup>26,27</sup> Recent studies have correlated these measures of cone density with outer retinal reflectivities as measured using OCT.<sup>28</sup> Adaptive optics has also supplied the first data regarding the proportion, and arrangement, of each cone photoreceptor class (blue [S], green [M], or red [L]) in the human eye.<sup>29</sup> Regional variabilities in cone topography have also been explored,<sup>30</sup> as well as the effects of refractive status. Cone packing appears to be less dense in highly myopic eyes versus emmetropic eyes – a finding consistent with the reduced visual

acuity and contrast sensitivity observed in the eyes of axial myopes.<sup>31</sup>

**FIG. 7.5** Visualization of photoreceptors, retinal pigment epithelium (RPE) and retinal vasculature using adaptive optics. (A) The complete foveal cone mosaic and (B) the complete peripheral photoreceptor mosaic showing both rods and cones, imaged at 10° temporal and 1° inferior. Scale bars: 20 μm. (C) Adaptive optics scanning laser ophthalmoscopy image revealing a patchy foveal cone mosaic with increased cone spacing, and resulting visualization of the RPE cells (three RPE cells in the bottom left corner have been outlined, and the preferred retinal locus is also indicated by the dashed circle in the image). (D) Three successive frames demonstrate a single leukocyte's (1) change in position from left to right in each frame. A second leukocyte (2) has just come into view in the last frame. Scale bar: 100 μm. (Panels A and B are reproduced with permission from Rossi EA, Chung M, Dubra A, et al. Imaging retinal mosaics in the living eye. *Eye* 2011; 25(3):301–308. Panel C reproduced with permission from Roorda A, Zhang Y, Duncan JL. High-resolution in vivo imaging of the RPE mosaic in eyes with retinal disease. *Invest Ophthalmol Vis Sci* 2007;48(5):2297–2303. Panel D reproduced with permission from Martin JA, Roorda A. Direct and

Rod photoreceptors are abundant in the peripheral retina but are also seen in the macular region of human eyes. Rods are not as easily visualized in the normal retina, even in areas of the retina where they outnumber cones approximately 10-fold.<sup>12</sup> The difficulty in imaging rods is consistent with their smaller size (approximately 2  $\mu\text{m}$  in diameter), and their broad angular tuning, which reflects less light back through the pupil where it can be collected for imaging. However, recent advances, including the use of smaller confocal pinholes and improvements in registration algorithms, have allowed clear images of single rods to be obtained in the living human eye (as well as aiding visualization of the smallest cones at the foveal center) (Fig. 7.5A).<sup>32</sup>

Rod and cone photoreceptors rest on a monolayer of RPE cells. Each RPE cell in the monolayer has an approximate diameter of 10  $\mu\text{m}$ , dimensions well within the resolution limits of adaptive optics systems; however, direct in vivo visualization of single RPE cells remains challenging. Unlike cone photoreceptors, the intrinsic contrast of RPE cells is poor. In addition, much of the light scattered by the RPE is masked by the overlying photoreceptors, which are also highly scattering. As a result, direct imaging of the RPE was initially only possible in human subjects with retinal disease where absence of cone photoreceptors allowed visualization of the underlying RPE (Fig. 7.5B).<sup>33</sup> More recently, use of a “dark-field” imaging technique has achieved moderate success in noninvasive visualization of the hexagonal RPE mosaic in healthy human volunteers.<sup>34</sup> In this approach, the traditional small confocal aperture is replaced by a larger aperture with a central filament. The central filament attenuates the light back scattered from the photoreceptors (the direct signal), while the larger aperture collects light multiply scattered by the RPE cells (the indirect, or so-called dark-field signal).

Adaptive optics may also be used to allow high-resolution, noninvasive visualization of the retinal nerve fiber layer (RNFL). Using adaptive optics, it is possible to identify individual retinal nerve fiber layer bundles, their direction of travel and width, and other features such as fiber “bridges” among bundles. The

separation of bundles by hyperreflective Müller cell septae may also be seen.<sup>35</sup> Adaptive optics OCT has been used to investigate the microarchitecture of the lamina cribrosa.<sup>36</sup>

Finally, adaptive optics-based imaging allows high-resolution visualization of the retinal vascular parenchyma and the assessment of retinal blood constituents and flow. Although conventional fundus photography/angiography allows mapping of the retinal vasculature, this is mainly achieved through visualization of the retinal vessel contents as opposed to direct visualization of the vessel walls or their substructure (retinal vessel mural cells are of relatively low contrast). However, using dark-field adaptive optics, visualization of distinct mural cells lying along the lumen of retinal arteries and arterioles (precapillary retinal arterioles and larger) has recently been described.<sup>37</sup> By contrast, with “standard” adaptive optics, the retinal vascular map appears as a dark outline only. Adaptive optics SLO systems allow video image acquisition and, using this approach, bright particles can be seen to flow within parafoveal capillaries. These bright particles may represent direct visualization of circulating leukocytes, or may be reflections from the underlying photoreceptors passing through the transparent leukocytes (i.e., indirect leukocyte visualization). These bright particles are followed by “dark tails” – black “tadpole-like” regions darker than the normal vessel shadow, which are thought to represent aggregates of erythrocytes.<sup>38</sup> Retinal imaging with adaptive optics may also be useful for detection of structural changes in the retinal vasculature not visible with other imaging modalities, such as microaneurysms and hard exudates in diabetic retinopathy.<sup>39</sup>

Adaptive optics SLO imaging can also be performed after injection of sodium fluorescein as a contrast agent (akin to a very high resolution fluorescein angiogram).<sup>40</sup> In the “unaffected” fellow eyes of patients with central retinal vein occlusion (CRVO), adaptive optics SLO fluorescein angiography has been used to show nonperfused capillaries and reductions in microvascular density – a hitherto unseen finding.<sup>40</sup>

## Clinical Applications

The cellular-level resolution provided by adaptive optics retinal imaging allows direct measurement of photoreceptor density and diameter and is, therefore, an ideal tool for the examination of patients with inherited retinal degenerations (Fig. 7.6). On examination with adaptive optics, diseased cones do not show the same reflectance pattern as healthy photoreceptors, resulting in dark gaps or areas of “drop-out” within the cone photoreceptor mosaic.<sup>41</sup> With gene therapy trials ongoing, or about to start, adaptive optics imaging of patients with choroideremia and achromatopsia are of particular interest.<sup>42,43</sup> This is particularly the case as significant correlations have been found between parafoveal cone density and a number of functional parameters, including best corrected visual acuity, contrast sensitivity and detection sensitivities for visual stimuli recorded using multifocal electroretinography.<sup>44–46</sup>

**FIG. 7.6** Adaptive optics scanning laser ophthalmoscope (AO-SLO) images at different magnifications with corresponding features on the fundus photograph (A). (B) Six-degree montage from 3° adaptive optics images of the central macula of the cone–rod dystrophy patient's right eye. In addition to the features detected in the fundus photograph, detailed structures in the granular pattern of the retinal pigment epithelium in the atrophic bull's-eye lesion are observed. Within the central relatively spared region (box), photoreceptors are seen as gray dots. (C) Three-degree montage from 1.5° images. The photoreceptors are visible in the central relatively spared area of the retina. (Reproduced with permission from Wolfing

High-resolution adaptive optics imaging has been used to demonstrate evidence of photoreceptor loss or perturbation in a range of conditions, including subretinal drusenoid deposits,<sup>47</sup> white dot syndromes,<sup>48</sup> macular telangiectasia type 2,<sup>49</sup> screening for hydroxychloroquine toxicity,<sup>50</sup> and following retinal detachment repair.<sup>51</sup> In patients with uveitis, adaptive optics has been used to show paravascular opacification in retinal vasculitis – findings consistent with a putative ocular “glymphatic” system.<sup>52, 53</sup> In patients with glaucoma and other optic neuropathies, adaptive optics has revealed evidence of structural changes, both the peripapillary RNFL bundles,<sup>54</sup> and their associated cone photoreceptors.<sup>55</sup>

## Conclusions

It is clear that the addition of adaptive optics to existing retinal imaging platforms is an important step for clinical ophthalmology, providing extremely high-resolution images of the retina. While commercial adaptive optics devices are now available, image acquisition needs to become quicker and easier, for both the patient and the clinician. Adaptive optics devices are also limited by a small field of view and difficulties in acquiring good quality images in patients with poor fixation, poor compliance, or with significant disruption of their retinal anatomy.

## Doppler Imaging: Assessment of Blood Flow

### Basic Principles

The Doppler effect, first described in the 19th century by the Austrian physicist Christian Doppler, is the change in frequency of a wave as it is reflected off a moving object; if the reflecting object is moving away from the observer/transducer, the frequency of the reflected waves is lower than that of the waves emitted, and vice

versa. As the frequency shift is dependent on the velocity of the moving object, this effect can be used to measure the velocity of blood flowing in the eye.<sup>56</sup> Importantly, the Doppler effect is also dependent on the angle between the axis of the wave and the axis of movement of the object. Therefore, if the observer/transducer is not parallel to the axis of the moving object, calculations must be performed using a Doppler angle correction formula.

Accurate measurement of this Doppler angle is a significant obstacle to the noninvasive assessment of ocular blood flow. Furthermore, as the Doppler angle increases between 60° and 90°, velocity calculations are subject to significant errors.

Utilization of the Doppler effect in ocular imaging systems allows calculation of ocular blood flow velocities.<sup>56</sup> Reductions in blood flow velocity may occur as a result of vascular degenerative changes in diseases such as diabetic retinopathy, or as a result of vascular occlusion in diseases such as CRVO. However, changes in retinal blood flow velocity may also occur as a result of either constriction or dilation of vessels during normal physiologic autoregulation (according to Bernoulli's principle, constriction of a blood vessel increases the velocity of the blood but decreases its pressure). Therefore, measurements of the absolute quantities of "blood flow" may represent a more clinically relevant parameter.

Blood flow ( $Q$ ) is the volume of blood passing through a vessel in a given time, and is determined by the velocity of the blood ( $V$ ) multiplied by the cross-sectional area of the blood vessel through which it passes ( $\pi r^2$ ).<sup>57</sup> Consequently, if blood flow velocity can be measured using the Doppler effect, and the diameter of the blood vessel can also be measured, then absolute values for blood flow may be determined. Measurements of retinal vascular diameter can be acquired from fundus images obtained with standard optical imaging techniques (e.g., fundus photography).<sup>58,59</sup> However, in order to measure retinal vascular diameters in real units of length, the magnification of the image induced by the eye, as well as the magnification of the camera, must be known (failure to account for such magnification will result in significant errors).

## Non-Doppler Assessment of Retinal Blood

## Flow

Measurement of retinal blood flow is possible using quantitative angiography, based on use of dye-dilution techniques.<sup>56,58,59</sup> In this method, the concentration of fluorescent dye within the blood at a specific observation point is graphed over time, producing a dye-dilution curve. The enhanced contrast provided by SLO systems is particularly suited to this approach, and it can be used to evaluate vascular parameters such as retinal arteriovenous passage (AVP) time and mean dye velocity. The increased contrast provided by SLO images also allows measurement of blood velocities in the small vessels surrounding the fovea and the optic nerve head (in the future, this technique is likely to be enhanced through the incorporation of adaptive optics).<sup>59</sup> Indocyanine green angiography (ICGA) may also be used to evaluate the choroidal circulatory flow, as the infrared light sources employed penetrate the RPE more efficiently than the shorter wavelengths used in fluorescein angiography. In one analysis method, the choroid is divided into six regions, and dye dilution curves are created for each region (Fig. 7.7A). Parameters such as 10% filling time and maximum brightness can then be calculated.<sup>59</sup> SLO-based fluorescein and ICGA provides significant information regarding retinal and choroidal blood velocities. However, without measurement of corresponding vascular diameters, it is not possible to measure blood flow. In addition, the invasive nature of the dye injections required for these approaches precludes their routine use in many clinical scenarios.

**FIG. 7.7** Evaluation of chorioretinal blood flow. (A) Quantification of choroidal blood flow using indocyanine green angiography. Six locations, each a 6° square, are identified on the image for dye dilution analysis. (B) Color Doppler image (CDI) of the central retinal artery and vein. The Doppler shifted spectrum (time velocity curve) is displayed at the bottom of the image. Red and blue pixels represent blood movement toward and away from the transducer, respectively. (C) Confocal scanning laser Doppler flowmetry (Heidelberg Retinal Flowmeter) of optic nerve head and peripapillary retina. The left arrow indicates a 1×1 pixel measurement window, which collects flow values from the entire retina except for large vessels, for new pixel-by-pixel analysis. The right arrow indicates a 10×10 pixel measurement window used for conventional analysis. (Reproduced with permission from Harris A, Chung HS, Ciulla TA, et al. Progress in measurement of ocular blood flow and relevance to our understanding of glaucoma and age-related macular degeneration. *Prog Retin Eye Res* 1999; 18(5):673–677.)

## Doppler Ultrasound

Color Doppler imaging (CDI) is an ultrasound technique that combines B-scan grayscale imaging of tissue structure, color representation of blood flow based on Doppler shifted frequencies,

and pulsed-Doppler measurement of blood flow velocities (Fig. 7.7B).<sup>56,59</sup> As in other Doppler-based methods, blood flow velocity is determined by the shift in the frequency of sound waves reflected from the moving blood column. Color is then added to the B-scan grayscale image of the eye to represent the motion of blood through the vessels. The color varies in proportion to the flow velocity and is typically coded red–white for motion toward the probe, and blue–white for motion away from the probe. Using the color Doppler image, the operator can then identify the vessel of interest and place the sampling window for pulsed Doppler measurements (this window is generally situated in the centre of the vessel). At this point, the general flow axis of the blood flow is detected simply by observation to determine the Doppler flow angle for the appropriate calculation of velocity. Flow-velocity data is then graphed against time, and the computer identifies the peak and trough of the waves.

Current CDI analysis focuses primarily on the arteries located behind the globe: ophthalmic artery, central retinal artery, and posterior ciliary arteries. CDI can be used to describe blood flow to the eye in terms of a set of well-defined parameters including (1) peak systolic velocity (PSV), (2) end-diastolic velocity (EDV), and (3) resistance index.<sup>56,59</sup> It does not provide absolute measurements of blood flow (no quantitative information on vessel diameter is obtained). With a 7.5-MHz probe, CDI is able to resolve structures 0.2 mm (200  $\mu\text{m}$ ) or larger, but can also be used to measure Doppler shifts in smaller vessels such as the posterior ciliary arteries (diameter of approximately 40  $\mu\text{m}$ ). CDI may be of particular use for the primary evaluation and follow-up of orbital vascular lesions, such as varices, arteriovenous malformations, and carotid-cavernous sinus fistulas. It has also been used for the semiquantitative assessment of perfusion in retinal and choroidal vascular disease. Specifically, in patients with CRVO, the central retinal artery PSV and EDV have been found to be much lower than in unaffected fellow eyes and in healthy control subjects.<sup>60</sup> Patients with ocular ischemic syndromes also present reduced PSVs in the central retinal and posterior ciliary arteries, as well as increased resistance.<sup>61</sup>

## Laser Doppler Velocimetry

Bidirectional laser Doppler velocimetry (LDV) is a technique used to quantify maximum blood velocity in large retinal vessels.<sup>56,62</sup> Instruments based on this principle typically consist of a modified fundus camera where the body of the camera has been replaced by a fiberoptic unit. A low-powered laser light source casts a beam onto the ocular fundus, which is positioned by the operator on the retinal vessel of interest. The Doppler shifted frequency spectra of the returning light can then be measured. These spectra exhibit large fluctuations up to a clearly measurable maximum shift – this maximum shift arises from scattered light from red blood cells flowing at the maximum speed at the center of the vessel. If the Doppler angles are then known, the maximum frequency shift can be used to calculate the maximum vessel velocity; however, these angles are difficult to measure reproducibly. Therefore, a bidirectional technique was developed to expand the capability of LDV to provide absolute measurements of maximum velocity.<sup>62</sup> In the bidirectional technique, one incident beam is used to illuminate a sight along a retinal vessel. The light scattered by the blood cells at the illuminated site is then detected simultaneously in two distinct directions separated by a known, fixed angle. Two Doppler shifted frequency spectra are measured and the difference between their maximum shifts is then used to calculate the maximum velocity in units of speed.

By combining an eye-tracking system with a retinal laser instrument based on bidirectional LDV, Canon have developed a commercially available instrument (Canon Laser Blood Flowmeter (CLBF)-100, Tokyo, Japan).<sup>63</sup> This device allows concomitant measurement of blood vessel diameter; as a result, total retinal blood flow in a single vessel can be calculated in absolute units. Thus far, the smallest vessels in which the blood flow rate has been measured were approximately 40  $\mu\text{m}$  in diameter.<sup>44</sup> It has been used to investigate retinal blood flow in diabetic patients with kidney disease,<sup>64</sup> and both with and without diabetic retinopathy.<sup>65</sup>

## Laser Doppler Flowmetry

Laser Doppler flowmetry (LDF) is a technique where laser light is

not directed at a retinal vessel, but on an area of vascularized retinal tissue with no large vessels visible.<sup>56,58</sup> LDF instruments are based on the theories of Bonner and Nossal, which describe the characteristics of laser light injected at one point into capillary tissue and collected at an adjacent point.<sup>62</sup> This theory relates the Doppler shift of the light to the total number of blood cells moving in the illuminated tissue volume, and to the flow rate of the moving cells. By using this theory, relative measurements of the mean velocity of the red blood cells, and the blood volume, can be obtained. Relative values of blood flow can then be calculated as the product of velocity and volume. However, such measurements are not absolute, and variations in vascular density and vessel orientation, even within relatively small volumes of tissue, can lead to considerable differences in the scattering properties between subjects.

Scanning laser Doppler flowmetry combines the principles of scanning laser tomography and LDF with the commercially available Heidelberg Retina Flowmeter (HRF), providing two-dimensional flow maps of the retina and optic nerve head (Fig. 7.7C).<sup>66</sup> In this system, the HRF images a  $2880\ \mu\text{m} \times 720\ \mu\text{m}$  area of the retina or optic nerve, at a resolution of approximately  $10\ \mu\text{m}/\text{pixel}$ . After the scan is performed, the HRF computer performs a fast Fourier transform to extract the Doppler shift spectrum from each measured pixel of reflected light. The HRF device is simple to use and sensitive to small changes over time in the same eye. However, the flow measurements are displayed in arbitrary units and there is a lack of accuracy when dealing with very high and very low blood speeds. Furthermore, contributions to blood flow measurements from the underlying choriocapillaris cannot be excluded and previous experimental tests of the instrumentation have demonstrated that large flow readings can be obtained from sample volumes even when they contain no moving cells.<sup>62</sup> The HRF device has, perhaps, most commonly been used in the investigation of patients with glaucoma. A number of such studies have investigated the correlation between optic nerve head morphology (as assessed using scanning laser tomography) and peripapillary retinal blood flow (as assessed using laser Doppler flowmetry). These studies suggest that decreased retinal blood flow

is associated with glaucomatous structural damage.<sup>67</sup>

## Doppler Optical Coherence Tomography

OCT, first described by Huang et al. in 1991, uses interferometry to generate high resolution cross-sectional images of the neurosensory retina.<sup>68</sup> Since the mid-1990s, Doppler measurements have been incorporated into prototype OCT imaging systems (Fig. 7.8).<sup>16</sup> In the original time-domain OCT systems, the blood velocity can be determined by measurement of the Doppler shift of the interference fringe frequency after Fourier transformation of the data, whereas, in newer spectral domain OCT systems, direct recording of the interference fringe frequency is possible. However, in this approach, blood velocity sensitivity and image spatial resolution are coupled and inversely related (increasing the velocity sensitivity decreases the spatial resolution). In order to overcome this limitation, a number of Doppler OCT prototypes utilize the phase change between sequential A-scans in order to generate information regarding the Doppler shift.<sup>16</sup>

**FIG. 7.8** Doppler optical coherence tomography (OCT). (A) Fundus photograph showing the double circular pattern of the OCT beam scanning retinal blood vessels emerging from the optic disc. (B) The relative position of a blood vessel in the two OCT cross-sections is used to calculate the Doppler angle  $\theta$  between the beam and the blood vessel. (C) Color Doppler OCT image showing the unfolded cross-section from a circular scan. Arteries and veins can be distinguished by the direction of flow as determined by the signs (blue or red) of the Doppler shift and the angle  $\theta$ . (Reproduced with permission from Wang Y, Fawzi AA, Varma R, et al. Pilot study of optical coherence tomography measurement of retinal blood flow in retinal and optic nerve diseases. *Invest Ophthalmol Vis Sci* 2011; 52(2):841.)

Although Doppler OCT can generate cross-sectional images of retinal blood flow (so-called “OCT angiography”), accurate quantification of this flow remains challenging: to achieve this it is necessary to measure the geometry of the vessel and, in particular, the Doppler angle. Furthermore, current Doppler OCT systems are limited in terms of the maximal velocities measurable, and in terms

of the smallest vessel diameters measurable (capillary flow involves single erythrocyte movement rather than continuous fluid flow). In a recent study, measurements of total retinal blood flow from Doppler OCT were combined with measurements of oxygen saturation using a spectral approach (see below). This combination allowed calculation of oxygen extraction and thus has considerable promise for investigation of oxygen metabolism within the retina.<sup>69</sup>

## Conclusions

The prospects for quantification of retinal blood flow with Doppler OCT appear good, yet it is still at an early stage in its development pathway. Furthermore, due to the complexity of retinal hemodynamics, extensive validation and reproducibility studies are required before acceptance of any new measurement approach.

# Spectral Imaging: Assessment of Retinal Oxygenation

## Basic Principles

Spectroscopy is the study of the interaction between any form of matter and radiated energy (e.g., visible light). By measuring radiation intensity as a function of wavelength, and through the identification of characteristic signatures, it is possible to determine the constituents of a material. For example, in astronomy, spectral analysis can be used to derive many properties of distant stars and galaxies. As well as its uses in remote sensing, spectroscopy has also been adapted for a number of laboratory-based applications. In biologic systems, the combination of spectroscopy with conventional imaging techniques – “spectral imaging” – allows determination of the spatial distribution of spectroscopic data.<sup>70</sup> In clinical settings, the application of spectroscopic principles has been of particular use for oximetry – the measurement of oxygen saturation in a patient's blood. From as early as 1935, transillumination of the ear has been used as a method of continuously measuring oxygen saturation in human blood. The subsequent incorporation of plethysmography (the analysis of

pulsatile components of the arterial cycle) has facilitated development of pulse oximeters capable of measuring arterial oxygen saturation in isolation.

The use of spectral imaging to perform blood oximetry is dependent on assumptions about the relationship between light transmittance through the blood and its oxygen saturation.<sup>70</sup> According to the Lambert–Beer law, for any given wavelength of light, its transmittance through blood is dependent on the extinction coefficient of the blood ( $\epsilon$ ), the concentration of blood ( $c$ ), and the path length ( $d$ ) through which the light travels. The extinction coefficient of blood ( $\epsilon$ ) is dependent on its main absorbing component – hemoglobin, which, in turn, is dependent on its oxygen concentration. As the extinction coefficient of blood varies with wavelength, analyzing the optical density of blood at multiple wavelengths compensates for variables such as the concentration and path length and ultimately allows estimation of oxygen levels in the blood (the exact details of these calculations are beyond the scope of this chapter, but have been reviewed in detail by Harris et al.).<sup>71</sup> However, in retinal oximetry, it is impractical to determine optical densities (and thus oxygen concentrations) through the measurement of light transmittance. Instead, measurements of light reflected from the retina are typically used. Although the principles described above require a number of assumptions that may not hold true in the real world, measurement of light reflected from the retina at multiple wavelengths, in this manner, forms the basis for a number of noninvasive retinal oximetry technologies.

## Technology

Spectral imaging devices typically employ one of three different approaches: (1) multispectral imaging; (2) hyperspectral imaging; (3) imaging spectroscopy.<sup>70,71</sup> Initial efforts by Hickam et al. in the 1950s employed film-based fundus cameras; more recently, digital fundus cameras and confocal scanning laser ophthalmoscopes have also been employed. Early attempts have also been made at the utilization of OCT in association with spectral analysis techniques.<sup>72</sup>

Multispectral imaging involves the measurement of reflected

light from images obtained at discrete and somewhat narrow spectral bands. Adopting a similar approach to that first described by Beach et al.,<sup>73</sup> Stefansson and coworkers have recently developed "Oxymap," a commercially available device approved for investigational usage.<sup>74</sup> This device consists of a fundus camera, which is coupled with a beamsplitter and a digital camera. The beamsplitter separates the original image into four optical channels, each of which contains a different narrow band-pass filter (each band-pass filter only allows light of specific wavelengths to pass). This simultaneously yields four fundus images, each with a specific wavelength of light. Specialized software automatically selects measurement points on these images and calculates the optical density of retinal vessels at two wavelengths, 605 nm and 586 nm (optical density is sensitive to oxygen saturation at 605 nm but not at 586 nm). The ratio of these optical densities is approximately linearly related to the hemoglobin oxygen concentration. The oximeter is then calibrated to yield relative oxygen saturation values. This approach has been shown to be sensitive to changes in oxygen concentration and to yield reproducible results. In recent years, efforts have also been made to generate normative databases for retinal oxygenation measurements across different ethnic groups.<sup>75,76</sup> In lightly pigmented individuals, it has even been possible to use this device to measure choroidal oxygenation.<sup>77</sup> Finally, using Oxymap software, it has been possible to adapt an ultrawide-field SLO system (Optomap 200Tx, Optos Inc., Scotland) to perform retinal oximetry (this device uses two lasers for image acquisition, 532 and 633 nm, and thus can be used for multispectral imaging).<sup>78</sup>

Hyperspectral imaging involves the measurement of light from images obtained at narrow spectral bands over a contiguous spectral range. Mordant et al. have recently described the validation of a hyperspectral fundus camera for noninvasive retinal oximetry (Fig. 7.9).<sup>79</sup> In their system, a commercial fundus camera is linked to a liquid crystal tunable filter in the optical path of the camera's light source; this enables the electronic selection of a combination of desired wavelengths between 400 and 700 nm. A CCD camera is then used to record a sequence of spectral images between 500 and 650 nm in 2-nm increments (this process takes approximately 10–15

minutes in healthy volunteers). Further image processing and analysis then takes place: the images are registered, the retinal vessel profiles extracted, and their optical densities estimated. Oxygen saturations can then be calculated. Use of hyperspectral imaging in this manner may provide more accurate measurements of oxygen saturation than two-wavelength multispectral approaches (such approaches have been reported to overestimate oxygen saturation). However, such an approach requires the use of sensitive detectors and powerful computers to enable fast and accurate processing of images. In 2014, Kashani et al. described human studies of another form of hyperspectral imaging device, using computed tomography (CT) algorithms to extract spectral data patterns.<sup>80</sup>

**FIG. 7.9** Spectral imaging of the retina. (A) Color fundus photograph demonstrating a left inferotemporal branch retinal arteriole occlusion. (B) Pseudocolor oximetry map showing abnormally low oxygen saturation within the affected inferotemporal retinal

arteriole in contrast to the normal OS levels in the unaffected superotemporal arteriole. The corresponding inferotemporal retinal venule has a normal level of oxygen saturation. (Reproduced with permission from Mordant DJ, Al-Abboud I, Muyo G, et al. Spectral imaging of the retina. Eye 2011; 25(3):317.)

A third method utilized for the noninvasive measurement of retinal oxygen saturation involves imaging spectroscopy. Schweitzer et al. have described an imaging ophthalmospectrometer, which consists of a modified fundus camera and an attached spectrograph.<sup>81</sup> The instrument illuminates the retina with a small slit of light and then simultaneous measurements are made at 76 different wavelengths – in this discrete area – using a spectrometer. This approach may be the most accurate, however a major limitation is that measurements are made at one single cross-section of one or two retinal vessels. By contrast, a complete two-dimensional mapping of oxygen saturation in the retinal vascular tree is needed for clinical diagnostics.

## Clinical Applications

Using the Oxymap system, Hardarson et al. have evaluated retinal vasculature oxygen saturations in patients following central retinal vein and branch retinal vein occlusion (CRVO/BRVO).<sup>82,83</sup> In patients with CRVO, they demonstrated that retinal venular oxygen saturation is lower than in fellow eyes. However, they also demonstrated considerable variability within and between CRVO eyes. Similarly, in patients with BRVO, they found considerable variability in oxygen saturation between patients. They found evidence of hypoxia in some patients but not others and speculated that this reflected variable disease severity in terms of degree of occlusion, recanalization, collateral circulation, and coexistent tissue atrophy. Traustason et al. used the Oxymap system to examine retinal oxygenation in patients receiving intravitreal ranibizumab for CRVO. They showed that retinal venous oxygen saturation was markedly reduced in untreated CRVO, but was “halfway” normalized during the course of this intravitreal therapy.<sup>84</sup>

A growing body of work has begun to evaluate Oxymap measurements in patients with diabetic retinopathy.<sup>85</sup> This work suggests that retinal vessel oxygen saturation is higher in patients with diabetic retinopathy than in healthy controls. Possible explanations for this include shunting of blood through preferential channels, bypassing nonperfused capillaries in the capillary network. Thus parts of the retina may be hypoxic while blood in larger blood vessels has higher oxygen saturation. Oxymap measurements are now also being incorporated into clinical trials of diabetic retinopathy, e.g., the CLEOPATRA trial looking at the role of light masks in the treatment of early diabetic macular edema.<sup>86</sup>

Hardarson et al., have also used this system to examine the effects of glaucoma filtration surgery, and topical anti-glaucoma medications, on retinal vascular oxygen concentrations.<sup>87</sup> A wide variety of other conditions have now been examined also, including age-related macular degeneration (AMD), retinitis pigmentosa, high myopia, and following pars plana vitrectomy and/or long-term silicone oil tamponade. Perhaps most interestingly, use of the Oxymap system has demonstrated abnormalities in retinal oxygen metabolism in Alzheimer's disease.<sup>88</sup>

Using the Imedos system, Hammer et al. found that, in patients with diabetes, increasing severity of retinopathy was associated with increased retinal venous oxygen saturations (from  $63 \pm 5\%$  for mild nonproliferative retinopathy, to  $75 \pm 8\%$  for proliferative retinopathy).<sup>89</sup> Conversely, earlier work by Tiedeman et al. demonstrated evidence of increased oxygen consumption (i.e., decreased retinal venous oxygen saturation) in diabetic patients with acute hyperglycemia.<sup>90</sup> The Imedos system has shown changes in retinal vascular oxygen saturation in patients with inherited retinal dystrophies (especially rod–cone dystrophies) and glaucoma. Interestingly, it has also been used to show reduced oxygen metabolism in patients with giant cell arteritis but without ocular symptoms,<sup>91</sup> and in patients with chronic obstructive pulmonary disease (COPD).<sup>92</sup>

## Spectral Imaging – Other Applications

Spectral imaging approaches may also be used to estimate the

optical density of other absorbers in the eye, including lens optical density, macular pigments (lutein and zeaxanthin), melanin, lipofuscin, and visual pigments. A triple wavelength, multispectral reflectometer has recently been described which has the potential to allow rhodopsin density and regeneration mapping.<sup>93</sup>

## Conclusions

Although major progress has been made in recent years, there is currently no consensus on the optimal method for measurement of oxygen saturation in the retinal vasculature. A number of spectral imaging devices provide relative, rather than absolute, measurements of oxygen saturation. Furthermore, all devices rely, to a certain extent, on biophotonic assumptions that may not hold true for in vivo imaging. Therefore, it is vital that detailed validation and reproducibility assessments be performed on all new retinal oximeters before such devices can be widely adopted for clinical or research purposes.

## Photoacoustic Imaging: Assessment of Retinal Absorption

### Basic Principles

In large part, contemporary retinal imaging modalities are based on the measurement of light reflected from the retina, e.g., fundus photography, SLO, OCT systems.<sup>2</sup> In contrast, no ophthalmic imaging modality exists that can directly measure the absorption of light by retinal tissues. Hemoglobin and melanin are particularly strong absorbers of light, so this information is potentially of great clinical interest. For example, light absorption by hemoglobin may provide contrast for generation of enhanced retinal angiographic maps, while light absorption by melanin could aid visualization of the highly pigmented RPE cell mosaic. Assessment of optical absorption profiles at multiple wavelengths may also improve the accuracy of retinal vascular oxygen saturation measurements (current “spectral imaging” determines optical density ratios indirectly, through the measurement of reflected light). Fortunately,

through recent advances in microscopy, utilizing the photoacoustic effect, it has become possible to acquire optical absorption profiles in the context of noninvasive ophthalmic imaging – photoacoustic ophthalmoscopy (PAOM).<sup>94,95</sup>

The photoacoustic effect was first recognized by Alexander Graham Bell in the 1880s when he discovered that thin discs of Selenium emit sound when exposed to a rapidly interrupted beam of sunlight. This phenomenon occurs as energy absorbed from the incident light is converted into kinetic energy, which results in local heating and, thus, generation of a pressure wave or sound. In the recently described photoacoustic microscopy (PAM),<sup>96</sup> a laser is used to irradiate a target tissue and thus induce ultrasonic pressure waves as a result of specific optical absorption. These pressure waves can then be recorded using a high-resolution ultrasonic transducer, and images generated. As PAOM is the only existing optical-absorption-based ophthalmic imaging modality, it can be readily integrated with other reflectance-based imaging modalities – fundus cameras, SLO devices, fluorescein angiography, fundus autofluorescence, and OCT – for “true” multimodal imaging.<sup>97</sup>

## Technology

Through the integration of OCT technology with a laser-scanning, optical resolution PAM, Jiao et al. have recently reported the use of PAOM in small animals.<sup>94,95</sup> In this system, the illumination source is a frequency doubled, Q-switched, Nd:YAG laser producing nanosecond laser pulses, combined with the output laser beam of a fiber-based spectral domain OCT system.<sup>94</sup> The photoacoustic waves induced from the retina are then detected by a stationary, unfocused ultrasonic transducer placed in contact with the eyelid (coupled by ultrasound gel). The resulting photoacoustic images can then be registered with the images generated from the integrated OCT system (Fig. 7.10). As with conventional OCT image sets, maximum amplitude “projection” images can be generated from photoacoustic datasets allowing two-dimensional visualization of the retinal vasculature. Volumetric images can also be generated following automated segmentation of the RPE and retinal vessels. The same group has tested the acquisition of

photoacoustic images in association with fundus autofluorescence signals (apart from generating heat, the absorbed photons may undergo other physical processes, such as stimulating autofluorescence when fluorophores are present). Multimodal imaging in this manner may thus provide spatial information on the distribution of both melanin and lipofuscin via photoacoustic and autofluorescent signals respectively.<sup>98</sup> More recently, Doppler OCT has been integrated with PAM, allowing for quantification of retinal oxygen metabolic rates,<sup>99</sup> and for quantification of RPE melanin in vivo.<sup>100</sup>

**FIG. 7.10** Comparison of optical coherence tomography (OCT) and photoacoustic ophthalmoscopy (PAOM) images acquired simultaneously in vivo. (A) PAOM B-scan image in pseudocolor. (B) OCT B-scan image. (C) Projection image of the PAOM data set. Scale bar: 100  $\mu\text{m}$ . *HA*, hyaloid artery; *RPE*, retinal pigment epithelium. (Reproduced with permission from Jiao S, Jiang M, Hu J, et al. Photoacoustic ophthalmoscopy for in vivo retinal imaging. *Optics Express* 2010;18(4):3971.)

The combination of OCT imaging with PAM requires two

separate light sources – OCT needs a broadband light source to achieve depth resolution, while PAM requires a pulsed laser. Using a single light source to achieve simultaneous OCT and PAM imaging was first reported in 2012.<sup>101</sup> The technique was termed optical coherence photoacoustic microscopy (OC-PAM). In vivo retinal imaging using an OC-PAM system with center wavelength 830 nm has recently been described. Since the optical absorption of hemoglobin in the near-infrared (NIR) spectrum is much smaller than that in the visible spectrum, this system would not be expected to provide good contrast for imaging the retinal vasculature. However, it may be ideally suited to imaging of melanin distributions in the RPE and choroid.<sup>102</sup>

## Conclusions

The development of photoacoustic imaging techniques may greatly extend the scope of future retinal imaging; however, at present, the technology remains at an early stage in the development process. Virtually all the work to date, on photoacoustic imaging in the eye, has been performed in tissue samples or in animals. A number of technical hurdles remain before images can be obtained from living human subjects, or commercial, clinical devices can be introduced.

## Magnetic Resonance Imaging

The acquisition of retinal images is largely dependent on optical techniques such as fundus photography. However, many such techniques are constrained by a relatively small field of view, and are often limited when there is disease-induced opacification of the ocular media, such as lens opacity or vitreous hemorrhage. In the clinical setting, these limitations are addressed, at least in part, by acoustic imaging techniques such as ultrasonography. More recently, however, advances in magnetic resonance imaging (MRI) offer the prospect of retinal application in humans.<sup>103,104</sup> In addition to a wide field of view, and the ability to acquire images despite media opacification, retinal MRI may also aid in evaluation of novel functional parameters.

## Basic Principles

In MRI systems, a powerful magnetic field is applied to the body leading to alignment of the magnetization of its hydrogen nuclei or protons (the human body is largely made up of water molecules, which contain two hydrogen atoms). Radiofrequency fields are then used to systematically alter this alignment, causing the protons to spin and producing a rotating magnetic field detectable by the scanner. Detectors in the MRI system then evaluate a number of parameters (e.g., spin density, spin–lattice relaxation time [ $T_1$ ], spin–spin relaxation times [ $T_2$ ]), which vary depending on the local tissue environment. As a result, soft tissue images can be generated. Image contrast may be further enhanced through the use of exogenous paramagnetic contrast agents such as gadolinium. In this manner, clinical MRI scanners can produce high-resolution images of the entire body, both noninvasively and in a single setting.<sup>103</sup>

As well as its anatomical imaging capability, MRI scanning can also be used to measure blood flow.<sup>103</sup> MRI-derived quantification of blood flow may be performed by the use of exogenous intravenous contrast agents, e.g., with the use of fluorescent microspheres. However, it may also be performed noninvasively by magnetically labeling blood as a means of providing endogenous contrast, so-called continuous arterial spin labeling (CASL). These techniques have been widely used to quantify blood flow to the brain and have been cross-validated using positron emission tomography (PET).

Relative blood oxygen saturations can also be measured using the BOLD (blood oxygenation level dependent) technique. This technique detects differences in magnetic resonance signal intensity that arise from changes in the oxygen saturation of hemoglobin during brain activation – a local decrease in concentration of deoxygenated hemoglobin will increase the BOLD signal (while an increase will decrease the BOLD signal). In the brain, when a specific region is activated in response to stimulation, local blood flow increases in response to the increased metabolic demand; such increases in blood flow will provide a boost in oxygen delivery and thus decrease the concentration of deoxygenated hemoglobin.

Techniques that measure blood flow and oxygenation can thus be used to noninvasively image brain function – fMRI (functional MRI).<sup>103</sup>

## Retinal and Choroidal Imaging

To date, most work on retinal imaging using magnetic resonance has been reported in animal studies (Fig. 7.11).<sup>103</sup> As the spatial resolution of MRI is limited compared to that of OCT and other optical imaging modalities, current magnetic resonance-derived retinal imaging only allows delineation of three to four distinct retinal layers. Using gadolinium for contrast provides increased signal from the retinal and choroidal vasculature and thus aids in correlation of MRI retinal scans with histologic sections (the avascular photoreceptor layers do not show any enhancements using this method). Manganese has also been used as a contrast agent to improve the anatomic contrast between layers; using this approach, it has been possible to reveal seven distinct retinal bands of alternating hypo- and hyperintensity.<sup>103</sup>

**FIG. 7.11** Magnetic resonance imaging (MRI) of the retina in vivo. Higher-resolution  $T_2$ -weighted ( $TE = 40$  msec) and diffusion-weighted ( $b = 504$  seconds/ $mm^2$ ) images ( $TWI$ ,  $DWI$ ) at  $50 \times 100 \mu m$  resolution. Diffusion-

sensitizing gradients were placed along the x, y, or z axis separately. The small and large white arrows indicate the “inner” and “outer” strips, respectively.

(Reproduced with permission from Shen Q, Cheng H, Pardue MT, et al. Magnetic resonance imaging of tissue and vascular layers in the cat retina. *J Magn Reson Imaging* 2006;23(4): 470.)

In 2008, the first report of retinal blood flow assessment, using MRI in rats, was published.<sup>105</sup> In this study, a CASL technique was used to quantify basal blood flow levels and their responses to physiologic stimulation. With the improvements in spatial resolution afforded by new MRI devices, visualization of separate retinal and choroidal blood flow has become possible in human subjects. In 2014, an MRI study in human subjects demonstrated reductions in choroidal blood flow with age.<sup>106</sup>

In animals, using BOLD fMRI techniques, differential responses of the retinal and choroidal circulations to physiologic stimuli (e.g., hyperoxia versus hypercapnia), have been demonstrated.<sup>103</sup> BOLD fMRI studies have also suggested that the retinal vasculature is very responsive to visual stimulation, but that the choroidal vasculature only showed small percentage changes.

## Conclusions

Translation of retinal MRI from animal studies to human research and clinical practice faces a number of obstacles. The MRI scanners available in clinical environments currently have limited spatial resolutions and low signal to noise ratios. In addition, the issue of eye movements in awake humans is a major limiting factor. As a first step in addressing these issues, the feasibility of multimodal MRI has recently been tested on anesthetized large, nonhuman, primates (baboons) using a standard clinical scanner.<sup>107</sup> Studies of this nature allow optimization of MRI scanning parameters and represent a first step towards magnetic resonance-derived retinal imaging in humans. Zhang et al. have recently demonstrated, for the first time, the use of BOLD fMRI to examine the changes associated with oxygen and carbogen challenges in the unanesthetized human retina.<sup>108</sup> Although much work has still to be done, such imaging may prove a useful adjunct to more established

optical imaging methods, particularly when assessing the differential regulation of the retinal and choroidal circulations. Also of note, MRI scanning has lately been used to image the partial pressures of oxygen within the vitreous of human subjects.<sup>109</sup> The spatially heterogeneous  $PO_2$  maps generated may be of particular interest for the assessment of retinal vascular diseases.

## Molecular Imaging

Even the potential combination of adaptive optics with OCT will fail to visualize the earliest cellular and biochemical processes that occur in many retinal diseases. In molecular imaging, exogenous contrast agents with targeting ligands are used to enhance the capabilities of conventional imaging platforms, and thus to allow selective visualization of cell types or biochemical processes.<sup>110</sup>

## Contrast Agents

Fluorescent dyes are typically employed as contrast agents for use with fundus photographic and SLO imaging techniques. Sodium fluorescein and indocyanine green have a long history of use in humans, with derivatives such as fluorescein isothiocyanate (FITC) commonly used in animal studies. In recent years, however, the use of more novel nanoparticles has increasingly been explored.<sup>111</sup> For example, “quantum dots” are fluorescent nanocrystals consisting of a metalloid crystalline core (e.g., cadmium selenide) surrounded by a shell (e.g., zinc sulfide). The fluorescent properties of quantum dots offer a number of advantages for their use in optical imaging. The brightness of quantum dots is 10–100 times greater than most organic dyes or proteins. Quantum dots also show broad absorption characteristics with narrow emission spectra that are continuous and tunable due to quantum size effects. Quantum dots also possess a long fluorescence lifetime and undergo negligible photobleaching. Most importantly perhaps, quantum dots can be labeled to allow precise targeting of cellular structures. As a result of these features, quantum dots are increasingly being used for *in vivo* imaging in animal studies (Fig. 7.12), although concerns about cytotoxicity must be addressed before they will be suitable for use

in humans.

**FIG. 7.12** In vivo and intrasurgical spectral fluorescence imaging of a mouse injected with five-carboxyl quantum dots (565, blue; 605, green; 655, yellow; 705, magenta; 800, red), intracutaneously into the middle digits of the bilateral upper extremities, the bilateral ears, and at the median chin, as shown in the schema. Five primary draining lymph nodes (LNs) were simultaneously visualized with different colors through the skin in the in vivo image and are more clearly seen in the image taken at the surgery.

(Reproduced with permission from Kobayashi H, Hama Y, Koyama Y, et al. Simultaneous multicolor imaging of five different lymphatic basins using quantum dots. *Nano Letters* 2007;7(6):1714.)

The use of contrast agents for enhancement of OCT imaging has been less well explored, in large part because, as OCT is “coherence gated,” it is inherently blind to fluorescent probes. However, for a number of reasons, gold nanoparticles have potential for use as contrast agents with OCT.<sup>112</sup> Firstly, gold nanoparticles have the

property of localized surface plasmon resonance (LSPR) – this results in light scattering properties up to 40× greater than other identically sized particles that are not plasmonic. Secondly, they can be fabricated so that their light scattering properties attain a peak at the near-infrared wavelengths typically utilized by OCT systems. Thirdly, they can be readily conjugated with targeting ligands. Finally, they are water-soluble and potentially biocompatible – colloidal gold (suspensions of gold nanoparticles in fluid) has a long history of human use for treatment of conditions such as rheumatoid arthritis, while a number of newer gold nanoparticles are being evaluated in early phase clinical studies.<sup>111,113,114</sup>

## Targeting Ligands

Targeting ligands are commonly based on macromolecules, such as peptides, antibodies, or proteins, and aimed at molecular imaging of (1) retinal ganglion cells (RGC); (2) RPE; (3) endothelial cells; and (4) leukocytes.<sup>110</sup> Perhaps the most advanced of these areas is the molecular imaging of retinal ganglion cells. This work is driven in large part by the role of retinal ganglion cell dysfunction and apoptosis in glaucomatous optic neuropathy (using conventional imaging techniques and visual field measurements, early recognition of retinal ganglion cell dysfunction is not possible). Using a technique called “detection of apoptosing retinal cells” (DARC), single-cell detection of retinal ganglion cell apoptosis has recently been demonstrated in animal models.<sup>115</sup> In this approach, fluorescently labeled Annexin V is administered via intraocular or intravenous injection and binds specifically to phosphatidylserine on apoptosing retinal ganglion cells (during apoptosis, this molecule is translocated from the inner to the outer plasma membrane, rendering it accessible to extracellular targeting ligands). These apoptosing cells can then be visualized using conventional ophthalmic imaging devices such as a confocal SLO. Significant regulatory hurdles must be overcome before any such testing can be performed in humans. Considerable safety and toxicology testing has already been performed, however, and early phase clinical trials are expected to commence in the near future.<sup>116</sup>

## Conclusions

A large number of other nanoparticle groups are currently being investigated for their biomedical potential, with examples including carbon nanotubes, dendrimers, perfluorocarbons, and lipid-based nanoparticles.<sup>117</sup> The unique and tunable optical properties of many nanoparticles, along with their small size and capacity for cellular targeting, make them strong candidates for use as contrast agents in retinal imaging. Using these agents in combination with techniques such as OCT may ultimately allow visualization of many retinal structures (e.g., Müller cells), and cellular processes (e.g., apoptosis), in clinical practice. While such usage has yet to be demonstrated in humans, the previous commercialization of magnetic nanoparticles for MRI, and the early clinical trials of gold nanoparticle therapy in humans, provide grounds for optimism in this regard.

## Conclusions and Future Directions

In the past 25 years, advances in retinal imaging have revolutionized the diagnosis and management of retinal disease. As recently as 1990, the conventional wisdom held that axial image resolution was fundamentally constrained by geometric optics and the depth of focus.<sup>12</sup> However, with the advent of OCT, axial resolution has now been improved 1000-fold over that previously thought possible. In the short to medium term, continued advances in OCT will be coupled with advances in adaptive optics technology to provide unprecedented, noninvasive, cellular imaging. In parallel with this, functional extensions of these, and other, imaging modalities will provide greatly enhanced information regarding parameters such as retinal blood flow and oxygenation. Increasing use of nanotechnology may provide “molecular” imaging capabilities, and allow evaluation of biochemical processes such as apoptosis. In the longer term, a number of fundamental limits will need to be overcome, including (1) constraints imposed by maximum light exposure that can be delivered safely to the eye; (2) windows of spectral transmittance imposed by the cornea and lens; and (3) diffraction limits imposed

by the wave nature of light.<sup>12</sup> While many of these barriers seem impenetrable, some early breakthroughs have already taken place in each area. In particular, the diffraction limit has already been surpassed in the field of microscopy,<sup>118</sup> and the use of such techniques may allow a leap forward to much smaller spatial scales in future retinal imaging.

## Disclosure

Dr Keane has received a proportion of his funding from the Department of Health's NIHR Biomedical Research Centre for Ophthalmology at Moorfields Eye Hospital and UCL Institute of Ophthalmology. The views expressed in the publication are those of the authors and not necessarily those of the Department of Health.

Dr Keane has received travel grants from Allergan as part of the Allergan European Retina Panel. He has also given educational presentations for Topcon, Heidelberg, Bayer, Novartis, and Allergan.

Dr Sadda is a consultant for Optos and Carl Zeiss Meditec, and has received research instruments from Optos, Carl Zeiss Meditec, Topcon, and Nidek.

## Introduction

This chapter introduces quantitative approaches to retinal image analysis. Special emphasis is placed on familiarizing the reader with basic concepts in imaging and image analysis, and machine learning and deep learning, the main approaches to retinal image

analysis. Fundus and optical coherence tomography (OCT) image analysis are reviewed, as well as the use of these modalities in providing comprehensive descriptions of retinal morphology and function. Relevant translational clinical applications are discussed, including automated early detection of diabetic retinopathy and image analysis-assisted management of choroidal neovascularization. This chapter allows the reader to understand concepts in retinal image analysis, and critically review the clinical and translational impact of the research in this field.

## History of Retinal Imaging

The optical properties of the eye that allow image formation prevent direct inspection of the retina. Though existence of the red reflex has been known for centuries, special techniques are needed to obtain a focused image of the retina. The first attempt to image the retina, in a cat, was completed by the French physician Jean Mery, who showed that if a live cat is immersed in water, its retinal vessels are visible from the outside.<sup>1</sup> The impracticality of such an approach for humans led to the invention of the principles of the ophthalmoscope in 1823 by Jan Evangelista Purkyňe and its reinvention in 1845 by Charles Babbage.<sup>2,3</sup> Finally, the ophthalmoscope was reinvented yet again and reported by von Helmholtz in 1851.<sup>4</sup> Thus, inspection and evaluation of the retina became routine for ophthalmologists, and the first images of the retina (Fig. 8.1) were published by the Dutch ophthalmologist van Trigt in 1853.<sup>5</sup> Earlier sketches by Purkyňe provided drawings of his own retinal vasculature.<sup>6</sup>

**FIG. 8.1** First known image of human retina as drawn by Van Trigt in 1853. (Reproduced from Trigt AC. *Dissertatio ophthalmologica inauguralis de speculo oculi*. 1853.)

The first useful photographic images of the retina, showing blood vessels, were obtained in 1891 by the German ophthalmologist Gerloff.<sup>7</sup> In 1910, Gullstrand developed the fundus camera, a concept still used to image the retina today,<sup>8</sup> he later received the Nobel Prize for this invention. Because of its safety and cost-effectiveness at documenting retinal abnormalities, fundus imaging has remained the primary method of retinal imaging.

In 1961, Novotny and Alvis published their findings on fluorescein angiographic imaging.<sup>9</sup> In this imaging modality, a fundus camera with additional narrow band filters is used to image a fluorescent dye injected into the bloodstream that binds to leukocytes. It remains widely used, because it allows an understanding of the functional state of the retinal circulation.

The initial approach to depict the three-dimensional shape of the retina was stereo fundus photography, as first described by Allen in 1964, where multiangle images of the retina are combined by the human observer into a three-dimensional shape.<sup>10</sup> Subsequently, confocal scanning laser ophthalmoscopy was developed, using the

confocal aperture to obtain multiple images of the retina at different confocal depths, yielding estimates of three-dimensional shape. However, the optics of the eye limit the depth resolution of confocal imaging to approximately 100  $\mu\text{m}$ , which is poor when compared with the typical 300–500  $\mu\text{m}$  thickness of the whole retina.<sup>11</sup>

Optical coherence, based on Michelson's description of interferometry in 1872,<sup>12</sup> was first used as a method for time of flight measurement of the depth of mechanical structures.<sup>13,14</sup> It was then extended to a tissue imaging technique to determine the position of structures in tissue described by Huang et al. in 1991,<sup>15</sup> termed optical coherence tomography (OCT). In 1993, in vivo retinal OCT was accomplished for the first time.<sup>16</sup> Today, OCT has become a prominent biomedical tissue-imaging technique, especially in the eye, because it is particularly suited to semi-transparent tissues, but also for any tissue imaging requiring micrometer resolution.

## History of Retinal Image Processing

Matsui et al. were the first to publish a method for retinal image analysis, primarily focused on vessel segmentation.<sup>17</sup> Their approach was based on mathematical morphology and they used digitized slides of fluorescein angiograms of the retina. In the following years, there were several attempts to segment other anatomical structures in the normal eye, all based on digitized slides. The first method to detect and segment abnormal structures was reported in 1984, when Baudoin et al. described an image analysis method for detecting microaneurysms, a characteristic lesion of diabetic retinopathy.<sup>18</sup> Their approach was also based on digitized angiographic images. They detected microaneurysms using a “top-hat” transform, a step-type digital image filter.<sup>19</sup> This method employs a mathematical morphology technique that eliminates the vasculature from a fundus image yet leaves possible microaneurysm candidates untouched. The field dramatically changed in the 1990s with the development of digital retinal imaging and the expansion of digital filter-based image analysis techniques. These developments resulted in an exponential rise in the number of publications, which continues today. Most recently,

so-called deep-learning techniques, a form of machine learning consisting of multilayer neural networks, and specifically convolutional neural networks, have been gaining attention for retinal imaging tasks.<sup>20–22c</sup>

## Current Status of Retinal Imaging

Retinal imaging has developed rapidly during the last 160 years and is now a mainstay of the clinical care and management of patients with retinal as well as systemic diseases. Fundus photography is widely used for population-based, large-scale detection of diabetic retinopathy, glaucoma, and age-related macular degeneration (AMD). OCT and fluorescein angiography are widely used in the daily management of patients in a retina clinic setting. OCT has also become an increasingly helpful adjunct in preoperative planning and postoperative evaluation of vitreoretinal surgical patients.<sup>23</sup> The overview below is partially based on an earlier review paper.<sup>24</sup>

## Fundus Imaging

Fundus imaging is the process whereby reflected light is used to obtain a two-dimensional (2D) representation of the three-dimensional, semi-transparent, retinal tissues projected onto the imaging plane. Thus, any process that results in a 2D image where the image intensities represent the amount of a reflected quantity of light, is fundus imaging. Consequently, OCT imaging is not fundus imaging, while the following modalities/techniques all belong to the broad category of fundus imaging:

1. **Fundus photography** (including so-called red-free photography) – image intensities represent the amount of reflected light of a specific waveband.
2. **Color fundus photography** – image intensities represent the amount of reflected R (red), G (green), and B (blue) wavebands, as determined by the spectral sensitivity of the sensor.

3. **Stereo fundus photography** – image intensities represent the amount of reflected light from two or more different view angles for depth resolution.

4. **Scanning laser ophthalmoscopy (SLO)** – image intensities represent the amount of reflected single wavelength laser light obtained in a time sequence.

5. **Adaptive optics SLO** – image intensities represent the amount of reflected laser light optically corrected by modeling the aberrations in its wavefront.

6. **Fluorescein angiography and indocyanine angiography** – image intensities represent the amounts of emitted photons from the fluorescein or indocyanine green fluorophore that was injected into the subject's circulation.

There are several technical challenges in fundus imaging. Since the retina is normally not illuminated internally, both external illumination projected into the eye as well as the retinal image projected out of the eye must traverse the pupillary plane. Thus the size of the pupil, usually between 2 and 8 mm in diameter, has been the primary technical challenge in fundus imaging.<sup>8</sup> Fundus imaging is complicated by the fact that the illumination and imaging beams cannot overlap because such overlap results in corneal and lenticular reflections diminishing or eliminating image contrast. Consequently, separate paths are used in the pupillary plane, resulting in optical apertures on the order of only a few millimeters. Because the resulting imaging setup is technically challenging, fundus imaging historically involved relatively expensive equipment and highly trained ophthalmic photographers. Over the last ten years or so, there has been a concerted effort and several important developments that have made fundus imaging more accessible, resulting in less dependence on such experience and expertise. There has been a shift from film-based to digital image acquisition, and as a consequence the importance of Picture Archiving and Communication Systems (PACS) has substantially increased in clinical ophthalmology, also allowing integration with electronic medical records. Requirements

for population-based early detection of retinal diseases using fundus imaging have provided the incentive for effective and user-friendly imaging equipment. Operation of fundus cameras by nonophthalmic photographers has become possible due to nonmydriatic imaging, digital imaging with near-infrared focusing, and standardized imaging protocols to increase reproducibility.

Though standard fundus imaging is widely used, it is not suitable for retinal tomography, because of the mixed backscatter caused by the semitransparent retinal layers.

## Optical Coherence Tomography Imaging

OCT is a noninvasive optical medical diagnostic imaging modality that enables in vivo cross-sectional tomographic visualization of the internal microstructure in biologic systems. OCT is analogous to ultrasound B mode imaging except that it measures the echo time delay and magnitude of light rather than sound, therefore achieving unprecedented image resolutions (1–10  $\mu\text{m}$ ).<sup>25</sup> Optical coherence tomography is an interferometric technique, typically employing near-infrared light. The use of relatively long wavelength light with a very wide-spectrum range allows OCT to penetrate into the scattering medium and achieve micrometer resolution.

The principle of OCT is based upon low coherence interferometry,<sup>26a</sup> where the backscatter from more outer, retinal tissues can be differentiated from that of more inner tissues, because it takes longer for the light to reach the sensor. Because the differences between the most superficial and the deepest layers in the retina are around 300–400  $\mu\text{m}$ , the difference in time of arrival is very small and requires interferometry to measure.<sup>26a</sup>

In OCT, the central wavelength is usually in the near infrared. The principle of low coherence, or low correlation, means that the light coming from the light source is only correlating over a short amount of time. In other words, the autocorrelation function of the light wave is only large for a short duration, and at all other times it is essentially zero. If the light is fully coherent, the autocorrelation

is high forever, and it becomes impossible to create an interference pattern and determine when the light was emitted. If the light is entirely incoherent, there can be no interference at all. Thus, the low coherence nature of the light allows each infinitesimal short duration of light to be “labeled”; the label is its unique wave-pattern over that short duration. This unique wave-pattern sent out at a specific timepoint can be differentiated from the light sent out a little bit later as this has a different wave-pattern. Though wave-pattern is used, it is important to understand that the light wave is actually continuous, not pulsed. A lower coherence means that the wave-pattern is unique over a shorter duration, and this allows a better depth resolution.

The label can uniquely indicate when reflected light was emitted, and thus we can measure differences between arrival times of light. To be able to measure differences, the low coherent light is optically split into two bundles, called arms, before being sent into the eye. One arm, the reference arm, is aimed at a mirror at a known distance, and from there reflected to the interferometer; the other, the sample arm, is sent into the eye and reflects back from the different tissues, primarily the retina, at yet unknown depth, so that light at inner retinal layers is reflected back earlier than that at more outer layers. If the distance to the mirror is exactly the same as the distance to a retinal structure, and thus the timepoint when they were emitted is the same, the two arms, optically combined at the interferometer, will show maximum correlation (they have the same “label”), which results in a high intensity called interference. The more difference in emission time, the less correlation, and the less interference. This is because the more the two light waves resemble each other at a moment in time, the higher the interference; remember that after splitting, each carried the same low coherence “label.” Because the optical properties of the eye add noise and thus slightly change the reflected reference arm light wave, the interference will never be perfect, even if the distance to the mirror exactly matches the distance to the retinal structure. Though the coherence pattern or label changes continuously over time, once they are split, they have the same label (but changing rapidly over time), so that the interference will be high as long as the reference and sample distances are the same, and only if light

from both arms has travelled the “same” optical distance (“same” meaning a difference of less than a coherence length). The energy or envelope of the interference is then measured as intensity using a photo sensor. This is then displayed as the familiar grayscale values of the OCT signal intensity. By changing the position of the reference arm mirror, we can “interrogate” the amount of interference at different sample tissue depths. By changing the position of the sample arm on the retina, we can scan the retina, resulting in the familiar B-scans and volumes. Snapshot OCT, where all A-scans are obtained simultaneously, using a lenslet array, has also been described.<sup>26b</sup>

The importance of the choice of a good low-coherence source is clear – with either an incoherent or fully coherent source, interferometry is impossible. Such light can be generated by using superluminescent diodes (superbright light-emitting diodes) or lasers with extremely short pulses, femtosecond lasers. The optical setup typically consists of a Michelson interferometer with a low-coherence, broad-bandwidth light source (Fig. 8.2). By scanning the mirror in the reference arm, as in time domain OCT, modulating the light source, as in swept source OCT, or decomposing the signal from a broadband source into spectral components, as in spectral domain OCT (SD-OCT), a reflectivity profile of the retina can be obtained, as measured by the interferogram. The reflectivity profile, called an A-scan, contains information about the spatial dimensions and location of structures within the retina. A cross-sectional tomograph (B-scan) may be achieved by laterally combining a series of these axial depth scans (A-scan). En face imaging (C-scan) at an acquired depth is possible depending on the imaging engine used.

**FIG. 8.2** Schematic diagram of operation of optical coherence tomography, emphasizing splitting of the light in two arms, train of overlapping bursts “labeled” based on their autocorrelogram, and their interference after being reflected from retinal tissue as well as from the reference mirror (assuming the time delays of both paths are equal).

In conventional interferometry with long coherence length (laser interferometry), interference of light occurs over a distance of meters. In OCT, this interference is shortened to a distance of micrometers, possible due to the use of broadband light sources, i.e., sources that can emit light over a broad range of wavelengths. Light with broad bandwidths can be generated by using superluminescent diodes (superbright LEDs) or lasers with extremely short pulses, femtosecond lasers. White light is also a broadband source with lower power.

The transverse resolution of OCT scans ( $x$ ;  $y$ ) depends on the speed and quality of the galvanic scanning mirrors and the optics of

the eye, and is typically 20–40  $\mu\text{m}$ . The resolution of the A-scans along the z direction depends on the coherence of the light source and is currently 4–8  $\mu\text{m}$  in commercially available scanners. Isotropic (or isometric) means that the size of each imaged element, or voxel, is the same in all three dimensions. Current commercially available OCT devices routinely offer voxel sizes of  $30\times 30\times 2$   $\mu\text{m}$ , achieving isotropicity in the x–y plane only. Available spectral domain OCT scanners are never truly isotropic, because the retinal tissue in each A-scan is sampled at much smaller intervals in depth than are the distances between A- and/or B-scans. The resolution in depth, also known as the z-dimension, is currently always higher than the resolution in the x–y plane. The primary advantage of x–y isotropic imaging when quantifying properties of the retina is that fewer assumptions have to be made about the tissue in-between the measured samples, thus potentially leading to more accurate indices of retinal morphology.

## Time Domain OCT

With time domain OCT, a reference mirror is moved mechanically to different positions, resulting in different flight time delays for the reference arm light. Because the speed at which the mirror can be moved is mechanically limited, only thousands of A-scans can be obtained per second. The envelope of the interferogram determines the intensity at each depth.<sup>15</sup> The ability to image the retina two-dimensionally and three-dimensionally depends on the number of A-scans that can be acquired over time. Because of motion artifacts such as saccades, safety requirements limiting the amount of light that can be projected onto the retina, and patient comfort, 1–3 seconds per image or volume is essentially the limit. Thus, the commercially available time domain OCT, which allowed collecting of up to 400 A-scans per second, has not yet been suitable for 3D imaging.

## Frequency Domain OCT

In frequency domain OCT, the broadband interference is acquired with spectrally separated detectors, either by encoding the optical frequency in time with a spectrally scanning source or with a

dispersive detector, like a grating and a linear detector array. The depth scan can be immediately calculated by a Fourier-transform from the acquired spectra, without movement of the reference arm. This feature improves imaging speed dramatically, while the reduced losses during a single scan improve the signal to noise proportional to the number of detection elements. The parallel detection at multiple wavelength ranges limits the scanning range, while the full spectral bandwidth sets the axial resolution.

## Spectral Domain OCT

A broadband light source is used, broader than in time domain OCT, and the interferogram is decomposed spectrally using a diffraction grating and a complementary metal oxide semiconductor (CMOS) or charged-couple device (CCD) linear sensor. The Fourier transform is again applied to the spectral correlogram intensities to determine the depth of each scatter signal.<sup>27</sup> With spectral domain OCT, tens of thousands of A-scans can be acquired each second, and thus true 3D imaging is routinely possible. Consequently, 3D OCT is now in wide clinical use, and has become the standard of care.

## Swept Source OCT

Instead of moving the reference arm as with time domain OCT imaging, in swept source OCT the light source is rapidly modulated over its center wavelength, essentially attaching a second label to the light, its wavelength. A photo sensor is used to measure the correlogram for each center wavelength over time. A Fourier transform on the multiwavelength or spectral interferogram is performed to determine the depth of all tissue scatters at the imaged location.<sup>27</sup> With swept-source OCT, hundreds of thousands of A-scans can be obtained every second, promising additional increase in scanning density when acquiring 3D image volumes.

## Areas of Active Research in Retinal Imaging

Retinal imaging is rapidly evolving and newly completed research findings are quickly translated into clinical use.

## Portable, Cost-Effective Fundus Imaging

For early detection and screening, the optimal place for positioning fundus cameras is at the point of care: primary care clinics, public venues (e.g., drug stores, shopping malls), etc. Though the transition from film-based to digital fundus imaging has revolutionized the art of fundus imaging and made telemedicine applications feasible, the current cameras are still too bulky, expensive, and may be difficult to use for nontrained staff in places lacking ophthalmic imaging expertise. Several groups are attempting to create more cost-effective and easier-to-use handheld fundus cameras, employing a variety of technical approaches.<sup>28,29</sup>

## Functional Imaging

For the patient as well as for the clinician, the outcome of disease management is mainly concerned with the resulting organ function, not its structure. In ophthalmology, current functional testing is mostly subjective and patient-dependent, such as assessing visual acuity and utilizing perimetry, which are all psychophysical metrics. Among more recently developed “objective” techniques, oxymetry is a hyperspectral imaging technique, in which multispectral reflectance is used to estimate the concentration of oxygenated and deoxygenated hemoglobin in the retinal tissue.<sup>30</sup> The principle allowing the detection of such differences is simple: deoxygenated hemoglobin reflects longer wavelengths better than does oxygenated hemoglobin. Nevertheless, measuring absolute oxygenation levels with reflected light is difficult because of the large variety in retinal reflection across individuals and the variability caused by the imaging process. The retinal reflectance can be modeled by a system of equations, and this system is typically underconstrained if this variability is not accounted for adequately. Increasingly sophisticated reflectance models have been developed to correct for the underlying variability, with some reported success.<sup>31</sup> Near-infrared fundus reflectance in response to visual stimuli is another way to determine the retinal function in

vivo and has been successful in cats. Initial progress has also been demonstrated in humans.<sup>32</sup>

## Adaptive Optics

The optical properties of the normal eye result in a point spread function width approximately the size of a photoreceptor. It is therefore impossible to image individual cells or cell structure using standard fundus cameras because of aberrations in the human optical system. Adaptive optics uses mechanically activated mirrors to correct the wavefront aberrations of the light reflected from the retina, and thus has allowed individual photoreceptors to be imaged in vivo.<sup>33</sup> Imaging other cells, especially the clinically highly important ganglion cells, has thus far been unsuccessful in humans. (See also [Chapter 7, Advanced imaging technologies](#).)

## Longer Wavelength OCT Imaging

Three-dimensional OCT imaging is now the clinical standard of care for several eye diseases. The wavelengths around 840  $\mu\text{m}$  used in currently available devices are optimized for imaging of the retina. Deeper structures, such as the choroidal vessels, which are important in AMD and uveitis, and the lamina cribrosa – a deep structure in the optic nerve relevant for glaucomatous damage – are not as well depicted. Low-coherence swept source lasers with center wavelengths of 1000–1300  $\mu\text{m}$  are now available in commercially available clinical devices, allowing resolution of detail in the choroid and lamina cribrosa.<sup>34</sup>

## Angiographic OCT

Except for the changes caused by blood particles flowing through the retinal and choroid blood vessels, most retinal tissue changes only slowly over time, on the scale of hours to years. The difference in the timescale of changes allows those voxels where blood flows to be visualized, by displaying brightly voxels that change reflectance rapidly, i.e., between two rapid (on a timescale of ms) sequence sweeps of A-scans. In other words, the rapid *change* in optical properties of blood caused by lymphocytes and erythrocytes

moving through the location of the A-scan is displayed as an intensity, and the faster the blood is flowing, the greater the change in A-scan reflectance, and the brighter it is displayed. This recent important innovation allows, for example, the capillaries in the foveal avascular zone to be imaged with high precision. Because angiographic OCT will only image those blood vessels with relatively rapid flow, slower phenomena such as (fluorescein angiographic) *leakage* from damaged capillaries in diabetic macular edema, cystoid macular edema, and choroidal neovascularization cannot be displayed.

## Clinical Applications of Retinal Imaging

The most obvious example of a retinal screening application is retinal disease detection, in which the patient's retinas are imaged in a remote telemedicine approach. This scenario typically utilizes easy-to-use, relatively low-cost fundus cameras, automated analyses of the images, and focused reporting of the results. This screening application has spread rapidly over the last few years, and with the exception of the automated analysis functionality, is one of the most successful examples of telemedicine.<sup>35</sup> While screening programs exist for detection of glaucoma, AMD, and retinopathy of prematurity, the most important screening application focuses on early detection of diabetic retinopathy (DR). (See [Chapter 53, Telescreening for diabetic retinopathy](#); [Chapter 65, Telescreening for retinopathy of prematurity](#).)

### Early Detection of Diabetic Retinopathy

Early detection of DR via population screening associated with timely treatment has been shown to prevent visual loss and blindness in patients with retinal complications of diabetes.<sup>36,37</sup> Almost 50% of people with diabetes in the United States currently do not undergo any form of regular documented dilated eye examination, in spite of guidelines published by the American Diabetes Association, the American Academy of Ophthalmology,

and the American Optometric Association.<sup>38</sup> In the United Kingdom, a smaller proportion or approximately 20% of diabetics are not regularly evaluated, as a result of an aggressive effort to increase screening for people with diabetes. Blindness and visual loss can be prevented through early detection and timely management. There is widespread consensus that regular early detection of DR via screening is necessary and cost-effective in patients with diabetes.<sup>39–42</sup> Remote digital imaging and ophthalmologist expert reading have been shown to be comparable or superior to an office visit for assessing DR and have been suggested as an approach to make the dilated eye examination available to unserved and underserved populations that do not receive regular examinations by eye care providers.<sup>43,44</sup> If all of these underserved populations were to be provided with digital imaging, the annual number of retinal images requiring evaluation would exceed 32 million in the United States alone (approximately 40% of people with diabetes with at least two photographs per eye).<sup>44,45</sup> In the next decade, projections for the United States are that the average age will increase, the number of people with diabetes in each age category will increase, and there will be an undersupply of qualified eye care providers, at least in the near term. Several European countries have successfully instigated in their healthcare systems early detection programs for DR using digital photography with reading of the images by human experts. In the United Kingdom, 1.7 million people with diabetes were screened for DR in 2007–2008. In the Netherlands, over 30,000 people with diabetes were screened since 2001 in the same period, through an early detection project called EyeCheck.<sup>46</sup> The United States Department of Veterans Affairs (VA) has deployed a successful photo screening program through which more than 120,000 veterans were screened in 2008. While the remote imaging followed by human expert diagnosis approach was shown to be successful for a limited number of participants, the current challenge is to make the early detection more accessible by reducing the cost and manpower required, while maintaining or improving DR detection performance. This challenge can be met by utilizing computer-assisted or fully automated methods for detection of DR in retinal images.<sup>47–49</sup>

## Early Detection of Systemic Disease From Fundus Photography

In addition to detecting DR and AMD, it also deserves mention that fundus photography allows cardiovascular risk factors to be determined. Such metrics are primarily based on measurement of retinal vessel properties, such as the arterial to venous diameter ratio, or A–V ratio, and indicate the risk for stroke, hypertension or myocardial infarct.<sup>50,51</sup>

## Image-Guided Therapy for Retinal Diseases With Three-Dimensional OCT

With the introduction of 3D OCT imaging, the wealth of new information about the retinal morphology has enabled its usage for close monitoring of retinal disease status and guidance of retinal therapies. The most obvious example of successful image-guided management in ophthalmology is its use in diabetic macular edema (DME). Currently, OCT imaging is widely used to determine the extent and amount of retinal thickening. Detailed analyses of retinal layer morphology and texture from OCT has the potential to allow direct image-based treatment to be guided by computer-supported or automated quantitative analysis. This can be subsequently optimized allowing personalized approach to retinal disease treatment to become a reality.

Another highly relevant example of a disease that will benefit from image-guided therapy is exudative AMD. With the advent of the anti-VEGF agents ranibizumab and bevacizumab, it has become clear that outer retinal and subretinal fluid is the main indicator of a need for anti-VEGF retreatment.<sup>52–56</sup> Several studies are underway to determine whether OCT-based quantification of fluid parameters and affected retinal tissue can help improve the management of patients with anti-VEGF agents.

## Image Analysis Concepts for Clinicians

Image analysis is a field that relies heavily on mathematics and physics. The goal of this section is to explain the major, clinically relevant concepts and challenges in image analysis, with limited use of mathematics or equations. For a detailed explanation of the underlying mathematics, the reader is referred to the appropriate textbooks.<sup>57</sup>

## The Retinal Image

### Definition of a Retinal Image

As interpreted by a computer, an image is a set of elements with values that are organized. The elements, called pixels, each have a single value, the intensity, when the image is a monochrome or an OCT image; and multiple values, when the image is a color image. For example, in an angiogram or OCT image, the intensity value of each pixel is the amount of reflected light that was measured at that pixel position. In a color image, there are usually three intensity values (for red, blue, and green) assigned to a pixel, which combine make up the color of that pixel.

### Retinal Image Quantities

Because computers use a binary system (1s and 0s) to store and process information, and do not use the decimal system, image intensities typically have values ranging between 0–255, 0–65536, or –32767 to +32767, instead of the 0–1000 or 100,000 that one might expect if computers used the decimal system. This can be explained by the fact that, typically, 1, 2, or 3 bytes are used to store the intensity values for a pixel, as combinations of 1s and 0s. Though more bytes take up more space, the precision of the intensity values becomes greater. Psychophysical research has shown that the human visual system can differentiate at most 500 different levels of gray, and at most 10 million different colors, so that increasing the precision of the intensity values beyond these levels will not increase the visual perception of quality of an image. However, there may be some value in increasing the precision despite this fact since image analysis algorithms can discern a higher number of levels than humans can.

## Retinal Image Compression

Image compression is useful because it decreases the amount of memory required to store images digitally or communicate these images over a network such as the Internet. Image compression can be “loss-less” or “lossy,” and makes use of the fact that images are always somewhat repetitive. If the intensity value of a pixel has a certain value, the values of the pixels in its surround usually have similar values.

In order to explain the concept of an image compression algorithm, let us proceed with an example. We start with an image in which an area of 50 pixels all have the same intensity value. We will pick the value 128. Instead of storing 50 memory elements, all having the value 50 (typically requiring 50 bytes total), the simple image compression algorithm counts the number of repetitions of an intensity value, reducing this number to two memory elements: the first one, the repeat value 50, and the second one, the repeated intensity 128 (requiring only two bytes of storage). To restore the original image area, an uncompression algorithm takes the two elements and reconstitutes the 50 pixels each having 128 as intensity.

Because no image information is lost, and the uncompression algorithm can reconstitute the image perfectly, this is loss-less compression.

## Lossy Image Compression

To improve image compression rates even more, lossy compression algorithms make use of the fact that the human visual system does not notice small intensity changes in the image. A lossy compression algorithm would compress the image in the example above in exactly the same manner. However, if we take an image where the 50 pixels in the area did not have exactly the same value, but varied slightly around the value 128, the image compression algorithm would compress the image differently. For the human visual system, this area would be hard to differentiate from the same area where all 50 pixels had intensity values of 128. The simple loss-less algorithm above would not be able to compress this area, because the pixels in the area have different intensities, and would store the 50 pixels as 50 elements. The lossy algorithm is

“smarter” and “knows” the limits of human visual perception, and will assign all pixels varying only a “little” from 128 the intensity value of 128, and store the repeat value, and the repeated intensity. The uncompression algorithm would assign all 50 pixels the same 128 as intensity. Thus the original information in the image is lost, though typically this is not noticeable to the human visual system.

## **Legal Issues With Lossy Image Compression**

Lossy compression is widely used in ophthalmic imaging, especially for storing acquired images in image databases (see [PACS](#) section below). In theory, but so far not in practice, a medicolegal situation could arise as a result of lossy compression artifact. In a hypothetical case where the diagnosis of a clinician is disputed, that clinician may have seen an abnormality on an image immediately after acquisition, which subsequently underwent lossy compression, was stored and thus became part of the medical record. Because lossy compression causes irreversible loss of information, that abnormality may not be visible anymore on the archived image after uncompression, making it impossible to view the same image that the clinician originally saw and upon which his/her diagnosis was based. One can certainly envision the legal implications and liability of this scenario.

Examples of loss-less compression image formats are compressed TIFF, GIF, and PNG file formats, as well as the “raw” formats that are generated directly by the imaging device. Common lossy compression-based image formats are JPEG and MPEG.

## **Storing and Accessing Retinal Images: Ophthalmology Picture Archiving Systems**

After an image is acquired on a fundus camera or OCT device, it becomes part of the medical record. It therefore should be stored in some form, so that it can be communicated to other clinicians and providers, or consulted at a later date.

Images can be stored directly on the imaging device, but so-called Picture Archiving Systems (PACS) are available that make image storage more practical, allowing images from a variety of imaging devices to be stored and reviewed. PACS may be standalone, or

may be integrated into an electronic health record. PACS do not need to be separate, and some are an integral part of an Electronic Medical Record System. Most PACS offer manufacturer independence: the images are stored in such a manner that they can still be viewed even if the device they were recorded on is no longer available, and are not lost when the “old” device is retired.

With the advent of SD-OCT technology and dense OCT scanning which can result in image sizes of a gigabyte per examination, deciding how clinical images are stored, and whether all data acquired is stored or just the clinically relevant images, is becoming more and more important for the practitioner, as is choosing the level and type of image compression.

For small practices, keeping images stored on the device can still be a cost-effective solution. For larger practices, storage in a PACS accessible over the clinic computer network allows a patient's images to be accessible in the patient area during clinic. Typically, PACS takes care of compression and uncompression calculations **Box 8.1** the scenes” (Box 8.1).

## Different Strategies for Storing Ophthalmic Images

## Standards for Storage and Communication of Ophthalmology Images

### Digital Exchange of Retinal Images and DICOM

DICOM stands for Digital Imaging and Communications in Medicine and is an organization founded in 1983 to create a standard method for the transmission of medical images and their

associated information across all fields of medicine. For ophthalmology, Working Group 9 (WG-9) of DICOM is a formal part of the American Academy of Ophthalmology (AAO). Until recently, the work of WG-9 has focused on creating standards for fundus, anterior segment, and external ophthalmic photography, resulting in DICOM Supplement 91 Ophthalmic Photography Image SOP Classes, and on OCT imaging in DICOM Supplement 110: Ophthalmic Tomography Image Storage SOP.<sup>58</sup> Later WG-9 went to work on OCT imaging, resulting in DICOM Supplement 110: Ophthalmic Tomography Image Storage SOP.<sup>58</sup>

DICOM standards build as much as possible upon other standards. For example, DICOM does not prescribe an image compression standard, and thus images stored as DICOM images can contain the actual image data. A typical example of this is a JPEG image. DICOM 91 and 110 standardize how metadata for an image, such as patient and visit data, acquisition modes and camera settings, compression settings and data formats, and clinical interpretation, is stored as an integral part of the image, using so-called DICOM “tags.” Because the continuous development of new retinal imaging techniques and analysis tools, such as OCT angiography, requires new tags to be added, Supplements 110 and 91 are regularly revised.

## Retinal Image Analysis

Image analysis is a process by which meaningful information or measurements can be extracted from digital images, typically by computer algorithms. In ophthalmology, image analysis is primarily used to extract clinically relevant measurements from images of the eye, but also to estimate retinal biomarkers, most commonly from fundus color images and from OCT images. The purpose of this section is to familiarize the reader with the main concepts used in the ophthalmic image analysis literature. Image analysis is best understood as a process consisting of a combination of steps. Not all steps are performed in all image analysis algorithms, and some steps may be explicit as multiple steps in one algorithm and form a combined step in another, different algorithm, but the following steps are typical:

Preprocessing remove variability without losing essential information

Detection locate specific structures of interest, or features

Segmentation determine precise boundaries of objects

Registration find similar regions in two or more images

Interpretation integration of previous steps, and output clinically relevant information.

Though these processing steps are typically explicitly created by the image analysis developers, so called *deep-learning* approaches do not have these explicit steps, instead having learnt these implicitly, as will be clarified further below.

## Preprocessing

The purpose of preprocessing is to remove as much variability as possible from the image, without losing essential information. There are many sources of variation during image acquisition. Image device manufacturer and type, different sizes of field of view, variations in flash illumination, exposure duration, patient movement, variability in retinal pigmentation or in cornea/lens/vitreous opacities are all examples of variation between images taken for the same purpose. These variations do not contribute to the understanding of the image, but they may alter further image analysis steps.

Preprocessing attempts to eliminate some or all of these sources of variation, as much as possible. A simple example is field of view: by scaling the image, and subtracting unexposed areas of the image, images from different cameras are normalized to a “standard fundus image”. Another example is illumination correction, where the pixel intensity values of underexposed areas are increased, and those of overexposed intensities reduced, so that the pixel intensities fall into a more narrow and more predictable range.

There are many parallels between image preprocessing using computers and human retinal image processing in ganglion cells.<sup>59</sup>

## Detection

The purpose of detection is to locate, typically in a preprocessed image, the specific structures of interest, or features, without yet determining their exact boundaries. Examples of such features can be edges, dark or bright spots, oriented lines, and dark–bright transitions in OCT images. Other terms in use for the concept “structure of interest” are wavelets, textures, or filters. Typically, each individual pixel in the image is examined for the presence of one or more features, and usually the surrounding area, or context, of each pixel is included in this examination. The examination itself usually involves a mathematical computation of the similarity between prototypes of the feature and each pixel and its surround. Conceptually similar terms used in the image analysis literature resembling similarity computation are “correlation,” “convolution,” “lifting,” “matching,” and “comparison.” Usually a nonlinearity is utilized to convert the similarity estimate into a discrete value, for example, “present” versus “nonpresent.”

The output of the matching process indicates if and where the features were detected in the image. In some image analysis system, this output is interpreted directly, while in others, a segmentation step (see below) is used to determine the exact boundaries of the object represented by the features.

There are many parallels between the features and the convolution process in digital image analysis, and the filters in the human visual cortex.<sup>28</sup>

## Segmentation

The purpose of segmentation is to determine the precise boundaries of objects in the image, when the presence of specific object features has been determined in the detection step. For example, if the ganglion cell layer in an OCT image is detected but still has separate edges and dark–bright transitions, the segmentation step connects these disjointed features into a connected boundary. Commonly used segmentation techniques are graph search and dynamic programming, both of which try to find the mathematically best-fitting boundary, given the specific detection output(s). The output of the segmentation step can be used directly for assessment, for example when showing the different layers on

an macular OCT scan, or can be the input for an interpretation step.

## Registration

The purpose of registration is to find similar regions in two or more images so they can be colocalized. Registration is often used to overlay an angiogram on an OCT image, compare images from the same patient from two different visits, to detect improvement or worsening of the patient's condition between visits, or mosaicking, where several fundus images are stitched together into one image covering a larger area of the retina. The registration step often utilizes similar functions as the detection step.

## Interpretation

Usually when the preceding steps have been completed, an interpretation step is used to output clinically relevant information from the combined input of the previous steps. If the boundaries of the macular retinal layers have been segmented, interpretation involves calculating the distance between the boundaries, so the user can see the thickness of the different layers at specific locations. These thicknesses can even be compared to a database of normal thicknesses at that same location, so that the output represents how likely it is that the retina is thickened at a specific location. Or, after microaneurysms and exudates have been detected and segmented in multiple images from the same patient, these outputs are combined into the clinically relevant information determining whether the patient has more than minimal diabetic retinopathy or not.<sup>60</sup>

## Machine Learning and Image Analysis

The design and development of a retinal image analysis system involves the combination of some of the processing steps as explained above, with specific sizes of features and specific operations used to map the input image into the desired interpretation output. Instead of being programmed, the steps can also be learnt, through *machine learning*, so that for example the features used for detection<sup>61</sup> as in pixel classification (below), or how to combine the output of feature detectors into an output can

be learned.<sup>62</sup>

This term, machine learning, is used when an algorithm is improved incrementally by changing parameters so that it is slightly improved every step. During training, the correct interpretation, or reference standard, also called ground truth, is required, which is typically created by retinal specialists or ophthalmologists.<sup>63</sup> A theoretical disadvantage of using a supervised system with a training set is that the provenance of the different settings is implicit and may not be clear – resulting in a black box. However, because all retinal image analysis algorithms undergo some optimization of parameters based on their initial performance, this is only a relative, not absolute difference.

As mentioned, two distinct stages are required for a supervised learning/classification algorithm to function: A training stage, in which the algorithm “statistically learns” to correctly classify images, regions of images, or even pixels from the reference standard, and a deployment, testing or classification stage in which the algorithm classifies previously unseen images keeping the algorithm settings constant as established during learning. For proper assessment of supervised classification method functionality, training data and performance testing data sets must be completely separately.<sup>57</sup>

Until recently, retinal image analysis used machine learning in modular fashion, i.e., one or more of the processing steps are implemented using machine learning. Recent studies are showing remarkable performance improvements using convolutional neural networks, a machine learning approach where all steps are learnt, as will be explained below.

## **Pixel Feature Classification**

Pixel feature classification is a machine learning technique that assigns one or more classes to the pixels in an image for the detection step. Pixel classification uses multiple pixel features including numeric properties of a pixel and the surroundings of a pixel. Originally, pixel intensity was used as a single feature. More recently, n-dimensional multifeature vectors are utilized, including pixel contrast with the surrounding region and information regarding the pixel's proximity to an edge. The image is

transformed into an n-dimensional feature space and pixels are classified according to their position in space. The resulting hard (categorical) or soft (probabilistic) classification is then used to either assign labels to each pixel (for example “vessel” or “nonvessel” in the case of hard classification), or to construct class-specific likelihood maps (e.g., a vesselness map for soft classification). The number of potential features in the multifeature vector that can be associated with each pixel is essentially infinite. One or more subsets of this infinite set can be considered optimal for classifying the image according to some reference standard. Hundreds of features for a pixel can be calculated in the training stage to cast as wide a net as possible, with algorithmic feature selection steps used to determine the most distinguishing set of features. Extensions of this approach include different approaches to subsequently classify groups of neighboring pixels by utilizing group properties in some manner, for example cluster feature classification, where the size, shape, and average intensity of the cluster may be used.

## **Deep Learning and Convolutional Neural Networks**

As explained above, in classical retinal image analysis, the steps are explicit and their sequence is completely under control of the developers of the image analysis system. Within these steps, forms of machine learning, such as learning the characteristic features,<sup>64</sup> or the fusion of feature detectors,<sup>62</sup> have previously been incorporated.

Deep learning, where all transformation levels are learnt from training data, instead of being designed by experts,<sup>65</sup> has been highly successful in a large number of computer vision and image analysis tasks, substantially outperforming all classical image analysis techniques, and typically implemented as Convolutional Neural Networks (CNNs).<sup>66</sup> Indeed, the highest performing algorithms in the recent Kaggle competition, to identify signs of DR in retinal images, all used CNNs.<sup>67a</sup> As of this writing, the two highest performing algorithms for automated screening of DR, both employ CNNs, though in different ways – see below.<sup>67b,67c</sup>

In these CNNs, the processing steps are learnt and implemented implicitly. The only design work for the developer of such systems is the number of layers and their interconnectedness in the CNN,

and the appropriate choice of training images.

The history of CNNs stretches back far, and because of their complexity, for a long time they were used on extremely simple image analysis tasks, where training on the fastest computers could still take months. In 1980, Fukushima published a study of the pattern recognition performance of one of the first multilayer neural networks, called Neocognitron.<sup>65</sup> This multilayer neural network was directly inspired by the mammalian visual system, with the different *layers* representing the retina, the lateral geniculate nucleus, and the first synaptic layer in the visual cortex (V1). Each layer in the network consists of neurons (with a state, a number between  $[0,1]$ ), with each neuron in a specific layer connected to all neurons in the previous and next layer, and the strength of these connections represented by a *weight*, typically a number between  $[0-1]$  or  $[-1,1]$  – though many weights can be zero. The neurons in a layer combine the inputs from the previous layer, consisting of the neuron's state multiplied by the connections' weight, aggregate these in a specified mathematical way, and output to the neurons in the next layer. Convolutional neural networks are a special form of multilayer neural network where the weights are copied among neurons within a layer so that that layer performs the same operation over the entire previous layer, an operation called convolution, whence their name. These multilayer neural networks are strictly forward networks, i.e., information flowed from the input layer through the layers to the output layers, and no feedback to earlier layers was possible.

When faster computers became available, and especially with the more recent development of Graphics Processor Units (GPUs), LeCun and others revised and simplified the architecture and learning rules for CNN. In 2011, a first GPU-implementation of CNNs was described. To be clear, GPUs did not influence any of the fundamental underpinnings, rather, allowed faster training on bigger training datasets so that convergence became practical rather than theoretical.<sup>22a</sup>

Training of CNNs consists of changing all weights in a subtle manner using retinal image examples and the reference standard, for example whether that retinal image contains diabetic retinopathy. Proper learning involves changing the weights only

slightly with each example, according to specific mathematical rules, and then slowly converging to the optimal output for all retinal image in the training set. Because all the processing has to be learnt by the CNN, large amounts of examples are required (typically in the tens of thousands) for the neural network learning phase to converge to a meaningful output for a previously unseen image.

Interestingly, but maybe not surprisingly, the second layer weights of CNNs trained on retinal images typically resemble those originally and painstakingly implemented in the classic systems such as Gabor wavelets.<sup>68a</sup> Integration of CNNs into retinal image analysis is thus proceeding rapidly. An interesting discussion, from a retinal image analysis perspective, has been evolving around how to integrate CNNs into algorithms for the automated detection and diagnosis of retinal diseases, especially DR. Some advocate the use of image-based CNNs: a single CNN is trained to associate a whole set of retinal images with a diagnostic output, such as the presence of DR.<sup>68b</sup> Advantages of this approach are its generalizability, because the same CNN, can be used to detect a wide variety of retinal diseases, if it is trained with different training datasets, making optimization easier, as well as the minimal importance of clinical experts being involved in the design, as these systems learn to associate the image input directly with a diagnostic output, without intervening biomarker or lesion detection. This black-box nature is also a major disadvantage: there are currently no analysis methods to determine how such an image-based CNN works, and it is well known that image-based CNNs are highly sensitive to catastrophic failure, because of small changes in the input image – so called adversarial images.<sup>68c,68d</sup> Others advocate a hybrid or clinically based DR detection system, where multiple CNNs are used that each are trained to detect specific biomarkers or lesions such as hemorrhages, and the outputs of these individual moderately redundant CNNs are combined using standard approaches.<sup>68e</sup> The advantages are that each of these detector CNNs can be individually validated at the lesion level. There is some evidence to suggest that, because it mimics how clinical experts evaluate retinal images, this hybrid approach is more robust and less sensitive to catastrophic failure. Additional studies are

obviously needed to shed more light on this discussion.

In summary, CNNs are making rapid inroads in retinal image analysis, and rapidly increasing computing powers are likely to add to their impact.

## Measuring Performance of Image Analysis Algorithms

Crucial for the acceptance of image analysis algorithms are evaluations of its performance. Most often performance is compared to human experts, though this raises its own set of issues as explained below. The agreement between an automatic system and an expert reader may be affected by many influences – system performance may become impaired due to the algorithmic limitations, the imaging protocol, properties of the camera used to acquire the fundus images, and a number of other causes. For example, an imaging protocol that does not allow small lesions to be depicted and thus detected will lead to an artificially overestimated system performance if such small lesions might have been detected with an improved camera or better imaging protocol. Such a system then appears to be performing better than it truly is if human experts and the algorithm both overlook true lesions.

### Sensitivity and Specificity

The performance of a lesion detection system can be measured by its *sensitivity*, which is the number of true positives divided by the sum of the total number of (incorrectly missed) false negatives plus the number of (correctly identified) true positives.<sup>57</sup> System *specificity* is determined as the number of true negatives divided by the sum of the total number of false positives (incorrectly identified as disease) and true negatives. Sensitivity and specificity assessment both require ground truth, which is represented by location-specific discrete values (0 or 1) of disease presence or absence for each subject in the evaluation set. The location-specific output of an algorithm can also be represented by a discrete number (0 or 1). However, the output of the assessment algorithm is often a continuous value determining the likelihood  $p$  of local disease presence, with an associated probability value between 0

and 1. Consequently, the algorithm can be made more specific or more sensitive by setting an operating threshold on this probability value  $p$ .

## **Receiver Operator Characteristics**

If an algorithm outputs a continuous value, as explained above, multiple sensitivity/specificity pairs for different operating thresholds can be calculated. These can be plotted in a graph, which yields a curve, the so-called Receiver Operator Characteristics or ROC curve.<sup>57,69a</sup> The area under this ROC curve (AUC, represented by its value  $A_z$ ) is determined by setting a number of different thresholds for the likelihood  $p$ . Sensitivity and specificity pairs of the algorithm are then obtained at each of these thresholds. The ground truth is kept constant. The maximum AUC is 1, denoting a perfect diagnostic procedure, with some threshold at which both sensitivity and specificity are 1 (100%).

## **Repeatability and Variability**

In addition to the above measures, the performance of an algorithm is also measured by its test–retest variability. With all other variables such as disease state, patient factors, imaging device, and operator held constant while obtaining multiple images, this measure determines how much the algorithm's output remains constant on the “same” input. For an algorithm, test–retest variability is not comparable to intraobserver variability. Almost all image analysis algorithms are deterministic, and if the input image is exactly the same, the output will also be exactly the same.

## **The Reference Standard or Gold Standard**

Typically these performance measurements are made by comparing the output of the image analysis system to some standard, usually called the reference standard or gold standard. Because the performance of some image analysis systems, for example for detection of diabetic retinopathy, is starting to exceed that of individual clinicians or groups of clinicians, creating the reference standard is an area of active research.<sup>47</sup>

The problem is that the true disease state of the patient is *difficult*

and in fact, impossible, to measure. For example, at the limit of retinal specialists' detection performance, one of them may see a microaneurysm in the macula on clinical exam of a patient suspected of having diabetic retinopathy, while another sees only some pigmentary variation. In most cases it is impossible to state that one of these clinicians is right and the other is wrong.

Given that determining the true state of disease necessary to create the reference standard is so challenging, the following options have been developed and are in wide use.<sup>47</sup>

- (a) Using the modality under study. The images are read and adjudicated by multiple trained readers according to a standardized protocol. This is less biased and a better estimate than a single clinician, but has higher cost. This method is often used, but the true disease is not known this way.
- (b) Using a different modality. In the case of a microaneurysm, an angiogram would be a suitable modality. It requires expert interpretation, and preferably multiple experts. It is less biased towards the imaging modality and may therefore be a better estimate. Because of the added procedure it is less patient-friendly, and has higher cost associated with it.
- (c) Doing a biopsy. Often this may be ethically unacceptable. It also displaces the problem, because the biopsy would necessarily be interpreted by human expert(s), for example a pathologist, with their intra- and interobserver variability. It is more unequivocal, but also more invasive and has higher cost.
- (d) Outcome based. If the clinically relevant question is not so much whether a microaneurysm is present or absent, but instead whether the patient is at risk of going blind from proliferative disease, we can wait for that outcome to occur. However, the true state of disease at this moment would still not be known, only the true state at some time in the past. Clinical outcome is maximally unequivocal and minimally subjective.
- (e) True state of disease, which is an unknowable quantity as explained above.

As we have seen, in practice the reference standard therefore almost never represents the true state of the disease of a patient. In addition, there is the problem of what we call “diagnostic drift.”

Research studies in radiology and cardiology have shown that, over time, clinicians increasingly deviate from image reading protocols as these were defined in the original standards<sup>69b,69c</sup> that often led to management and treatment standards. For example, determining whether a red lesion is a microaneurysm or a hemorrhage, which can make the difference between a mild versus moderate level of DR – levels that were used by the reading center in the primary outcome studies that to a great degree still determine the management of diabetic retinopathy: DRS,<sup>70</sup> ETDRS,<sup>71</sup> and EDIC/DCCT.<sup>72</sup> It is thus important to employ image reading protocols.

### **Clinical Safety Relevant Performance Measurement**

Performance of a system that has been developed for screening should not be evaluated based solely on its sensitivity and specificity for detection of that disease. Such metrics do not accurately reflect the complete performance in a screening setup. Rare, irregular, or atypical lesions often do not occur frequently enough in standard datasets to affect sensitivity and specificity but can have dramatic health and safety implications. To maximize screening relevance, the system must therefore include a mechanism to detect rare, atypical, or irregular abnormalities, for example in DR detection algorithms.<sup>48</sup> For proper performance assessment, the types of potential false negatives – lesions that can be expected or shown to be incorrectly missed by the automated system – must be determined. While detection of red lesions and bright lesions is widely covered in the literature, detection of rare or irregular lesions, such as hemorrhages, neovascularization, geographic atrophy, scars, and ocular neoplasms has received much less attention, despite the fact that they all can occur in combination with diabetic retinopathy and other retinal diseases, as well as in isolation. For example, presence of such lesions in isolated forms and without any cooccurrence of small red lesions are rare in DR and thus missing these does not affect standard metrics of performance to a measurable degree.<sup>46</sup> One suitable approach for detecting such lesions is to use a retinal atlas, where the image is routinely compared to a generic normal retina. After building a retinal atlas by registering the fundus images according to a disc,

fovea, and a vessel-based coordinate system, image properties at each atlas location from a previously unseen image can be compared to the atlas-based image properties. Consequently, locations can be identified as abnormal if groups of pixels have values outside the normal atlas range.

## Fundus Image Analysis

Planar fundus imaging is the most established method of retinal imaging. Until recently, fundus image analysis was the only source of quantitative indices reflecting retinal morphology. Retinal structures that lend themselves for fundus image analysis include retinal vessels, hemorrhages, microaneurysms, pigment epithelial abnormalities (scars, laser spots), drusen, hyper- or hypopigmentation, choroid related abnormalities or lesions, segmentation of retinal layers. In this section we will discuss retinal vessel detection, retinal lesion detection, construction of fundus-imaging-based retinal atlases, and assessment of image analysis algorithms. The previous section on image analysis concepts for clinicians will be helpful in understanding the concepts in this overview. The next section will explain image analysis of OCT images.

### Detection of Retinal Vessels

Automated segmentation of retinal vessels has been highly successful in the detection of large and medium vessels<sup>73-75</sup> (Fig. 8.3). Because retinal vessel diameter and especially the relative diameters of arteries and veins are known to signal the risk of systemic diseases including stroke, accurate determination of retinal vessel diameters, as well as the ability to differentiate veins from arteries, have become more important. Several semiautomated and automated approaches to determining vessel diameter have now been published.<sup>76-78</sup> Other active areas of research include separation of arteries and veins, detection of small vessels with diameters of less than a pixel, and analysis of complete vessel trees using graphs.

**FIG. 8.3** Automated vessel analysis. From left to right: fundus image; retinal specialist annotation; vesselness map from Staal algorithm;<sup>75</sup> vesselness map from direct pixel classification. (Reproduced from Niemeijer M, van Ginneken B, Staal J, Suttorp-Schulten MS, Abramoff MD. Automatic detection of red lesions in digital color fundus photographs. *IEEE Trans Med Imaging* 2005;24:584-92.)

Vessel detection approaches can be divided into region-based and edge-based approaches. Region-based segmentation methods label each pixel as either inside or outside a blood vessel. Niemeijer et al. proposed a pixel-based retinal vessel detection method using a Gaussian derivative filter bank and k-nearest-neighbor (k-NN) classification.<sup>73,75</sup> Staal et al. proposed a pixel feature-based method that additionally analyzed the vessels as elongated structures.<sup>75</sup> Edge-based methods can be further classified into two categories: window-based methods and tracking-based methods. Window-based methods estimate a match at each pixel against the pixel's surrounding window. The tracking approach exploits local image properties to trace the vessels from an initial point. A tracking approach can better maintain the connectivity of vessel structure. Lalonde et al.<sup>79</sup> proposed a vessel tracking method by following an edge line while monitoring the connectivity of its twin border on a vessel map computed using a Canny edge operator. Breaks in the connectivity will trigger the creation of seeds that serve as extra starting points for further tracking. Gang et al. proposed a retinal vessel detection using a second-order Gaussian filter with adaptive filter width and adaptive threshold.<sup>80</sup>

## Detection of Fovea and Optic Disc

Location of the optic disc and fovea benefits retinal image analysis (Fig. 8.4). It is often necessary to mask out the normal anatomy

before finding abnormal structures. For instance, the optic disc might be mistaken for a bright lesion if not detected. Secondly, the distribution of the abnormalities is not uniform on fundus photographs. Specific abnormalities occur more often in specific areas on the retina. Most optic disc detection methods are based on the fact that the optic disc is the convergence point of blood vessels and it is normally the brightest structure on a fundus image. Most fovea detection methods depend partially on the result of the optic disc detection.

**FIG. 8.4** Typical steps necessary for analysis of fundus images, in this case for early diabetic retinopathy. Top row: large sequence of images sets from multiple patients; second row: image set of four retinal images for a single patient; third row: (A) original image; (B) vesselness map; (C) automatically detected red lesions in white; (D) automatically detected bright lesions in white; (E) detection of fovea (black) and optic disc (yellow) as well as automatically detected red lesions indicated in shades of green, bright lesions in shades of blue superimposed on original image.

Hoover et al. proposed a method for optic disc detection based on the combination of vessel structure and pixel brightness.<sup>81</sup> If a strong vessel convergence point is found in the image, it is regarded

as the optic disc. Otherwise the brightest region is detected. Foracchia et al. proposed an optic disc detection method based on vessel directions.<sup>82</sup> A parabolic model of the main vascular arches is established and the model parameters are the directions associated with different locations on the parabolic model. The point with a minimum sum of square error is reported as the optic disc location. Lowell et al., by matching an optic disc model using the Pearson correlation, determined an initial optic disc location, and then traced the optic disc boundary using a deformable contour model.<sup>83</sup>

Most fovea detection methods use the fact that the fovea is a dark region in the image and that it normally lies in a fixed orientation and location relative to the optic disc and the main vascular arch. In Fleming, approximate locations of the optic disc and fovea are obtained using the elliptical form of the main vascular arch.<sup>84</sup> Then, the locations are refined based on the circular edge of the optic disc and the local darkness at the fovea. Li and Chutatape also proposed a method to select the brightest 1% pixels in a gray level image.<sup>85</sup> The pixels are clustered and principal component analysis based on a trained system is applied to extract a single point as the estimated location of optic disc. A fovea candidate region is then selected based on the optic disc location and the main vascular arch shape. Within the candidate region, the centroid of the cluster with the lowest mean intensity and pixel number greater than one-sixth disc area is regarded as the foveal location. In Sinthanayothin's paper, the optic disc was located as the area with the highest variation in intensity of adjacent pixels, while the fovea was extracted using intensity information and a relative distance to the optic disc.<sup>86</sup> Tobin et al. proposed a method to detect the optic disc based on blood vessel features, such as density, average thickness, and orientation.<sup>87</sup> Then the fovea location was determined based on the location of optic disc and a geometry model of the main blood vessel. Niemeijer et al. proposed a method to automatically localize both the optic disc and fovea in 2008.<sup>88,89</sup> For the optic disc detection, a set of features are extracted from the color fundus image. A k-NN classification is used to give a soft label to each pixel on the test image. The probability image is blurred and the pixel with the highest probability is detected as optic disc. Relative position information between the optic disc and the fovea is used to

limit the search of fovea into a certain region. For each possible location of the optic disc, a possible location of the fovea is given. The possible locations for the fovea are stored in a separate image and the highest probability location is detected as the fovea location.

## Detection of Retinal Lesions

In this section, we will primarily focus on detection of lesions in DR. DR has the longest history as a research subject in retinal image analysis. Fig. 8.4 shows examples of a fundus photograph with the typical lesions automatically detected. After preprocessing, most approaches detect candidate lesions after which a mathematical morphology template is utilized to segment and characterize the candidates (Fig. 8.5). This approach or a modification thereof is in use in many algorithms for detecting DR and AMD.<sup>90</sup> Additional enhancements include the contributions of Spencer, Cree, Frame, and coworkers.<sup>91,92</sup> They added additional preprocessing steps, such as shade-correction and matched filter postprocessing, to this basic framework, to improve algorithm performance. Algorithms of this kind function by detecting candidate microaneurysms of various shapes, based on their response to specific image filters. A supervised classifier is typically developed to separate the valid microaneurysms from spurious or false responses. However, these algorithms were originally developed to detect the high-contrast signatures of microaneurysms in fluorescein angiogram images. An important development was the addition of a more sophisticated filter, a modified version of the top-hat filter, so-called because of its cross-section, to red-free fundus photographs rather than angiogram images, as was first described by Hipwell et al.<sup>93</sup> They tested their algorithm on a large set of >3500 images and found a sensitivity/specificity operating point of 0.85/0.76. Once this filter-based approach had been established, development accelerated. The next step was broadening the candidate detection step, originally developed by Baudoin to detect candidate pixels, to a multifilter filter-bank approach.<sup>73,94</sup> The responses of the filters are used to identify pixel candidates using a classification scheme. Mathematical morphology and additional classification steps are

applied to these candidates to decide whether they indeed represent microaneurysms and hemorrhages (Fig. 8.6). A similar approach was also successful in detecting other types of DR lesions, including exudates and cotton-wool spots, as well as drusen in AMD.<sup>95</sup>

**FIG. 8.5** Red lesion pixel feature classification. (A) Part of green color plane of a fundus image. Shown are pieces of vasculature and several red lesions. Circles mark location of some of the red lesions in the image. (B) After subtracting median filtered version of the green plane large background gradients are removed. (C) All pixels with a positive value are set to zero to eliminate bright lesions in the image. Note that exudates often partially occlude red lesions. Nonoccluded parts of red lesions show up clearly in this image. An example of this is marked with a rectangle. (D) Pixel classification result produced by contrast enhancement step. Nonoccluded parts of hemorrhages are visible together with the vasculature and a number of red lesions. (Reproduced from Niemeijer M, van Ginneken B, Staal J, et al. Automatic detection of red lesions in digital color fundus photographs. *IEEE Trans Med Imaging* 2005;24:584-92.)

**FIG. 8.6** Red lesion detection. (A) Thresholded

probability map. (B) Remaining objects after connected component analysis and removal of large vasculature. (C) Shape and size of extracted objects in panel (B) does not correspond well with actual shape and size of objects in original image. Final region growing procedure is used to grow back actual objects in original image which are shown here. In (B) and (C), the same red lesions as in Fig. 8.8(A) are indicated with a circle. (Reproduced from Niemeijer M, van Ginneken B, Staal J, et al. Automatic detection of red lesions in digital color fundus photographs. IEEE Trans Med Imaging 2005;24:584-92.)

Small red retinal lesions, namely microaneurysms and small retinal hemorrhages, are typical for multiple retinal disorders including diabetic retinopathy, hypertensive retinopathy, venous occlusive disease, and other less common retinal disorders such as idiopathic juxtafoveal telangiectasia. The primary importance of small red lesions is that they are the leading indicators of diabetic retinopathy. Because they are difficult to differentiate for clinicians on standard fundus images from nonmydriatic cameras, hemorrhages and microaneurysms are usually detected together and associated with a single combined label. Historically, red lesion detection algorithms focused on detection of normal anatomical objects, especially the vessels, because they can locally mimic red lesions. Subsequently, a combination of one or more filtering operations combined with mathematical morphology is employed to detect red lesion suspects. In some cases, suspect red lesions are further classified in individual lesion types and refined algorithms are capable of detecting specific retinal structures and abnormalities.

Initially, red lesions were detected in fluorescein angiograms because their contrast against the background is much higher than that of microaneurysms in color fundus photography images.<sup>91,92,96</sup> Hemorrhages mask out fluorescence and present as dark spots in the angiograms. These methods employed a mathematical morphology technique that eliminated the vasculature from a fundus image but left possible microaneurysm candidates untouched, as first described in 1984.<sup>18</sup> Later, this method was extended to high-resolution red-free fundus photographs by Hipwell et al.<sup>93</sup> Instead of using morphology operations, a neural

network was used, as demonstrated by Gardner et al.<sup>97</sup> In their work, images are divided into  $20 \times 20$  pixel grids and the grids are individually classified. Sinthanayothin et al. used a detection step to find blood-like regions and to segment both vessels and red lesions in a fundus image.<sup>98</sup> A neural network was used to detect the vessels exclusively, and the remaining objects were labeled as microaneurysms. Niemeijer et al. presented a hybrid scheme that used a supervised pixel classification-based method to detect and segment the microaneurysm candidates in color fundus photographs.<sup>94</sup> This method allowed for the detection of larger red lesions (i.e., hemorrhages) in addition to the microaneurysms using the same system. A large set of additional features, including color, was added to those that had been previously described.<sup>92,96</sup> Using the features in a supervised classifier distinguished between real and spurious candidate lesions. These algorithms can usually distinguish between overlapping microaneurysms because they give multiple candidate responses.

Other recent algorithms only detect microaneurysms and forego a phase of detecting normal retinal structures like the optic disc, fovea, and retinal vessels, which can act as confounders for abnormal lesions. Instead, the recent approaches find the microaneurysms directly using template matching in wavelet-subbands.<sup>99</sup> In this approach, the optimal adapted wavelet transform is found using a lifting scheme framework. By applying a threshold on the matching result of the wavelet template, the microaneurysms are labeled. This approach has meanwhile been extended to explicitly account for false negatives and false positives.<sup>47</sup> Because it avoids detection of the normal structures, such algorithms can be very fast, on the order of less than a second per image.

Bright lesions, defined as lesions brighter than the retinal background, can be found in the presence of retinal and systemic disease. Some examples of such bright lesions of clinical interest include drusen, cotton-wool spots, and lipoprotein exudates. To complicate the analysis, flash artifacts can be present as false positives for bright lesions. If the lipoprotein exudates would only appear in combination with red lesions, they would only be useful for grading diabetic retinopathy. The exudates can, however, in

some cases appear as isolated signs of diabetic retinopathy in the absence of any other lesion. Several computer-based systems to detect exudates have been proposed (Fig. 8.7).<sup>90,95,97,98,100</sup>

**FIG. 8.7** Bright lesion detection algorithm steps performed to detect and differentiate “bright lesions.” From left to right: exudates, cotton-wool spots, and drusen. From top to bottom: relevant regions in the retinal color image (all at same scale); a posteriori probability maps after first classification step; pixel clusters labeled as probable bright lesions (potential

lesions); bottom row shows final labeling of objects as true bright lesions, overlaid on original image. (Reproduced from Niemeijer M, van Ginneken B, Russell SR, et al. Automated detection and differentiation of drusen, exudates, and cotton-wool spots in digital color fundus photographs for diabetic retinopathy diagnosis. *Invest Ophthalmol Vis Sci* 2007;48:2260-7.)

Because the different types of bright lesions have different diagnostic importance, algorithms should be capable not only to detect bright lesions, but also be able to differentiate among the bright lesion types. One example algorithm capable of detection and differentiation of bright lesions was reported by Niemeijer et al. in 2007.<sup>95</sup> This algorithm is based on an earlier red lesion algorithm presented by Hipwell et al. in 2000<sup>93</sup> and includes the following traditional steps, which are illustrated in [Fig. 8.6](#).

These classification steps include:

1. Lesion candidate cluster detection where pixels are clustered into highly probable lesion regions.
2. True bright lesion detection where each candidate cluster is classified as a true lesion based on cluster features including surface area, elongatedness, pixel intensity gradient, standard deviation of pixel values, pixel contrast, and local “vesselness” (as derived from a vessel segmentation map).
3. Differentiation of lesions into drusen, exudates, and cotton-wool spots where a third classifier determines the likelihood for the true bright lesion to represent specific lesion types.

## Vessel Analysis

Vessel measures, such as the average width of arterioles and venules, the ratio of arteriolar to venular widths, and the branching ratio, have been established to be predictive of systemic diseases, especially hypertension, and also have potential value in degenerative retinal diseases such as retinitis pigmentosa. The methods described in the section “[Detection of retinal vessels](#)” above locate the vessels, but cannot determine vessel width. Additional techniques are needed to accurately measure the vessel

width. Al-Diri et al. proposed an algorithm for segmentation and measurement of retinal blood vessels by growing a “Ribbon of Twins” active contour model. Their approach uses an extraction of segment profiles (ESP) algorithm, which uses two pairs of contours to capture each vessel edge.<sup>101</sup> The half-height full-width (HHFW) algorithm defines the width as the distance between the points on the intensity curve at which the function reaches half its maximum value to either side of the estimated center point.<sup>102–104</sup> The Gregson algorithm fits a rectangle to the profile, setting the width so that the area under the rectangle is equal to the area under the profile.<sup>101</sup> Xu et al. recently published a method based on graph search showing less variability than human experts (Fig. 8.8).<sup>105</sup>

**FIG. 8.8** Automated vessel width measurement. (A) Automated measurement of vessel width (black lines). (B) Three human experts marking the widths of the vessel manually (in green, blue and yellow).

A fully automated method from the Abràmoff group to measure the arteriovenous ratio (AVR) in disc center retinal images was published in 2011.<sup>106</sup> This method detects the location of the optic disc, determines an appropriate region of interest (ROI), classifies vessels as arteries or veins, estimates vessel widths, and calculates the AVR. The system eliminates all vessels outside the AVR measurement ROI. A skeletonization operation is then applied to the remaining vessels after which vessel crossings and bifurcation points are removed, leaving a set of vessel segments consisting of only vessel centerline pixels. Features are extracted from each centerline pixel in order to assign these a soft label indicating the

likelihood that the pixel is part of a vein. As all centerline pixels in a connected vessel segment should be the same type, the median soft label is assigned to each centerline pixel in the segment. Next, artery–vein pairs are matched using an iterative algorithm, and finally, the widths of the vessels are used to calculate the average AVR. Recently the required identification of arterial and venous vessel trees has been improved by analyzing the topography of all vessel trees in retinal images.<sup>107</sup>

## Retinal Atlas

The retina has a relatively small number of key anatomic structures (landmarks) visible using planar fundus camera imaging. Additionally, the expected shape, size, and color variations across a population are expected to be high. While there have been a few reports on estimating retinal anatomic structure using a single retinal image,<sup>87</sup> we are not aware of any published work demonstrating the construction of a statistical retinal atlas using data from a large number of subjects. The choice of atlas landmarks in retinal images may vary depending on the view of interest. Regardless, the atlas should represent most retinal image properties in a concise and intuitive way. Three landmarks can be used as the retinal atlas key features; the optic disc center, the fovea, and the main vessel arch defined as the location of the largest vein/artery pairs. The disc and fovea provide landmark points, while the arch is a more complicated two-part curved structure that can be represented by its central axis. The atlas coordinate system then defines an intrinsic, anatomically meaningful framework within which anatomic size, shape, color, and other characteristics can be objectively measured and compared. Choosing either the disc center or fovea alone to define the atlas coordinate system would allow each image from the population to be translated so pin-point alignment can be achieved. Choosing both disc and fovea allows corrections for translation, scale, and rotational differences across the population. However, nonlinear shape variations across the population would not be considered – which can be accomplished when the vascular arch information is utilized. The end of the arches can be defined as the first major bifurcations of the arch

branches. The arch shape and orientation vary from individual to individual and influence the structure of the remaining vessel network. Establishing an atlas coordinate system that incorporates the disc, fovea, and arches allows for translation, rotation, scaling, and nonlinear shape variations to be accommodated across a population.

An isotropic coordinate system is a system in which the size of each imaged element is the same in all three dimensions. This is desirable for a retinal atlas so images can refer to the atlas independent of spatial pixel location by a linear one-to-one mapping. The radial-distortion correction (RADIC) model attempts to register images in a distortion-free coordinate system using a planar-to-spherical transformation, so the registered image is isotropic under a perfect registration and places the registered image in an isotropic coordinate system (Fig. 8.9).<sup>108</sup> An isotropic atlas makes it independent of spatial location to map correspondences between the atlas and test image. The intensities in overlapping area are determined by a distance weighted blending scheme.<sup>109</sup>

**FIG. 8.9** Registration of fundus image pair using (A) quadratic model and (B) RADIC model. Vessel center lines are overlaid for visual assessment of registration accuracy. This registration is performed to disk-centered and macula-centered images to provide an increased anatomic field of view. (Reproduced from Lee S,

Abràmoff MD, Reinhardt JM. Retinal image mosaicking using the radial distortion correction model. In: Joseph MR, Josien PWP, editors.; 2008: SPIE; 2008. p.

691435.)

Retinal images in clinical practice are acquired under diverse fundus camera settings subjected to saccadic eye movement, and with variable properties including focal center, zoom, and tilt. Thus, atlas landmarks from training data need to be aligned to derive any meaningful statistical properties from the atlas. Since the projective distortion within an image is corrected in registration, the interimage variations in the registered images appear as the difference in the rigid coordinate transformation parameters of translation, scale, and rotation.

The atlas landmarks serve as the reference set so each color fundus image can be mapped to the coordinate system defined by the landmarks. As the last step of atlas generation, color fundus images are warped to the atlas coordinate system so that the arch of each image is aligned to the atlas vascular arch<sup>110</sup> (Fig. 8.10). Rigid coordinate alignment is done for each fundus image to register the disc center and the fovea. The control points are determined by sampling points from equidistant locations in radial directions from the disc center. Usually, the sampling uses smoothed trace lines utilizing third-order polynomial curve fitting to eliminate locally high tortuosity of vascular tracings which may cause large geometric distortions (Fig. 8.11).

**FIG. 8.10** Atlas coordinate mapping by thin plate spline (A) before and (B) after mapping. Naive main arch traces obtained by Dijkstra's line-detection algorithm are drawn as yellow lines that undergo polynomial curve fitting to result in blue lines. Atlas landmarks (disc center, fovea, and vascular arch) are drawn in

green, and equidistant radial sampling points marked with dots. (Reproduced from Abramoff MD, Garvin M, Sonka M. Retinal Imaging and Image Analysis. IEEE Reviews in Biomedical Engineering 2010:169-208.)

**FIG. 8.11** Registration of anatomic structures according to increasing complexity of registration transform 500 retinal vessel images are overlaid and marked with one foveal point landmark each (red spots). Rigid coordinate alignment by (A) translation, (B) translation and scale, and (C) translation, scale, and rotation. (Reproduced from Abramoff MD, Garvin M, Sonka M. Retinal imaging and image analysis. IEEE Reviews in Biomedical Engineering 2010:169-208.)

A retinal atlas can be used as a reference to quantitatively assess the level of deviation from normality. An analyzed image can be compared with the retinal atlas directly in the atlas coordinate space. The normality can thus be defined in several ways depending on the application purpose – using local or global chromatic distribution, degree of vessel tortuosity, presence of pathologic features, or presence of artifacts (Fig. 8.12). Other uses for a retinal atlas include image quality detection and disease severity assessment. Retinal atlases can also be employed in content-based image retrieval leading to abnormality detection in retinal images.<sup>111</sup>

**FIG. 8.12** Example application of employing retinal atlas to detect imaging artifacts. (A,C) Color fundus images with artifacts. (B,D) Euclidean distance maps in atlas space using atlas coordinate system. Note that distances are evaluated within atlas image. Consequently, field of view of distance map is not identical to that of fundus image. (Reproduced from Abramoff MD, Garvin M, Sonka M. Retinal imaging and image analysis. IEEE Reviews in Biomedical Engineering 2010:169-208.)

## Performance of Diabetic Retinopathy Detection Algorithms

Several groups have studied the performance of detection algorithms in a real-world setting. The main goal of such a system is to decide whether the patient should be evaluated by a human expert or can return for routine follow-up, based solely on automated analysis of retinal images.<sup>48,49</sup>

DR detection algorithms appear to be mature and competitive algorithms have now reached the human intrareader variability limit.<sup>46,47</sup> Additional validation studies on larger, well-defined, but more diverse populations of patients with diabetes are urgently needed, anticipating cost-effective early detection of DR in millions of people with diabetes to triage those patients who need further care at a time when they have early rather than advanced DR. Validation trials are currently underway in the United States, United Kingdom and the Netherlands.

To drive the development of progressively better fundus image analysis methods, research groups have established publicly available, annotated image databases in various fields. Fundus imaging examples are represented by the STARE,<sup>112</sup> DRIVE,<sup>73</sup> REVIEW<sup>113</sup> and MESSIDOR databases,<sup>114</sup> with large numbers of annotated retinal fundus images, with expert annotations for vessel segmentation, vessel width measurements, and diabetic retinopathy detection. Image analysis competitions, such as the Retinopathy Online Challenge,<sup>115</sup> have also been initiated.

The DRIVE database (Digital Retinal Images for Vessel Evaluation) was established to enable comparative studies on segmentation of retinal blood vessels in retinal fundus images. It contains 40 fundus images from subjects with diabetes, both with and without retinopathy, as well as retinal vessel segmentations performed by two human observers. Starting in 2005, researchers have been invited to test their algorithms on this database and share their results with other researchers through the DRIVE website.<sup>105</sup> At the same web location, results of various methods can be found and compared. Currently, retinal vessel segmentation research is primarily focusing on improved segmentation of small vessels, as well as on segmenting vessels in images with substantial abnormalities.

The DRIVE database was a great success, allowing comparisons of algorithms on a common dataset. In retinal image analysis, it represented a substantial improvement over method evaluations on unknown datasets. However, different groups of researchers tend to use different metrics to compare the algorithm performance, making truly meaningful comparisons difficult or impossible. Additionally, even when using the same evaluation measures,

implementation specifics of the performance metrics may influence final results. Consequently, until the advent of the Retinopathy Online Challenge ROC competition in 2009, comparing the performance of retinal image analysis algorithms was difficult.<sup>115</sup> This competition focused on detection of microaneurysms. Twenty-six groups participated in the competition out of which six groups submitted their results on time.

A logical next step was to provide publically available annotated datasets for use in the context of online, standardized asynchronous competitions. In an asynchronous competition, a subset of images is made available with annotations, while the remainder of the images are available with annotations withheld. This allows researchers to optimize their algorithm performance on the population from which the images were drawn (assuming the subset with annotated images is representative of the entire population), but they are unable to test–retest on the evaluation images, because those annotations are withheld. All results are subsequently evaluated using the same evaluation software, and research groups are allowed to submit results continuously over time.

## Areas of Active Research in Fundus Image Analysis

Major progress has been accomplished in fundus image analysis. Current challenges, on which multiple research groups worldwide are actively working, include the following areas: differentiating arteries from veins, assessing accurate vessel diameter (particularly in vessels only a few pixels in diameter) and vessel tortuosity, vessel tree analysis including tree branching patterns, detection of irregularly shaped hemorrhages, detection of lesion distribution patterns (i.e., drusen), and segmentation of atrophy. Finally, integration of fundus image-based quantification with other metrics of disease risk, such as serum glucose level or patient history, is an area of active research with immediate clinical application.

## Optical Coherence Tomography

## Image Analysis

Because of OCT's relatively recent presence in ophthalmic care compared to fundus photography, the use of image analysis techniques for processing OCT images has a shorter history. Nevertheless, it is a rapidly growing and important area, especially as spectral domain.

OCT (SD-OCT) technology has enabled true three-dimensional volumetric scans of the retina to be acquired. With this ever-increasing wealth of image information, the importance of developing advanced image analysis techniques to maximize the extraction of clinically relevant information is especially important. Nevertheless, the development of such advanced techniques can be challenging as OCT images are inherently noisy, thus often requiring the utilization of 3D contextual information ([Fig. 8.13](#)). Furthermore, the structure of the retina can drastically change during disease. Here are some of the important image analysis steps for processing OCT images. We start with the segmentation of retinal layers, one of the earliest, yet still extremely important, OCT image analysis areas. We then discuss techniques for flattening OCT images in order to correct scanning artifacts. Building upon the ability to extract layers, we discuss use of thickness information and use of texture information. This is followed by the segmentation of retinal vessels, which currently has its technical basis in many of the techniques used for segmenting vessels in fundus photography, but is beginning to take advantage of the 3D information available only in SD-OCT. Utilizing both layer-based and texture-based properties to detect the locations of retinal lesions is then described. A 3D-based approach for segmenting the boundaries of such lesions is described in the section "[Detection of retinal lesions](#)." The ability to segment layers in the presence of lesions is described in the section "[Intraretinal layer segmentation in the presence of SEADs](#)." This section is partially based on a review paper.<sup>59</sup>

## Retinal Layer Analysis From Three-Dimensional OCT

### Retinal Layer Detection

The segmentation of retinal layers in OCT scans has been an important goal, because thickness changes in the layers are one indication of disease status. Previous generation time domain scanning systems (such as the Stratus OCT by Carl Zeiss Meditec, Inc.) offered the ability to segment and provide thickness measurements for a single layer of the retina. In particular, the retinal nerve fiber layer (RNFL) thickness measurements of peripapillary circular scans and total retinal thickness measurements were available and used clinically. It can be assumed that commercialized methods utilized an inherently two-dimensional approach (i.e., if multiple 2D slices are available in a

particular scanning sequence they are segmented independently). Indeed, most of the early approaches that have been reported in the literature<sup>117-122</sup> for the segmentation of time domain scans are also 2D in nature.

While variations to each of the early 2D approaches exist for the segmentation of retinal boundaries, a typical 2D approach proceeds as follows: preprocess the image,<sup>117-119,121</sup> perform a 1D peak detection (detection) on each A-scan of the processed image to find points of interest, and (in some methods) correct for possible discontinuities in the 1D border detection.<sup>117</sup> Other 2D time domain approaches include the use of 2D dynamic programming by Baroni et al.<sup>123</sup> and manually initialized deformable models for the segmentation of fluid-filled regions, as well as the Cabrera Fernández group which found seven retinal layer boundaries by segmentation analysis.<sup>124,125</sup>

Haeker, Garvin and others reported the first true 3D segmentation approach for the segmentation of retinal layers on OCT scans, taking advantage of 3D contextual information.<sup>126-129</sup> Their approach was unique in that the layers were segmented simultaneously.<sup>130</sup> For time domain macular scans, they segmented 6–7 surfaces (5–6 layers), obtaining an accuracy and reproducibility similar to that of retinal specialists. By extending the approach to spectral domain OCT volumes,<sup>131</sup> utilization of 3D contextual information had more of an advantage (Fig. 8.14). By employing a multiscale approach, the processing time was subsequently decreased from hours to a few minutes while enabling segmenting additional layers.<sup>132</sup> A similar approach for segmenting the intraretinal layers in optic nerve head (ONH)-centered SD-OCT volumes was reported with an accuracy similar to that of the interobserver variability of two human experts.<sup>120</sup> A preliminary layer thickness atlas was built from a small set of normal subjects. Thickness loss of the macular ganglion cell layer in people with diabetes without retinopathy was thus demonstrated, showing that diabetes also leads to retinal neuropathy.<sup>133,134</sup>

**FIG. 8.14** Why using the complete three-dimensional contextual information in intraretinal layer segmentation process is superior. (A–C) Sequence of two-dimensional result on three adjacent slices within spectral-domain volume obtained using a slice-by-slice 2D graph-based approach. Note the “jump” in segmentation result for third and fourth surfaces in middle slice. (D–F) Sequence of 3D results on same three adjacent slices using same graph-based approach, but with addition of 3D contextual information. Three-dimensional contextual information prevented third and fourth surface segmentation from failing.

## OCT Image Flattening

SD-OCT volumes frequently demonstrate motion artifacts, and other artifacts may also be present, such as the tilting due to an off-axis placement of the pupil. Approaches for reducing these artifacts include 1D and 2D methods that use cross-correlation of either A-scans<sup>118</sup> or B-scans.<sup>98,135</sup> In some cases, a complete flattening of the volume is desired based on a surface segmentation to ensure a consistent shape for segmentation and visualization. Flattening the volumes makes it possible to truncate the image substantially in the axial direction (z-direction), thereby reducing the memory and time-requirements of an intraretinal layer segmentation approach. Flattening an image involves first segmenting the retinal pigment epithelial surface in a lower resolution, fitting a thin-plate spline to this surface, and then vertically realigning the columns of the volume to make this surface completely flat.<sup>131</sup>

## Retinal Layer Thickness Analysis

After flattening and segmentation, the properties of the macular tissues in each layer can be extracted and analyzed. In addition to

layer thickness, textural properties can also be quantified, as explained in the next paragraph. Measuring the thickening of specific layers is crucial in the management of diabetic macular edema and other retinal disorders.<sup>136</sup> Typically, it is useful to compare the obtained thickness values to a normative database or atlas, as is available in commercial machines for the total macular thickness and the retinal nerve fiber layer. However, a normative atlas for all the layers in 3D currently only exists within individual research groups.<sup>137</sup> Nevertheless, work has been done to demonstrate previously unknown changes in the ganglion cell layer in patients with diabetes.<sup>133,134</sup>

## Retinal Texture Analysis

Texture, defined as measures of the spatial distribution of image intensities, can be used to characterize tissue properties and tissue differences. Textural properties may be important for assessing changes in the structural or tissue composition of layers that cannot be measured by changes in thickness alone. Texture can be determined in each of the identified layers three-dimensionally.<sup>138-140</sup> 3D formulations of texture descriptors were developed for pulmonary parenchymal analysis<sup>141</sup> and have been directly employed for OCT texture analysis.<sup>142</sup> The wavelet transform, a form of feature detection, has been used in OCT analysis for de-noising and de-speckling<sup>143-145</sup> as well as for texture analysis.<sup>146</sup> Early work on 3D wavelet analysis of OCT images was based on a computationally efficient yet flexible nonseparable lifting scheme in arbitrary dimensions.<sup>142,147</sup>

Texture characteristics can be computed for each segmented layer, several adjacent layers, or in layer combinations (Fig. 8.12).

## Detection of Retinal Vessels From Three-Dimensional OCT

Segmenting the retinal vasculature in 3D SD-OCT volumes<sup>148,149</sup> allows OCT-to-fundus and OCT-to-OCT image registration (see [Optical coherence tomography imaging](#), above). The absorption of light by the blood vessel walls causes vessel silhouettes to appear below the position of vessels, which thus causes the projected vessel

positions to appear dark on either a full projection image of the entire volume<sup>149</sup> or a projection image from a segmented layer for which the contrast between the vascular silhouettes and background is highest as proposed by Niemeijer and others.<sup>150,151</sup> In particular, the work by Niemeijer et al. used the layer near the retinal pigment epithelium to create the projection image. Vessels were segmented using feature detection with Gaussian filter banks and a k-NN pixel classification approach. The performance of the automated method was evaluated for both ONH-centered as well as macula-centered scans. The retinal vessels were successfully identified in a set of 16 3D OCT volumes (8 optic nerve head and 8 macula-centered) with high sensitivity and specificity as determined using ROC analysis, AUC = 0.96. Xu et al.<sup>152</sup> reported an approach for segmenting the projected locations of the vasculature by utilizing pixel classification of A-scans. The features used in the pixel classification were based on a projection image of the entire volume in combination with features of the individual A-scans. Both of these reported prior approaches focused on segmenting the vessels in the region outside the optic disc region because of difficulties in the segmentation inside this region. The neural canal opening (NCO) shares similar features with vessels, thus causing false positives. Hu et al.<sup>146</sup> proposed a modified 2D pixel classification algorithm to segment the blood vessels in SD-OCT volumes centered at the ONH, with a special focus on better identifying vessels near the NCO. Given an initial 2D segmentation of the projected vasculature, Lee et al. presented an approach for segmenting the 3D vasculature in the volumetric scans<sup>153</sup> by utilizing a graph-theoretic approach (Fig. 8.15). One of the current limitations of that approach is the inability to properly resolve the depth information of crossing vessels.

**FIG. 8.15** Example of spectral three-dimensional optical coherence tomography (3D OCT) vessel

segmentation. (A) Vessel silhouettes indicate position of vasculature. Also indicated in red are slice intersections of two surfaces that delineate subvolume in which vessels are segmented (superficial retinal layers toward vitreous are at the bottom). (B) Two-dimensional projection image extracted from projected subvolume of spectral 3D OCT volume. (C) Automatic vessel segmentation. (D) Three-dimensional rendering of vessel around the optic nerve head. (Reproduced from Lee K, Abramoff M, Niemeijer MK, et al. 3D segmentation of retinal blood vessels in spectral-domain OCT volumes of the optic nerve head. Proc. SPIE Medical Imaging 2010:Biomedical Applications Molecular, Structural, Functional Imaging, Feb. 2010, vol. 7626, p. 76260V.)

## Detection of Retinal Lesions

Calculated texture and layer-based properties can be used to detect retinal lesions as a 2D footprint<sup>142</sup> or in 3D. Out of many kinds of possible retinal lesions, symptomatic exudate-associated derangements (or SEADs), a general term for fluid-related abnormalities in the retina, are of great interest in assessing severity of AMD, diabetic macular edema, and other diseases. Detection of drusen, cotton-wool spots, areas of pigment epithelial atrophy, or pockets of fluid under epiretinal membranes may be attempted in a similar fashion.

The deviation of local retinal tissue from normal can be computed by determining the local deviations from the normal appearance at each location  $(x; y)$  in each layer and selecting the areas where the absolute deviation is greater than a predefined cutoff. More generally, in order to build an abnormality-specific detector, a classifier can be trained, the inputs of which may be the z-scores computed for relevant features. Comprehensive z-scores are appropriate since an abnormality may affect several layers in the neighborhood of a given location  $(x; y)$ . The classifier-determined label associated with each column may be selected on relevant features by one of the many available cross-validation and/or feature selection methods,<sup>154-156</sup> thus forming a SEAD-ness or probabilistic abnormality map.

## Fluid Detection and Segmentation

In AMD, diabetic macular edema, and other retinal diseases, intraretinal or subretinal fluid is reflective of disease status and changes in fluid are an indicator of disease progression or regression. With the availability of anti-VEGF (vascular endothelial growth factor) therapy, assessment of the extent and morphology of fluid is expected to contribute to patient-specific therapy. While regions of fluid are inherently three-dimensional, determining their 2D retinal footprint is highly relevant. Following the above-described analysis, fluid detection employs generalization of properties derived from expert-defined examples. Utilizing the differences between normal regional appearance of retinal layers as described by texture descriptors and other morphologic indices, a classifier can be trained to identify abnormal retinal appearance. The fluid detection starts with 3D OCT layer segmentation resulting in 10 intraretinal layers plus an additional artificial layer below the deepest intraretinal layer so that subretinal abnormalities can also be detected.<sup>142</sup> Texture-based and morphologic descriptors are calculated regionally in rectangular subvolumes, the most discriminative descriptors are identified, and these descriptors are used for training a probabilistic classifier. The performance of a (set of) feature(s) is assessed by calculating the area under the receiver-operating characteristic curve of the fluid classifier. Once the probabilistic classifier is trained, fluid-related probability is determined for each retinal location. In order to obtain a binary footprint for fluid in an image input to the system, the probabilities are thresholded and the footprint of the fluid region in this image is defined as the set of all pixels with a probability greater than a threshold. Useful 3D textural information can be extracted from SD-OCT scans and – together with an anatomical atlas of normal retinas – can be used for clinically important applications.

## Fluid Segmentation in Three-Dimensional OCT

Complete volumetric segmentation of fluid from 3D OCT is the subject of active research. A promising approach is based on identification of a seed point in the OCT dataset that is “inside” and “outside” of a fluid region. These points can be identified automatically using a 3D variant of the probabilistic classification

approach outlined in the previous paragraphs. Once these two points are identified, an automated segmentation procedure that is based on regional graph-cut method<sup>157,158</sup> may be employed to detect the fluid volumetric region. The cost function utilized in a preliminary study was designed to identify dark 3D regions with somewhat homogeneous appearance. The desired properties of the fluid region are automatically learned from the vicinity of the identified fluid-region seed point. This adaptive behavior allows the same graph-cut segmentation method driven by the same cost function to reliably segment fluid of different appearance. Fig. 8.16 gives an example of 3D fluid region segmentations obtained using this approach. Note that the figure depicts the same locations in the 3D data sets imaged several times during the course of anti-VEGF treatment. The surfaces of the segmented fluid regions are represented by a 3D mesh, which can be interactively edited to maximize fluid region segmentation accuracy in difficult or ambiguous cases.

**FIG. 8.16** Symptomatic exudate-associated derangements (SEAD) segmentation from three-dimensional optical coherence tomography and SEAD development over time. Top row: 0, 28, and 77 days after first imaging visit; middle row: 0 and 42 days after first imaging visit; bottom row: 0, 14, and 28 days after first imaging visit. Three-dimensional visualization in

right column shows data from week 0. Each imaging session was associated with anti-vascular endothelial growth factor reinjection.

## **Intraretinal Layer Segmentation in the Presence of SEADs**

Another area of active research is layer segmentation in retina that contains SEADs. Most likely a two-step approach is necessary in which layers are initially segmented disregarding the SEAD presence, then SEADs are segmented, and used to constrain the second stage of layer segmentation. This process yields well-segmented retinal layers when fluid occupies a single intraretinal layer as well as in situations when the fluid resides in several adjacent retinal layers.

## **Multimodality Retinal Imaging**

Multimodality imaging, defined as images from the same organ, using different physical techniques, is becoming increasingly common in ophthalmology. For image information from multiple modalities to be usable in mutual context, images must be registered so that the independent information that was acquired by different methods can be concatenated and form a multimodality description vector. Thus, because of its importance in enabling multimodal analysis, retinal image registration reflects another active area of research. The several clinically used methods to image the retina were introduced above and include fundus photography, scanning laser ophthalmoscopy, fluorescence imaging, and OCT. Additional retinal imaging techniques such as hyperspectral imaging, oxymetry, and adaptive optics SLO will bring higher resolution and additional image information. To achieve a comprehensive description of retinal morphology and eventually function, diverse retinal images acquired by different or the same modalities at different time instants must be mutually registered to spatially combine all available local information. The following sections provide a brief overview of fundus photography and OCT registration approaches in both 2D and 3D. A more

detailed review is available.<sup>59</sup> Registration of retinal images from other existing and future imaging devices can be performed in a similar or generally identical manner.

## Registration of Fundus Retinal Photographs

Registration of fundus photographs taken either at different regions of the retina, or of the same area of the retina but at different times, are useful to expand the effective field of view of a retinal image, determine what part of the retina is being viewed, or aid in analyzing changes over time.<sup>159</sup> We have previously discussed some other uses for fundus–fundus registration in regard to retinal atlases. To register 2D or planar fundus images, most existing registration approaches utilize identification and extraction of features derived from retinal vasculature segmented separately from the individual fundus images. The choice of a specific image registration algorithm to align retinal images into a montage depends on the image characteristics and the application. Images acquired with only a small overlap may be optimally aligned using feature-based registration approaches, while images acquired with larger overlaps, may be satisfactorily aligned using intensity-based approaches. Examples of feature-based registration are global-to-local matching,<sup>160</sup> hierarchical model refinement,<sup>161</sup> and dual-bootstrap.<sup>162</sup> Local intensity features<sup>163</sup> are particularly useful when an insufficient number of vascular features are available. Following a step of vascular skeletonization, vascular branching points can be easily used as stable landmarks for determining image-to-image correspondence. As an example, the RADIC model<sup>164</sup> parameters are estimated during an optimization step that uses Powell's method<sup>165</sup> and is driven by the vessel centerline distance. The approach presented by Lee et al. in 2010 reported registration accuracy of 1.72 pixels (25–30  $\mu\text{m}$ , depending on resolution) when tested in 462 pairs of green channel fundus images.<sup>108</sup> The registration accuracy was assessed as the vessel line error. The method only needed two correspondence points to be reliably identified and was therefore applicable even to cases when only a very small overlap between the retinal image pairs existed. Based on the identified vascular features, the general approach can be

applied to any retinal imaging modality for which a 2D vessel segmentation is available. In registering poor quality multimodal fundus image pairs, which may not have sufficient vessel-based features available, Chen et al. proposed the detection of corner points using a Harris detector followed by use of a partial intensity invariant feature descriptor.<sup>166,167</sup> They reported obtaining 89.9% “acceptable” registrations (defined as registrations with a median error of 1.5 pixels and a maximum error of 10 pixels when compared with ground truth correspondences) when tested on 168 pairs of multimodal retinal images.

## Registration of OCT With Fundus Retinal Photographs

Registration of 2D fundus images with inherently 3D OCT images requires that the dimensionality of OCT be reduced to 2D via z-axis projection. Building on the ability to obtain vascular segmentation from 3D OCT projection images, the problem of fundus–OCT registration becomes virtually identical to that of fundus–fundus registration that was described in the previous section. Using the same general method, high-quality OCT–fundus registration can be achieved. Fig. 8.17 presents the main steps of the registration process and shows the achieved registration performance.

**FIG. 8.17** Registration of fundus images to two-dimensional optical coherence tomography (OCT) projection data. (A) Fundus camera image. (B) Two-dimensional projection (through depth dimension) of three-dimensional OCT data. (C) Registered and blended fundus–OCT images via application of affine transformation model with three identified vascular landmarks.

## Mutual Registration of Three-Dimensional OCT Images

Temporal changes of retinal layers leading to assessment of disease progression or regression can be accessed from longitudinal OCT images. Comparison of morphology or function over time requires that the respective OCT image data sets be registered. Since OCT is a three-dimensional imaging modality, such registration needs to be performed in 3D. For follow-up studies, image registration is a vital tool to enable more precise, quantitative comparison of disease status. Another important aspect of OCT to OCT registration is the ability to enlarge retinal coverage by registering OCT data resulting from imaging different portions of the retina. A fully three-dimensional SIFT-based (Scale-Invariant Feature Transform) approach was introduced by Niemeijer et al. in 2009.<sup>168</sup> In their work, the SIFT feature extractor locates minima and maxima in the difference of Gaussian scale space to identify salient feature points. Using calculated histograms of local gradient directions around each found extremum in 3D, the matching points are found by comparing the distances between feature vectors. An application of this approach to rigid registration of peripapillary (ONH-centered) and macula-centered 3D OCT scans of the same patient for which the macular and peripapillary OCT scans had only a limited overlap has been reported.<sup>168</sup> The work built on a number of analysis steps introduced earlier, including segmentation of the retinal layers and flattening of each of the two volumes to be registered and then determining 3D SIFT feature points.<sup>169,170</sup> Using the terminology usual for image registration when one of the registered images is called the “source” (say the macular image) and the other the “target” (say the peripapillary image), the feature point detection is performed in both the source and target images. After feature point extraction, those that are in corresponding positions in both images are identified. In a typical pair of two OCT scans, about 70 matching pairs can be found with a high level of certainty. Considering the already flattened 3D OCT image pair, the major remaining deformations that need to be resolved are translation and limited rotation. Consequently, simple rigid or

affine transform is appropriate to achieve the desired image registration. The transform parameters are estimated from the identified correspondence points. OCT–OCT registration of macular and peripapillary OCT scans, achieved 3D accuracy of 2:0 to 3:3 voxels, assessed as an average voxel distance error in 1572 matched locations.<sup>167</sup> Qualitative evaluation of performance demonstrated the utility of this approach to clinical-quality images. Temporal registration of longitudinally acquired OCT images from the same subjects can be obtained in an identical manner.

## Future of Retinal Imaging and Image Analysis

Translation of research in imaging and image analysis into the clinic has been relatively rapid in the past, and is likely to accelerate in the future. This is partially explained by the lower capital expenditure for ophthalmic imaging devices compared to radiologic imaging devices – the latter can often be 10 to 100 times more expensive – and partially because we as retinal specialists manage patients directly and are directly involved in the ordering and interpreting of images, while radiologists typically do not directly manage patients. This subtle difference in physician–patient relationship leads to a more direct coupling between imaging innovation and clinical impact that is so well visible in retinal image analysis. Thus, it can be expected that translation of fundamental research findings in retinal imaging will remain rapid in the future. The need to automate image interpretation is correspondingly high.<sup>171</sup> A global push toward cost-effective imaging and image analysis for wide scale retinal and/or systemic disease detection in a population screening setting will mandate continued efforts in perfecting automated image analysis.<sup>59</sup>

Likely, retinal image analysis and interpretation will be coupled to genetic and other assessment indices allowing truly personalized approaches to complex analyses of broad sets of patient-specific data. On the technologic side, this requires development and wide utilization of highly automated techniques for combined analysis of retinal image data in 2D, 3D, and 4D (3D+time), quantification of

temporal changes, including the assessment of local and/or systemic severity of the findings. On the patient management side, it will lead to broad utilization of semiautomated, clinician supervised management of retinal diseases, especially diabetic retinopathy, and choroidal neovascularization. Overall, we envision that in the next decade the utilization of retinal imaging will go far beyond the direct needs of retinal disease management, and that the quantified retinal examination will become broadly used in systemic disease assessment both for patient-specific care and for population studies.

Retinal imaging and image analysis have developed rapidly over the past 10 years, and image analysis plays a crucial role in the care of patients with retinal diseases, and other diseases that manifest in the retina. So far, image analysis has mostly operated reactively, i.e., waiting for what the newest imaging devices have as output, and then trying to find approaches to analyze and quantify the image data. Moving forward, we expect that imaging device development and image analysis research will start to operate more in concert and become closely integrated, so that retinal image analysis successes and difficulties can directly influence device developers to focus on details that will help reliably analyze the images and vice versa. Ultimately, retinal image analysis and the research and development behind it is driven by the overarching goal of preventing visual loss and suffering from retinal and systemic disease.

# Electrogenesis of the Electroretinogram

---

*Laura J. Frishman*

## **Introduction**

### **Generation of Extracellular Potentials: General Concepts**

### **Approaches for Determining the Origins of the Electroretinogram**

### **Standard Erg Tests in the Clinic**

### **Origin of the a-Wave**

### **Origin of the b-Wave**

### **Origin of the d-Wave**

### **Origin of the Photopic Fast-Flicker ERG**

### **Origin of the Multifocal ERG**

### **ERG Waves From Proximal Retina**

### **Closing Remarks**

## **Introduction**

The electroretinogram (ERG) is an electrical potential generated by the retina in response to a change in illumination. It is an excellent tool for evaluating retinal function in both the clinic and the

laboratory because it can be recorded noninvasively from the corneal surface in vivo under physiologic or nearly physiologic (anesthetized) conditions. However, the ERG response to a flash of light is complex. It is the summed activity of all retinal cells, and consists of overlapping positive and negative component potentials that originate from different stages of retinal processing. For the ERG to be an effective tool in assessing normal and pathologic retinal activity, it is important that the contributions of the various retinal cell types be distinguished and characterized.

This chapter will review current knowledge of the cellular origins and mechanisms of generation of the various ERG component waves, progressing from distal retina to proximal retina. As will be described, the ERG is generated by radial currents arising either directly from retinal neurons, or as a result of the effect on retinal glia of changes in extracellular potassium concentration ( $[K^+]_o$ ) brought about by retinal neuronal activity. Our understanding of the electrogenesis of the ERG was initially based on studies in a variety of cold-blooded vertebrates as well as some mammalian species, described in more detail in previous reviews.<sup>1,2</sup> Studies in a nonhuman primate model (macaque monkey) whose retina and ERG are very similar to that of humans (Fig. 9.1),<sup>3</sup> and particularly those over the past two decades, have improved our understanding of the electrogenesis of the ERG in humans. This work will be highlighted wherever possible in this chapter. Clinical applications of the ERG will be described in the [Chapter 10](#) (Clinical electrophysiology). Another recent review has examined the electrogenesis of a common animal model for retinal disease, the mouse.<sup>3</sup>

A

Dark- and light-adapted full-field flash electroretinograms (ERGs) of human subjects and macaque monkeys. (A) Top: Dark-adapted (scotopic) ERGs in response to brief high-energy flashes from darkness occurring at time zero for a normal human subject (left) and an anesthetized macaque monkey (right). The stimulus energy was  $\sim 400$  sc td/s. Bottom: Light-adapted (photopic) flash ERGs in response to longer-duration flashes on a rod-saturating background for a normal human subject (left) and a macaque monkey (right). For the human subject the stimulus was a 150-ms white full-field flash of 4.0 log ph td presented on a steady background of 3.3 log sc td. For the macaque, the same stimulus was used, but the flashes were

200 ms in duration (Adapted from Sieving PA, Murayama K, Naarendorp F. Push-pull model of the primate photopic electroretinogram: a role for hyperpolarizing neurons in shaping the b-wave. *Vis Neurosci* 1994;11:519-32.)

(B) ERG recording setup: recordings are made using a traditional ganzfeld bowl (left) or more modern light-emitting diode-based

full-field stimulator. Burian–Allen and DTL fiber electrodes<sup>4</sup> are illustrated. ERG recordings are amplified and sent to a computer for averaging, display, and analysis.

**FIG. 9.1**

## Generation of Extracellular Potentials: General Concepts

Extracellular potentials that can be recorded noninvasively, such as the ERG (and visual evoked potential of the cortex), are the result of localized conductance changes in the membranes of activated cells that give rise to inward or outward currents. These currents also flow in the extracellular space (ECS) and create extracellular potentials. The current flowing through the conductive fluid surrounding a cell whose activation has given rise to a local current is directed mainly toward the relatively less activated parts of the cell. Thus, when neurons are arranged so that the extracellular currents of many synchronously activated cells all flow in the same direction, the resulting extracellular potential change, called a “field potential,” may be large enough to be recorded at a distance, e.g., at the cornea in the case of the ERG. In the retina, because all neurons generate light-evoked currents, in principle they should all contribute to the retinal field potentials. However, depending upon various factors, considered below, the contribution from any particular cell type could be quite large, or not discernible in the response.

An important factor affecting a given cell's contribution to the ERG is its orientation in the retina. Radially oriented neurons in the retina (photoreceptors and bipolar cells) and glial cells (Müller cells and retinal pigment epithelial [RPE] cells) make larger contributions to the ERG than cells that are oriented more irregularly or laterally (e.g., horizontal and amacrine cells) (Fig. 9.2). The currents around cells that underlie the ERG enter the ECS at

one retinal depth (the current source), and return into the cell at another depth (the current sink), creating a current dipole. Although most of the extracellular current flowing from source to sink traverses the ECS within the retina, some travels extraretinally – through the vitreous humor, extraocular tissues, sclera, choroid, the high resistance of the RPE (R-membrane), and back into the neural retina.

**FIG. 9.2** Schematic of rod and cone pathways of the mammalian retina. The blue-filled cells indicate the cone pathways; the yellow-filled cells indicate the primary rod pathway. The green-filled cell is a Müller glia cell. *A*, amacrine cell; *DCB*, depolarizing (ON) cone bipolar cell; *GC*, ganglion cell; *GCL*, ganglion cell layer; *HC*, horizontal cell; *HCB*, hyperpolarizing (OFF) bipolar cell; *ILM*, inner limiting membrane; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *IS*, inner segment; *NFL*, nerve fiber layer; *OLM*, outer limiting membrane; *ONL*, outer nuclear layer; *OPL*, outer plexiform layer; *OS*, outer segment; *RBC*, rod bipolar

cell; *RPE*, retinal pigment epithelium. Scale bar: 20  $\mu\text{m}$ .

The polarity and amplitude of the recorded ERG will depend upon the location of the active and reference electrodes. In noninvasive studies, a common location for the active electrode is on the cornea via a contact lens electrode, e.g., as illustrated in [Fig. 9.1B](#), a Burian–Allen electrode, or jet electrode, or another type of surface conductive electrode (e.g., a DTL fiber electrode,<sup>4</sup> H–K loop,<sup>5</sup> or gold foil electrode). For comfort, skin electrodes, which yield smaller signals, are sometimes used instead. In invasive studies of ERG components in animals, the active electrode may be positioned anywhere in the current path, including at different retinal depths, near particular cell types. The reference electrode also can be positioned anywhere in the path, but is often placed behind the RPE in studies of isolated retina, or retrobulbar in intact eyes. In noninvasive and clinical applications, the reference is positioned either under the eyelids, such as the speculum of the Burian–Allen electrode for bipolar recording between the contact lens electrode and the reference on the same eye, or remote from the eye (e.g., on the temple) for monopolar recording. The exact position of the remote reference is of minor consequence except for possible contamination of the retinal signal by other sources.

Other factors that influence the magnitude of the contribution to the ERG of a particular cell type include stimulus conditions, such as the strength of the stimulus and its wavelength (spectrum), the background illumination (that determines adaptation level of the retina), the duration and spatial extent of the stimulus, and the location of the stimulus within the visual field, as these stimulus parameters have different effects on the responses of the different cells. For example, the relative contributions of various cell types are different under dark-adapted (scotopic) and light-adapted (photopic) conditions when rod and cone pathways, respectively, are involved in generating responses. Spatially extended diffuse stimuli, i.e., full-field (*ganzfeld*) flashes that fill the retina evenly, using stimulators such as those illustrated in [Fig. 9.1B](#), are commonly used to elicit the major ERG waves (a-, b-, and d-waves) from photoreceptors and bipolar cells. Contributions from these cells generally increase with the area of the retina stimulated as the

number of cells, and hence the total extracellular current, is increased. In contrast, contributions of retinal ganglion cells (and other cells with antagonistic regions within their receptive fields) to the full-field flash ERG will be limited by the strength of surround antagonism. For photopic ERGs, particularly from subjects with trichromatic color vision, such as the macaque and human, stimulus wavelength also affects contributions from cells whose responses are dependent upon spectral antagonism.<sup>6,7</sup>

## Spatial Buffering by Glial Cells

Spatial buffering of  $[K^+]_o$  by radially oriented Müller cells, RPE cells, and perhaps astrocytes in the optic nerve head is an important mechanism for generating the currents underlying several ERG components, to be described later in this chapter, e.g., c-wave, slow PIII, tail of the b-wave, scotopic threshold response (STR), M-wave, and photopic negative response (PhNR). Due to its importance in generating ERGs, an overview of  $[K^+]_o$  spatial buffering in Müller cells will be presented here.

$[K^+]_o$  spatial buffering is important for maintaining the electrochemical gradients across cell membranes necessary for normal neuronal activity and for minimizing the changes in local  $[K^+]_o$  that occur as a consequence of neuronal activation. Membrane depolarization leads to the leak of  $K^+$  from neurons, causing  $[K^+]_o$  to be elevated, particularly in synaptic layers of the retina (Fig. 9.3); membrane hyperpolarization leads to reduced  $[K^+]_o$  as the leak conductance is reduced, but the  $Na^+$ - $K^+$  ATPase in the membranes continues to pump  $K^+$  into (and  $Na^+$  out of) cells.  $K^+$  from the ECS enters the Müller cells via inwardly rectifying  $K^+$  channels and is carried radially as an intracellular (spatial buffer) current to regions of lower  $[K^+]_o$ . Thus a current loop is set up: the current inside the Müller cell is carried by  $K^+$  and, to complete the circuit, the dominant extracellular ions,  $Na^+$  and  $Cl^-$ , carry the extracellular return current. Because the magnitude of the  $[K^+]_o$  changes depends upon the integral of  $K^+$  flow rate into the ECS, ERG components that reflect this glial current will be slower than components that reflect the currents around neurons. This “slowing” would be

equivalent to low-pass filtering of the neuronal signal.

**FIG. 9.3** Model of  $K^+$ -induced flow of current through Müller cells and extracellular space. The Müller cell  $K^+$  currents (*grey arrows*) are induced by  $[K^+]_o$  increases in the inner plexiform layer or  $[K^+]_o$  decreases in the subretinal space; the return currents in the extracellular space are carried by  $Na^+$  and  $Cl^-$  ions.  $K^+$  enters the Müller cell via strongly rectifying Kir channels (perhaps Kir2.1) in and around the synaptic layers (*short arrows on left*) and leave the cell via weakly rectifying Kir4.1 channels near the vitreous body, blood vessels, and subretinal space (*bidirectional arrows on bottom*). The  $I_2$  current generates slow PIII. Abbreviations as Fig. 9.2. (Adapted from Frishman LJ, Steinberg RH. Light-evoked increases in  $[K^+]_o$  in proximal portion of the dark-adapted cat retina. *J Neurophysiol* 1989;61:1233–43 and Kofuji P, Biedermann B, Siddharthan V, et al. Kir potassium channel subunit expression in retinal glial cells: implications for spatial potassium buffering. *Glia* 2002;39:292–3.)

The electrical properties of the Müller cell membrane are

important for the creation of spatial buffer currents. The membrane is selectively permeable to  $K^+$ ,<sup>8,9</sup> but the  $K^+$  conductance is not distributed evenly over the cell surface. Instead, it is concentrated in the vicinity of extracellular sinks (i.e., the vitreous body, subretinal space, and blood vessels). This regional distribution facilitates “ $K^+$  siphoning” from synaptic areas where  $[K^+]_o$  is high, to those regions of high  $K^+$  conductance where  $[K^+]_o$  is lower.<sup>10,11</sup> In mouse retina, as indicated in Fig. 9.3, strongly inward rectifying Kir channels (perhaps Kir2.1) channels have been localized to synaptic layers (indicated in the figure by short arrows on the left) where  $K^+$  moves from the ECS into Müller cells, whereas less strongly rectifying Kir4.1 channels at the extracellular sinks allow  $K^+$  to leave the Müller cell.<sup>12</sup>

## Approaches for Determining the Origins of the Electroretinogram

Historically, several different approaches have been used to determine the neuronal origins and cellular mechanisms of generation of the ERG.

### Intraretinal Depth Recordings

A microelectrode positioned at some locus in the retinal ECS records a field potential called the “local” or “intraretinal” ERG.<sup>13</sup> The recorded potential reflects electrical activity of the cells located near the microelectrode tip, and when a local stimulus, such as a small spot of light, is used, the local activity will be the entire signal. However, when full-field diffuse flashes are used, currents can be sufficiently large to produce a corneal ERG simultaneously with the local ERG. Local potentials with a similar timecourse to that of the corneal ERG components can be helpful in locating the cells of origin. However, this type of analysis has some complications:

1. Field potentials that spread over long distances will superimpose in space and time, making it difficult to locate the cells of origin

with certainty.

2. Retinal resistivity varies between and within retinal layers,<sup>14,15</sup> which causes currents passing through layers of different resistance to set up complex voltages.

Both of these problems occur in the intact eye when a scleral reference is used, and the local signal recorded with a microelectrode is contaminated by the diffuse ERG, due to the high resistance of the RPE and sclera. Some of this contamination can be eliminated by using a vitreal reference.<sup>16</sup>

Current source density (CSD) or “source-sink” analysis can provide a solution to these problems. Local field potentials are measured and analyzed, but in addition, radial resistance is taken into account to obtain direct estimates of radial current.<sup>17</sup> The result is a spatiotemporal profile of relatively well-localized current sources and sinks that can be compared with the retinal structure (layers) and physiology. CSD analysis has elucidated the origins of particular ERG components (e.g., for the bipolar cell origin of the b-wave).<sup>18,19</sup>

For ERG components believed to depend specifically on glial K<sup>+</sup> spatial buffer currents, intraretinal depth recordings with ion-selective microelectrodes have been used to locate the retinal layer(s) where neurally induced changes of [K<sup>+</sup>]<sub>o</sub> were largest and most similar in timecourse to a particular component.<sup>20–25</sup> Application of barium (Ba<sup>2+</sup>) to block Kir channels in glial cell membranes,<sup>26,27</sup> and the ERG components dependent upon the spatial buffer currents, or genetic inactivation of Kir4.1 channels in mice,<sup>28</sup> have been used to provide evidence for the role of Müller cells in generating certain slow waves of the ERG.

## Correlation of ERG With Single-Cell Recordings

Correlations of the ERG with single-cell electrophysiology are most useful when the light-evoked currents from a particular cell type are the primary determinant of an ERG component, as is the case for rod photoreceptors and the currents around the photoreceptor

that generate the scotopic a-wave,<sup>29</sup> or rod bipolar cells and the scotopic b-wave in mammals.<sup>30,31</sup> Correlation also may be useful for identifying the origin of a response property, such as oscillatory potentials (OPs) in the ERG, and the light-evoked oscillatory behavior in amacrine cells as a possible source for the potentials. However, if currents from several cell types contribute to a local field potential, the relationship between field potential and local cellular responses may be difficult to determine without using other tools, such as pharmacologic agents.

## Pharmacologic Dissection

The use of pharmacologic agents that have specific effects on cellular functions has been very helpful in determining origins of ERG components. In Granit's classical pharmacologic study of the dark-adapted ERG of the cat, he observed that components disappeared sequentially during induction of ether anesthesia.<sup>32</sup> He called the components "processes" and numbered them in the order of disappearance: PI, the positive c-wave, was first to leave, then PII, the positive b-wave, disappeared, and finally, PIII, the negative a-wave. We now know that these processes correspond roughly to RPE, bipolar, and photoreceptor cell contributions to the ERG respectively. The terms PII and PIII are still used.

In recent years, much has been learned about retinal microcircuitry and biophysics, including information at cellular and molecular levels about retinal neurotransmitters (their identity, release mechanisms, and receptors), signal transduction cascades, ion channels, and other cellular proteins. This knowledge has allowed better use of pharmacologic tools in isolating ERG components and in interpreting experimental observations. For example, specific knowledge about glutamatergic neurotransmission in the retina and appropriate agonists and antagonists for specific receptors has improved our understanding of the major waves of the ERG, including the ERG in primates.<sup>33-35</sup> Use of the voltage-gated Na<sup>+</sup>-channel blocker tetrodotoxin (TTX) has made it possible to identify ERG components resulting from the Na<sup>+</sup>-dependent spiking activity of inner retinal cells.

## Site-Specific Lesions/Pathology or Targeted Mutations

Removal of a cell type or types or circuits allows assessment of their role in the electrogenesis of the ERG. A specific cell type can be lesioned selectively (e.g., retinal ganglion cells as a consequence of optic nerve section) or lost due to pathologic changes (e.g., ganglion cells in glaucoma), or inherited degenerations (e.g., rod and/or cone dystrophy). Cellular functions, such as light responses or synaptic transmission, can be abnormal or eliminated due to inherited or acquired conditions, or targeted genetic manipulation, most commonly done in mice.

## Modeling of Cellular Responses and ERG Components

As our understanding of the function of retinal cell types has improved, it has been possible to develop quantitative models that predict the light responses of those cells, and to apply the models to analysis of the ERG. Models based on suction electrode recordings from single photoreceptor outer segments have been used to predict the leading edge of the a-wave,<sup>36-38</sup> although currents around more proximal portions of the photoreceptor cell will also participate in its generation.<sup>39</sup> The models have been extended to predict the leading edge of the scotopic b-wave.<sup>30</sup> Models of stimulus–response relations of specific retinal cells can be used to analyze amplitude versus energy curves obtained from ERG measurements into the components related to the different cell types.<sup>40,41</sup>

## Standard ERG Tests in the Clinic

Standard and more specialized tests for use in the clinic that examine key aspects of light- and dark-adapted retinal (and more central visual) function have been described in various publications by the International Society for the Clinical Electrophysiology of Vision (ISCEV), with the most recent update for the flash and flicker ERG in 2015.<sup>42</sup> The “standard” tests advocated by ISCEV for

basic ERG testing are listed in [Box 9.1](#), and typical responses to these tests are illustrated in [Fig. 9.4](#). The standards were developed so that ERGs recorded in clinics around the world would be comparable. The ISCEV publications, which now cover several other ERG tests as well, i.e., the ones with an asterisk in [Box 9.1](#), [Box 9.1](#) basic technology and clinical protocols.

## Standard and More Specialized Electoretinogram (ERG) Tests

### Standard ERG Tests Described by ISCEV Standard for Full-Field Clinical Electoretinography (2015 Update)<sup>42,a</sup>

Dark-adapted 0.01 ERG (“a rod-driven response of ON bipolar cells”)

Dark-adapted 3.0 ERG (“combined responses arising from photoreceptors and bipolar cells of rod and cone systems, rod dominated”)

Dark-adapted 10.0 ERG (“combined responses with enhanced a-wave reflecting photoreceptor function”)

Dark-adapted 3.0 oscillatory potentials (“responses primarily from amacrine cells”)

Light-adapted 3.0 ERG (“responses of the cone system; a-wave arises from cones and OFF bipolar cells, b-wave arises from ON and OFF cone bipolar cells”)

Light-adapted 3.0 flicker ERG (“a sensitive cone system response”)

Recommended additional response: flashes stronger than dark-adapted 10.0 ERG

### Specialized Types of ERG and Recording Procedures

Macular or focal ERG

Multifocal ERG<sup>b</sup>

Pattern ERG<sup>b</sup>

Early receptor potential (ERP)

Scotopic threshold response (STR), negative and positive

Photopic negative response (PhNR)

Direct-current (dc) ERG

Electro-oculogram<sup>b</sup>

Long-duration light-adapted ERG (ON–OFF responses)

Paired-flash ERG

Chromatic stimulus ERG (including S-cone ERG)

Dark and light adaptation of the ERG

Dark-adapted and light-adapted luminance response analyses

Saturated a-wave slope analysis

Specialized procedures for young and premature infants<sup>b</sup>

---

<sup>a</sup>All numbers are stimulus calibrations in  $\text{cd s/m}^2$ .

<sup>b</sup>See relevant standard or guideline published by International Society for the

Data from McCulloch DL, Marmor MF, Brigell MG, et al. ISCEV standard for full-field clinical electroretinography (2015 update). Doc Ophthalmol 2015;130:1-12.

**FIG. 9.4** Six standard electroretinogram (ERG) tests with full-field stimulation recommended by the International Society for the Clinical Electrophysiology of Vision (ISCEV) for use worldwide in clinical electrodiagnostic facilities. This figure shows examples, but not norms, of ERG responses to the recommended test stimuli in normal human subjects.

Light calibrations in candela seconds per meter squared (cd s/m<sup>2</sup>) for each test are indicated above the ERGs. *Large vertical arrowheads* indicate the time at which the stimulus flash occurred; *horizontal arrows* show common ways to measure the time-to-peak (*t*, implicit time); *small vertical arrows* mark a- and b-wave peak amplitude. Marmor MF, Brigell MG, et al. ISCEV standard for full-field clinical electroretinography (2015 update). Doc Ophthalmol 2015;130:1-12.)

## Distal Retinal Components: Slow PIII, c-Wave, Fast Oscillation Trough, and Light Peak

After the onset of a step of light, the early waves of the dark-

adapted ERG, the a- and b-waves, are followed by the c-wave and then by a succession of slower responses that include the fast oscillation trough (FOT), which is a negative deflection, and the light peak, which is a large slow positive deflection (Fig. 9.5A). Because these responses are so slow, lasting seconds to minutes, patients cannot keep their eyes steady long enough for them to develop. Therefore, in the clinic, these slower responses are generally recorded by using electro-oculography.

**FIG. 9.5** Subretinal recordings from the intact cat eye.

(A) The vitreal, transretinal, and transepithelial potentials were recorded simultaneously in response to a 5-minute period of illumination. The a- and b-waves cannot be seen using this compressed timescale. In the vitreal electroretinogram (ERG), the c-wave is followed by the fast oscillation trough (FOT) and then the light peak. The intraretinal recordings show that the c-wave is composed of two (sub)components: the larger cornea-positive retinal pigment epithelial (RPE) transepithelial response, and the slightly smaller cornea-negative transretinal component, the Müller cell-generated slow PIII response. For the light peak,

only an RPE component is present. (B) Schematic showing the recording arrangement for transretinal and transepithelial recordings in the intact eye. The transretinal ERG is recorded between a vitreal reference and a retrobulbar reference. The microelectrode is referenced to the vitreal reference for the transretinal recording and to the retrobulbar reference for the transepithelial recording. Double-barreled microelectrodes were used to measure field potentials and changes in  $[K^+]_o$ . (Panel A reproduced with permission from Steinberg RH, Linsenmeier RA, Griff ER. Retinal pigment epithelial cell contributions to the electroretinogram and electrooculogram. *Prog Retin Res* 1985;4:33–66. Panel B reproduced with permission from Frishman LJ, Steinberg RH. Light-evoked increases in  $[K^+]_o$  in proximal portion of the dark-adapted cat retina. *J Neurophysiol* 1989;61:1233–43.)

The electro-oculogram (EOG) is an eye movement-dependent voltage recorded between electrodes placed near the eye at the inner and outer canthus. The patient is asked to look back and forth between a pair of fixation lights separated by 30° of visual angle, situated in a ganzfeld bowl. The source of the voltage is a corneofundal potential, also called the “standing potential” that renders the cornea positive with respect to the back of the eye. Light-evoked changes in the EOG reflect changes in the transepithelial potential (TEP) of the RPE. These changes have been studied experimentally in human and animal preparations using direct current electroretinography (dc-ERG<sup>43</sup>), and these studies will be reviewed briefly here.

Electrogenesis of the c-wave, FOT, and light peak of the dc-ERG involves ion concentration changes in the subretinal space between photoreceptors and the RPE that in turn produce slow membrane responses in the Müller and RPE cells that face the space. Müller and/or RPE component voltages overlap in time and sum to produce the recorded dc-ERG components. The (sub)component voltages from Müller cells and RPE have been recorded in anesthetized animals by placing a microelectrode in the subretinal space, and simultaneously recording the potentials across neural retina and the RPE, as illustrated in the schematic in [Fig. 9.5B](#). Such experiments have provided a good understanding of the origins and mechanisms of generation of the c-wave and other slow

potentials from distal retina.

## c-Wave

The cornea-positive c-wave that follows the b-wave is the sum of two major (sub)component voltages: a cornea-negative voltage, generated by the neural retina, and a cornea-positive voltage of similar latency and timecourse, generated by the RPE (Figs. 9.5 and 9.6). The c-wave is cornea-positive when the RPE component is larger than the neural retinal component. If the two components are equal in amplitude, the c-wave will be absent, as observed in some monkeys.<sup>44</sup>

**FIG. 9.6** The components of c-wave of the dark-adapted cat (DC) electroretinogram (ERG): the (sub)components, and correlation of recorded  $[K^+]_o$  and the retinal pigment epithelial (RPE) apical membrane hyperpolarization. Stimuli were 4-second flashes at  $8.3 \log q \text{ deg}^2/\text{s}^2$ . (A) The vitreal c-wave consists of a transepithelial component (TEP c-wave) and a transretinal component (slow PIII). B-wave deflections can be seen in both recordings; the b-wave current generated in neural retina creates a passive voltage drop across the large resistance of the RPE and

sclera. (B) RPE apical membrane and subretinal  $[K^+]_o$  in response to the same stimulus as in part A, recorded in a separate experiment. The apical membrane potential was derived by subtracting an intracellular recording of the basal membrane potential from the transepithelial potential. (Reproduced with permission from Steinberg RH, Linsenmeier RA, Griff ER. Retinal pigment epithelial cell contributions to the electroretinogram and electrooculogram. *Prog Retin Res* 1985;4:33–66.)

There is longstanding evidence that two components of opposite polarity form the ERG c-wave. For example, intravenous injection of sodium iodate in rabbit, which poisons primarily the RPE, abolishes the cornea-positive c-wave and leaves a cornea-negative potential,<sup>45</sup> as occurs in vitro when recording from an isolated neural retina preparation.<sup>46</sup> Microelectrode recordings in retinas of several species,<sup>43</sup> including monkey,<sup>47</sup> have confirmed the presence of the two components. An example of such recordings in intact cat eye is shown in Fig. 9.6. The component from the neural retina is commonly termed slow PIII, to distinguish it from fast PIII, the photoreceptor current. The component from the RPE is the RPE c-wave.

Both slow PIII and the RPE c-wave are responses to the light-evoked decrease in  $[K^+]_o$  in the subretinal space that occurs in response to intense light stimulation of the dark-adapted retina. When measurements of  $[K^+]_o$  were made with ion-selective microelectrodes, either in intact eyes or in vitro preparations, the timecourse of the  $[K^+]_o$  decrease was found to predict that of the ERG c-wave and its component parts (Fig. 9.6). Blocking  $K^+$  conductance (via Kir channels) with various agents eliminated both the slow PIII<sup>48</sup> and the RPE c-wave.<sup>49</sup>

### **Müller Cell Contribution (Slow PIII)**

Intraretinal recording at various depths<sup>50</sup> have shown that slow PIII is generated by a radially oriented current across the neural retina. A Müller cell generator, rather than a neuronal generator, was suggested because slow PIII persisted after treatment with aspartate, a nonselective glutamate agonist, to suppress all

responses of postreceptoral neurons.<sup>51</sup>

Studies in amphibians and mammals have shown that slow PIII is initiated when the distal ends of the Müller cells are passively hyperpolarized by a photoreceptor-dependent decrease in subretinal  $[K^+]_o$ . This sets up a transretinal “ $K^+$  spatial buffer” current,<sup>25</sup> and the current drop across the extracellular resistance produces the slow PIII voltage.<sup>50,52,53</sup> The slow hyperpolarization recorded in Müller cells was observed to be similar in timecourse to both the subretinal  $[K^+]_o$  decrease and to slow PIII.<sup>20,21,53</sup> Further, when  $Ba^{2+}$  was used to block Müller cell Kir channel conductance, slow PIII was suppressed but there was little effect on the light-evoked subretinal  $K^+$  decrease.<sup>22,27,54</sup> Finally, slow PIII was not present in ERGs of mice with the dominant Kir channels (Kir4.1) in Müller cells, genetically inactivated.<sup>28</sup>

## Distal Versus Proximal PIII

Intraretinal depth recordings in isolated rabbit retina have identified a component of similar timecourse and polarity to slow PIII that is eliminated by aspartate, and therefore, unlike slow PIII, is generated by cells proximal to the photoreceptors.<sup>55</sup> Proximal PIII is now thought to originate from Müller cell  $K^+$  currents that flow in the same direction in the retina as slow PIII currents. However, the proximal PIII currents are initiated by an increase in  $[K^+]_o$  due to neuronal activation in proximal retina, rather than the decrease in  $[K^+]_o$  in the subretinal space. The term “proximal PIII” is not commonly used now that responses have been identified that are Müller cell, or perhaps astrocyte-mediated, responses to  $[K^+]_o$  changes in proximal retina, e.g., STR and PhNR (described in later sections).

## Retinal Pigment Epithelial Component

The RPE c-wave is a cornea-positive potential that reflects an increase in the TEP of the RPE, a major component of the standing potential of the eye. The TEP exists because the apical and basal membranes of RPE cells are electrically separated by high-resistance tight junctions that encircle the monolayer of cells (the “R

membrane"). The TEP is equal to the difference between the apical ( $V_{ap}$ ) and basal ( $V_{ba}$ ) membrane potentials.<sup>43</sup>  $V_{ap}$  is generally more hyperpolarized than  $V_{ba}$ , making the TEP cornea-positive. During c-wave generation in response to an increase in light, the TEP increases (becomes even more positive). This is initiated by a hyperpolarization of the apical membrane, and passive shunting of current to the basal membrane, resulting in a (smaller) hyperpolarization of basal membrane, and a greater difference in potential between the two membranes.<sup>43</sup>

As was observed for Müller cells, the slow hyperpolarization of the apical membrane, with its large  $K^+$  conductance,<sup>56</sup> and the RPE c-wave have a timecourse that is very similar to the subretinal  $[K^+]_o$  decrease, as illustrated in Fig. 9.6. In an isolated RPE preparation (where only the apical bath  $[K^+]$  was altered), Oakley et al.<sup>57</sup> demonstrated that the RPE c-wave was due solely to the  $[K^+]_o$  decrease.

## The Fast Oscillation Trough

The FOT (usually measured by EOG) is a change in the corneoretinal potential – it decreases and increases in synchrony with an alternating light/dark stimulus. The response in the dc-ERG that corresponds to the EOG decrease (trough) also is termed the FOT. The FOT response to maintained illumination follows the c-wave peak, and, when a light peak occurs, it appears as a dip between the c-wave and the light peak (Fig. 9.5A).

The FOT originates from both neural retina and RPE. It involves recovery of Müller and RPE cells from their peak polarizations as subretinal  $K^+$  reaccumulates following the reduction in concentration caused by light. This recovery may be greater than predicted by the reaccumulation, particularly for the RPE component. Light initially elicits a hyperpolarization of the apical membrane that increases the TEP and then produces a delayed basal hyperpolarization that decreases the TEP. This extra decrease in TEP underlies most of the cornea-negative potential of the FOT.<sup>43</sup>

The ionic mechanisms of the basal membrane hyperpolarization involve  $Cl^-$  conductances.<sup>58</sup> In intact sheets of RPE/choroid from human fetal eyes, the Miller lab distinguished two types of basal

membrane  $\text{Cl}^-$  channels: a 4,4'-diisothiocyanostilbene-2, 2'-disulfonate (DIDS)-inhibitable  $\text{Ca}^{2+}$ -sensitive  $\text{Cl}^-$  channel, and a cyclic AMP-dependent channel that is inhibited by DIDS as well as by 5-nitro-2-(3phenylpropylamino) benzoate (NPPB), which identifies it as a cystic fibrosis transmembrane regulator (CFTR) channel.<sup>59</sup> In CF patients, the FOT, but not the light peak (see below), is reduced, implicating CFTR in generation of the FOT.

## The Light Peak

Maintained illumination causes a slow increase in the standing potential in the dc-ERG called the light peak that can be recorded as a slow oscillation of the EOG (Fig. 9.6). Intraretinal recordings in several species,<sup>43,58</sup> including monkey,<sup>47</sup> have shown that this cornea-positive potential originates solely from an increase in the TEP (Fig. 9.5A). Intracellular RPE recordings localized the origin of the increase to a slow depolarization of the basal membrane caused by an increase in basal  $\text{Cl}^-$  conductance. In both chick RPE and human RPE cell sheets the  $\text{Cl}^-$  conductance increase was suppressed by DIDS.<sup>58,59</sup> In mouse, the light peak is also dependent on a  $\text{Cl}^-$  conductance, and it is regulated by voltage-dependent  $\text{Ca}^{2+}$  channel CaV1.3 subunits.<sup>60</sup>

Although the light peak voltage originates from the RPE basal membrane, it is initiated in neural retina via the photoreceptors.<sup>61</sup> Light stimulation leads to a change in concentration of a "light peak substance" which then affects the basal membrane via a second-messenger system. The identities of the "light peak substance" and the second messenger(s) involved in producing the light peak are unresolved. Although dopamine affected the light peak in the perfused cat eye,<sup>62</sup> studies in chick did not support its being the "light peak substance."<sup>61</sup> Epinephrine also has been proposed as a candidate, and a role for ligands binding to adrenergic alpha-1 receptors on the apical membrane is likely.<sup>59</sup> Cyclic AMP has been investigated as a second messenger in light peak generation but, as described above, it may be involved in generation of the FOT, rather than the light peak.<sup>59</sup>

## Origin of the a-Wave

Fig. 9.7 shows the dark- and light-adapted flash ERG of macaque monkey, a good animal model for studying the origins of the human response, as illustrated in Fig. 9.1. The a-wave in the dark-adapted ERG is the initial negative wave that occurs in response to strong stimuli from darkness (Fig. 9.7, top left column) and it is primarily rod-driven (scotopic), but contains a cone contribution when flashes are very strong. When the background is rod-saturating the a-wave is cone-driven (photopic; right column). Under both dark- and light-adapted conditions, the a-wave is followed by the rise of the positive-going b-wave that originates primarily from ON bipolar cells,<sup>30</sup> as reviewed below. The slow negative wave in the dark-adapted ERG in response to the weakest stimuli, called the STR, is not the a-wave, but instead is initiated by amacrine and/or ganglion cell activity. This is known because STR is eliminated when postreceptoral activity is blocked pharmacologically.<sup>63,64</sup>

**FIG. 9.7** Dark- and light-adapted electroretinograms (ERGs) of the macaque retina. (Left) Dark-adapted full-field ERGs of anesthetized macaque monkeys were measured in response to brief (<5 ms) flashes from darkness generated by computer-controlled light-emitting diodes (LEDs). Responses were recorded differentially between DTL fibers on the two eyes. Flash strength was increased over a 6-log-unit range. Responses to the weakest stimuli were rod-driven (scotopic), whereas for the strongest stimuli there were mixed rod–cone responses. (Right) Light-adapted full-field ERGs of anesthetized macaques were measured using Burian–Allen electrodes. Stimulus strength was controlled with neutral-density (ND) filters. Stimulus strength increased over a 1.3-log-unit range to a maximum at 0 ND of 4.0 log ph td for 220-ms flashes. Stimuli were presented on a steady rod-saturating background of 3.3 log sc td. The 20  $\mu$ V calibration bar applies both to the dark-adapted ERG responses to weak stimuli and to the light-adapted ERGs. (Left panel reproduced with permission from Robson JG, Frishman LJ. Dissecting the dark-adapted electroretinogram. *Doc Ophthalmol* 1998;95:187–215. Right panel reproduced with permission from Sieving PA, Murayama K, Naarendorp F. Push–pull mode of the primate photopic electroretinogram: a role for hyperpolarizing neurons in shaping the b-wave. *Vis Neurosci* 1994;11:519–32.)

## The a-Wave as a Reflection of Rod and Cone Receptor Currents

Early intraretinal depth studies in intact cat eyes<sup>13,65</sup> found that the signal at the timecourse of the a-wave was largest in the vicinity of the photoreceptors. The case for a receptor origin for PIII was strengthened by microelectrode recordings in macaque monkey retina, with the inner retinal circulation clamped to suppress retinal activity proximal to the photoreceptors.<sup>66</sup>

Penn and Hagins<sup>67</sup> in CSD analyses of the isolated rat retina demonstrated that light suppressed the circulating (dark) current of the photoreceptors, and proposed that this suppression was seen in the ERG as the a-wave. Fig. 9.8 provides a schematic of the photoreceptor layer current from a review by Pugh et al.<sup>68</sup> The

figure shows that, in the dark, cation channels ( $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{Mg}^{2+}$ ) in the receptor outer segment (ROS) are open, current flows into the ROS (a current sink with respect to the ECS), and  $\text{K}^+$  leaks out of the inner segment (a current source), creating dipole current. This dipole current produces a corneal (and vitreal) potential that is positive with respect to the scleral side of the retina. Suppression of the dark current reduces the cornea-positive potential, creating the negative-going a-wave. Consistent with this view, as illustrated in Fig. 9.9, intraretinal recordings and CSD analyses in the intact macaque retina have localized current sources and sinks for a local potential, corresponding to the a-wave, to the distal third of the retina.<sup>18</sup>

**FIG. 9.8** Schematic of a longitudinal section of the mammalian retina illustrating how circulating currents in the photoreceptor layer create an extracellular field potential, in which the vitreal side of the retina has a more positive potential than the scleral side. A very bright flash will suppress the circulating current around the photoreceptor, leading to a vitreal or corneal response which is negative relative to the resting preflash baseline. (Reproduced with permission from Pugh EN Jr., Falsini B, Lyubarsky A. The origin of the major rod- and cone-driven components of the rodent electroretinogram and the effects of age and light-rearing history on the magnitude of these components. Photostasis and related phenomena. New York: Plenum Press; 1998. p 93–128.)

**FIG. 9.9** Depth profiles and current source density results in anesthetized macaque monkey retina for the a-wave and the b-wave. (Left) Monopolar depth profiles using an intraretinal microelectrode referenced to the forehead. (Right) Bipolar depth profiles using a coaxial electrode with a distance of 25  $\mu\text{m}$  between the tips to measure field potential amplitudes at the peak time of the receptor component, the b-wave and the dc component of the macaque light-adapted electroretinogram. The pluses and minuses indicate the current sources (+) and sinks (–) for the components, as calculated from current source density analyses based on the coaxial electrode recordings and resistance measurements. The a-wave source and sink are in the distal quarter of the retina. The b-wave has a large sink near the outer nuclear layer and a distributed source extending to the vitreal surface of the retina. Plots represent means of 26 penetrations.

(Adapted from Heynen H, van Norren D. Origin of the electroretinogram in the intact macaque eye – II. Current source-density analysis. *Vision Res* 1985;25:709–

15.)

Hood and Birch<sup>38</sup> sought to relate the timecourse of the leading edge of the ERG a-wave directly to the leading edge of the photoreceptor outer-segment response to light. They demonstrated that both the linear and the nonlinear (i.e., saturating) behavior of

the leading edge of the a-wave in the human ERG was reasonably well predicted by a model of photoreceptor function derived from in vitro suction electrode recordings of currents around the outer segments of primate rod photoreceptors.<sup>69</sup> Subsequently a simplified kinetic model of the leading edge of the photoreceptor response (in vitro current recordings) that took into account the stages of the biochemical phototransduction cascade was developed by Lamb and Pugh.<sup>70</sup> This model could be fit to the leading edge of the human a-wave generated by strong stimuli and it has been used in noninvasive studies of human rod<sup>36,71</sup> and cone photoreceptor<sup>72</sup> function. More recent analyses suggest that the a-wave generated in response to strong stimuli reflects additional currents associated with more proximal regions of the photoreceptor cell, including capacitive currents in the outer nuclear layer, that form a transient “nose” on the leading edge of the response that quickly relaxes to the level of the photocurrent.<sup>39</sup>

## Postreceptoral Contributions to the a-Wave

The receptor origins of the a-wave (Granit's PIII),<sup>32</sup> as well as postreceptoral contributions of similar timecourse, have been clarified in pharmacologic studies. In early in vitro studies of the isolated retina (amphibian and human), the nonspecific glutamate agonist aspartate in the perfusate suppressed all postreceptoral responses, and isolated the a-wave, revealing its presence under the b-wave.<sup>51,73</sup> Our understanding of the receptor and postreceptoral contributions to the light-adapted a-wave, as well as other waves of the macaque monkey photopic ERG, was greatly advanced by studies of Sieving and colleagues in which they utilized more specific glutamate analogs than aspartate to dissect retinal circuits, and particularly ON versus OFF circuits set up by depolarizing and hyperpolarizing bipolar cells, respectively (Fig. 9.2).<sup>33,35</sup> They made intravitreal injections in anesthetized macaques of an mGluR6 receptor agonist, 2-amino-4-phosphonobutyric acid (APB, L isomer, also called L-AP4) to block metabotropic glutamatergic neurotransmission to depolarizing (ON) bipolar cells. This eliminated light-evoked responses of ON bipolar cells as well as contributions from more proximal cells of the retinal ON pathway.

Alternatively, they injected *cis*-2,3-piperidine dicarboxylic acid (PDA) (or kynurenic acid) to block major ionotropic glutamate receptors in the retina ( $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate receptors).<sup>74</sup> These ionotropic receptors, blocked by PDA, mediate signal transmission to hyperpolarizing (OFF) bipolar cells and horizontal (Hz) cells, as well as to amacrine and ganglion cells of both OFF and ON pathways. Results of such experiments are illustrated in [Fig. 9.10A](#) for responses to fairly weak stimuli presented on a rod-suppressing background; functions relating a-wave amplitude and stimulus strength over a wider range of stimuli in the same study are shown in [Fig. 9.10B](#). The a-wave was reduced in amplitude by PDA (or kynurenic acid, not shown), but not by APB. [Fig. 9.10](#) also shows that PDA had a similar effect to that of aspartate, or to cobalt ( $\text{Co}^{2+}$ ), which was used to block the voltage-gated  $\text{Ca}^{2+}$  channels which are essential for vesicular release of glutamate.

**FIG. 9.10** Postreceptoral contributions to the a-wave of the macaque electroretinogram (ERG). (A) Comparison of the effects of 2-amino-4-phosphonobutyric acid (APB:1 mM vitreal

concentration) and APB + *cis*-2,3-piperidine dicarboxylic acid (PDA: 5 mM) with those of aspartate (50 mM) and cobalt (10 mM,  $\text{CO}^{2+}$ ) on the photopic ERG a-wave of three different eyes of two anesthetized monkeys. The inset at the top shows the response of eye number 1 to the 200-ms stimulus of 3.76 log td (2.01 log  $\text{cd}/\text{m}^2$ ) on a steady background of 3.3 log td (1.55  $\text{cd}/\text{m}^2$ ). The a-waves for eyes 1, 2, and 3 were all in response to the same stimulus. For this stimulus, most of the small a-wave (10  $\mu\text{V}$ ) that was elicited was postreceptoral in origin. In the clinic the a-wave elicited by brief flashes often is larger, 20  $\mu\text{V}$  or more, and therefore also will include several microvolts of photoreceptor contribution, as shown in part B. (B) Stimulus response function (V log I plot) of the photopic a-wave of the macaque measured at times corresponding to the a-wave peak in the control responses (*filled circles*). Amplitudes after APB (*open circles*) and after APB + PDA (*triangles*) were measured at the same latency as the trough of the control a-waves measured at the same stimulus intensity. The points are connected by solid lines. In this figure, as in part A, APB had no effect on the a-wave amplitude. In contrast, PDA reduced the amplitude, and the postreceptoral contribution was maximally between 10 and 15  $\mu\text{V}$ , about 50% of a 20  $\mu\text{V}$  a-wave, but less than 25% of a saturated a-wave of about 65  $\mu\text{V}$ . (Reproduced with permission from Bush RA, Sieving PA. A proximal retinal component in the primate photopic ERG a-wave. Invest Ophthalmol Vis Sci 1994;35:635–45.)

When the effects of PDA versus APB on the photopic a-wave amplitude were evaluated over a wider range of stimuli, PDA-sensitive postreceptoral neurons, rather than photoreceptors, or APB-sensitive contributions from ON pathway, were found to generate the leading edge for the first 1.5 log units of flash strengths that elicited a measurable a-wave (Fig. 9.10B). Postreceptoral cells in the OFF pathway and inner retina continued to contribute 10–15  $\mu\text{V}$  to the total a-wave amplitude when photoreceptor contributions also were present. Postreceptoral contributions to the a-wave in alert humans have also been demonstrated, by analysis of ERGs.<sup>75</sup>

Postreceptoral contributions to the dark-adapted a-wave have

been observed as well in the monkey.<sup>34,76</sup> For weak to moderate stimuli from darkness, a-waves are dominated by rod signals, but a strong flash elicits a mixed rod–cone ERG like the macaque ERG illustrated in Fig. 9.11. To study purely rod-driven responses it is therefore necessary to separate the rod- and cone-driven responses to strong stimuli when investigating their relative contributions to the ERG.

**FIG. 9.11** Dark-adapted electroretinogram (ERG) of a macaque showing the mixed rod–cone a-wave and separate components measured (symbols) and modeled (solid lines fit to the leading edge of the a-wave) for two stimulus strengths. (A) Responses of an anesthetized macaque to a brief blue light-emitting diode (LED) flash of 188 sc td/s (57 ph td/s) and (B) responses to a xenon white flash of 59, 000 sc td/s (34, 000 ph td/s). In both parts, the largest response (*open circles* panel A, *solid red circles* panel B) is the entire mixed rod–cone a-wave; the black solid line restricted to the leading edge shows the modeled mixed rod–cone response. The second largest response is the (isolated) rod-driven response (*red filled symbols* panel A, *blue symbols* panel B); the

black dot—dash line through the leading edge is the modeled rod photoreceptor contribution. The second to smallest response (*green symbols*) is the (isolated) cone-driven response, including the postreceptoral contribution; the black dashed line through the leading edge shows the modeled cone-driven response. The smallest response (*black dotted line*) is the modeled cone photoreceptor contribution, based on post *cis*-2,3-piperidine dicarboxylic acid (PDA) findings for the cone-driven response. Given the animal's 8.5-mm pupil, the stimulus for part A was about 1 cd s/m<sup>2</sup>, i.e., about three times less intense (for cones) than International Society for the Clinical Electrophysiology of Vision (ISCEV) standard flash of 3 cd s/m<sup>2</sup>, whereas the stimulus for part B is about 2000 times stronger. ISCEV also suggests flashes of 10 and 30 cd s/m<sup>2</sup> for mixed rod–cone ERG. (Adapted from Robson JG, Saszik SM, Ahmed J, et al. Rod and cone contributions to the a-wave of the electroretinogram of the macaque. *J Physiol* 2003;547:509–30.)

The rod-driven response can be extracted by subtracting the isolated cone-driven response to the same stimulus from the mixed rod–cone response. Isolated cone-driven responses in [Fig. 9.11](#) (*green triangles*) were obtained by briefly suppressing the rod response with an adapting flash, and then measuring the response to the original test stimulus presented a few hundred milliseconds (300 ms) after offset of the adapting flash. Cone-driven responses in primates recover to full amplitude within about 300 ms whereas rod-driven responses take at least a second, making it possible to isolate the cone-driven response.<sup>34</sup>

The effect of PDA on the rod-isolated a-wave of the macaque is shown in [Fig. 9.12](#) for a range of stimulus strengths.<sup>34</sup> Most of the leading edge of the a-wave in response to the weakest stimulus was eliminated ([Fig. 9.12A](#)), and much of the leading edge that occurred later than 15 ms after the flash was removed in response to stronger stimuli ([Fig. 9.12B](#)), and even for stimuli that saturated the response (not shown). When APB was injected along with PDA, to eliminate remaining ON bipolar cell contributions as well ([Fig. 9.13B](#)), the shape of the early portion of PIII could be seen to form a nose, generally obscured by negative-going signals removed by PDA,

and the b-wave removed by APB (Fig. 9.12C).

**FIG. 9.12** Postreceptoral contribution to rod-driven dark-adapted macaque electroretinogram (ERG). Rod-driven responses from an anesthetized macaque were obtained after subtracting isolated cone-driven response from the mixed rod–cone ERG. Rod-driven responses are shown to a range of stimulus energies (15.8–509 sc td/s) before (A) and after (B) intravitreal injection of *cis*-2,3-piperidine dicarboxylic acid (PDA) (4 mM). For comparison, the ERG remaining after adding PDA and 2-amino-4-phosphonobutyric acid (APB) is shown in part C. The stimulus was a xenon white flash of 59 000 sc td/s, and cone signals were

not removed in this recording. The control response in part C is shown by the *green line*, the post PDA+APB by the *dashed black line*. (Panels A and B, adapted from Robson JG, Saszik SM, Ahmed J, et al. Rod and cone contributions to the a-wave of the electroretinogram of the macaque. J Physiol 2003;547:509–30; C, from unpublished data.)

**FIG. 9.13** Dark-adapted electroretinogram response of the anesthetized macaque monkey to three different test stimulus strengths (0.28, 1.24, and 6.86 sc td/s) and the derived rod photoreceptor response for each test stimulus. The photoreceptor response was derived using the paired-flash approach of Pepperberg et al.,<sup>78</sup> in which a rod-saturating probe flash follows a test flash at fixed intervals after its onset, and the residual response of the probe is subtracted from the probe alone to derive the rod receptor response at each time point (data points). The model lines used modifications of equations from Robson et al.<sup>34</sup> (From Frishman LJ, Robson JG, unpublished observations.)

PDA blocks signal transmission not only to hyperpolarizing bipolar and horizontal cells, but also to amacrine and ganglion cells of the inner retina. In order to test whether the effect of PDA on the a-wave was due to OFF bipolar cells or more proximal cells, it was

necessary selectively to suppress amacrine and ganglion cell activity. This was done using *N*-methyl-D-aspartate (NMDA), as only the proximal retinal neurons have functional NMDA (ionotropic glutamate) receptors. Results (not shown) were similar in the dark-adapted ERG to those after PDA alone, indicating a proximal retinal origin for most of the rod-driven postreceptoral contributions to the dark-adapted a-wave, rather than a contribution from OFF bipolar cells.<sup>77</sup>

## The Timecourse of the Photoreceptor Response

The leading edge of the a-wave is the only visible portion of the photoreceptor response in the normal ERG. In order to see the entire timecourse of the photoreceptor response it is necessary to remove postreceptoral contributions, as was done pharmacologically for the ERGs in [Figs. 9.11](#) and [9.12](#). However, such a manipulation is invasive, and does not eliminate slow PIII and the c-wave, should they be present. Another approach is to use the paired-flash technique developed by Pepperberg and colleagues<sup>78</sup> to derive, *in vivo*, the photoreceptor response. The derived photoreceptor response (underneath) and the full ERG responses to three stimuli of the same strength are shown for a macaque monkey in [Fig. 9.13](#). The timecourse of the derived response is similar to that of current recordings *in vitro* from individual rod photoreceptor outer segments in the macaque, although it reaches its peak a little earlier *in vivo* in the ERG than *in vitro*. However, the amplitude of the derived response is rather large, perhaps twice that expected for the photocurrent. The large amplitude of the derived response may occur because the method for deriving responses uses measurements in the “nose” portion of saturated a-wave ([Fig. 9.12C](#)), which reflects currents from more proximal regions of the photoreceptor in addition to outer-segment currents.<sup>39</sup>

## Origin of the b-Wave

The cornea-positive b-wave, Granit's PII, is the largest component

of the dark-adapted diffuse-flash ERG. There is general consensus that the neuronal generator of the b-wave is primarily the depolarizing (ON) bipolar cells.<sup>30,31,79,80</sup> APB (L-AP4), which binds to mGluR6 receptors of ON bipolar cells and removed the cone b-wave in experiments of Sieving et al., also removed the dark-adapted b-wave in several species, including primates.<sup>30,80</sup> The b-wave is also absent, causing a negative ERG (Fig. 9.12C). Negative ERGs also occur in patients and murine models with complete congenital stationary night blindness (cCSNB) who have mutations that cause a breakdown of the signal transduction cascade in ON bipolar cells.<sup>81,82</sup> However, experimental support also exists for a Müller cell contribution, likely due to K<sup>+</sup> currents as a consequence of bipolar cell depolarization, particularly at times past the leading edge of the response, as described below.

Resolving the role of bipolar cells and Müller cells in generating the b-wave has been difficult. Early intraretinal depth recordings demonstrated a negative-going intraretinal b-wave with a (negative) peak amplitude in distal retina, near the outer plexiform layer (OPL), and the largest change in amplitude across the inner nuclear layer (INL).<sup>13,65</sup> These results suggested that the b-wave was generated by current flowing through a radially oriented cell that acted as a dipole. Bipolar cells, the only radially oriented neurons that span the INL, and Müller cells, the radially oriented glial cells, were implicated.

## Müller Cell Hypothesis

CSD profiles for the b-wave from intraretinal recordings in frog retina<sup>83</sup> showed an OPL current sink and a current source extending from the OPL almost all the way to the vitreal surface, and this also was found in monkey retina (Fig. 9.9).<sup>18</sup> Due to the extensive radial spread of sinks and sources, it was hypothesized that Müller cells generate b-wave currents, and supporting this, Miller and Dowling<sup>84</sup> found that intracellular recordings of Müller cell responses in amphibian resembled b-wave responses to the same stimuli. However, studies of local changes in [K<sup>+</sup>]<sub>o</sub> and Müller K<sup>+</sup> conductances were not fully consistent with the Müller cell hypothesis.

Measurements using intraretinal  $K^+$ -selective microelectrodes of local changes in light-evoked  $[K^+]_o$  skate,<sup>85</sup> amphibian,<sup>20,86</sup> and rabbit<sup>21</sup> retinas demonstrated only small transient  $[K^+]_o$  increases in the OPL at light onset, presumably from dendrites of ON bipolar cells. The Müller cell hypothesis required a large sink activity in the OPL. In contrast, a large sustained inner plexiform layer (IPL)  $[K^+]_o$  increase was recorded in the proximal retina of several species at the onset, or at onset and offset of a light stimulus.<sup>87</sup> The large proximal  $[K^+]_o$  increase reflected activation of amacrine and ganglion cells as well, and is now understood to contribute strongly to Müller cell or astrocyte-mediated ERG components of proximal retinal origin, e.g., M-wave, STR, or PhNR.

As described in the section on spatial buffering above, the selective permeability of the Müller cell membrane to  $K^+$  and the nonuniform distribution of  $K^+$  conductances (Fig. 9.3) provide the opportunity for  $K^+$  siphoning from synaptic layers where  $[K^+]_o$  is high to regions of lower  $[K^+]_o$ . In species with avascular retinas, e.g., amphibian and rabbit, the Müller cell endfoot adjacent to the vitreous has more than 90% of the  $K^+$  conductance in the cell, as shown in the Newman lab study of enzymatically isolated Müller cells subjected to puffs of  $K^+$  (Fig. 9.14).  $K^+$  entering the Müller cell via strongly inward rectifying Kir channels in synaptic regions will exit predominantly from the vitreal endfoot where the  $K^+$  conductance is only weakly rectifying (Fig. 9.3).<sup>28</sup> The OPL  $[K^+]_o$  increase could establish a current loop that extends all the way to the vitreal surface. The IPL  $[K^+]_o$  increase would contribute to the same current loop, creating a vitreal positive proximally generated potential in addition to the bipolar cell-dependent b-wave. However, as noted above, the OPL increases in  $[K^+]_o$  were small, and because of this, did not predict the large b-wave recorded in the ERG.

**FIG. 9.14** Distribution of  $K^+$  conductance over the surface of enzymatically dissociated Müller glia cells. The magnitude of depolarizations in response to focal  $K^+$  ejections is plotted as a function of ejection location along the Müller cell surface. Responses are normalized to response magnitude at the endfoot. In species with avascular retinas (salamander, rabbit, guinea pig),  $K^+$  conductance is largest at the endfoot. In vascularized species, conductance is largest nearer the cell soma and retinal capillaries (mouse, monkey) or at the distal end of the cell (cat). (Reproduced with permission from Newman EA. Distribution of potassium conductance in mammalian Müller (glial) cells: a comparative study. *J Neurosci* 1987;7:2423–32.)

In contrast, in species with vascularized retinas such as mouse and monkey,  $K^+$  conductance, although high at the endfoot, is greatest in the INL, near capillaries. In cat,  $K^+$  conductance is greatest near the subretinal space (Fig. 9.14). In these species with vascularized retinas the Müller cell current that arises as a consequence of the proximal  $[K^+]_o$  increase contributes to a distally directed current loop (like slow PIII), thereby producing a cornea-negative potential (e.g., m-wave or negative STR), rather than positive b-wave.

## ON Bipolar Cells as the Generator of the b-Wave

Experiments using  $Ba^{2+}$  to block Kir channels have not supported the Müller cell hypothesis for generation of the b-wave. Although  $Ba^{2+}$  blocks slow PIII<sup>48</sup> as well other responses associated with Müller cell  $K^+$  currents, it is far less effective in blocking the b-wave.<sup>23,54,88,89</sup> In CSD studies in frog<sup>88</sup> and rabbit,<sup>89</sup> only the proximal sink source activity associated with the inner retinal M-wave was removed by  $Ba^{2+}$ . At least two-thirds of the OPL sink was retained, and the IPL source involved in generating the b-wave was enhanced. These results indicated that the major b-wave generator is the bipolar cell itself.

### Scotopic b-Wave (PII) in Mammals

In the mammalian retina, the scotopic ERG response to weak stimuli reflects activity of the sensitive primary rod circuit, including rods, the main interneuron, rod bipolar cells, AII amacrine cells, cone bipolar cell terminals, and ganglion cells (Fig. 9.2). Given the simplicity of the circuit, with contributions from amacrine and ganglion cells pharmacologically suppressed, the isolated b-wave (Granit's PII) should reflect the rod bipolar cell response, either directly as the bipolar cell current, or via Müller cell  $K^+$  currents resulting from  $K^+$  outflow from bipolar cells. Only for strong stimuli would the underlying photoreceptor PIII be a significant factor in the ERG. Fig. 9.15A shows pharmacologically isolated PII from ERGs, recorded in vivo, of four normal C57BL/6 mice, in response to a weak stimulus. An intravitreal injection of the inhibitory neurotransmitter  $\gamma$ -aminobutyric acid (GABA) was used to suppress inner retinal activity.<sup>31,90</sup> Also included in the figure is PII isolated from human ERG using weak adapting backgrounds to suppress the very sensitive STRs.<sup>91</sup> The isolated PII responses have been superimposed on an average of several patch electrode current recordings in a mouse retinal slice preparation of rod bipolar cell responses to a stimulus of similar effect on the rods. The timecourse of the ERG and the single cell currents is very similar, supporting the view that isolated PII reflects rod bipolar cell activity. If Müller cell currents had generated PII, the signal would have been delayed

relative to the bipolar cell responses recorded in the slice, due to the time necessary for accumulation of  $K^+$  ions in the ECS.

**FIG. 9.15** Rod bipolar cell component (PII) of the dark-adapted electroretinogram (ERG) of mouse, cat, and human. (A) Comparison of rod bipolar cell current from patch recordings in mouse retinal slice (courtesy of F. Rieke) with isolated PII (by weak light adaptation) from humans, isolated PII from ERGs of six C57BL/6 mice by intravitreal injection of  $\gamma$ -aminobutyric acid (GABA: 32–46 mM) and additionally from a  $Cx36^{(-/-)}$  mouse lacking ganglion cells and the scotopic threshold responses. (B) Pharmacologically isolated cat PII (by inner retinal blockade). The response has been analyzed into a fast component, proposed to be a direct reflection of the postsynaptic current, and a slow component, that is a low-pass filtered version of the faster component, believed to be the Müller cell response, contributing mainly to the tail of the response. Identification of the Müller cell component is supported by the observation (shown in the inset) that intravitreal injection of  $Ba^{2+}$ , used to block Kir channels in Müller cells removed a similar portion of the total PII response. For stronger stimuli, in order to isolate the bipolar cell response, it would be necessary also to remove the underlying negative (photoreceptor) PIII signal.

(Panel A reproduced with permission from Cameron AM, Mahroo OA, Lamb TD. Dark adaptation of human rod bipolar cells measured from the b-wave of the scotopic electroretinogram. *J Physiol* 2006;575:507–26. Panel B reproduced with permission from Robson JG, Frishman LJ. Dissecting the dark-adapted

Pharmacologically isolated PII of cat (Fig. 9.15B) revealed a response similar to that in mouse in its rising phase, but recovered more slowly to baseline. The cat PII response to a brief flash can be analyzed into a fast component and a slow component that is a low-pass filtered version of the fast component, as indicated by the lines in Fig. 9.15B. The inset to Fig. 9.15B shows that intravitreal Ba<sup>2+</sup> eliminated a slow portion of the response that was very similar in timecourse to the modeled slow component, but did not alter the fast component, suggesting that bipolar cell current provides the leading edge of PII in the cat, and the Müller cell current contributes at later times. Although the slow component (in response to a brief flash) was lower in amplitude than the fast component, the area under the two curves was similar. With longer stimulus durations such as those used in early studies of the b-wave origins, the contribution to the ERG of the two sources would be about equal.<sup>85</sup> Pharmacologic isolation of macaque PII showed a similar waveform to that in cat.<sup>3</sup>

### Cone-Driven b-Wave

The photopic ERG is commonly measured in the presence of a rod-suppressing background. Depth profiles of the rod b-wave measured under dark-adapted conditions and the cone b-wave, under light-adapted conditions, are similar in cat<sup>92,93</sup> and monkey retinas, suggesting a similar origin for the two responses, but in the case of the photopic ERG, depolarizing cone rather than rod bipolar cells are involved.

Sieving and colleagues<sup>33,35</sup> studied the origins of the photopic b-wave in monkeys using glutamate analogs in the same series of experiments as those in which the a-wave was studied. Fig. 9.16 shows the macaque photopic ERG response to long-duration flashes, before and after APB was injected into the vitreal cavity (eye 1, left panel). APB removed the transient b-wave supporting ON bipolar cells as the generators (although the possibility of glial mediation was not eliminated in these studies). However, when PDA was injected first in another eye (eye 2, right panel), to remove

the OFF pathway (and horizontal cell inhibitory feedback), a much larger and more sustained b-wave was revealed. These findings indicate that the normally transient nature of the cone b-wave is due to truncation of a more prolonged depolarizing bipolar cell response. This truncation is due to some combination of (PDA-sensitive) OFF pathway response of opposite polarity to the ON bipolar cell contribution to the ERG (a push-pull effect<sup>28</sup>), and inhibition via (PDA-sensitive) horizontal cells of ON bipolar cell signals. The isolated photoreceptor response remaining after all postreceptoral activity was eliminated either by APB followed by PDA, or PDA followed by APB, was similar.

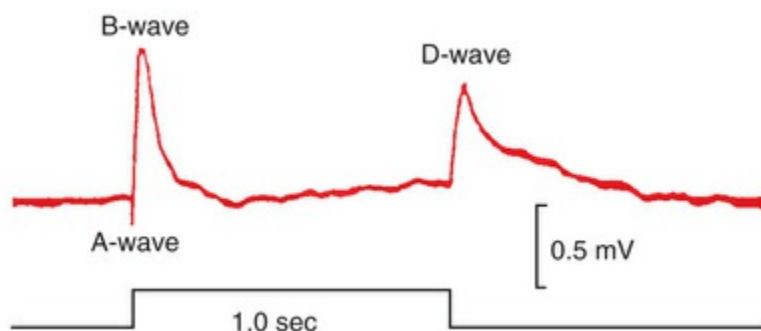

**FIG. 9.16** Effects of 2-amino-4-phosphonobutyric acid (APB) and *cis*-2,3-piperidine dicarboxylic acid (PDA) on the light-adapted photopic electroretinogram of a monkey's two eyes. Drugs were given sequentially, APB followed by PDA for eye 1, and PDA followed by APB for eye 2. The vertical line shows the time of the a-wave trough in the control response. The 200-ms stimulus was 3.76 log td (2.01 log cd/m<sup>2</sup>) on a steady rod-saturating background of 3.3 log td (1.55 cd/m<sup>2</sup>).

(Reproduced with permission from Bush RA, Sieving PA. A proximal retinal component in the primate photopic ERG a-wave. *Invest. Ophthalmol Vis Sci* 1994;35:635-45.)

## Origin of the d-Wave

The d-wave is a positive-going deflection at light offset that occurs in the photopic ERG. It is best seen when the light step is prolonged. In mammals, the d-wave is very prominent in the all-cone retina of the ground squirrel, as seen in the response to a long-duration stimulus in Fig. 9.17, and in the monkey retina, with its mixture of rods and cones, the d-wave, although less prominent, is easily identified when stimulus duration is extended, e.g., Figs. 9.1 and 9.9. Although d-waves have been described in scotopic ERG of mammals, they are probably not “true” d-waves that, as described below, include a strong contribution from the offset of the cone photoreceptor, and the depolarization at light offset of OFF cone bipolar cells. In the predominantly rod-driven cat ERG, the small positive deflection that Granit<sup>32</sup> called a “d-wave” occurred only in response to offset of very intense and long-duration stimuli for which the decay of the rod receptor potential appeared as a small positive deflection that followed, at light offset, the negative-going offset of PII.

**FIG. 9.17** Electroretinogram from the all-cone retina of the ground squirrel in response to a 1-second light step. Recordings were made under light-adapted conditions between a contact lens electrode on the cornea and an electrode on the forehead. (Reproduced with permission from Arden GB, Tansley K. The spectral sensitivity of the pure-cone retina of the grey squirrel (*Sciurus carolinensis leucotis*). *J Physiol* 1955;127:592–602.)

Intraretinal analysis in monkey retina indicated that the corneal

d-wave represents a combination of the rapid positive-going offset of the cone receptor potential followed by the negative-going offset of the b-wave.<sup>16,66</sup> Although the early work on primate ERG cited above did not identify OFF bipolar cells as major contributors to the d-wave, more recent studies using intravitreal injection of glutamate analogs have demonstrated that these cells provide a significant portion of the response.<sup>35,94</sup> Figs. 9.10 and 9.16 both show that PDA, which blocks OFF bipolar cell responses, reduced the d-wave, eliminating it entirely when a large b-wave was present. The effect of PDA was not replicated by NMDA blockade of inner retinal cells, that also would have been affected by PDA, confirming a role of the OFF bipolar cells themselves. PDA, but not the blockade of inner retinal cells, also eliminated a small positive wave that occurs in the falling phase of the b-wave, or just after it, in the brief flash ERG in monkeys and humans, called the “i-wave.”<sup>95</sup>

## Photopic Hill

The stimulus response function acquired by measuring b-wave peak amplitudes in response to brief flashes over a range of increasing stimulus strengths has a characteristic inverted “U” shape. More specifically, Peachey et al.<sup>96</sup> observed that the b-wave amplitude increased with increasing stimulus strength until it reached a peak and then decreased for stronger stimuli. This function was later named the “photopic hill” by Wali and Leguire.<sup>97</sup> A model of the stimulus response function has indicated that the positive peak of the function is formed by addition of a saturating b-wave from ON pathway,<sup>98</sup> and an early d-wave from OFF pathway, and this has been confirmed in experiments using glutamate analogs in macaques.<sup>99</sup>

## Origin of the Photopic Fast-Flicker ERG

The fast-flicker ERG (nominally 30 Hz flicker) is used to examine cone-driven responses in humans because rod-driven responses generally do not respond to fast flicker. For many years the human

(or macaque) photopic ERG response to fast-flickering stimuli was believed to reflect primarily the response of cone photoreceptors. However pharmacologic dissection studies have shown that most of the fast-flicker response seen clinically with a full-field stimulus (or focal stimulus) is generated postreceptorally.

Bush and Sieving<sup>100</sup> used glutamate analogs to remove selectively postreceptor ON and OFF pathway responses, as was done in studies of a-, b-, and d-waves. Intravitreal injection of APB to remove the b-wave left a delayed flicker response, reflecting OFF bipolar contribution. When both APB and PDA were used, the flicker response was practically eliminated. From experiments of this type they concluded that postreceptor cells that normally produce the b- and d-waves are strong contributors to the fast-flicker response. Further experiments in macaques have more thoroughly investigated the interaction of the ON and OFF pathways over a wide range of temporal frequencies and stimulus conditions.<sup>101</sup> The amplitude in both humans and macaques dips around 12 Hz, as ON and OFF inputs cancel, and it reaches a peak around 50 Hz. Other studies have demonstrated a small inner retinal contribution to the flicker response, and particularly to the second harmonic component of the response, which has a strong input from TTX-sensitive sodium-dependent spiking activity of ganglion and perhaps amacrine cells.<sup>102</sup>

## Origin of the Multifocal ERG

Multifocal electroretinography (mfERG) was developed by Sutter and Tran<sup>103</sup> as a means of recording many focal retinal responses simultaneously in a brief time period (e.g., 7 minutes) to achieve a topographical array of little ERGs. Recording ERGs from many different focal regions of the retina otherwise would be impractical, due to the time involved in averaging of the small signals. The common mfERG stimulus is an array of hexagons (e.g., 64 or 103 hexagons over 30–40° of central visual field). In the standard mode for stimulation each hexagon reverses in contrast, according to a predetermined random “m-sequence,” at the frame rate of the visual display monitor, often 75 Hz for CRTs and 60 Hz for LCD displays. At any given time, each hexagon has a 50% chance of

being light or dark. The m-sequence for all hexagons is the same, except for a specific and unique lag (number of frames) in initiation of the sequence for each hexagon, to allow extraction of the locally generated response by a correlation approach. The resulting “first-order” focal ERGs to the rapidly changing stimulation look similar but not identical to full-field flash ERGs that integrate responses over a longer period of time. The mfERG is generally recorded under photopic conditions, for which the foveal response is large, and is useful for detecting local changes in function that may not be detected in a full-field ERG, such as those that occur in macular dystrophies.

Experiments using intravitreal injections of glutamate analogs, APB, and PDA in macaques showed that, despite differences in the mfERG and full-field flash ERG, the cellular origins of the major negative and positive waves are essentially the same in two types of ERG.<sup>104</sup> The outcome of such experiments is shown in [Fig. 9.18](#), where the findings from the experiments on macaque mfERG were applied to the human response. When blank frames were interposed so that flashes occurred every 100 or 200 ms, a complete ERG including OPs could form before the next m-frame. For this slow-sequence ERG, experiments in macaques again yielded origins similar to full-field flash ERG, and provided some evidence for spike-dependent oscillatory activity related to the optic nerve head component in the mfERG, proposed by Sutter and Bearse.<sup>105-107</sup>

## ERG Waves From Proximal Retina

### Origin of the Proximal Negative Response and the M-Wave

The proximal negative response (PNR) is a light-evoked field potential recorded intraretinally in proximal retina, named and most fully described by Burkhardt.<sup>108</sup> The PNR consists of a sharp, negative-going transient at onset and again at offset of a small light spot centered on the microelectrode tip placed in the IPL. It can be recorded in a range of vertebrate retinas, including the cat<sup>109</sup> and primate.<sup>110</sup> A PNR contribution to the transretinal ERG is necessarily small because the intraretinal response, which is largest in response to small spots, will be shunted through adjacent low-resistance retinal regions that are not activated by the light.

The M-wave, like the PNR, is a light-evoked field potential, recorded in proximal retina with microelectrodes in response to the onset and offset of a small well-centered spot, but it has a slower timecourse than the PNR. The M-wave was initially described in studies of amphibians,<sup>87</sup> but also has been identified in the cat,<sup>23,92</sup> as illustrated in Fig. 9.19.

**FIG. 9.19** Effect of  $\text{Ba}^{2+}$  on the M-wave of the light-adapted cat retina. Effect of intravitreal barium chloride ( $\text{BaCl}_2^{2+}$ , 3 mM vitreal concentration) on the depth distribution of field potentials and  $[\text{K}^+]_o$  changes in light-adapted retina. Recordings were made before (A) and 30–60 minutes after (B)  $\text{BaCl}_2^{2+}$  was injected. The stimulus was a small spot ( $0.8^\circ$  in diameter); steady background illumination was  $10.5 \log q \text{ deg}^2/\text{s}$ ; flash illumination was  $11.6 \log q \text{ deg}^2/\text{s}$ . (Adapted from Frishman LJ, Yamamoto F, Bogucka J, et al. Light-evoked changes in  $[\text{K}^+]_o$  in proximal portion of light-adapted cat retina. *J Neurophysiol* 1992;67:1201–12.)

In retinas in which both an M-wave and a PNR can be recorded (amphibia and cats), the PNR is thought to be the transient neuronally generated portion of the proximal retinal response, while the slower M-wave reflects spatial buffer currents in Müller cells, generated as a consequence of  $\text{K}^+$  release from the same proximal neurons.<sup>23,87</sup> As illustrated in Fig. 9.19, for cat, changes in  $[\text{K}^+]_o$  recorded in proximal retina show a similar timecourse to the simultaneously recorded field potentials. In isolated amphibian retina it was shown that the Kir channel blocker  $\text{Ba}^{2+}$  had only minor effects on light-evoked neural activity (PNR) and the proximal retinal  $[\text{K}^+]_o$  increase, but it blocked the M-wave and  $\text{K}^+$  spatial buffer currents.<sup>25</sup> Similar findings in intact cat retina are illustrated in Fig. 9.19. Note that after intravitreal  $\text{Ba}^{2+}$  injection, the proximal  $[\text{K}^+]_o$  increase was larger, but the more distal increase seen in control records was absent. This is consistent with blockade by  $\text{Ba}^{2+}$  of spatial buffer currents that normally would carry the  $\text{K}^+$  away from proximal retina to the distal extracellular sinks where  $[\text{K}^+]_o$  was lower.

The local M-wave's contribution to the transretinal ERG would be small. The contribution of the M-wave may be greater when periodic stimuli such as grating patterns that stimulate large regions of retina are used. Sieving and Steinberg<sup>111</sup> showed that the M-wave is tuned to a spot diameter similar to the bar width of the optimal spatial frequency for the intraretinal pattern ERG (PERG) in the cat. The contribution of the proximal retina to the ERG can also be enhanced by using full-field stimulation.

## Origin of the Photopic Negative Response

In contrast to the PNR and M-wave, which provide small contributions at most to the transretinal ERG, negative-going responses from proximal retina to full-field stimulation are present in the corneal ERGs of several species, including cats, monkeys, and humans.<sup>40,63,92,93,112-114</sup> These responses, called the PhNR and STR, are generated by mechanisms similar to those documented above for the M-wave.

The PhNR is a negative-going wave in the photopic ERG that occurs after the b-wave in response to a brief flash, and again after the d-wave in response to a long flash. It is more prominent in primates than in rodents. In humans and monkeys, the PhNR is thought to reflect spiking activity of retinal ganglion cells.<sup>113,114</sup> As shown in Fig. 9.20, the PhNR is reduced in macaque eyes with experimental glaucoma (also after TTX injection)<sup>113</sup> and in humans with primary open angle glaucoma. It is reduced in several other disorders affecting inner retina and optic nerve head as well. The slow timecourse of the PhNR suggests glial involvement, perhaps via  $K^+$  currents in Müller cells or astrocytes in the optic nerve head set up by increased  $[K^+]_o$  due to spiking of ganglion cells. In intraretinal microelectrode recordings in cats, local signals of the same timecourse as the PhNR were largest in and around the optic nerve head and the PhNR was disrupted in cats by  $Ba^{2+}$ , indicating glial involvement in generation of the response (Viswanathan and Frishman, unpublished observations).

**FIG. 9.20** Photopic negative response (PhNR) in macaque monkey and human in normal and glaucomatous eyes. (A) Full-field flash electroretinogram (ERG) showing the PhNR of a macaque in response to long (top) and brief (middle) red light-emitting diode (LED) flashes on a rod-saturating blue background (3.7 log sc td) from the control (left) and “experimental” (middle) fellow eye with laser-induced glaucoma, and the difference between control and experimental records (right). *Arrows* mark the amplitude of the PhNR. The mean deviation (MD, static perimetry, C24–2 full threshold program) for the experimental eye was  $-2.65$  dB. (B) Full-field flash ERGs of an age-matched 63-year-old normal human subject and a patient with primary open angle glaucoma (POAG) under similar stimulus conditions to those used above for monkeys. The MD

(static perimetry, C24–2 full threshold program) for the patient's eye was  $-16.2$  dB. (Panel A adapted from Viswanathan S, Frishman LJ, Robson JG, et al. The photopic negative response of the macaque electroretinogram: reduction by experimental glaucoma. *Invest Ophthalmol Vis Sci* 1999;40:1124-36, with permission. Panel B adapted from Viswanathan S, Frishman LJ, Robson JG, et al. The photopic negative response of the flash electroretinogram in primary open angle glaucoma. *Invest Ophthalmol Vis Sci* 2001;42:514–22.)

PhNRs can be evoked using white flashes on a white background, if the flash is strong enough. However a red LED flash on a blue background, as was used for ERGs shown in Fig. 9.20, elicits PhNRs over a wider range of stimulus strengths. The red flash may minimize spectral opponency that would reduce ganglion cell responses, and use of a blue background suppresses rods while minimizing light adaptation of L-cone signals.<sup>7</sup> Blue stimuli on a yellow background which minimize spectral antagonism are good stimuli as well. The PhNR can be enhanced relative to other major ERG components, and can dominate the ERG when using focal stimuli in the region of the macula.<sup>115–117</sup>

## Relation to the Pattern ERG

The PERG has been the most commonly used noninvasive retinal measure of ganglion cell activity. It is a small response of a few microvolts elicited by contrast reversal of a bar grating or checkerboard pattern that shows some spatial tuning, consistent with a ganglion cell origin. In response to pattern stimulus, in which mean luminance does not change, the linear signals that produce a- and b-waves cancel, leaving only the nonlinear (mainly second harmonic) signals in the ERG. The PERG is eliminated by loss of ganglion cells as a consequence of optic nerve section.<sup>118</sup> It has been used widely in clinical studies assessing ganglion cell function in eyes with glaucoma and other diseases of inner retina (see reviews by Holder<sup>117</sup> and by Bach and Hoffmann<sup>116</sup>).

PERGs can be recorded as a transient response to low reversal frequencies (1–2 Hz) or as a steady-state response to higher frequencies, i.e., 8 Hz. For 1–2-Hz reversals of the pattern stimulus, a positive wave occurs within about 50 ms of each reversal ( $P_{50}$ ) and

a negative wave,  $N_{95}$ , is maximal at about 95 ms. The  $N_{95}$  is often reduced in glaucomatous eyes (the effects on the smaller  $P_{50}$  response are less consistent). Because the PhNR has a similar implicit time to the  $N_{95}$ , Viswanathan et al.<sup>119</sup> compared effects of experimental glaucoma and of TTX on the two responses in macaques, and found similar effects on both, indicating common retinal origins. Furthermore, the PERG waveform for a given stimulation frequency (2 or 8 Hz) could be simulated by adding together the ERGs at onset and offset of a uniform field, with strong contributions of PhNRs in generation of  $N_{95}$ . More recent work using glutamate analogs and simulations has found that both ON and OFF pathways contribute equally to the transient PERG, but the ON pathway dominates the 8 Hz PERG.<sup>120</sup>

Given the similar origins of PhNR and PERG, the PhNR may have some advantages over PERG as a clinical indicator of proximal retinal dysfunction. With appropriate stimulus conditions, the PhNR is a much larger response, it does not require refractive correction, and will be less affected by opacities in the ocular media than the PERG.

## Origin of the Scotopic Threshold Response

For very weak flashes from darkness, near psychophysical threshold in humans,<sup>33,90</sup> small negative (n) and positive (p) STR dominate the ERG of most mammals that have been studied. This response, which is more sensitive than the b-wave (or a-wave) and saturates at a lower light level than either component, was thus named because of its sensitivity.<sup>63</sup> As shown in Fig. 9.7, for the monkey and human, the nSTR at stimulus onset dominates the dark-adapted diffuse flash ERG in response to the weakest stimuli. The nSTR is distinct from the scotopic a-wave, although it can appear as a “pseudo a-wave” at light levels where it can be removed by suppressing inner retinal activity pharmacologically.<sup>121,122</sup> The STRs occur in response to stimuli much weaker than those that elicit more distally generated waves of the ERG because convergence of the rod signal in the retinal circuitry increases the gain of responses generated by inner retinal neurons.

The nSTR was initially observed to be generated more proximally

(IPL) than PII (INL) in intraretinal depth analysis studies in cats.<sup>63</sup> As shown in Fig. 9.21, the field potential recorded in proximal retina in response to a weak diffuse stimulus was negative-going for the duration of the stimulus, and returned slowly to baseline after light offset. For stimuli too weak to elicit PII, the nSTR reversed polarity in midretina and became a positive-going signal in the mid- and distal retina. This reversal suggests a source proximal to, and a sink distal to, the reversal point (see description of the Müller cell mechanism, below). For stronger stimuli, the reversed nSTR in mid- and distal retina was replaced by PII, which then dominated the ERG. The similarity of the onset times and timecourse of the proximal retinal STR and the negative STR in the cat vitreal ERG can be seen in Fig. 9.21.

**FIG. 9.21** The scotopic threshold response (STR) dominates intraretinal recordings and the electroretinogram (ERG) at low stimulus intensities below the threshold for the b-wave (PII). On the left, the top trace is the surface ERG recorded about 25  $\mu\text{m}$  from the retinal surface, and the bottom two traces are recordings of the STR in the proximal retina (about 6% retinal depth) and the inverted STR around 50% retinal depth. On the right, the scaled STR recorded in the proximal retina is superimposed on the surface ERG to show the similarity of the responses. For the surface ERG, a microelectrode was referenced to a wire in the vitreous in order to reduce the effects of stray light. This minimized contributions to the ERG of retinal

regions distant from the recording site of the intraretinal signals (spot diameter, 9.9°; spot illumination, 4.8 log q deg<sup>2</sup>/s). (Adapted from Sieving PA, Frishman LJ, Steinberg RH. Scotopic threshold response of proximal retina in cat. *J Neurophysiol* 1986;56:1049–61.)

The nSTR also can be separated from PII using pharmacologic agents (GABA, glycine, or NMDA<sup>30,90,121</sup>) to suppress responses of the amacrine and ganglion cells proximal to bipolar cells. These agents remove the STR, but not PII (Fig. 9.15). In contrast, APB eliminates both the scotopic b-wave (PII) and STR, indicating that the STR will not be generated if the primary rod circuit is no longer mediated by rod bipolar cells (Fig. 9.2).

There is a similarly sensitive positive STR in the scotopic ERG of animals that have a negative STR.<sup>40,90</sup> Because the pSTR is small and of opposite polarity to the nSTR, it can easily be cancelled out in the ERG. An instance of this can be seen in the dark-adapted macaque ERG in Fig. 9.7. The delayed onset of nSTR for the weakest stimulus is due to the presence of a pSTR that is slightly larger than the nSTR at early times. In response to a stimulus about 1 log unit higher (just above), the pSTR rides on the emerging PII as an early positive potential. Most pharmacologic agents that eliminate the nSTR also eliminate the pSTR.<sup>40,90</sup> For example, NMDA eliminated both the nSTR and pSTR in the macaque ERG for responses such as those seen for the two weakest stimuli in Fig. 9.7 (Frishman, unpublished observations).

A linear model of the contributions of pSTR, nSTR, and PII to the dark-adapted cat ERG is shown in Fig. 9.22. The model assumes that each ERG component initially rises in proportion to stimulus strength, and then saturates in a characteristic manner, as has been demonstrated in single-cell recordings in mammalian retinas, as well as for ERG a- and b-waves in numerous studies. Only with the inclusion of a small pSTR does the model accurately predict the whole ERG at a given “fixed” time in response to a weak stimulus. The model was fit in Fig. 9.22 to responses measured at 140 ms after a brief full-field flash (<5 ms), which was the peak of the nSTR in the cat scotopic ERG. Similar models have been applied to mouse<sup>90</sup> and human ERG.<sup>40</sup>

**FIG. 9.22** Amplitude of cat dark-adapted electroretinogram responses measured 140 ms after a brief flash at the maximum negativity of the negative scotopic threshold response (nSTR). *Dashed lines* show model curves for the positive scotopic threshold response (pSTR), nSTR, and PII. Explicitly, the pSTR rises as a linear function that saturates abruptly at  $V_{\max}$ , while the exponential saturation of the nSTR is defined by:

$$V = V_{\max} (1 - \exp(-I/I_0))$$

where  $V_{\max}$  is the maximum saturated amplitude, and  $I_0$  is the intensity for an amplitude of  $(1 - 1/e)V_{\max}$ , while the hyperbolic relation used for PII is defined by:

$$V = V_{\max} I / (I + I_0)$$

where  $V_{\max}$  has the same meaning but  $I_0$  is the intensity at which the amplitude is  $V_{\max}/2$ . The inset shows the pSTR and nSTR at the lowest light levels that were used. ( $1 \text{ q deg}^2$  is equivalent to  $\sim -7.5 \text{ log sc cd m}^2/\text{s}$ ).

## **K<sup>+</sup> Müller Cell Mechanism for Generation of the STR**

The STR, like the M-wave, is associated with Müller cell responses to  $[K^+]_o$  released by proximal retinal neurons. In intraretinal studies in cat, a proximal increase in  $[K^+]_o$  was observed that had clear similarities to the local STR that was simultaneously recorded: the dynamic range from “threshold” to saturation of the light-evoked proximal  $[K^+]_o$  increase was similar to that of the field potentials, and the retinal depth maxima for the two responses were the same.<sup>22,54</sup> A causative role for the  $[K^+]_o$  increase in generating the nSTR (and a slow negative response in the vitreal ERG following the initial STR) was supported by the finding (Fig. 9.23) that  $Ba^{2+}$  removed the proximal retinal field potential and the nSTR in the ERG but did not, initially, eliminate the light-evoked increase in  $[K^+]_o$ . The cornea-negative polarity of the nSTR suggests a distally directed Müller cell  $K^+$  current (similar to M-wave and PIII currents in the vascularized cat retina). As noted above for the light-adapted M-wave, in the dark-adapted retina  $Ba^{2+}$  also appears to block  $K^+$  siphoning by the Müller cells. Whereas the proximal  $[K^+]_o$  increase remained intact when related field potentials were abolished, the distal  $[K^+]_o$  increase was eliminated by  $Ba^{2+}$ .

**FIG. 9.23** Effect of  $Ba^{2+}$  on the scotopic threshold response (STR) and b-wave (PII) in scotopic electroretinogram (ERG) of the cat. (A) Effect of intravitreal  $Ba^{2+}$  ( $BaCl_2$ , 3.9 mM vitreal concentration) on the intraretinal STR and slower  $K^+$ -related negative response in response to a 4-second stimulus and the simultaneously recorded light-evoked decrease in  $[K^+]_o$  ( $V_{K^+}$ ) in the proximal retina measured at 10% retinal depth, proximal to the peak  $K^+$  change at 17% depth. Top response was measured before  $Ba^{2+}$  and the

bottom response 56 minutes after  $Ba^{2+}$  injection. (B) Effect of intravitreal  $BaCl_2$  (3.9 mM vitreal concentration) on the STR and slow negative response in the vitreal ERG (left) and the simultaneously recorded change in  $[K^+]_o$  in the subretinal space. Measurements of the amplitude of dark-adapted responses in the proximal retina and the light-evoked increase in  $[K^+]_o$  in proximal and distal retina before and after intravitreal injection of  $Ba^{2+}$  were made with double-barreled  $K^+$ -sensitive microelectrodes. (Reproduced with permission from Frishman LJ, Steinberg RH. Light-evoked increases in  $[K^+]_o$  in proximal portion of the dark-adapted cat retina. *J Neurophysiol* 1989;61:1233–43.)

## Neuronal Origins of the STR

Whether the neurons involved in the genesis of the nSTR and pSTR are amacrine or ganglion cells is species-dependent. In monkeys it is likely that the nSTR arises predominantly from ganglion cells. It was absent in eyes in which the ganglion cells were eliminated as a consequence of experimental glaucoma<sup>112</sup> and by intravitreal injection of TTX to block  $Na^+$ -dependent spiking activity of those neurons; the pSTR remained intact. In contrast, in cats and humans<sup>122</sup> as well as in rodents,<sup>3</sup> the nSTR is not eliminated by ganglion cell loss, and thus may be more amacrine cell-based. In rodents the pSTR relies upon the integrity of ganglion cells. A characteristic of Müller/glial cell-mediated ERG components is their slow timecourse. Glial cell mediation of the nSTR was demonstrated most directly in cat, but the timecourse of the nSTR is slow in all species. Glial mediation may explain the similarity in timecourse of nSTR across species regardless of the particular type of neuron producing the local changes in proximal  $[K^+]_o$  that generate the response.

## Origin of Oscillatory Potentials

The OPs of the ERG consist of a series of high-frequency, low-amplitude wavelets, mainly superimposed on the b-wave, that occur in response to strong stimulation. OPs are present under

light- and dark-adapted conditions, with contributions from both rod- and cone-driven signals.<sup>123</sup> The mixed rod–cone ERG in humans in the ISCEV standards in Fig. 9.4 shows at least four OPs that can be extracted with a filter with a low-frequency cutoff of 75 Hz. OPs are of postreceptoral origin, and occur in isolated retinas in the absence of the RPE.<sup>73</sup> The number of OPs induced by a flash of light varies between about 4 and 10 depending upon species and stimulus conditions; the temporal frequency of the OPs varies as well. Fig. 9.24 shows the photopic flash ERG of a macaque monkey (top); at least five OPs at frequency of about 150 Hz can be seen by filtering the response to extract the high-frequency signals.

**FIG. 9.24** Full-field flash photopic electroretinogram of a macaque monkey (top) and the oscillatory potentials (OPs) extracted from these records. Filtering was between 90 and 300 Hz for OPs that occurred between 100 and 200 Hz. The stimulus was a xenon flash presented on a rod-saturating blue background. (Adapted from Rangaswamy NV, Hood DC, Frishman LJ. Regional variations in local contributions to the primate photopic flash ERG: revealed using the slow-sequence mfERG. *Invest Ophthalmol Vis Sci* 2003;44:3233–47).

There is consensus that OPs are generated in proximal retina.

Three important and unresolved questions regarding their origins follow: (1) Do all the OPs have the same origin? (2) Which cells generate the OPs? (3) What mechanisms are involved in generating OPs?

## **Do All the OPs Have the Same Origin?**

In amphibians, where early studies were done, the various OPs do not all have the same origin. Depth profiles from isolated frog retina showed that the earliest OPs in the response arose near the IPL whereas the later OPs arose more distally, perhaps in the INL. Studies of Wachmeister<sup>124</sup> in amphibian retina also found that earlier OPs were depressed by GABA antagonists, the dopamine antagonist haloperidol,  $\beta$ -alanine, and substance P; whereas later OPs were depressed by the glycine antagonist strychnine and by ethanol.

In primates, intraretinal studies using stimuli that would elicit responses from both rod and cone systems did not find differences in the depth profiles of the different OPs.<sup>44,125</sup> Considering the complexity of inner retinal circuitry, the similarity in depth profiles does not necessarily mean that the same neurons were involved in all cases. For example, in the photopic flash ERG response to brief stimuli, the major OPs are APB-sensitive in primates and other mammals, indicating an origin in the ON pathways, but later OPs and at light offset originate in the OFF pathway.<sup>105,126</sup> Such a difference could lead to differences in the depth distribution in the IPL which is stratified in outer OFF sublamina and inner ON sublamina.

Pharmacologic agents that block inner retinal activity, such as glycine and GABA, remove OPs in mammals, as does PDA,<sup>105</sup> but the effects were not reported to be specific for given OPs. On the other hand, genetic deletion of a major GABA receptor in the IPL, the GABA<sub>C</sub> receptor, enhances the OPs.<sup>127</sup>

## **Which Cells Generate the OPs?**

The observations described above indicate that amacrine or perhaps, in some instances, retinal ganglion cells are involved in generating OPs. A study of rabbit ERG indicates a distal to

proximal progression in origin, with the late but not early OPs having input from spiking cells.<sup>126</sup> The role of ganglion cells in the generation of OPs has been controversial, with inconsistent reports on the effects of ganglion cell loss on OPs. In Ogden's studies in primates, optic nerve section resulted in ganglion cell degeneration and disappearance of the OPs, and antidromic stimulation of the optic nerve reduced OP amplitudes.<sup>125</sup> Further, in the primate photopic ERG elicited using a multifocal paradigm with a slow sequence to allow formation of OPs, both TTX and experimental glaucoma removed or reduced a high-frequency band of OPs, while affecting a lower-frequency band less.<sup>105,106</sup> It is possible in primates that high-frequency OPs (centered around 150 Hz, compared to >100 Hz for the lower-frequency band) under fully photopic conditions reflect activity in ganglion cell axons, and the manifestation of an optic nerve head component of the ERG. Under conditions where rod signals are also involved, the ganglion cell contribution may be less prominent. In other mammals, TTX-sensitive OPs may be among the late ones.

## **What Mechanisms Are Involved in Generating OPs?**

### **Neuronal Interaction: Inhibitory Feedback Circuits.**

Two mechanisms are commonly proposed for generating OPs: neuronal interactions/feedback circuits, and the intrinsic membrane properties of cells, both of which implicate amacrine cells. The case for an inhibitory feedback mechanism is supported by involvement of receptors for GABA and glycine, which are prominent in feedback circuits in the inner retina. Gap junctions between inner retinal neurons can also be involved in feedforward mechanism.

### **OPs in Intracellular Responses From Neurons.**

In retinal intracellular recordings from many different species, high-frequency oscillations have rarely been observed in responses of photoreceptors, horizontal, or bipolar cells. In contrast, membrane oscillations have been observed in recordings from amacrine cells, especially in turtle and fish retina. For example, GABAergic wide-field ACs isolated from white bass retina generated oscillatory membrane potentials in response to extrinsic

depolarization, as illustrated in Fig. 9.25, that reached more than 100 Hz for strong depolarization. Analysis of the mechanism of generation of the oscillatory membrane potentials in these isolated cells indicated that they arose from “a complex interplay between voltage-dependent  $\text{Ca}^{2+}$  currents and voltage- and  $\text{Ca}^{2+}$ -dependent  $\text{K}^{+}$  currents.”<sup>128</sup>

**FIG. 9.25** Oscillatory potentials of isolated wide-field amacrine cells in the white perch retina. Oscillatory membrane potentials (OMPs) were elicited by depolarizing current steps of increasing amplitude obtained in whole-cell recordings from isolated amacrine cells that were maintained in culture. The duration and frequency of the OMPs increased with depolarization. Voltage traces are shifted vertically for

visibility. Bottom: application of depolarizing pulse. The magnitude of depolarizing current is indicated with each trace. Holding potential was  $-70$  mV. (Reproduced with permission from Vigh J, Solessio E, Morgans CW, et al. Ionic mechanisms mediating oscillatory membrane potentials in wide-field retinal amacrine cells. *J Neurophysiol* 2003;90:431–43.)

In summary, there is consensus that high-frequency OPs originate from the inner retina. The exact cellular origins may depend upon species and stimulus conditions. The mechanisms by which they are generated are unresolved, with evidence for both involvement of feedback circuitry, and for intrinsic membrane mechanisms in amacrine cells.

## Closing Remarks

This chapter has reviewed the increasingly specific information about the electrogenesis of the ERG that has become available as our understanding of retinal microcircuitry and cellular and synaptic mechanisms has increased. Due to the extensive research on ERG, it has become feasible to use it to assess retinal function at every level, from the RPE to the optic nerve head; also see other recent reviews on this subject.<sup>3,129–131</sup> Tables 9.1 and 9.2 summarize our current understanding of the origins of ERGs recorded in standard and specialized tests. Continued refinement of stimuli, protocols, and analysis will further enhance the power of this noninvasive tool in the laboratory and the clinic.

**Simultaneous Recording of Focal Macular ERG and VEP**

In this chapter we describe the method and value of various clinical electrophysiologic tests and how they play a role in the diagnosis, analysis of pathogenesis, prognostic evaluation, and understanding of the underlying genetics of retinal disorders, using several examples of clinical cases. We also demonstrate the role of the focal macular electroretinogram (ERG) and multifocal ERG (mfERG) for particular diseases where the affected region is limited to a certain area of the retina. During the recent history of clinical electrophysiology, several new clinical entities have been defined by analyzing electrophysiologic results. These new entities will also be discussed in this chapter.

## **Standard Full-Field ERG**

## Stimulus and Recording Devices

The human ERG recorded at the cornea and elicited by a full-field stimulus is a mass response generated by cells across the entire retina. To obtain reproducible amplitudes and implicit times in the response, the stimulus and background light should be homogeneous and cover the entire retina, so all of the receptors are stimulated or adapted in a relatively homogeneous manner. The full-field, or Ganzfeld, stimulator represents such a stimulus. It consists of a large-diameter (40-cm) hemispheric dome (see [Chapter 9](#), Electrogenesis of the electroretinogram) with a xenon stroboscopic light bulb placed at the top of the dome. This stimulus system has been recommended by the International Society of Clinical Electrophysiology for Vision (ISCEV) Standards Committee<sup>1</sup> for use when obtaining clinical ERG recordings internationally.

The ERG is recorded using corneal electrodes, usually referred to surface reference electrodes at the ipsilateral outer canthi or zygomatic fossae. Electrodes in common use<sup>2</sup> include the Burian–Allen and the ERG jet, both of which are contact lens electrodes, the gold foil, Dawson–Trick–Litzkow (DTL), and H–K loop electrodes, which are noncontact approaches. The representative electrodes are shown in [Fig. 10.1](#).

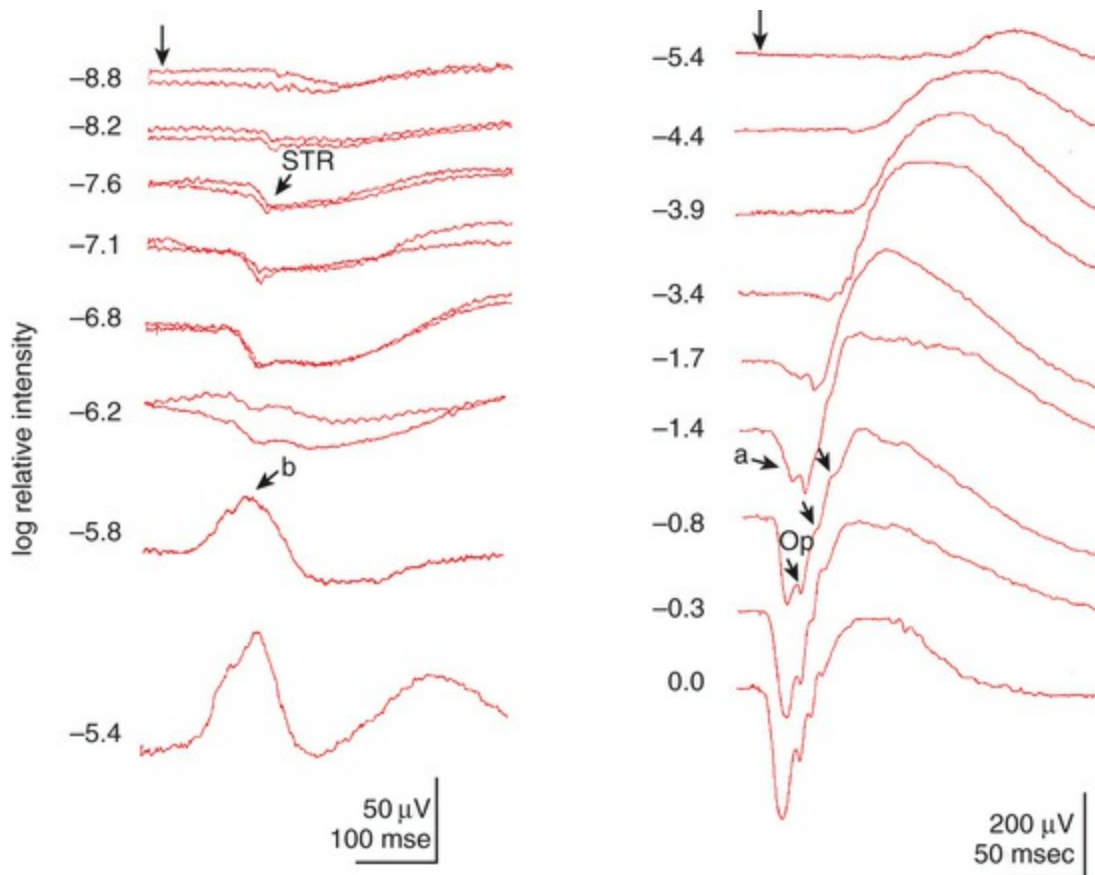

**FIG. 10.1** Representative electroretinogram recording

electrodes. (Top) Burian–Allen electrode. A contact lens-type electrode with a lid speculum to minimize the effect of blinking and eyelid closure. (Bottom) Dawson–Trick–Litzkow (DTL) electrode – a conductive Mylar thread usually placed in the lower fornix, it contacts the inferior bulbar conjunctiva or the corneal limbus. Dots show 10-mm distance.

## Stimulus Intensity Versus ERG Responses and Components

### Scotopic Condition

Fig. 10.2 shows the full-field ERGs elicited by increasing stimulus intensities from a normal subject after 1 hour of dark adaptation. The ERGs elicited by relatively weak stimulus intensities are shown at the left and those by stronger stimulus are shown at the right. The calibrations for the amplitude and time are different for the weak- and strong-stimulus ERGs. The maximum stimulus luminance (0 log unit) is  $44.2 \text{ cd m}^{-2} \text{ s}^{-1}$ .

**FIG. 10.2** The full-field electroretinogram (ERG) elicited by increasing stimulus intensities recorded from a normal subject after 1 hour of dark adaptation. The left column shows responses elicited by relative low intensity and the right by relative high intensity. Note that the calibration differs for the ERGs in the two columns. Arrowheads indicate the stimulus onset. *STR*, scotopic threshold response; *b*, b-wave; *a*, a-wave; *Op*, oscillatory potentials. (Reproduced with permission from Miyake Y, Horiguchi M, Terasaki H, et al. *Invest Ophthalmol Vis Sci* 1994;35:3770–5.)

At the left, the scotopic threshold response (STR),<sup>3</sup> a cornea-negative wave, is first recorded at  $-8.2$  log units, approximately 0.6 log units higher than psychophysical threshold. The maximum amplitude of STR is approximately  $20 \mu\text{V}$  before it is masked by the developing b-wave. The implicit time of the STR near threshold is approximately 160 ms, and the implicit time decreases as the stimulus intensity increases. The STR originates from retinal neurons that are postsynaptic to the photoreceptors (see [Chapter 9](#), Electrogenesis of the electroretinogram).

The b-wave is first seen at an intensity of  $-5.8$  log units; the amplitude increases and the implicit time shortens as the stimulus intensity increases. The amplitude of b-wave essentially saturates at  $-3.4$  log units; and at intensities higher than  $-0.8$  log unit, the oscillatory potentials (OPs) become clearly visible on the ascending limb of the b-wave. The a-wave is first seen at  $-1.7$  log units and increases progressively as the stimulus intensity increases.

As described in [Chapter 9](#) (Electrogenesis of the electroretinogram), many studies have shown that the a-wave of the full-field ERGs recorded in the dark is the leading edge of the photoreceptor potential.<sup>4</sup> The b-wave originates indirectly from bipolar and Müller cells in the middle layers of the retina.<sup>5</sup> The OPs are seen as a series of three or four rhythmic wavelets having almost equal intervals of about 6.5 ms in humans.<sup>6</sup> The best experimental evidence indicates that the OPs reflect the activity of feedback synaptic circuits within the retina and represent an inhibitory or modulating effect of amacrine cells on the b-wave.<sup>7</sup>

### **Photopic Condition**

The photopic, short-flash ERGs elicited by increasing stimulus intensities in a normal subject are shown in [Fig. 10.3](#).<sup>8</sup> At lower stimulus intensities, the amplitude of the b-wave increases with increasing stimulus until it reaches a maximum at a stimulus intensity of  $3.0$  log cd m<sup>-2</sup>. Further increases in the stimulus intensity result in a progressive decrease in the amplitude of the b-wave. Because a plot of the b-wave amplitude as a function of the stimulus intensity has an inverted U shape, this phenomenon has been termed the photopic hill phenomenon.<sup>9</sup>

**FIG. 10.3** Photopic short-flash electroretinograms elicited by various stimulus intensities from a normal subject. Stimulus duration is 5 ms and the constant background illumination is  $40 \text{ cd m}^{-2}$ . The vertical dashed line indicates 30 ms. The b-wave amplitude increases with increasing stimulus intensity until  $3.0 \text{ cd m}^{-2}$ . It decreases with further increases in stimulus intensity. When the b-wave amplitude is plotted against stimulus intensity, it shows an inverted U shape; this phenomenon has been termed the photopic hill phenomenon. (Reproduced with permission from Kondo M, Piao CH, Tanikawa A, et al. *Jpn J Ophthalmol* 2000;44:20–8.)

## Bright Flash Mixed Rod–Cone ERG

ERG recorded with a bright flash of light after dark adaptation for 30 minutes or longer (0 log unit in Fig. 10.2) shows mixed rod–cone

response, which can provide variable information about retinal pathology and is of significant diagnostic value. We have an impression that about 70% of ERG information can be obtained by the evaluation of only the mixed rod–cone ERG. The five different types of mixed rod–cone ERG are shown in [Fig. 10.4](#).

**FIG. 10.4** The five different types of mixed rod–cone electroretinogram (ERG). *OP(-)*, selective reduction of oscillatory potentials; *subnormal*, both a- and b-waves are attenuated approximately to the same degree; *negative*, the amplitude of the b-wave is smaller than that of the a-wave; *extinct*, no discernible a- or b-wave.

## Normal

The normal type shows a-wave, b-wave, and OPs. The amplitude of b-wave is always larger than that of a-wave in the regular stimulus intensity range. The normal ERG can be seen in patients with localized macular dysfunction, optic nerve diseases, and central nervous system disease such as amblyopia. Even when the entire retina is ophthalmoscopically abnormal, such as in rubella retinopathy or in a female carrier of ocular albinism or

choroideremia (Fig. 10.5), the ERG can be essentially normal.

**FIG. 10.5** Fundus photograph (A) and fluorescein angiogram (B) obtained from a 20-year-old man with rubella retinitis. Fundus photograph from a 60-year-old female carrier of choroideremia (C). The electroretinograms in these two patients were normal. (Reproduced with permission from Miyake Y. *Electrodiagnosis of retinal diseases*. Tokyo: Springer-Verlag; 2006.)

### Selectively Abnormal Oscillatory Potentials

An OP abnormality means either reduction of amplitude or delay of implicit time, or both. A selective OP abnormality is observed in the early stage of diabetic retinopathy<sup>10,11</sup> (Fig. 10.6) or mild circulatory disturbance of retina such as central retinal vein occlusion.

**FIG. 10.6** Oscillatory potentials (OPs) of full-field electroretinograms recorded from a normal subject (top) and two patients with diabetic retinopathy (*DR*). The oscillatory potentials were found to have delayed implicit time (Case 1) or reduced amplitude (Case 2). (Reproduced with permission from Miyake Y. *Electrodiagnosis of retinal diseases*. Tokyo: Springer-Verlag; 2006.)

## Subnormal

The amplitudes of all components are reduced approximately to the same degree. A reduced a-wave indicates abnormal photoreceptor function. Relatively early stages of rod–cone dystrophy may show subnormal ERG<sub>a</sub>. This pattern is also seen in patients with localized damage of the photoreceptors, such as partial retinal detachment or sectoral retinal degeneration. The amplitude of the full-field ERG is proportional to the area of functioning retina. This principle is evident when the extent of retinal detachment is compared with the ERG (Fig. 10.7).

**FIG. 10.7** Mixed rod–cone (bright flash) electroretinograms (left) and fundus drawings of three patients with rhegmatogenous retinal detachment (right). The reduction of the electroretinogram amplitude corresponds proportionally to the extent of retinal detachment.

This principle is also demonstrated in eyes receiving panretinal photocoagulation (PRP) for diabetic retinopathy. Following PRP, the amplitudes of ERG components are reduced by 40–45%, but the b-wave : a-wave (b/a) ratio is not changed significantly.<sup>11</sup> When the

media is hazy due to vitreous hemorrhage and the fundus is invisible, the presence or absence of retinal detachment is an important evaluation preoperatively. By combining ERG and ultrasonography, the differentiation between a totally detached retina and dense vitreous membranes may be possible, as shown in Fig. 10.8. When the ERG is recordable, even if the amplitude is small, the thick membrane in the vitreous cavity is not totally detached retina, but vitreous membrane.

**FIG. 10.8** Ultrasonographic (US) image (top) and mixed rod–cone electroretinogram (ERG) (bottom) from eyes with vitreous hemorrhage. Ultrasonography shows thick membrane-like reflex in the vitreous cavity in both eyes. When the ERG is recordable, even if the amplitude is small, the thick membrane in the vitreous cavity is not totally detached retina, but vitreous membrane (Case 1). In contrast, when the ERG is unrecordable, the thick membrane is most likely totally detached retina (Case 2).

## Negative

The negative ERG indicates that the amplitude of the b-wave is smaller than that of the a-wave ( $b/a$  ratio  $<1.0$ ). As mentioned

above, the amplitude of the b-wave is always larger than that of the a-wave in normal subjects. A normal a-wave with a reduced b-wave localizes the defect to postphototransduction processes. The negative ERG can be of useful prognostic or diagnostic value in retinal diseases.

### Prognostic Value.

Among the acquired retinal diseases, the negative ERG may be seen in severe retinal circulatory disturbances such as central retinal arterial occlusion or proliferative diabetic retinopathy. In central retinal vein occlusion, the ischemic type shows a negative ERG more frequently than the nonischemic type, indicating that the b/a ratio can be an important index for evaluating the prognosis of central retinal vein occlusion.<sup>12,13</sup> Fig. 10.9 shows a patient with an initially normal, but later lower, b/a ratio which resulted in negative configuration in ERG.<sup>11</sup> The fluorescein angiogram evolved from a nonischemic pattern to an ischemic pattern, demonstrating an extensive area of nonperfusion.

**FIG. 10.9** (Top panel) A 39-year-old woman had a central retinal vein occlusion in the right eye (top left). Fluorescein angiogram (top center) and electroretinogram (ERG) (top right) showed nonischemic pattern at her initial visit. (Bottom panel) One month later, the retinal hemorrhage increased

(bottom left), the fluorescein angiogram showed extensive areas of nonperfusion (bottom center), and the waveform of the ERG became negative (right).

(Reproduced with permission from Miyake Y. *Electrodiagnosis of retinal diseases*.

Tokyo: Springer-Verlag; 2006.)

When massive vitreous hemorrhage prevents ophthalmoscopic examination of the fundus in patients with proliferative diabetic retinopathy, it makes it difficult to predict the surgical and visual outcome after vitrectomy. In these eyes, the amplitudes of the ERGs may be markedly reduced by various factors: pathologic changes induced by the diabetic retinopathy, earlier PRP, and vitreous hemorrhage. As mentioned above, PRP reduces the ERG amplitude without changing the b/a ratio.<sup>11</sup> Because most diabetic patients with vitreous hemorrhage have undergone PRP, it is difficult to arrive at a prognosis of the outcome after vitrectomy using only the amplitudes. The b/a ratio provides more useful information about the visual prognosis after vitrectomy.<sup>14</sup> The preoperative mixed rod–cone ERGs were classified into three groups in patients with diabetic retinopathy associated with significant vitreous hemorrhage (Fig. 10.10, left). Group A indicates those with a b/a ratio >1.0 and the OPs are clearly recordable. Group B includes those with a b/a ratio >1.0 but the OPs are absent. Group C comprises those with a b/a ratio <1.0 with absent OPs. Thick proliferative tissues were found at the disc (Fig. 10.11) intraoperatively in 36% of the eyes in group A, 67% in group B, and 90% in group C.<sup>14</sup> It was suggested that the fibrous proliferation at the disc may restrict the retinal circulation by compressing the central retinal artery.

**FIG. 10.10** Preoperative full-field electroretinograms (ERGs) recorded from a normal control and three diabetic patients with vitreous hemorrhage (*HM*) who were classified into three groups (left). Postoperative visual acuity in the three groups classified according to the ERG waveform (right), showing that the postoperative visual acuity for group C was significantly worse than that for group A or group B. (Reproduced with permission from Hiraiwa T, Horio N, Terasaki H et al. *Japn J Ophthalmol* 2003;47:307-11.)

**FIG. 10.11** Proliferative tissue on the optic disc in a patient with diabetic retinopathy. (Reproduced with permission from Miyake Y. *Electrodiagnosis of retinal diseases*. Tokyo: Springer-Verlag; 2006.)

The distribution of the postoperative visual acuity for each group is shown in [Fig. 10.10](#) (right).<sup>14</sup> The postoperative visual acuity for group C was significantly worse than for group A or group B. The low b/a ratio may indicate more severe ischemic retina, which in turn may account for the relatively good correlation with visual acuity. However, among the patients in group C, there were some whose postoperative visual acuity was good, indicating that a b/a ratio <1.0 is not necessarily a contraindication for vitrectomy. Another important finding is that most patients who have distinct OPs preoperatively have favorable visual acuity after vitrectomy. This observation is important when we discuss the visual prognosis with patients before surgery. The light-filtering effect of a dense vitreous hemorrhage should also be considered when evaluating the preoperative ERG in diabetic patients. Severe vitreous hemorrhage reduces the intensity of the stimulus light reaching the retina, which can increase the b/a ratio (see [Fig. 10.2](#)). When the vitreous hemorrhage is extremely dense, the intensity of stimulus light may be decreased and the effective stimulus light to evoke ERG may not reach the retina. In such situations, we need a much brighter stimulus than the standard maximum stimulus to evoke the ERG. Such an example is shown in [Fig. 10.12](#). In such cases, we have an impression that the ERG often has a negative configuration, as shown in this patient.

**FIG. 10.12** Ultrasonographic image (top) and mixed rod–cone electroretinograms (ERGs) (bottom) with various stimulus intensities from eyes with extremely dense vitreous hemorrhage. As the intensity of the stimulus light is decreased, a sufficiently bright stimulus to evoke the ERG may not reach the retina. In this situation, a much brighter stimulus than the regular maximum stimulus may evoke the ERG response. In such cases, it appears that the ERG frequently shows negative configuration.

In the prognostic evaluation of eyes that develop

endophthalmitis after intraocular lens implantation, the b/a ratio is also valuable.<sup>15</sup> Eyes with early (within 1 week) endophthalmitis associated with a b/a ratio of  $<1.0$  have a worse postoperative prognosis than eyes with late-onset endophthalmitis and/or a b/a ratio of  $>1.0$ . These observations are quite important when deciding on the appropriate time to perform vitrectomy for treatment. For example, a patient with endophthalmitis that was detected within 1 week of intraocular lens implantation and with an ERG b/a ratio of  $<1.0$  should undergo vitrectomy urgently. On the other hand, when endophthalmitis develops a relatively long time after surgery and the ERG b/a ratio is  $>1.0$ , the timing of the vitrectomy may not be as critical. Representative examples<sup>15</sup> are shown in Fig. 10.13.

**FIG. 10.13** (Left) Preoperative mixed rod–cone (bright flash) electroretinograms (ERGs) recorded from two patients with endophthalmitis after intraocular lens implantation. The negative configuration of the ERG (Case 1) suggests poorer visual prognosis after

vitrectomy than for the patient with normal-shaped ERGs (Case 2). (Right) Postoperative fundus. Case 1 showed extensive retinal vascular occlusions (*arrows*), with poor postoperative visual function, as expected. Case 2 showed an essentially normal fundus with good postoperative visual function. (Reproduced with permission from Horio N, Terasaki H, Yamamoto E, et al. *Am J Ophthalmol* 2001;132:258–9.)

## Diagnostic Value.

The negative ERG is seen in some hereditary retinal diseases, which provides diagnostic information, particularly when the a-wave amplitude is normal. The representative diseases, where the negative ERG is of diagnostic value, include complete-type congenital stationary night blindness<sup>16</sup> (CSNB: see [Fig. 10.20](#)), incomplete-type CSNB<sup>16</sup> (see [Fig. 10.20](#)), X-linked juvenile retinoschisis<sup>11</sup> (XLRs: see [Fig. 10.20](#)), juvenile-onset neuronal ceroid lipofuscinosis,<sup>17</sup> and infantile Refsum disease. Since both complete and incomplete CSNB show essentially normal fundi and most patients with CSNB have moderately low visual acuity,<sup>16</sup> the negative ERG finding is extremely important to identify these disorders, differentiating them from other diseases with normal fundi, low visual acuity, and normal ERG, such as psychologic eye problems, amblyopia, optic nerve disease, central nervous system disease, or occult macular dystrophy (OMD). The detailed findings separating rod and cone components will be described in subsequent sections.

When the a-wave amplitude is normal and the b/a ratio is  $<1.0$ , a selective abnormality of the second-order neuron is indicated. On the other hand, when the amplitude of the a-wave is smaller than normal with the b/a ratio  $<1.0$ , there are two potential interpretations. One is the combined dysfunction of photoreceptor and middle retinal layer. This situation is often observed in patients with retinitis pigmentosa. The other possibility is the ERG showing the photopic hill phenomenon<sup>8,9</sup> (see above). When the rod function is completely absent and the cone function is well preserved, the ERG shows a cone ERG waveform even in the dark. In this condition, when the stimulus light intensity is strong, the ERG reveals the photopic hill phenomenon (see [Fig. 10.3](#)), showing a

negative configuration with a small a-wave. Examples are seen when obtaining a bright flash mixed rod–cone ERG in the dark in Oguchi disease or fundus albipunctatus (see [Fig. 10.16](#)).

In acquired diseases, negative ERG may be seen in melanoma-associated retinopathy,<sup>18,19</sup> birdshot choroidopathy,<sup>20</sup> ocular siderosis, quinine retinopathy, and methanol toxicity. The negative configuration of the ERG provides important diagnostic value in these disorders (see [Chapter 79](#), White spot syndromes and related diseases; [Chapter 80](#), Autoimmune retinopathies; [Chapter 92](#), Drug toxicity of the posterior segment; and [Chapter 138](#), Remote effects of cancer of the retina).

## Extinct

The extinct ERG is often seen in the advanced stage of rod–cone dystrophy, including retinitis pigmentosa, gyrate atrophy or choroideremia, and total retinal detachment. In retinitis pigmentosa, gyrate atrophy, or choroideremia, even when the macular area is preserved, ERG may become undetectable. Cancer-associated retinopathy,<sup>19</sup> an autoimmune retinopathy, may also show an extinct ERG and should be differentiated from retinitis pigmentosa.

## Isolation of Rod and Cone Components in Standardized ERG

Although the rods outnumber the cones 13 to 1 in the normal human retina, the cone ERG response accounts for 20–25% of the ERG response amplitude. For the purposes of diagnosis, it often becomes necessary for the examiner to evaluate rod and cone activity separately. The full-field ERGs using the ISCEV Standard (see [Chapter 9](#), Electrogenesis of the electroretinogram) in a normal subject are shown in [Fig. 10.14](#).

**FIG. 10.14** Standard full-field electroretinograms with isolation of the rod and cone components. *Arrowheads* indicate the stimulus onset; *arrow* indicates photopic negative response.

After 30 minutes of dark adaptation, a rod (scotopic) ERG is recorded with a dim flash of light at approximately  $-3.9$  log units in Fig. 10.2. A bright flash (mixed rod–cone) ERG is elicited by a single flash of white light at a maximum intensity of log 0 units in Fig. 10.2. Cone and 30-Hz flicker ERG are recorded with a stimulus intensity of 3.3 log units in Fig. 10.3 under the background illumination of  $40 \text{ cd m}^{-2}$ , which is sufficient to suppress all rod activity. The photopic recordings (cone and 30-Hz flicker ERG) are made after 10 minutes of light adaptation to  $40 \text{ cd m}^{-2}$ , because the maximum photopic ERG can be obtained when recorded after light adaptation.<sup>11</sup> In addition to the conventional ERG components, the photopic negative response (PhNR) was introduced:<sup>21</sup> this originates from retinal ganglion cells and is described in more detail in subsequent sections.

The representative patients diagnosed by the isolation of rod and cone components of full-field ERG are shown below in relation to the abnormal cells of the retina.

## Cone Photoreceptor Dysfunction

The congenital stationary disorder of cone dysfunction is represented by rod monochromacy which is inherited in an autosomal recessive mode. This disorder is characterized in the complete form by complete absence or severe depression of color vision, reduced visual acuity, nystagmus, and photophobia<sup>11</sup> (see [Chapter 46](#), Abnormalities of cone and rod function). There is also an incomplete form of this disorder, where color vision and/or visual acuity is not severely affected<sup>11</sup> (see [Chapter 46](#), Abnormalities of cone and rod function). In both forms, the fundus and fluorescein angiograms are normal, and the most characteristic feature in terms of the diagnosis is selective reduction or absence of the photopic components with preservation of the normal scotopic components of the full-field ERG, even in incomplete forms ([Fig. 10.15](#)). Molecular genetic studies have shown that mutations in the *CNGB3* gene encoding the beta-subunit of the cone photoreceptor cGMP-gated channel are responsible for rod monochromacy.<sup>22</sup>

**FIG. 10.15** Full-field electroretinograms (ERGs) and Farnsworth dischromous panel D-15 test from patients with cone photoreceptor dysfunction. Second and third columns (from left), full-field ERGs recorded from two siblings with rod monochromacy showing selective absence of the photopic components. During 10-year follow-up, their visual function remained stable and their fundi remained normal. Visual acuity was 0.1/0.4 in a 13-year-old sister and 1.0/1.0 in an 18-year-old brother. The sister showed mild acquired red–green deficiency and the brother had normal color vision due to functional cones preserved only in the fovea. Fourth and fifth (columns from left), full-field ERGs recorded from a family with blue cone monochromacy (carrier

mother and son) showing normal rod components and nearly absent cone components. Although the blue cone ERG is normally present, the amplitude of the normal blue cone ERG is too small to be detected in the regular full-field cone ERG, and the implicit time is too long to follow 30-Hz flicker ERG stimuli. Rightmost column, Farnsworth dischromous panel D-15 test from Case 1 showing that several crossing lines were perpendicular to the tritan axis. (Revised and reproduced with permission from Terasaki H, Miyake Y. *Jpn J Ophthalmol* 1992; 36:132-41.)

Blue cone monochromacy shares many characteristics with rod monochromacy, except that the hereditary mode is X-linked recessive<sup>11</sup> (see [Chapter 46](#), Abnormalities of cone and rod function). The visual acuity is approximately 0.2–0.3, which is slightly better than that of the complete form of rod monochromacy. Unlike rod monochromacy, the blue cone function is selectively preserved. Panel D-15 test shows several crossing lines perpendicular to the tritan axis ([Fig. 10.15](#)). The fundus is essentially normal, although in the late stage some atrophic changes may develop in the macula. Molecular genetic studies indicate that mutations exist in the red and green opsin in the blue cone monochromacy. The full-field ERGs are similar to those of rod monochromacy, showing nearly normal rod ERGs with absence of the photopic ERG ([Fig. 10.15](#)).<sup>23</sup> Although the blue cone ERG is normally present, the amplitude of the normal blue cone ERG is too small to be detected in the regular full-field cone ERG, and the implicit time is too long to follow 30-Hz flicker ERG stimuli<sup>23</sup> (see section on S-cone ERG, below).

## Rod Photoreceptor Dysfunction

The model diseases with congenital rod photoreceptor dysfunction include Oguchi disease and fundus albipunctatus (FA), both of which are categorized as CSNB.

Oguchi disease, first reported by Oguchi<sup>24</sup> in 1907, is an unusual form of CSNB with autosomal recessive inheritance. It is characterized by a peculiar grayish-white discoloration of the fundus. This unusual fundus coloration disappears after a long period of dark adaptation, which is called the Mizuo–Nakamura

phenomenon<sup>25</sup> (see [Chapter 46](#), Abnormalities of cone and rod function). Only the rod function is abnormal and is absent after 30 minutes of dark adaptation, but the subjective and electroretinographic rod function may increase after 2–3 hours of dark adaptation.<sup>26</sup> Mutations in the genes for arrestin<sup>27</sup> or rhodopsin kinase,<sup>28</sup> both of which are important in rod phototransduction, are known to cause the recessive form of Oguchi disease.

Full-field ERGs ([Fig. 10.16](#))<sup>26</sup> recorded after 30 minutes of dark adaptation show absent rod ERG and essentially normal cone-mediated ERG. The mixed rod–cone ERG has a negative configuration with relatively well-preserved OPs. The a-wave amplitude in Oguchi disease is reduced compared to that of normal controls. As mentioned above, this ERG reflects the cone ERG in spite of the fact that the ERG is recorded in the dark and after 30 minutes of dark adaptation, because rod function is absent even under this condition. When the cone ERG is recorded with a bright flash of light, it shows the photopic hill phenomenon, and the ERG configuration is negative with a small a-wave. After 3 hours of dark adaptation, the amplitudes of the a-wave and b-wave of the mixed rod–cone ERGs are larger, but they are still negative in configuration. As the mutated genes indicate, the pathogenesis that only the rod itself is impaired in Oguchi disease is comparable to the normal photopic ERG and negative configuration with a small a-wave in mixed rod–cone ERG, but the negative configuration with a normal a-wave after a long period of dark adaptation may implicate additional abnormalities of bipolar cell function. Electro-oculogram (EOG) is abnormal with low light-to-dark ratio in most patients with Oguchi disease.<sup>26</sup>

**FIG. 10.16** Full-field electroretinograms (ERGs) recorded from normal control, patients with Oguchi disease, fundus albipunctatus (FA), and FA with cone dystrophy. Bright flash ERGs were recorded after 30 minutes and after 3 hours' dark adaptation (DA). In Oguchi disease, full-field ERGs recorded after 30 minutes of dark adaptation show absent rod ERG and essentially normal cone-mediated ERG. The mixed rod–cone ERG has a negative configuration with relatively well-preserved oscillatory potentials. Because the rod function is absent, it shows photopic hill phenomenon, and the ERG configuration is negative with a small a-wave. But the negative configuration with normal a-wave after 3 hours' dark adaptation may suggest some additional abnormalities of the bipolar cell function. In FA, the rod ERG is absent after 30 minutes of dark adaptation but becomes normal after 3 hours of dark adaptation. The mixed rod–cone ERG after 30 minutes of dark adaptation shows a negative configuration with a small a-wave, just as is seen in the photopic phenomenon of Oguchi disease. However, unlike Oguchi disease, it becomes normal after 3 hours of dark adaptation. About one-third of patients with FA have associated cone dystrophy, often showing bull's-eye maculopathy (see Fig. 10.17). Such patients show extremely

abnormal photopic ERGs in addition to the characteristic ERG findings of FA.

The pathogenesis of Oguchi disease has long been attributed to defects in rod bipolar function, as seen in complete CSNB, because reports published many years ago<sup>29</sup> indicated a normal a-wave with reduced b-wave (negative ERG) as well as a normal EOG. In addition, normal rhodopsin kinetics were shown by rhodopsin densitometry.<sup>30</sup> We demonstrated, however, that many patients with Oguchi disease show a smaller a-wave than normal as well as an abnormal EOG, suggesting that there is in fact a dysfunction of phototransduction.<sup>26</sup> Our hypothesis, derived from electrophysiologic results, seems to have been confirmed as the relevant mutations in Oguchi disease have been identified.<sup>27,28</sup>

FA has been considered to be a type of CSNB with autosomal recessive inheritance. The fundus has a characteristic appearance of a large number of discrete, small, round or elliptical yellowish-white regions at the level of the retinal pigment epithelium (see [Chapter 46](#), Abnormalities of cone and rod function). The most characteristic property of their visual function is a delay in dark adaptation, which can be detected by the psychologically determined dark adaptation curve, ERGs and EOGs. It requires 2–3 hours to attain the final dark adaptation threshold, the maximum scotopic ERG response, and the normal EOG light rise.<sup>11,30–32</sup> Examples of full-field ERGs after 30 minutes of dark adaptation and after 3 hours of dark adaptation in a typical patient with FA are shown in [Fig. 10.16](#). The scotopic (rod) ERG is absent after 30 minutes of dark adaptation but becomes normal after 3 hours of dark adaptation. The mixed rod–cone ERG after 30 minutes of dark adaptation shows a negative configuration with a small a-wave, just as is seen in Oguchi disease. However, unlike Oguchi disease, it becomes normal after 3 hours of dark adaptation. EOG is abnormal when measured using the regular method of 15 minutes of dark adaptation; however it becomes normal when the dark adaptation is prolonged.<sup>31</sup> Mutations in the gene encoding 11-*cis* retinol dehydrogenase (*RDH5*) cause delayed dark adaptation and FA.<sup>32</sup>

Although FA has been believed to be a stationary condition, our study indicated that about one-third of patients with FA are progressive, and associated with cone dystrophy.<sup>33</sup> Such patients

often have bull's-eye maculopathy (Fig. 10.17). In addition to the characteristic ERG findings of FA, the photopic ERGs are extremely abnormal (see Fig. 10.16). All of these patients also showed *RDH5* gene mutations.<sup>34</sup> The ERG results have changed the disease concept of FA, which previously had been believed to be a subtype of CSNB.

**FIG. 10.17** Fundus of a patient with fundus albipunctatus associated with bull's-eye maculopathy. (Reproduced with permission from Miyake Y, Shiroyama N, Sugita S, et al. Fundus albipunctatus associated with cone dystrophy. *Br J Ophthalmol* 1992;76:375–9, with permission from BMJ Publishing Group.)

## Rod–Cone or Cone–Rod Photoreceptor Dystrophy

Patients with cone–rod or rod–cone dystrophy belong clinically and genetically to a heterogeneous group of patients with inherited retinal dystrophies featuring a progressive disease process. They are characterized by widespread degeneration of predominantly the cone (cone dystrophy) or the rod (rod dystrophy) photoreceptors in the early stage and, at the advanced stage, patients also have remaining rod (cone–rod dystrophy) or cone (rod–cone dystrophy) degeneration. The fundus in patients with cone or cone–rod dystrophy may be within normal limits or may have subtle changes in the early stage. In such cases, patients may

be misdiagnosed as having optic nerve disease, central nervous system disease, amblyopia, or OMD (see below). These changes may progress to bull's-eye maculopathy and diffuse atrophy of the RPE in the far-advanced stage. Patients with rod–cone dystrophy show abnormal scotopic vision first, followed by abnormal photopic vision. The diseases include retinitis pigmentosa, choroideremia, gyrate atrophy, and others. Full-field ERG is important to differentiate between cone–rod and rod–cone dystrophy, particularly in their early stages.

Full-field ERGs in a typical patient with cone dystrophy and rod–cone dystrophy are shown in Fig. 10.18. Selective abnormalities of the photopic components (cone and 30-Hz flicker ERG) are seen in cone dystrophy and a more severe abnormality in rod than cone function is shown in retinitis pigmentosa as a representative example of rod–cone dystrophy. At the advanced stage, most patients with cone dystrophy also have abnormal scotopic vision (cone–rod dystrophy) and may sometimes be difficult to differentiate from rod–cone dystrophies, such as retinitis pigmentosa.

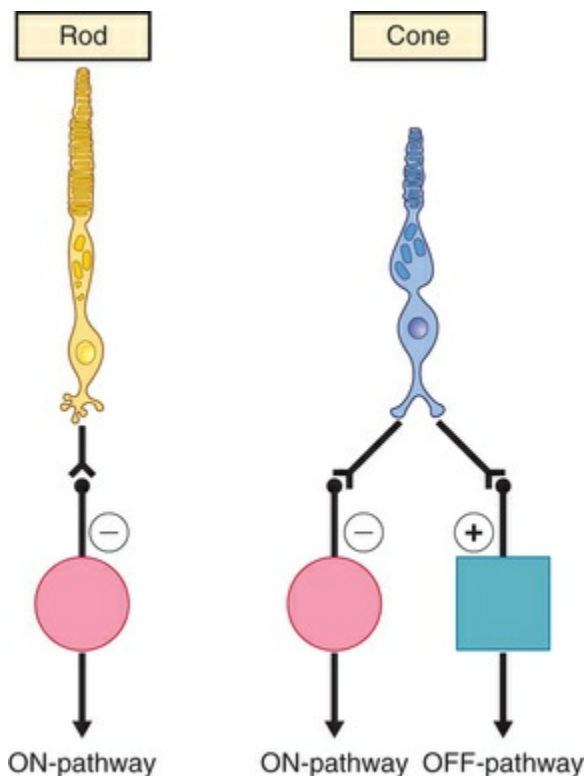

**FIG. 10.18** Full-field electroretinograms (ERGs) recorded from a normal control (top) and a patient with retinitis pigmentosa at an early stage (middle) and a

patient with cone dystrophy (bottom). The more severe abnormality in rod than cone function is shown in retinitis pigmentosa as a representative disease of rod–cone dystrophy and selective abnormalities of the photopic components (cone and 30-Hz flicker ERG) are seen in cone dystrophy. At the advanced stage, most patients with cone dystrophy also have abnormal scotopic vision (cone–rod dystrophy) and may sometimes be difficult to differentiate from a rod–cone dystrophy, such as retinitis pigmentosa. (Reproduced with permission from Miyake Y. *Electrodiagnosis of retinal diseases*. Tokyo: Springer-Verlag; 2006.)

## **Second-Order Neuron Dysfunction**

The fundamental differences between rod and cone connections to the bipolar cells are shown in [Fig. 10.19](#).<sup>35</sup> The photoreceptors transmit visual information to the bipolar cells, which are the second-order neurons. Rods contact only depolarizing (ON) bipolar cells (DBC), creating ON visual pathways. On the other hand, cones have more extensive postsynaptic connections. They synapse onto both depolarizing DBCs and hyperpolarizing OFF bipolar cells.

**FIG. 10.19** Simplified schema showing retinal wiring of the rod and cone pathway. The photoreceptors transmit visual information to the bipolar cells, which are the second-order neurons. Rods contact only depolarizing bipolar cells (DBC: ●), creating ON visual pathways. On the other hand, cones have more extensive postsynaptic connections. They synapse on to depolarizing DBCs and hyperpolarizing OFF bipolar cells (HBC: ■).

Complete and incomplete CSNB were classified as independent clinical entities based mainly on the analysis of full-field ERGs.<sup>36</sup> Unlike Oguchi disease and FA, where the responsible pathology lies mainly in the rod itself, complete and incomplete CSNB are caused by the dysfunction of ON or ON-OFF bipolar cells, respectively.<sup>35,37</sup> They are the model disorders of bipolar cell dysfunction. EOGs in both diseases are normal.<sup>36</sup> It should be noted that all of this new information in terms of the classification and pathology of both complete and incomplete CSNB was obtained from detailed analysis of ERG,<sup>36,37</sup> and molecular genetics subsequently confirmed these ERG-derived observations.

The hereditary mode of complete CSNB is X-linked recessive or autosomal recessive.<sup>36</sup> X-linked complete CSNB has a mutation of

the leucine-rich repeat proteoglycan (*NYX*) gene,<sup>38</sup> and autosomal recessive complete CSNB has a mutation in the *GRM6* gene<sup>39</sup> encoding the metabotropic glutamate receptor mGluR6 and transient receptor potential cation channel subfamily member 1 (*TRPM1*).<sup>40</sup> All these proteins are distributed on the postsynaptic ON bipolar cells and are required for the depolarization of the cell. The visual functions and ERGs are essentially the same in patients with these three different gene mutations, which have an almost complete block of ON synaptic transmission from the photoreceptors to the bipolar cells in both rod and cone visual pathways, preserving the OFF pathway intact.<sup>11</sup>

X-linked incomplete CSNB has a mutation of the calcium channel (*CACNA1F*) gene.<sup>41</sup> Loss of the functional channel impairs the calcium influx into rods and cones that is needed to sustain the tonic release of neurotransmitters from the presynaptic terminals. Therefore it is conceivable that patients with incomplete CSNB have an incomplete defect of the synapses in the ON and OFF bipolar cells in both rod and cone visual pathways.<sup>11</sup>

The comparison of full-field ERGs between complete and incomplete CSNB is shown in Fig. 10.20. The mixed rod–cone ERG shows a negative configuration with a normal a-wave in both types, but OPs can be better recorded in the incomplete type than the complete type. The normal a-wave with reduced b-wave suggests that both types of CSNB have a defect not in the rod photoreceptors but in the second-order neurons or their synapses in the rod visual pathway. These findings are comparable to molecular genetics.<sup>36–41</sup> Rod ERG is absent in the complete type but present with subnormal amplitude in the incomplete type. Absent rod ERG in complete CSNB and subnormal rod ERG in incomplete CSNB are comparable to the pathology of complete defect (complete CSNB) and incomplete defect (incomplete CSNB) of rod bipolar cell transmission. On the other hand, cone and 30-Hz flicker ERGs appear nearly normal in the complete type except that the a-wave of the cone ERG has a plateau-like bottom (Fig. 10.20). In contrast, the cone and 30-Hz flicker ERGs are extremely reduced in incomplete CSNB, which is highly characteristic and extremely important for the differential diagnosis.

**FIG. 10.20** Full-field electroretinograms (ERGs) recorded from a normal control, patient with complete or incomplete congenital stationary night blindness (CSNB), and patient with X-linked retinoschisis (XLRS). In CSNB, the mixed rod–cone ERG shows negative configuration with a normal a-wave in both types, suggesting a defect not in the rod photoreceptors but in the second-order neurons or their synapses in the rod visual pathway. However, oscillatory potentials can be recorded better in the incomplete type than the complete type. Rod ERG is absent in the complete type but present with subnormal amplitude in the incomplete type. On the other hand, cone and 30-Hz flicker ERGs appear nearly normal in the complete type except that the a-wave of the cone ERG has a plateau-like bottom. In contrast, the cone and 30-Hz flicker ERGs are extremely reduced in incomplete CSNB, which is highly characteristic and extremely important for the differential diagnosis. In XLRS, the mixed rod–cone ERG shows a negative configuration, which is observed even when the retinoschisis is confined to the fovea ophthalmoscopically. The full-field ERG findings similar to those of incomplete CSNB suggest that both ON and OFF bipolar cell function is mainly impaired in the rod and cone visual pathways. (Reproduced

with permission from Miyake Y. *Electrodiagnosis of retinal diseases*. Tokyo:

Springer-Verlag; 2006.)

In spite of the complete defect of the ON visual pathway, cone and 30-Hz flicker ERG responses in complete CSNB appear nearly

normal. This mechanism can be explained by the analysis of photopic long-flash ERG,<sup>35,37</sup> as shown in Fig. 10.21. Using photopic ERGs elicited by long-duration square-wave stimuli, the cone ON response generated by depolarizing ON bipolar cells is selectively and severely depressed in patients with complete CSNB; moreover, the waveform is similar to that of monkeys after 2-amino-4-phosphonobutyric acid (APB) is injected into the vitreous to block the synapse between photoreceptors and ON bipolar cells.<sup>35</sup> The OFF response, on the other hand, which is generated by hyperpolarizing bipolar cells, is intact in patients with complete CSNB, leading us to hypothesize that the ON function of both the rod and cone visual pathway is completely blocked in eyes with complete CSNB.<sup>35,37</sup> The mechanism as to why normal-looking brief-flash cone ERG can be obtained under this condition is shown in Fig. 10.22. With long-duration stimuli, the a-waves, b-waves, and d-waves are clearly separated. As the stimulus duration is shortened (brief-flash stimuli), the positive component of the photopic ERG consists mainly of the d-wave. Therefore even when the b-wave, a component of the ON response, is absent (as in complete CSNB), the d-wave replaces the b-wave, and a positive wave is recorded with brief-flash stimuli.<sup>11</sup> With incomplete CSNB, on the other hand, the ON and OFF response are both subnormal, suggesting that the ON and OFF systems are incompletely disturbed at the level of the bipolar cells.<sup>11,37</sup>

**FIG. 10.21** Comparison of photopic long-duration electroretinograms (ERGs) recorded from a monkey and a human. (Left) Normal control ERG for the monkey eye and after being treated by 2-amino-4-phosphonobutyric acid (APB). (Right) ERGs recorded from a normal human control, from a patient with complete congenital stationary night blindness (CSNB), and from a patient with incomplete CSNB. The cone ON response generated by depolarizing ON bipolar cells is selectively depressed whereas the OFF response, which is generated by hyperpolarizing bipolar cells, is intact in patients with complete CSNB; moreover, the waveform is similar to that of monkeys treated with APB. (Reproduced with permission from Kondo M, Piao CH, Tanikawa A, et al. *Jpn J Ophthalmol* 2000;44:20–8, with permission.)

**FIG. 10.22** Photopic electroretinograms (ERGs) elicited by square-wave stimuli of various durations from a normal control and a patient with complete congenital stationary night blindness (CSNB), explaining why complete CSNB shows normal-looking brief-flash cone ERG. With long-duration stimuli, the a-waves, b-waves, and d-waves are clearly separated. As the stimulus duration is shortened (brief-flash stimuli), the positive component of the photopic ERG consists mainly of the d-wave. Therefore even when the b-wave, a component of the ON response, is absent (as in complete CSNB), the d-wave replaces the b-wave, and a positive wave is recorded with brief-flash stimuli. Thick lines underneath the responses represent the stimulus duration. (Reproduced with permission from Miyake Y. *Nippon Ganka Gakkai Zasshi* 2002;106:737–56.)

XLRS is a vitreoretinal dystrophy that manifests early in life. XLRS is one of the more common causes of juvenile macular degeneration in males. Intraretinal cysts form in the macula and splitting of the retinal layers occurs in the peripheral retina (see [Chapter 43](#), Hereditary vitreoretinal degenerations). Most patients, including young individuals show moderately poor visual acuity that gradually decreases with increasing age. Hypermetropia has

been shown to be a frequent accompaniment of this disorder.<sup>42</sup> In fact many patients with XLRS are first diagnosed with hypermetropic amblyopia or heterotropia during infancy.

As mentioned above, mixed rod–cone ERG is of significant diagnostic value because of the negative configuration. The negative ERG is observed even when the retinoschisis is confined to the fovea ophthalmoscopically. The full-field ERG findings (see Fig. 10.20) are similar to those of incomplete CSNB, suggesting that both ON and OFF bipolar cell function is mainly impaired in the rod and cone visual pathways. The EOG in XLRS is normal.

The schisis occurs in the plane of the nerve fiber and ganglion cell layers of the retina. It has long been suggested that degenerating Müller cells or inner retinal cells may be the primary cause of the pathologic changes in XLRS. The XLRS gene was cloned in 1997 and was designated *RS1*.<sup>43</sup> However, the RS1 protein is heavily expressed in inner segments of both rod and cone photoreceptors and is also seen in cells of the inner nuclear layer. There is some discrepancy between the results of full-field ERG and genetic findings. Although the expression of RS1 protein is heavily concentrated in the inner segments of both rods and cones, ERG studies suggest that it does not inherently affect the photoreceptor function of either cell type. And from the above ERG and EOG results, it currently is reasonable to propose that both ON and OFF pathways are defective, although precise subcellular localization has not yet determined whether both depolarizing and hyperpolarizing bipolar cells are involved.<sup>44</sup>

## Focal ERG

In order to record the ERG responses with focal stimuli, there are two methods that have been previously described. The conventional focal macular ERG can show a similar waveform as a conventional photopic ERG from the limited area of the macula.<sup>45</sup> The advantage of this method is that the analysis of ERG components can be done using the same concept as that of full-field photopic ERG. By analyzing several components, layer-by-layer macular function can be evaluated.

Another method is the mfERG technique, which was developed

in 1992.<sup>46</sup> With this method, focal ERGs can be recorded simultaneously from multiple retinal locations during a single recording session using cross-correlation techniques. Unlike conventional focal macular ERGs, there are still questions about how this method works and what it measures because the technique is relatively new. We have an impression that the layer-by-layer analysis of the macula can be done more precisely using focal macular ERG than with mfERG.

## Principle, Method, and Characteristics

The focal macular ERG is primarily used to evaluate macular function. The full-field ERG is unable to detect small focal lesions or pathologies in the retina, and may be normal in the presence of macular diseases. In contrast, the full-field ERG may be undetectable when only macular function is preserved, such as in patients with retinitis pigmentosa.<sup>11</sup>

The principle of recording of the focal macular ERG includes presenting a small stimulus to the macula and recording the response from the stimulated area by summing the responses using a computer. To eliminate contaminating stray light responses, background illumination must be used to depress the sensitivity of the area surrounding the stimulus. By combining the focal stimulus with background illumination properly, focal responses can be recorded. It is also essential to monitor the location of the stimulus on the fundus during the recordings, particularly in eyes with a central scotoma, to be certain that only the fovea is stimulated. An example of a recording system of focal macular ERG is shown in [Fig. 10.23](#). The examiner records the ERGs while monitoring the fundus by the infrared television fundus camera. The optical system of an adequate combination of stimulus light and background illumination for focal stimulus is installed in the fundus camera, and the focal macular ERGs can be recorded under the fundus monitor by summing the responses with a computer. Focal macular ERGs recorded from a normal subject demonstrating the various components are shown in [Fig. 10.24](#). All components of photopic ERG can be recorded: they are a-waves, b-waves, OPs, PhNR, ON and OFF components, and 30-Hz flicker responses.<sup>11</sup>

**FIG. 10.23** Overall view of the observation and stimulation systems for focal macular electroretinogram (ERG) and visually evoked response (VER) recordings. The examiner records the ERGs while monitoring the stimulus on the fundus by the infrared television fundus camera (A). A plastic

hemisphere with miniature lamps is attached to the top of the camera to obtain background illumination for the peripheral retina (B). A Burian–Allen bipolar contact lens is used to record the ERGs (C). (Revised with permission from Miyake Y, Yanagida K, Kondo T, et al. *Nippon Ganka Gakkai Zasshi* 1981;85:1521–33.)

**FIG. 10.24** Components of the focal macular electroretinogram recorded from a normal subject. ON and OFF responses recorded with 1-Hz stimulus frequency (top); a-wave, b-wave, and oscillatory potentials recorded with 5-Hz stimulus frequency (middle); and 30-Hz flicker responses (bottom) are shown. Arrows indicate photopic negative response. T.C., time constant. (Reproduced with permission from Miyake Y. *Electrodiagnosis of retinal diseases*. Tokyo: Springer-Verlag; 2006.)

Several important characteristics of focal macular ERG in humans were detected, particularly in macular OPs.<sup>45</sup> An example is shown in [Fig. 10.25](#), demonstrating nasotemporal asymmetry.<sup>47</sup> Semicircular stimuli were used to compare the ERGs elicited by stimulating the temporal and nasal macula. The amplitudes and

implicit times of the a-waves and b-waves in the nasal retina are almost identical to those from the temporal retina, whereas the amplitudes of the OPs are much larger in the temporal retina than in the nasal retina. The amplitude of the focal ERGs recorded with circular stimulus is approximately the same sum as the amplitudes of the temporal and nasal ERGs.

**FIG. 10.25** Comparison of focal electroretinograms using semicircular stimuli with the edge of the semicircle passing through the vertical axis (top) on the nasal and temporal macular areas and a circular stimulus (15°). The oscillatory potentials in the temporal macula are significantly larger than those in the nasal macula, and only the oscillatory potentials show this significant asymmetry. T.C., time constant.

*Invest Ophthalmol Vis Sci* 1989;30:1743–9.)

The principle, recording method, and clinical applications of mfERG are described in an ISCEV guideline.<sup>48</sup> Readers are also referred to [Chapter 9](#) (Electrogenesis of the electroretinogram), where the origin of the mfERG is described in detail.

## Clinical Applications

The examples of value of focal ERG are shown here. In focal macular ERG, the macular OPs are the most sensitive indicator in variable macular diseases. The selective reduction of macular OP amplitude is observed in the early stage of macular edema,<sup>49</sup> epimacular membrane,<sup>50</sup> and the convalescent stage of central serous chorioretinopathy.<sup>51</sup> The fluorescein angiograms and focal macular ERGs in an eye with pseudophakic cystoid macular edema (CME) and after resolution of CME are illustrated in [Fig. 10.26](#). The OPs of the focal macular ERGs are selectively reduced compared with that of a normal fellow eye. The visual acuity of this eye with CME was 0.6. Six months later, the CME resolved spontaneously, and fluorescein angiography disclosed a normal pattern; the visual acuity improved to 1.2. The focal macular ERGs returned to normal levels, with the amplitude of the OPs comparable to those from the normal fellow eye.<sup>51</sup>

**FIG. 10.26** Focal macular electroretinograms (ERGs) (left) and fluorescein angiograms (right) in a 51-year-old man with pseudophakic cystoid macular edema (CME: top) and after the resolution of CME (bottom). The oscillatory potentials of the focal macular ERGs are selectively reduced compared with that of a normal fellow eye. The visual acuity of the eye with CME was 0.6 (20/30). After spontaneous resolution of the CME, the focal macular ERGs returned to normal levels, with the amplitude of the oscillatory potentials comparable to those from the normal fellow eye. The visual acuity improved to 1.2. T.C., time constant. (Reproduced with permission from Miyake Y, Miyake K, Shiroyama N, et al. *Am J Ophthalmol* 1993;116:576–83.)

Occult macular dystrophy (OMD) is one of the most representative disorders where the focal macular ERG or multifocal ERG is a key for diagnosis. OMD was discovered by focal macular

ERG in 1989.<sup>52</sup> The clinical findings of OMD are progressive decrease of visual acuity, normal fundus and fluorescein angiograms, normal full-field ERGs, but abnormal focal macular ERG and multifocal ERG (Fig. 10.27). Although the fundus appearance and fluorescein angiogram show normal findings in OMD, optical coherence tomography (OCT) may reveal some mild photoreceptor abnormalities even in its early stage. Whether focal macular ERG or OCT is more sensitive to detect early abnormality is an interesting topic of debate. The key point, though, is that OMD may not be a rare disorder and many patients with OMD may be misdiagnosed as having several other diseases, such as a psychologic eye problems, optic nerve disorders, central nervous system disease, or amblyopia.<sup>53</sup>

**FIG. 10.27** The clinical findings of occult macular dystrophy. (Left top) Normal fundus and fluorescein angiograms; (left middle) optical coherence tomography images from a normal person and a patient with occult macular dystrophy. The horizontal section through the foveal center demonstrates an abnormality, especially in the outer retinal bands at the

fovea in the patient. (Left bottom) Wave three-dimensional topography and multifocal electroretinogram (ERG) trace array from a normal person and a patient, showing markedly reduced response density in the central 7° of the retina. (Right top) Full-field ERGs showing normal responses; (right bottom) focal macular ERG showing abnormal responses in the patient.

The hereditary mode of OMD is autosomal dominant, although some patients show a sporadic mode.<sup>52,53</sup> Our genetic studies have detected mutations in retinitis pigmentosa 1-like 1 (*RP1L1*) gene in autosomal dominant OMD.<sup>54</sup> It was demonstrated that *RP1L1* plays an essential role in cone function in humans and that disruption of *RP1L1* function leads to OMD.

Acute zonal occult outer retinopathy is characterized by an acute zonal loss of one or more large zones of central retinal function in one or both eyes, predominantly in young women.<sup>55</sup> Other ocular findings include initially minimum ophthalmoscopic changes, photophobia, and permanent visual field loss, often associated with late development of retinal pigmentary changes and narrowing of the retinal vessels in the affected zones (see [Chapter 79](#), White spot syndromes and related diseases). Since the full-field ERG may be normal or only slightly abnormal, it is not informative. The responses of mfERG become abnormal in the limited area where visual field loss is present<sup>11</sup> ([Fig. 10.28](#)).

**FIG. 10.28** Clinical findings of a patient with acute zonal occult outer retinopathy. A 22-year-old female

developed acute central visual loss in the right eye. Visual acuity was 0.5 (20/40) in the right eye and 1.2 (25/20) in the left eye. The top and bottom left panels are 61 response arrays and three-dimensional plots of the multifocal electroretinograms, respectively, showing abnormal responses in the limited area, where visual field loss is present in the right eye. The top right panels are the deviation plot of the static visual field, showing reduced sensitivity in the central area in the right eye. The bottom right panels are Fourier-domain optical coherence tomographic (FD-OCT) images from the affected right eye and intact left eye, respectively, showing that both the border of the photoreceptor inner- and outer-segment line (IS/OS line, also called ellipsoid zone, EZ) and the cone outer-segment tip (COST, also called interdigitation zone, IZ) line between the EZ and the retinal pigment epithelium (RPE) are absent in the macular area of the right eye. The EZ, IZ, and RPE/Bruch membrane are intact in the left eye.

## Other Special Responses or Techniques in ERG

### Photopic Negative Response

Photopic negative response (PhNR) has already been described and is a negative wave in the photopic ERG that is evoked following the b-wave (see [Figs. 10.14](#) and [10.24](#)). The origin of the PhNR is the retinal ganglion cells,<sup>21</sup> and this is fully described in [Chapter 9](#) (Electrogenesis of the electroretinogram). Significant reduction in PhNR was reported in patients with open angle glaucoma and several other optic neuropathies.<sup>21</sup> Moreover, recent analysis of PhNR recorded in focal macular ERG (see [Fig. 10.24](#)) and mfERG has enabled objective assessment of retinal ganglion cell damage in glaucoma, optic nerve disease, and retinal vascular diseases.<sup>56,57</sup> Other studies showed that PhNR can be correlated with retinal sensitivity as well as retinal microstructure such as nerve fiber layer thickness.<sup>58</sup>

## ERG Recordings by Light-Emitting Diodes

Light-emitting diodes (LEDs) (Fig. 10.29) have been a topic of great interest recently, as light sources to elicit and record full-field ERG.<sup>59</sup> The LEDs are small and inexpensive, and they require low currents to drive them. They can be controlled by a simple electronic circuit to provide either a continuous light output or extremely brief flashes over a large range of intensities. The stimulus and recording system using LED can be used not only for routine full-field ERG but also for some other special applications of clinical ERG described below.

**FIG.10.29** Structure of the white light-emitting diode (LED) contact lens electrode. (A) Relative spectral emission of the LED. (B) Output that appears as visible white. (C) Structure of the contact lens electrode with three built-in white LEDs. *PMMA*, polymethylmethacrylate. (Reproduced with permission from Kondo M,

Piao CH, Tanikawa A, et al. *Doc Ophthalmol* 2001;102:1–9.)

## ERG Recording Under General Anesthesia<sup>11</sup>

ERG recordings with LED are useful for recording standard ERGs from pediatric patients under general anesthesia. The equipment

needed to obtain recordings that correspond to ISCEV standard ERGs is compact and easily portable.<sup>60</sup> The ERGs recorded using an LED system on a 3-month-old baby under general anesthesia and a normal adult are compared in Fig. 10.30.

**FIG. 10.30** Full-field electroretinograms (ERGs) recorded with white light-emitting diode (LED) contact lens electrodes from a normal adult subject (left) and a normal 3-month-old baby (right). The pictures show standard full-field ERG recording from a baby using this system. (Top) LED contact lenses are placed in both eyes under general anesthesia. (Bottom) Background illumination from the contact lens is used during the recording of the photopic ERGs in the dark. (Reproduced with permission from Miyake Y. *Electrodiagnosis of retinal diseases*. Tokyo: Springer-Verlag; 2006.)

Tokyo: Springer-Verlag; 2006.)

## ERG Monitoring During Eye Surgery

As vitreoretinal surgery continues to advance, close monitoring of retinal function during these procedures has become important. Although ERGs directly reflect retinal function, monitoring during surgery has proven difficult. Each recording must be made quickly under aseptic conditions, and the instruments and electrodes must be such that they do not cause interference for the retinal surgeon. Furthermore, the eye undergoing surgery is intensively light-

adapted.

The LED contact lens electrode has been found to be highly suitable for this purpose.<sup>61</sup> It is easily sterilized and is used as both a stimulus source and a recording electrode for 30-Hz flicker ERGs during vitreoretinal surgery (Fig. 10.31). An example of ERG monitoring during vitrectomy from a patient with epimacular membrane is shown in Fig. 10.31. The ERGs recorded after local anesthesia (*Start*), and after the introduction of the infusion needle into the vitreous cavity (*Infusion*) were not significantly different in regard to amplitude and peak time. However, after vitrectomy, which required 10 minutes, the peak time was delayed and the amplitude decreased (*Vitrectomy*). Additional studies have demonstrated that lowering the intravitreal temperature by applying an infusion solution kept at room temperature can alter the ERG during vitrectomy. Filling the whole vitreous cavity with air after the epimacular membrane was peeled off resulted in a markedly reduced amplitude and delayed peak time (fluid–air exchange). This extreme reduction of ERG following fluid–air or fluid–silicon oil exchange in the vitreous cavity results from reduced electrical conductivity in the vitreous cavity. Five days after surgery, when the air was resolved from the vitreous cavity, the ERG recovered to the postoperative amplitude and peak time.

**FIG. 10.31** Full-field electroretinogram (ERG) recording during vitrectomy. (Left) A light-emitting diode (LED) electrode is sterilized and placed on the cornea undergoing surgery. (Right) 30-Hz flicker ERGs recorded during vitrectomy in a patient with epimacular membrane. *Start* indicates the time when local

anesthesia was completed and *Infusion* denotes the time the infusion needle was introduced into the vitreous cavity. (Reproduced with permission from Miyake Y.

Electrodiagnosis of retinal diseases. Tokyo: Springer-Verlag; 2006, and Horiguchi M, Miyake Y. Arch Ophthalmol 1991;109:1127–9.)

## S-Cone ERG

Recording short-wavelength cone (S-cone) ERGs is valuable clinically because it allows us to evaluate the S-cone visual system. S-cone ERGs have been recorded using stimulation with strong blue stimuli on a bright yellow background, which suppresses the middle- and long-wavelength (LM) cone system.<sup>62</sup> LEDs emitting blue light can be used in the LED built-in contact lens electrode<sup>63</sup> (Fig. 10.32). By using bright yellow background illumination, the S-cone ERGs are recordable and are compared with LM cone ERGs (Fig. 10.32). The amplitude is much smaller and the implicit time is longer than those of the LM cone ERG. The components that reflect the OFF visual system (a-waves and d-waves) are essentially absent in S-cone ERGs because, unlike the LM cone system, the S-cone is mainly connected to the ON visual system.<sup>64</sup>

**FIG. 10.32** S-cone electroretinogram (ERG) recording with blue-emitting light-emitting diode (LED) built-in contact lens electrode. (Top) LED built-in contact lens electrode with blue-emitting LEDs. (Bottom) Comparison of long-wavelength (LM) cone and S-cone ERGs with long-duration stimuli in a normal subject. The a-wave and d-wave that reflect the OFF visual system are essentially absent in the S-cone ERGs, because, unlike the LM cone system, the S-cone is mainly connected to the ON visual system. (Reproduced with permission from Miyake Y. *Electrodiagnosis of retinal diseases*. Tokyo: Springer-Verlag; 2006, and Horiguchi M, Miyake Y, Kondo M, et al. *Invest Ophthalmol Vis Sci* 1995;36:1730–2.)

## Electro-Oculogram

In 1849, Du Bois Reymond<sup>65</sup> reported that in the normal eye there is a flow of electrical current, because the cornea is positive with respect to the back of the eye. The source of the voltage is the corneofundal potential. This potential difference is referred to as the standing potential or resting potential of the eye. The EOG is an indirect measure of the amplitude of the standing potential, which changes during dark and light adaptation. To obtain an EOG in humans, electrodes are placed at the inner and outer canthi of the eyes and the patient is asked to look back and forth between a pair of fixation lights. When the cornea moves closer to one of the electrodes, it becomes more positive and the other electrode becomes more negative. The opposite happens when the eyes move to the other side.

The principle and practical use of EOG are described in the ISCEV standard.<sup>66</sup> The changes in the amplitude of the EOG in the dark-adapted and light-adapted state of a normal subject are shown in [Fig. 10.33](#). The smaller amplitudes are recorded when the eyes make the saccadic eye movements in the dark (dark trough); the peak amplitude is recorded against a steady light background (light peak). The light peak/dark trough (L/D) ratio is an index (Arden index)<sup>67</sup> used to assess retinal function. Generally, a ratio of 1.80 is the lower limit of normal.

**FIG. 10.33** Electro-oculogram (EOG) recordings. (Top) Diagram illustrating the EOG test and the determination of the light peak/dark trough (L/D) ratio (Arden ratio), which is 2.0 in this case. The smaller amplitudes are recorded when the eyes make saccadic eye movements in the dark (dark trough); the peak amplitude is recorded against a steady light background (light peak). (Bottom) Plottings of the amplitude of EOG in a normal subject and a patient with Best disease. The Arden ratio is 2.0 for the normal subject and 1.3 for the patient.

The origin of the retinal standing potential is thought to be in the retinal pigment epithelium. However, the light rise is generated by light stimulation of the photoreceptor–retinal pigment epithelium complex; and it is not detected when certain structures of the middle retinal layers are affected, such as in central retinal arterial occlusion.<sup>68</sup>

The EOG is generally abnormal in any condition in which the flash ERG is abnormal, except complete or incomplete CSNB.<sup>36</sup> The reverse, however, is not true. An abnormal EOG with a normal ERG may be seen in Best disease, pattern dystrophy of the RPE, and dominant drusen. The clinical relevance of EOG in each of these disorders is described in more detail in [Chapter 44](#) (Macular dystrophies).

# Visual Evoked Potential

The visual evoked potential (VEP) is the signal of the brain evoked by the visual stimulus. It is recorded, like the electroencephalogram (EEG), at the scalp in the occipital region by surface electrodes. The principle and practical use of clinical VEP are shown in the ISCEV standard.<sup>69</sup>

The cellular sources of the VEP are poorly understood. VEPs can be recorded under either transient or steady-state stimulus conditions. The transient VEP includes flash VEP, pattern reversal VEP, and pattern onset/offset VEP (Fig. 10.34).

**FIG. 10.34** Three standard responses in a clinical visual evoked potential (VEP) test. (Top) VEP stimulation. (Left) Flash stimulus is delivered with monitor or full-field dome. Such a dome is used for recording full-field electroretinogram as well and a pair

of fixation lights in the dome is used for an electro-oculogram test. (Middle) Reversing black-and-white checkerboard stimulus provided using cathode ray tube or light-emitting diode (LED) monitor. (Right) Reversing black-and-white checkerboard stimulus with diffuse blank screen at regular intervals is presented.

Several important features of the VEP can be stated:

1. The VEP is dominated by the central 20° of retina owing to “cortical magnification.”
2. The VEP is highly variable among individuals, but varies less than 10% bilaterally when responses from the two eyes of a single person are compared.
3. VEP abnormality can result from abnormality in the retina, optic nerve, optic tracts, optic radiations, or visual cortex.

The flash VEP is easy to record, so it is performed for evaluation of gross visual function in infants, small children, or in individuals who are unable to perform PERG because of poor fixation due to poor visual function, nystagmus, or poor cooperation. Since flash VEP may still be recordable in patients with undetectable ERGs, such as in retinitis pigmentosa or dense vitreous hemorrhage, simultaneous recordings of flash VEP and ERG may provide useful information.<sup>70</sup>

## Simultaneous Recording of Focal Macular ERG and VEP

Another useful evaluation featuring a layer-by-layer analysis of the visual pathway is simultaneous recording of focal macular ERG (fERG) and focal macular VEP (fVEP) with special reference to PhNR. The origin of PhNR is considered to be in the ganglion cells (see Fig. 9.20 in Chapter 9) and this component can also be recorded in fERG (see Fig. 10.24). Results of three patients are shown to illustrate how the simultaneous recording can work for layer-by-layer diagnosis in the visual pathway.<sup>71</sup>

**Fig. 10.35A** (left panel) shows the simultaneous recording of fERG and fVEP recorded (with stimuli 15° in diameter) from a 32-year-old man with longstanding central serous chorioretinopathy in his right eye. The onset was approximately 10 years ago and there still remained shallow retinal detachment in the macula with a few precipitates underneath the sensory retina, consistent with the history of central serous chorioretinopathy. His left eye was normal. In our initial examination, his visual acuity was 0.06 (right eye) and 1.5 (left eye). A relative central scotoma, approximately 15° in diameter, was detected in his right eye. fERG of the affected eye shows a definitely smaller amplitude than that of the normal fellow eye in all components, including PhNR. The amplitude of the fVEP, however, did not diminish significantly and the implicit time was slightly delayed as compared with the normal fellow eye. This finding can be a model of photoreceptor dysfunction in the macula.

**FIG. 10.35** Simultaneous recording of focal macular ERG (fERG) and focal macular VEP (fVEP). (A, left) Comparison of fERG and fVEP between affected eye and normal fellow eye in a 32-year-old man with longstanding central serous chorioretinopathy. (A, right) Comparison of fERG and fVEP between affected

eye and normal fellow eye in a 65-year-old man with unilateral optic atrophy. Bottom tracings indicate responses from photocoell. In panels A and C, positivity at inion electrode results in upward deflection in fVEP. (B) Visual field of left eye in a 56-year-old man with posterior cerebral arterial occlusion resulting in bilateral upper hemianopsia. (C) Location of hemicircular stimuli (top) and simultaneously recorded fERG and fVEP with these stimuli (bottom) of left eye of the patient in panel B. (Reproduced with permission from Miyake Y.

Japn J Ophthalmol 1990;34:225-2389, with permission.)

**Fig. 10.35A** (right panel) shows the results of a 65-year-old man with unilateral optic atrophy in his right eye. The fundus of the left eye was normal. His visual acuity was 0.08 (right eye) and 1.0 (left eye). The a-wave and b-wave of the fERG recorded with a 10° spot stimulation were almost identical in both eyes but the PhNR (*arrows*) of the affected eye was smaller than that of the normal fellow eye. fVEP was very abnormal in the affected eye. These results indicate that the abnormal PhNR and fVEP were caused by the dysfunction of the retinal ganglion cells.

A 56-year-old man had posterior cerebral arterial occlusion resulting in bilateral superior hemianopsia (**Fig. 10.35B**). Because of sparing of the fovea, visual acuity was 1.2 in both eyes. fERG and fVEP were simultaneously recorded in the left eye, with hemicircular stimuli (15° in diameter) projected onto the visual field defect (lower retina) and onto the opposite superior fundus with no visual field defect (**Fig. 10.35C**). The fovea (small fixating target) was not targeted with either stimulus, and the distance from the fovea of each stimulus was approximately the same. fVEP was very small in the area of the visual field defect, while it was normal in the area of normal visual field. fERG, however, did not show any difference between these two areas, including PhNR (*arrows*). This result indicates that the visual field defect is not caused by the ganglion cell dysfunction, but by an abnormality at the level of the visual cortex.

## Introduction

Ultrasonography is a pervasive diagnostic tool within medicine. It is used to obtain noninvasive images that can aid in the management of patients in almost all fields of medicine. Ultrasound technology has a unique role in ophthalmology since it can provide quantitative and qualitative assessments of the globe and orbit. Ultrasound images are formed by capturing the reflected acoustic signal from different tissues. These images can provide important details of almost every part of the eye from the anterior cornea and ciliary body to the posterior retina and choroid. This chapter will explain the principles involved in ophthalmic ultrasound as well as provide examples of its use within ophthalmology.

## Ultrasound – Past and Present

In 1880 the Curie brothers first demonstrated that a difference in electric potential could be created by mechanically pressing opposing surfaces of a tourmaline crystal.<sup>1-7</sup> This phenomenon is called the piezoelectric effect. This effect is the basis for ultrasound technology and was first applied in underwater sonar systems during World War II.<sup>8</sup> During that same era the medical community also adopted the use of ultrasound technology. Scientists realized the diagnostic potential of this technology when they were able to use acoustic wavelengths to study the consistency of a material without damaging the material itself.

In 1949 Ludwig used ultrasound to detect gallstones in patients. The first publication on the use of ophthalmologic ultrasound appeared in the medical literature in 1956.<sup>9</sup> By the mid-1970s, ophthalmologists were using ultrasound to determine axial length in a clinical setting. These measurements facilitated calculations of intraocular lens power which led to a revolution in cataract surgery.<sup>10</sup> Further innovations came when Baum and Greenwood introduced their two-dimensional B-mode image to ophthalmology.<sup>11</sup> Soon afterwards, Bronson et al.<sup>12</sup> developed a handheld contact transducer for this type of image acquisition which led to the rapid dissemination of ultrasound devices within ophthalmology clinics. The B-mode images could be used to accurately delineate retinal detachments, vitreous membranes, and choroidal tumors. In the early 1990s new technology made it possible to image the anterior segment of the eye with devices that captured images at higher frequencies of 35–50 MHz. This improved image resolution four- to fivefold and is still the gold standard for analysis of certain anterior-segment disease such as ciliary body effusions, infiltrates, and tumors.

## Examination Techniques

The ultrasound examination is performed with the patient in a reclined position. The frequency of the ultrasound cannot pass through air; therefore, a coupling medium is needed to transmit the sound waves from the transducer to the ocular tissues. A common coupling agent is methylcellulose (Fig. 11.1). The coupling agent is applied to the tip of the transducer probe, which is then placed on the patient's anesthetized cornea.

**FIG. 11.1** Ultrasound images simulating the effect of transducer (A) without tissue-coupling agent, (B) with partial tissue-coupling agent, and (C) with a complete coupling agent, such as a gel-like contact substance.

## A-Mode Technique

The A-scan is a linear representation of echo amplitude that is acquired along a single line of sight. Measurements of the ocular tissue can be achieved using the time interval between emission of the acoustic pulse and echo return to calculate the distance of the tissue being imaged. A-scan images should be obtained only through open lids since the eyelid tissue can attenuate the sound waves and decrease the resolution. The pressure applied by the examiner to the transducer tip is especially important when obtaining A-scan measurements. Excessive pressure can deform the cornea, and lead to inaccurate measurements.

## B-Mode Technique

The B-scan is a two-dimensional cross-section image formed by mechanically sweeping the transducer over an angle of 50–60 degrees with the probe oriented in a specific axis. A systematic approach should be used to acquire all images. One method is first to obtain axial scans of the globe by placing the probe in the center of the cornea with the transducer tip oriented toward 12 o'clock in order to image the posterior pole and optic nerve. Next, the transducer can be turned temporally 90 degrees to obtain images through the macula. Finally, radial and transverse images of the globe can be obtained by placing the probe at each clock-hour

around the limbus. Radial scans are acquired when the probe is placed perpendicular to the limbus and the transducer tip is oriented toward the cornea. Transverse scans are obtained by turning the probe 90 degrees, orienting the transducer tip parallel to the limbus. The images obtained are the acoustic reflections from the opposing inner surface of the globe.

The reflected sound waves are recorded by the device and can be viewed as a two-dimensional image on the screen (Fig. 11.2). The ocular structures can be examined individually. The cornea is characterized ultrasonographically by two separate acoustic interfaces. The anterior chamber appears planoconvex in cross-section. The iris diaphragm cannot be satisfactorily imaged because of the limited lateral resolution power of the normal B-mode. A clear lens is acoustically empty and appears as an ellipsoid structure in axial sections. Similarly, normal vitreous does not give an acoustic signal; however, the presence of a detached posterior vitreous membrane presents an interface that can be imaged by increasing the amplification of the echo signal. The sclera is the most strongly reflecting structure on ocular ultrasonography.

**FIG. 11.2** (A) Cross-sectional echogram through a normal globe. (B) Schematic drawing of the eye: the arrow marks the entrance of the optic nerve.

## High-Frequency Ultrasound Technique

High-frequency echograms can be used for ultrasound biomicroscopy (UBM). The shorter wavelengths provide better resolution of the anterior structures of the eye, including the cornea, lens, aqueous (Fig. 11.3), and ciliary body (Fig. 11.4).<sup>13</sup> High-frequency probes range from 50 to 100 MHz.<sup>14-16</sup> The 50-MHz probe provides the best balance between depth and resolution for UBM technique. One limitation of this technique is that the shorter wavelengths, from the higher frequency, have poor depth of penetration. UBM cannot visualize structures deeper than 4 mm from the surface.

**FIG. 11.3** The ultrasound biomicroscopy images of the anterior segment in (A) a phakic and (B) a pseudophakic eye with multiple echo of implant surface.

**FIG. 11.4** Ultrasound biomicroscopy of the ciliary body. The shorter wavelengths are able to obtain high-resolution images of the anterior structures.

UBM requires immersion of the transducer in a medium to transmit the higher-frequency wavelengths. Saline or methylcellulose can be used as the coupling agent and is held in place over the eye with the use of a custom cup during the examination. UBM is performed through open eyelids in order to obtain a good reflection signal. Images produced by UBM have a resolution of 30–40  $\mu\text{m}$ , which is similar to that seen with a low-power microscope.<sup>17</sup>

The cornea is the first structure seen on UBM. The anterior-chamber depth can be measured from the posterior surface of the cornea to the anterior lens pole. The posterior lens pole cannot be imaged by UBM due to its distance from the anterior surface. The iris is seen as a flat uniform echogenic area. The iris and ciliary body converge in the iris recess and insert into the scleral spur. The area under the peripheral iris and above the ciliary processes is defined as the ciliary sulcus. The angle of the eye can be studied in cross-section by orienting the probe in a radial fashion at the limbus. The scleral spur is the most important landmark in the angle on UBM.

## Doppler Ultrasound

Doppler images are obtained by using frequency shifts from acoustic reflections to measure movements within a tissue and flow conditions within vessels. These frequency shifts can be observed in tissue volumes of less than 0.01 mL. False color can be added to the images based on ultrasound frequency to distinguish between higher and lower flow states, which aids in the interpretation of the final result (Fig. 11.5).

**FIG. 11.5** Cross-sectional ultrasonogram through the posterior pole of the eye: color-coded signals from the central retinal artery (red) and the central retinal vein (blue) are displayed inside the optic nerve.

## Ultrasound Biometry

Basic physics formulae can be used to calculate the speed of sound as it passes through various ocular tissues. This number can then be used to calculate distance measurements within the eye (Fig. 11.6). In order to obtain accurate measurements, the specific speed of sound of the different intraocular media, such as the lens, aqueous, and vitreous, must be known.<sup>18</sup> These formulae provide precise measurements that can be used to measure intraocular tumors or to deduce the axial length of the globe for intraocular lens power calculations.

**FIG. 11.6** (A) Immersion A-scan biometry showing

peak amplitudes of the signal reflection. (B) B-scan image with distance measurement captured on a frozen scan. Measurements are obtained by placing the cursor marks on the image and reading the distance between points.

## Three-Dimensional Reconstructions

Real-time three-dimensional (3D) and four-dimensional (4D) images are currently used in some medical specialties, including gynecology, obstetrics, and cardiology, but their use in ophthalmology is limited. 3D ultrasonic images can be produced from a series of scan planes.<sup>19-22</sup> Silverman et al.<sup>23</sup> characterized the ciliary bodies in rabbits and human subjects using 3D high-resolution ultrasound. In the authors' laboratory, they developed a simple extension of the Ultrasound Biomicroscope Model 840 (Humphrey Instruments, Carl Zeiss Group) and VuMax UBM 35/50 (Sonomed) into a user-friendly 3D ultrasonic imaging system (Figs. 11.7 and 11.8).<sup>24-28</sup>

## Ultrasound in Intraocular Pathology

### Changes in the Shape of the Globe

#### Staphyloma

A staphyloma is an abnormal ectasia of the globe that involves uveal tissue. The ectasia typically has a smaller radius of curvature than the normal sclera of the globe. It can be identified on ultrasound by taking axial cross-sectional scans with the transducer probe (Fig. 11.9).

**FIG. 11.9** Staphyloma in a highly myopic eye (axial length 34.8 mm). (A) An axial section of the eccentric entrance of the optic nerve can be seen. (B) The misshapen globe is especially well demonstrated on a sectional plane which lies outside the optical axis. (C) Schematic drawing.

### Scleral Buckle.

A scleral buckle can create a posterior scleral deformity that looks similar to a staphyloma. It can be distinguished from a true staphyloma by a careful history or identification of the encircling band around the anterior sclera. Also, if silicone oil was used for repair, the higher index of refraction within the silicone oil can alter the reflectance of the ultrasound wavelengths, which might provide a false impression of globe deformation (Fig. 11.10).

**FIG. 11.10** (A) Scleral buckle produced by a silicone sponge explant. After placement of a scleral buckle, the deformity of the globe can be seen in an acoustic cross-section. Silicone explants almost completely reflect the ultrasound. They also cast an acoustic shadow. (B) Schematic drawing. *NO*, optic nerve; *P*, explant; *S*, sound shadow; *G*, syneretic, densified vitreous.

## Microphthalmos

Congenital microphthalmos is an abnormally small eye that can be associated with other ocular abnormalities. The main finding in microphthalmos is axial shortening. This can be identified with A-scan measurements. The B-scan mode can be used to obtain radial and transverse scans to identify abnormalities in the vitreous and posterior segment of the eye, which can also be associated features of microphthalmos. These features include the presence of a coloboma of the retina or optic nerve head, orbital cysts (Fig. 11.11), or persistent hyperplastic vitreous.

**FIG. 11.11** Microphthalmos with orbital cyst. (A) Cystoid space is seen on the B-scan within the muscle cone, which is interpreted as a “completely separated coloboma.” (B) A-scan image. (C) Schematic drawing.

## Phthisis

Phthisis is defined as severe atrophy of the globe associated with hypotony. Phthisis is characterized ultrasonographically by a thickened outer scleral wall. Occasionally, calcification or ossification may be observed (Fig. 11.12). This may be due to degenerative processes and from metaplasia of the retinal pigment epithelium (RPE). In advanced cases of phthisis, the sclera and choroid can represent up to 70% of the total volume of the globe. The degree of thickening of the globe in chronic hypotony can be an indication of impending phthisis, but the precise thickness threshold for phthisis formation is unknown.

**FIG. 11.12** Circumscribed calcification in the ocular wall in advanced phthisis bulbi. (A) Echographically we find highly reflective changes in the ocular wall from calcification or ossification of the choroid which casts a shadow on the soft tissue located posteriorly. (B) These strong echoes can be selectively imaged by reducing the amplification. (C) Schematic drawing.

## Vitreous

Echographic examination can provide information on vitreous structure, which is particularly useful when visualization of the posterior pole is poor due to anterior media opacities.

Ultrasonographic findings allow the examiner to differentiate dot-, strand-, and membrane-like reflections (Fig. 11.13). [Box 11.1](#) summarizes the most frequent conditions associated with pathologic changes in the vitreous.

**FIG. 11.13** Vitreous opacities. In maximal amplification, small heterogeneous spots can be seen echographically, even though the vitreous appears optically clear (left). They act as dot-like reflectors.

### **Box 11.1**

## **Clinical Conditions With Ultrasonographically Demonstrable Vitreous Changes**

- Changes in the shape of the globe
- Vitreous opacities
- Asteroid hyalosis
- Synchysis scintillans
- Acute posterior vitreous detachment
- Vitreous hemorrhage
- Uveitis (idiopathic)
- Uveitis (infectious)
- Intraocular foreign body
- Persistence and hyperplasia of the primary vitreous

## Vitreous Degeneration

Vitreous syneresis can appear as dot-like reflections which can be more pronounced in myopia or senile vitreous. During a symptomatic posterior vitreous detachment, the B-mode echo may demonstrate various stages of vitreous syneresis and may reveal the remaining adhesions of the hyaloid membrane to the retinal surface (Fig. 11.14).

**FIG. 11.14** (A) Detached posterior hyaloid membrane imaged as a floating structure of low reflectivity. (B) Schematic drawing.

## Asteroid Hyalosis

The calcium-containing lipids of asteroid hyalosis are suspended in the vitreous framework and act as distinctive sound reflectors (Fig. 11.15). They can demonstrate the dynamics of vitreous movements.

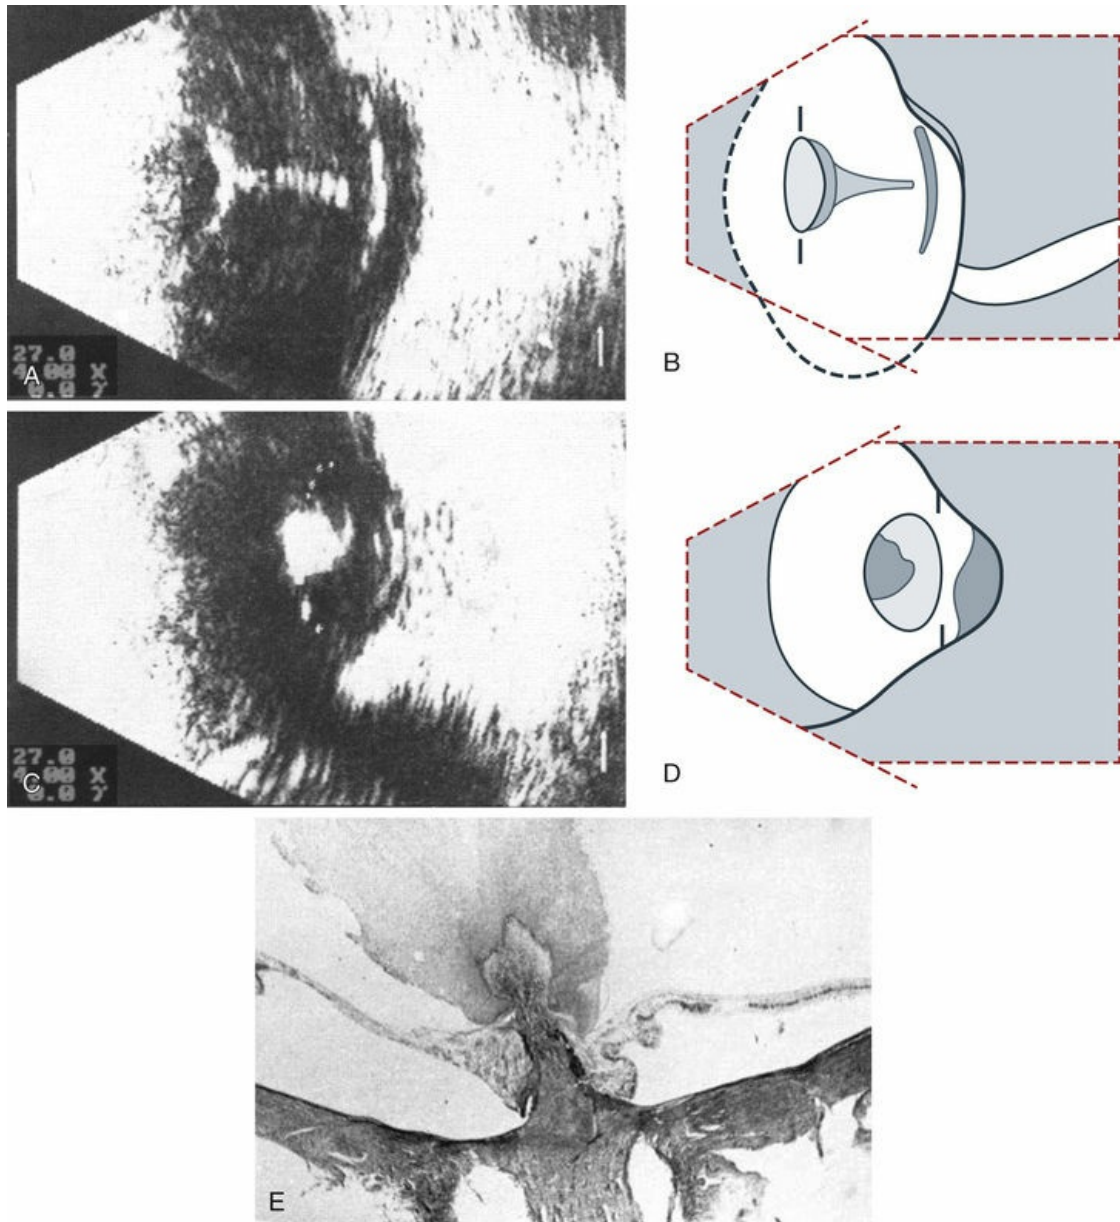

**FIG. 11.15** Asteroid hyalosis. (A) Slit-lamp microscopic photograph of the anterior vitreous space. (B) Histologic image of asteroid hyalosis shows the calcium crystals adherent to the vitreous scaffold. (C) B-scan cross-section of the crystals, which represent good reflectors for the ultrasound. There is always an echo-free retrovitreal space seen near the ocular walls. (D) Schematic drawing.

### **Synchysis Scintillans.**

In synchysis scintillans the vitreous is filled with cholesterol crystals. Unlike asteroid hyalosis, these crystals are not suspended within the vitreous but instead float freely in the vitreous space. When the globe moves, the crystals appear in the center of the vitreous body. This clinical picture may resemble asteroid hyalosis, but after a few seconds the cholesterol crystals will sink toward the bottom of the cavity. A-mode images display characteristic flickering spikes from the reflections of these crystals.

### **Persistent and Hyperplastic Primary Vitreous**

The primary vitreous contains the tunica vasculosa lentis, which is part of the fetal vasculature system. During development, the tunica vasculosa lentis emanates from the optic nerve head and supplies the posterior lens. This structure should involute prior to birth. Failure of the primary vitreous to regress fully is termed persistent hyperplastic primary vitreous. As mentioned earlier, this can be associated with microphthalmos and cataract formation in the newborn. The condition persistent hyperplastic primary vitreous can be ultrasonographically characterized by two features. The first is a strand of membrane that extends between the posterior surface of the lens and the area of the optic nerve head. The second is the reduced axial length of the globe from microphthalmos on ultrasound biometry (Fig. 11.16). If the anomaly is only mild, the lens may be clear at birth but may become cataractous when the posterior lens capsule ruptures.

**FIG. 11.16** (A–D) Posterior polar cataract in persistent hyperplastic primary vitreous (PHPV). An ultrasonographically demonstrable strand attached to the posterior lens pole points is suspicious for PHPV (A). Frontal plane taken temporally with maximal adduction of the globe (C). (B,D) Schematic drawings. The dark, hatched parts correspond to the opaque area of the posterior cortex and posterior capsule in a child with severe PHPV. (E) Histologic section of PHPV as seen at optic nerve head with loupe magnification.

## Vitreous Hemorrhages

An acute vitreous hemorrhage is an important indication for ultrasonography. Acute hemorrhages can fill the vitreous cavity with small opacities from the particles of the red blood cells. These opacities usually accumulate after a few hours in the lower circumference of the vitreous base (Fig. 11.17).

**FIG. 11.17** (A) Conspicuous bleeding into synergetic vitreous; erythrocytes within the vitreous create reflective opacities. A static picture may give the impression of a solid lesion. (B) After a few hours the opacities usually accumulate in the lower aspect of the vitreous cavity. (C) Schematic drawing.

If a detachment of the posterior hyaloid membrane precedes a vitreous hemorrhage, the erythrocytes frequently precipitate on to a vitreous strand (Fig. 11.18). This strand may be responsible for the development of a retinal tear, and its traction can be demonstrated directly in acoustic sectioning (Fig. 11.19). A circumscribed thickening of the ocular wall in cross-section may indicate the presence of a retinal operculum (Fig. 11.20). This area should be localized echographically and then carefully scrutinized with

ophthalmoscopy if possible.

**FIG. 11.18** Fresh vitreous hemorrhage. In a cross-sectional echogram the vitreous framework converges towards the ocular wall. Blood precipitates increase the acoustic reflectivity of the vitreous. Traction has to be assumed where the vitreous is in contact with the ocular wall.

**FIG. 11.19** (A) Recent vitreous hemorrhage. The low reflecting membranes float freely with ocular movement. A newly formed horseshoe tear may be present at their connection point to the wall. (B) Schematic drawing.

**FIG. 11.20** (A,B) Recent vitreous hemorrhage. Erythrocytes have precipitated on to the partly detached posterior hyaloid membrane, increasing its acoustic reflectivity. (C) Schematic drawing.

In larger hemorrhages, the blood can also disseminate into multiple preexisting vitreous compartments. In the early phase of this process, the erythrocytes will collect in the retrovitreal space ([Fig. 11.21](#)). The retrovitreal space may completely clear after a few days or weeks due to its high fluid exchange rate; however, blood on the vitreous framework absorbs much more slowly ([Fig. 11.22](#)).

**FIG. 11.21** (A) Vitreous hemorrhage with posterior vitreous detachment emphasizing the retrovitreal space. (B) In the early stage after the hemorrhage, erythrocytes accumulate in the retrovitreal space. They may ensheath the part of the vitreous that was free of blood and had a normal structure. (C) Schematic drawing.

**FIG. 11.22** The retrovitreal space may completely clear after a few days or weeks due to its high fluid exchange rate; however, blood on the vitreous

framework or located subretinally absorbs much more slowly (A). (B) Schematic drawing.

### Vitreous Hemorrhage From Neovascularization.

Hemorrhages that develop from proliferative changes in patients with diabetic retinopathy and retinal neovascularization will always be accompanied by pathologic changes in the vitreous. Vitreous membranes tent rectilinearly between the adhesions to the retina. The normal aftermovements that should occur in the vitreous after eye movements are extinguished in the presence of peripheral neovascular tufts. The vitreous tufts create adhesions that encircle the posterior pole. This is an ominous sign, which is indicative of early traction retinal detachment from these circular adhesions (Fig. 11.23). Choroidal neovascularization from age-related macular degeneration will have hemorrhage in multiple layers of the eye (Fig. 11.24).

**FIG. 11.23** (A) Beginning traction detachment at the posterior pole with vitreous contraction and proliferative diabetic retinopathy, which is hidden behind a diffuse vitreous hemorrhage. A springboard-like, taut, detached hyaloid membrane is still adherent to the retina at the posterior pole and has led to a traction detachment in several places. (B) Schematic drawing.

**FIG. 11.24** (A) Extensive vitreous hemorrhage from disciform macular degeneration. The blood dissipates into the preretinal or intrachoroidal space, into the area of the macular lesion and into the detached vitreous. The retrovitreal space is echo-free because of its high fluid exchange. (B) Schematic drawing.

## Terson Syndrome

Terson's sign is a multilayered, intraocular hemorrhage at the posterior pole that typically occurs after blunt trauma to the head. This is usually accompanied by a subarachnoid hemorrhage. If the posterior hyaloid membrane is still attached, the preretinal bleeding will slowly diffuse into the formed vitreous ([Fig. 11.25](#)). This can damage the underlying retina and may be an indication for an early vitrectomy.

**FIG. 11.25** (A,B) Retrovitreal bleeding associated with a subarachnoid hemorrhage (Terson syndrome). The bleeding originates from the area of the optic nerve head. (C) Schematic drawing.

## Intraocular Infections

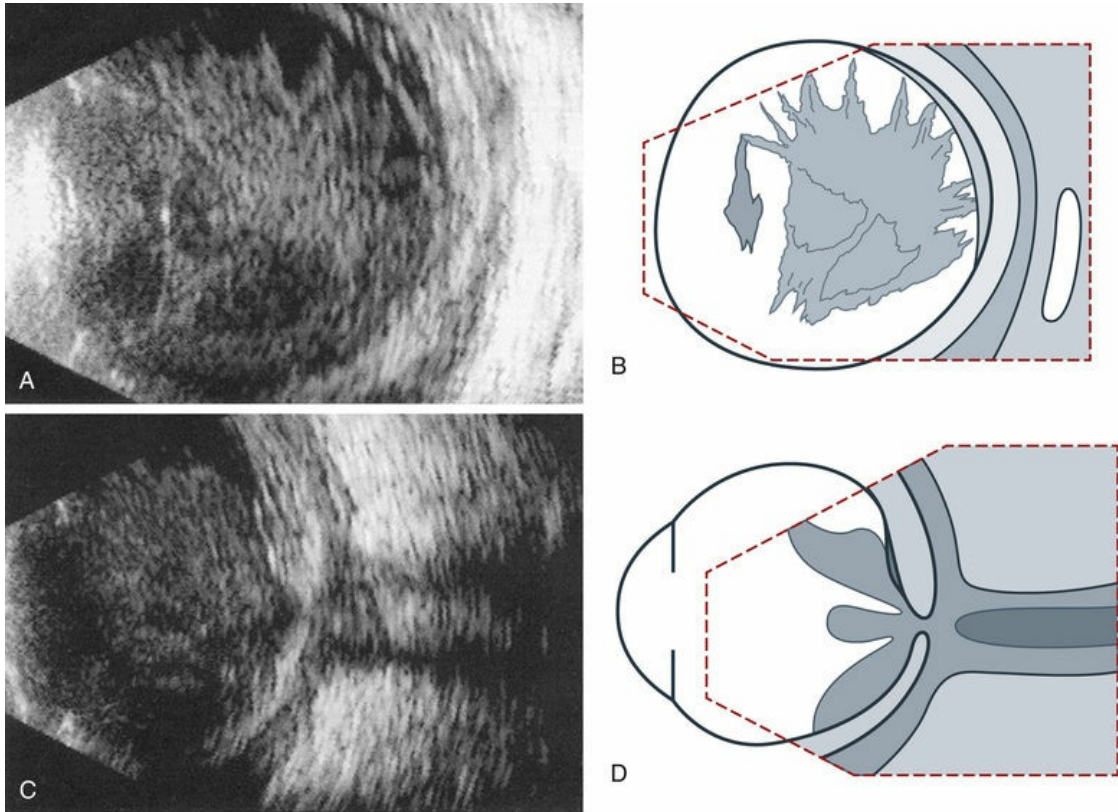

Ocular infection that extends toward the anterior segment or results in a hypopyon formation will have changes within the anterior vitreous space that are demonstrable on ultrasound. A thickening of the retina or choroid can be seen if the inflammation penetrates to the outer layers of the globe (Fig. 11.26). After only a few hours, these changes may involve the entire vitreous body (Fig. 11.27). If panophthalmitis follows a perforating injury, ultrasound evaluation can detect a local reaction at the entrance point of the infection (Figs. 11.28 and 11.29).

**FIG. 11.26** (A,B) Panophthalmitis after an intraocular operation. Widening of the ocular wall to about 2.1 mm indicates inflammatory choroidal infiltrates. (C) Schematic drawing.

**FIG. 11.27** Vitreous abscess that caused a bacterial orbital inflammation. (A) B-scan ultrasonography demonstrates a highly reflective vitreous body which is partly detached from the retina. (B) Schematic drawing of this image. (C) Posterior pole shows infiltration of Tenon's space and widening of the optic nerve sheath. (D) Schematic drawing.

**FIG. 11.28** Posttraumatic intraocular infection starting from the side of perforation. (A) B-scan ultrasonography demonstrates localized thickening of the ocular wall indicating the side of the perforation.

The vitreous is filled with inflammatory cells, the posterior hyaloid is thickened, and there is a localized retinal detachment. (B) Schematic drawing.

**FIG. 11.29** Chronic inflammation with massive vitreous infiltration after pars plana vitrectomy and scleral buckle. (A) Remnants of the infiltrated vitreous can be seen at the vitreous base anterior to the scleral buckle. (B,C) Cross-sections through the vitreous base. (D) Schematic drawing.

## Vitreous Inflammation

Inflammatory and hemorrhagic vitreous changes cannot be differentiated on the basis of ultrasonographic findings alone. Both conditions may cause densification of preexisting vitreous structures with subsequent shrinkage of the vitreous; tractional detachment of the retina can occur, especially if there are postinflammatory adhesions between the vitreous and retina. In chronic uveitis, an early and complete posterior vitreous detachment can occur and cause the formed vitreous to shrink and

form a frontal membrane that extends across the vitreous base (Fig. 11.30). If this membrane adheres to the ciliary body, it may detach the ciliary body and produce subsequent ocular hypotony.<sup>29</sup>

**FIG. 11.30** Phthisis oculi in chronic panuveitis. (A) The vitreous has shrunk to form a frontal membrane of high acoustic reflectivity. The ocular wall is widened to 2.9 mm. (B) Using linear amplification, the various layers of the ocular wall have become clearly outlined. (C) Isolated areas of the ocular wall show high acoustic reflectivity, which indicates calcification of the choroid or in the sclera. (D) Schematic drawing highlighting wall thickness.

## Intraocular Foreign Bodies

Intraocular foreign bodies induce a change in echo reflectivity which is based on the composition of the material (Figs. 11.31–11.33). The change in the reflectivity on the image should be a helpful clue in the localization of the foreign body within the globe; however, this is not always the case since the foreign bodies can also create signal artifact on echograms that can make identifying

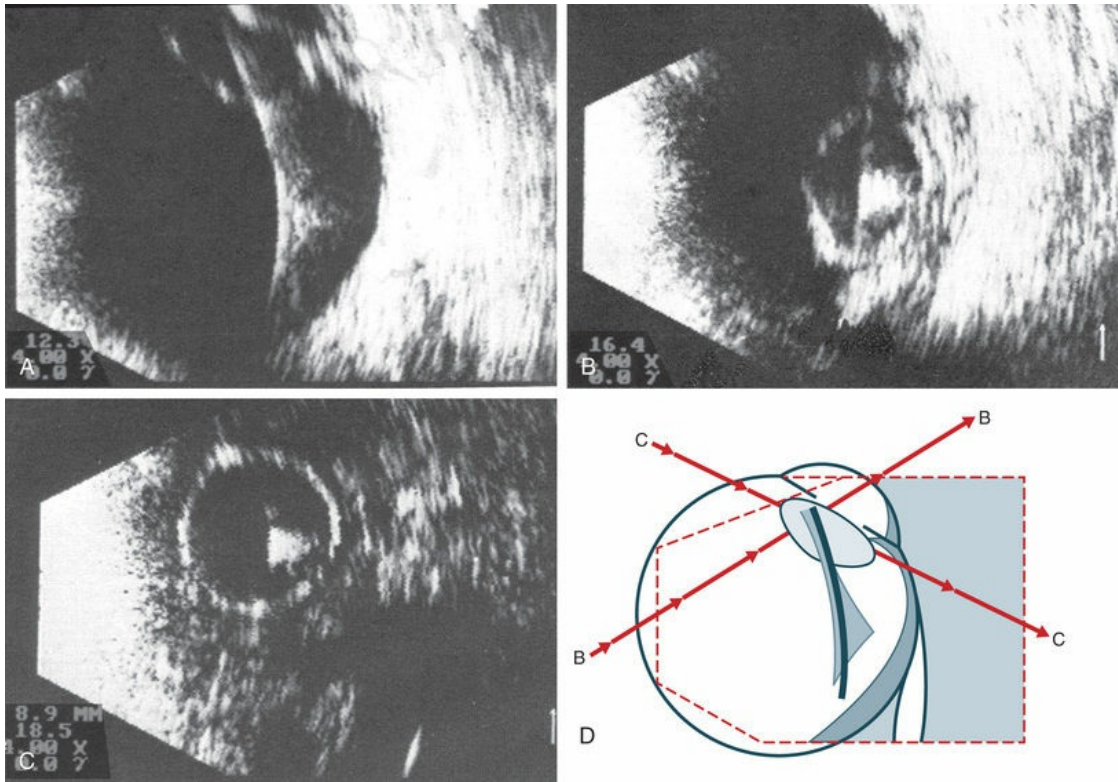

their exact location difficult. For example, large metallic foreign bodies have significant artifacts from strong reflected signals that can distort their true location. In addition, foreign bodies from trauma can be associated with air bubbles within the vitreous that can mask the presence of the nearby foreign body within the acoustic shadow (Fig. 11.34).

**FIG. 11.31** (A) Metallic foreign body in the vitreous with total retinal detachment. (B) The foreign-body spike is characterized by its high amplitude and repetitive echoes. (C) With reduced sensitivity the foreign body can almost be imaged as an isolated echo.

**FIG. 11.32** Acute perforating injury with intraocular metallic foreign body. (A) Ultrasonographically, there is a typical foreign-body echo with repetitive spikes in the vitreous about 2 mm in front of the ocular wall. (B) Decreasing the amplification displays the foreign-body echo as the only intraocular structure remaining visible on ultrasonography. (C) Schematic drawing.

**FIG. 11.33** (A) Intraocular foreign body of a piece of wire. (B) The anterior end of the wire remained visible in the lens. Cross-sectional image taken temporarily with maximal adduction of the globe. (C) Frontal section through iris and lens. (D) Schematic drawing.

**FIG. 11.34** Computed tomography image of a metallic foreign body wedged into the ocular wall with an air

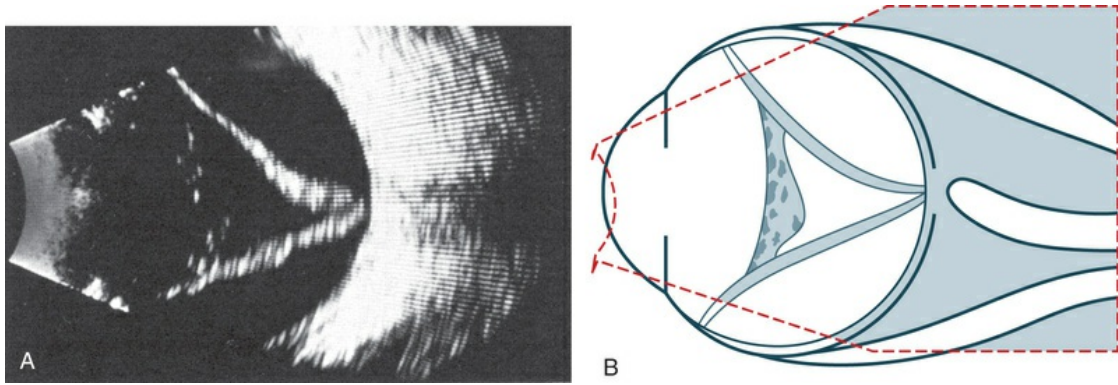

bubble adjacent to it.

## Retina

Ultrasound can be used to assess the structure of the retina in order to discern anatomic changes such as retinal tears and detachments. It can also be used to identify changes in retinal thickness from infiltrative or exudative ocular diseases. The sound reflections in ultrasound images can delineate these pathologic retinal changes even in eyes with opaque anterior media. This is a particularly useful tool since many diseases that affect the retina can also lead to vitreous changes that limit direct visualization. It is important to have a strong fundamental knowledge of ocular anatomy as well as a good technical approach for acquiring ultrasound images in order to make accurate assessments of retinal disease on ultrasound. This section will review the anatomic features of common retinal conditions as well as the special techniques needed to examine the retina with ultrasound.

### Acute Retinal Detachment

In a retinal detachment, the neurosensory retina separates from the RPE layer. This development allows fluid to collect in the potential space between these two layers. The detached neurosensory retina appears as a membrane in the vitreous space on ultrasound. Partial retinal detachments may still maintain connections to the optic nerve or ora serrata since these areas have the strongest connections to the retina. Identification of these connections on ultrasound can distinguish a partial retinal detachment from a vitreous or choroidal detachment, which would have different anatomic connections (Fig. 11.35). A complete retinal detachment can form a funnel shape due to the retina folding in the center of the globe.

**FIG. 11.35** (A) Complete retinal detachment extending between the optic nerve head and the ora serrata. Heterogeneous material in the anterior vitreous is a sign of vitreous reaction. (B) Schematic drawing.

Complicated retinal detachments with severe pathology can make it difficult to identify all the structures on ultrasound (Fig. 11.36). For example, in severe trauma cases that are associated with proliferative vitreoretinopathy or in advanced diabetic disease associated with proliferative retinopathy, the membranes formed within the vitreous can appear similar to a true retinal detachment. The following questions can guide the ultrasound examination of the retina in order to differentiate these common causes of vitreous membranes:

**FIG. 11.36** Development of a traction detachment with massive vitreous retraction. (A) Flat subtotal retinal detachment with folds; rigid vitreous strands. (B) In a frontal section, multiple contacts of the retina to the ocular wall can be demonstrated. (C) Schematic drawing.

- What is the spatial extent of the membrane? At which point is there contact with the ocular wall?
- What is the shape of a cross-section of the membrane, especially in the optic nerve head area?
- Which aftermovements occur?
- How great is the difference of the spike from the membrane in question to the scleral standard or to the echo from a standard reflector?

These questions should be clarified in the following way:

1. What is the spatial extent of the membrane? At which point is there contact with the ocular wall? A recent rhegmatogenous retinal detachment can be characterized in cross-section by a membranous structure of high reflectivity that converges in an acute angle

toward the ocular wall. If the imaged acoustic section is centered on the optic nerve head, then the border of the detached retina will be captured as it connects to the nerve head (Fig. 11.37). If the membrane passes over the optic nerve head instead of connecting to the optic nerve in the echo image, it is not a retinal detachment (Fig. 11.38). This feature can help identify retinal membranes from vitreous membranes.

**FIG. 11.37** (A) Sectoral retinal detachment. In acute retinal detachment, short aftermovements appear when the globe moves. These aftermovements extend like a whiplash from the area of the contact to the ocular wall. (B) Schematic drawing.

**FIG. 11.38** (A,B) Detached posterior hyaloid membrane. Vitreous membranes may reach an acoustic reflectivity similar to that of the retina seen on A-scan. A retinal detachment can be excluded if the membrane tents over the posterior pole without reaching the optic nerve head. (C) Schematic drawing.

2. What is the shape of a cross-section of the membrane, especially at the optic nerve head? In order to appreciate the shape of a retinal detachment, the performance of sonographic examinations in various planes is indicated. First, in a sagittal section, a total detachment looks like an isosceles triangle that is open toward the anterior segment (the sides of which may be unevenly tented: [Fig. 11.35](#)). Next, frontal-plane sections should be examined with the disc centered in the image. These sectional plans are obtained at a right-angle to the sagittal. The frontal planes can be examined best with the transducer probe placed in the temporal part of the lid fissure when the globe is maximally adducted. In these images, the conical shape of the detachment will appear oval to nearly circular in the various sections ([Fig. 11.39](#)).

**FIG. 11.39** (A) Clinical fundus photography of recurrent retinal detachment. (B–E) Recurrent retinal detachment with massive vitreous retraction. (B) Axial cross-sectional echogram. The amplitudes of the aftermovements decrease. High-frequency flicker of the taut membrane appears after the eye changes position. (D) Frontal section toward 6 o'clock. An epiretinal membrane of the retinal surface appears echographically as an apparent widening of the retina. (C,E) Schematic drawings.

3. Which aftermovements occur? Dynamic ultrasound can be obtained with patient participation. The quality of tissue movement at the end of the ocular saccade, or the aftermovement of the tissue,

can be used to distinguish vitreous tissue from retina tissue. An acute rhegmatogenous retinal detachment shows aftermovements of short duration that extend with a whiplash effect from the area where the retina is still attached, which is usually the optic nerve head. The amplitudes of these aftermovements are smaller and less extensive than those seen in the sinusoidal movements of a vitreous hemorrhage or in asteroid hyalosis.<sup>30</sup>

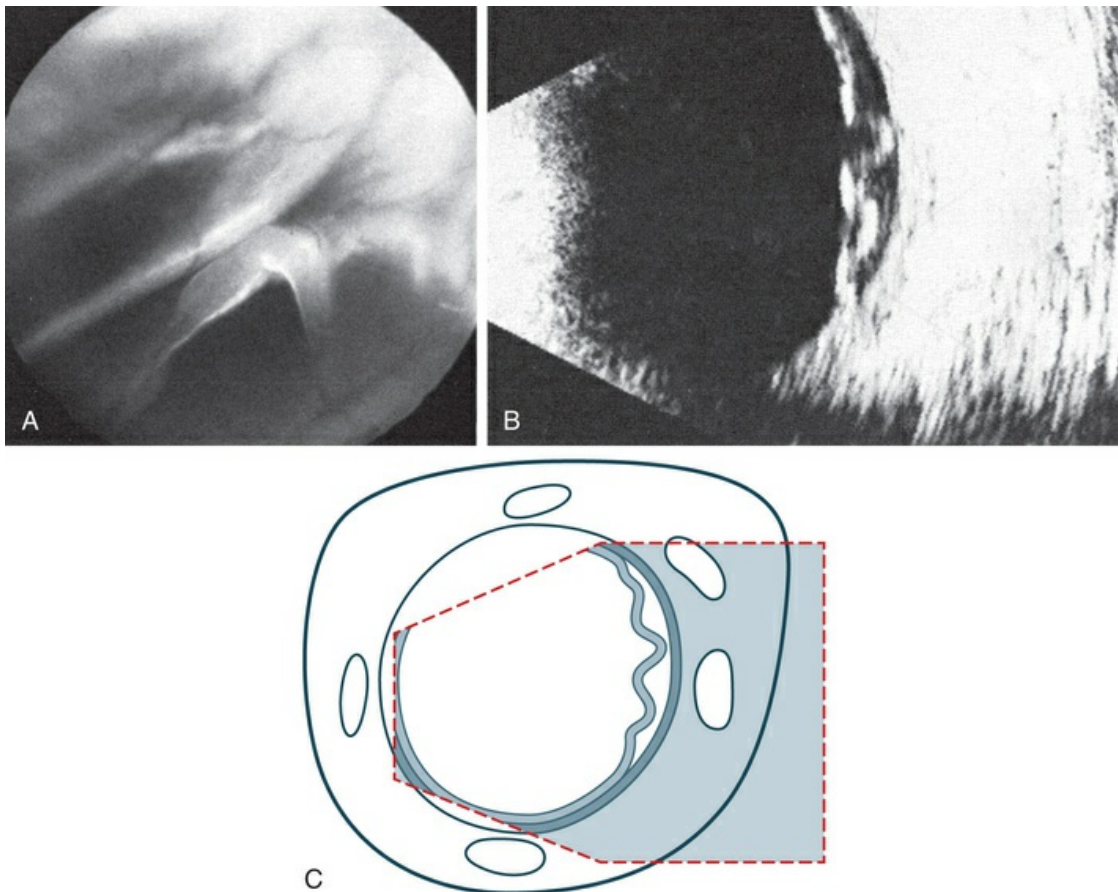

4. How great is the difference of the spike from the membrane in question to the scleral standard or to the echo from a standard reflector? Quantitative ultrasonography can detect a difference in the echo of the retina compared to that of the sclera, with a range extending from 8 to 15 db.<sup>31</sup> Unfortunately, these measurements provide only guidelines. Well-developed connective tissue membranes may show reflection properties quite similar to those of a detached retina. In complicated cases it may be difficult to correlate an isolated A-spike to the multiple membrane structures as they appear on B-mode.

## **Chronic Retinal Detachment**

The duration of a retinal detachment can affect the thickness and mobility of the retina, the shape and mechanical properties of the vitreous base, and the contents of the subretinal space. Identifying and understanding these changes can help with the management of these conditions.

A few weeks after a retinal detachment develops, changes in the proliferation of Müller cells and astrocytes will lead to alterations in the mechanical properties of the detached retina. The massive periretinal proliferation of these cells creates a decrease in the aftermovement amplitude of the retina (Fig. 11.40). The large excursions are replaced by a high-frequency flicker and the retina may appear thickened. After a longstanding retinal detachment, cyst-like cavities within the detached retina can be seen on ultrasound (Fig. 11.41). A longstanding detachment can also result in a funnel-shaped retinal detachment. The first step in this process is the proliferation of the epiretinal connective tissue that causes the vitreous to contract. This stage can be identified on ultrasound by the presence of new acoustic interfaces, which are seen as increased

vitreal signals that surround the detached retina (Fig. 11.42). The vitreous shrinks, which creates a narrowing of the retinal cavity, which typically begins to narrow anterior to the optic nerve head and continues to the posterior lens. Frontal “cyclitic membranes” can often be seen early, extending from the vitreous base (Fig. 11.43). Next, the peripheral retina is pulled closer to this membrane until the retinal detachment does not show any recognizable cavity of the original funnel. In frontal sections the shrunken retina appears as a strand, only a few millimeters in diameter (Fig. 11.44). Occasionally, a few retinal folds can be observed.

**FIG. 11.40** Massive periretinal proliferation with large retinal folds. (A) Ophthalmoscopic picture of large horseshoe tear. (B) The rigid, fixed retinal folds are echographically demonstrable. (C) Schematic drawing.

**FIG. 11.41** Longstanding total retinal detachment with macrocyst. Intraretinal cyst in the axial area seen on cross-sectional ultrasound (A) and frontal plan (B). The cysts form from coalescing microcystoid degeneration of the retina in chronic detachments. These cavities will not be involved in secondary vitreous changes, such as vitreous hemorrhages or cholesterol deposits. (C) Schematic drawing.

**FIG. 11.42** (A,B) Longstanding retinal detachment with increased connective tissue in the vitreous tunnel. Free-floating opacities accumulate in the subretinal space (possibly representing hemorrhage or cholesterol crystals). (C) Schematic drawing.

**FIG. 11.43** (A) Longstanding total retinal detachment. A tube-like remnant of the vitreous within the shrunken retinal tunnel can be seen. (B) Schematic drawing.

**FIG. 11.44** (A) Longstanding retinal detachment with completely obliterated vitreous space. In sagittal sections the extensive adhesions of the retinal leaves produce various acoustic sections. (B) Schematic drawing.

In addition to the above findings, the consistency of the subretinal space can change with increased duration of the detachment. The protein content will increase and may precipitate out of the subretinal fluid. This can be seen as free-floating opacities on ultrasound (Fig. 11.45). If these opacities appear as static particles and not free-floating, then intraocular tumor has to be excluded. Under these circumstances, ultrasonography provides a vital role in obtaining a diagnosis by distinguishing the freely moving protein precipitation in longstanding detachments from the fixed hyperechoic particles of malignant tumors.

**FIG. 11.45** (A,B) Longstanding retinal detachment with floating opacities in the subretinal space. The densifications in the vitreous space indicate a tendency for shrinkage. (C) Schematic drawing.

### Retinoschisis.

Retinoschisis is a splitting within the neurosensory layer of the retina. This condition frequently occurs in the inferotemporal quadrant. A cross-section echogram can display a membranous structure in the far periphery that has a convex border facing the vitreous (Fig. 11.46). In this situation, clinical correlation is important in order to distinguish the retinoschisis from a retinal detachment since these two entities can appear identical on static ultrasound. However, use of dynamic ultrasound and evaluation of the aftermovements can show that the aftermovements in retinoschisis are less conspicuous than in a retinal detachment. This is because in retinoschisis the retina is attached and there are no vitreous adhesions.

**FIG. 11.46** (A) Senile retinoschisis in the inferotemporal quadrant. The typical biconvex cross-sectional image in association with slight aftermovements supports a tentative diagnosis of retinoschisis. (B) The acoustic reflectivity corresponds to that of a detached retina. (C) Schematic drawing.

### Coats Disease.

Coats disease is an exudative retinopathy most commonly seen unilaterally. It mainly affects males in the first decade of life. A clinical diagnosis can be made if aneurysmal malformations of retinal vessels and yellowish subretinal plaques are associated with an exudative detachment. Coats disease should be differentiated from retinoblastoma, which can have a similar clinical appearance in this patient group. Ultrasound can differentiate these conditions with careful evaluation of the subretinal space. Retinoblastoma typically shows calcifications with high reflectivity. The exudative detachment that is seen in Coats disease has a different echo quality due to the subretinal cholesterol deposits (Fig. 11.47). In Coats disease, the crystals floating in the subretinal space are seen as floating opacities similar to the appearance of crystals in sychysis scintillans. They appear in an A-mode echogram as flickering spikes.<sup>32</sup> On B-mode images these high-frequency motions of the

echo spikes produce a blurred pattern in the subretinal space.

**FIG. 11.47** (A) Fundoscopic clinical photo of Coats disease. Circumscribed, strongly reflecting retinal detachment in Coats disease. (B) The A-scan shows the high-intensity signal from the strongly reflecting membrane of the retinal detachment depicted in the image. (C) The B-scan shows the retinal detachment in association with floating opacities in the subretinal space that corroborate the diagnosis of Coats disease.

## Retinoblastoma

Retinoblastoma is a life-threatening tumor that can present in children as isolated leukocoria or with a constellation of other ocular findings. Some findings can mimic benign ocular conditions. Since treatment of retinoblastoma can include ocular enucleation, making the appropriate diagnosis is critical. Ophthalmoscopy should be performed but sometimes is limited if there is cataract, hypopyon, vitreous seeding, or opacity. Ultrasound plays a critical role in these patients, especially since certain features on echography can be pathognomonic for retinoblastoma. The presence of calcium deposits in retinoblastoma lesions produces a high sound reflection that creates an acoustic shadow on more

distant structures such as the sclera (Fig. 11.48). The calcium deposits can be selectively demonstrated on the image by decreasing the amplification in the cross-section echogram until they are the only remaining tissue structure visible on the screen (Fig. 11.49). In some retinoblastomas the calcium appears only in a few areas, but any calcification is indicative of tumor burden and is an important feature for the diagnosis. In some cases, ultrasound can also define extraocular tumor extension in retinoblastoma and is of great prognostic and therapeutic importance. Additional imaging to supplement ultrasonography is important in retinoblastoma. Computed tomography can show calcification and magnetic resonance imaging can show tumor extension outside the orbit, optic nerve invasion, or pinealoma (Fig. 11.50).

**FIG. 11.48** Extensive retinoblastoma with varying appearance. As demonstrated in the cross-sectional echogram (A), the upper tumor portions show high acoustic reflectivity due to massive calcifications. The lower part of the tumor has less acoustic reflectivity than the adjacent sclera. A-scans of the eye (the scleral spikes in the acoustic scans (B,C) are marked

by *arrows*).

**FIG. 11.49** Large retinoblastoma with calcifications and acoustic shadow cast on the adjacent sclera and orbit.

(A) The calcifications light up in cross-sectional echograms. (B) In A-mode echograms, they can be quantified as the strongest reflecting structures in the examined area. (C) With reduced amplification, the calcified areas are the only visible signals. (D) Schematic drawing.

**FIG. 11.50** Extensive retinoblastoma. (A) A cross-sectional echographic image. The tumor is characterized by areas of high acoustic reflectivity alternating with areas of low reflectivity. (B) The differences in reflection can be quantified on A-mode echography: calcified parts of the tumor have markedly higher amplitudes as seen at point K as compared to the sclera reflection as seen at point S. (C) Schematic drawing of the ultrasonographical image in (A). (D) Computed tomography scan displays the calcified parts of the retinoblastoma that can be identified with greater certainty than in a plain X-ray picture. (E) A histologic sample of the infiltration into the optic nerve. NO, optic nerve; R, retinoblastoma. The calcium deposits explain the nearly pathognomonic echogram.

## Retinopathy of Prematurity

Early stages of retinopathy of prematurity can be diagnosed by indirect ophthalmoscopy. However, later stages with partial or complete traction retinal detachments from extensive fibrovascular tissue require ultrasonography for diagnosis and surgical planning. Machemer and Aalberg<sup>33</sup> emphasized the importance of information obtained by cross-section ultrasonography in these stages, such as the diameter of the retinal funnel in the retroretinal space (Fig. 11.51).

**FIG. 11.51** Stage V of retinopathy of prematurity. (A) In cross-sectional images we see a complete retinal detachment with a widening of the avascular peripheral retina toward the subretinal space. (B) Schematic drawing.

## Optic Nerve

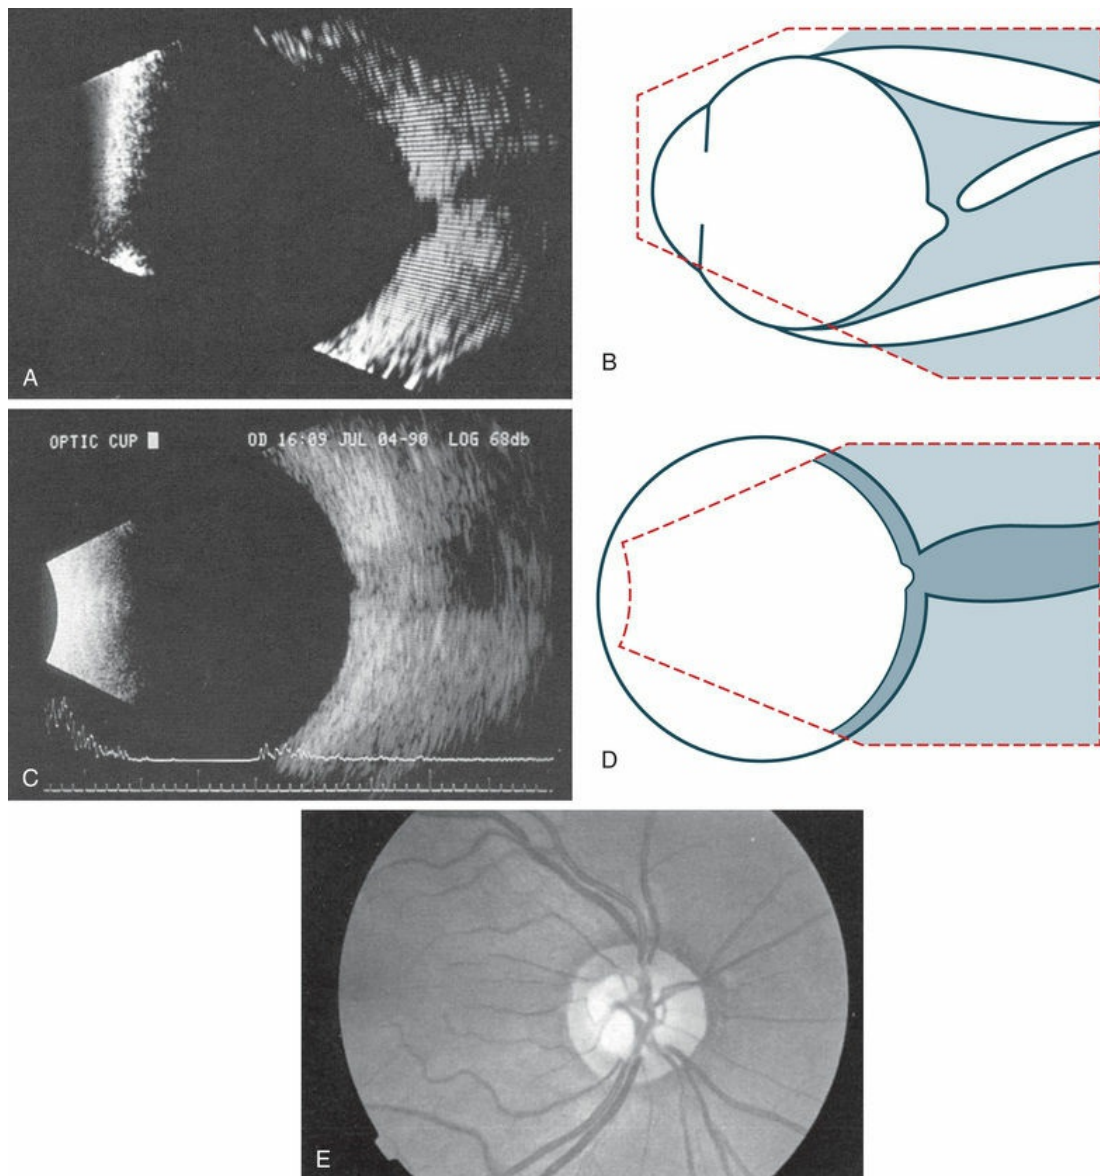

### Acute Optic Neuritis and Papilledema

In patients with acute optic neuritis and papilledema transorbital sonography may reveal a thickening of the retrobulbar portion of the optic nerve. Transorbital sonography is a sensitive, highly accessible technique for the detection of significant optic nerve thickening on the side affected by acute optic neuritis and represents an adjunctive tool for the diagnosis of papilledema.

### Coloboma of the Ocular Fundus

Colobomas can occur in the iris, lens, retina, and optic nerve. Some are spontaneous and some occur in association with systemic syndromes. Colobomas are also in the differential diagnosis of retinoblastoma.<sup>34</sup> Colobomas can be seen clearly by ultrasonography even if the fundus cannot be visualized optically (Fig. 11.52).

**FIG. 11.52** (A) Echogram of the small optic nerve coloboma depicted in (E). In comparison, B-scan section showing normal physiologic cupping of an optic nerve head (C). To obtain this vertical section a probe is placed temporal to the limbus, thereby avoiding any artifacts, caused by the lens. (B,D) Schematic

drawings. (E) Small coloboma of the optic nerve with a diameter of about 2.5 mm. Fundus photograph showing excavation within the nerve.

## Assessment of Optic Nerve Cupping

Evaluation of optic nerve cupping is important for treatment of glaucomatous changes. This is difficult with anterior media opacity. Recently, with improvement of the lateral resolution of B-scan images, optic nerve head cupping can be reliably measured and reproduced on ultrasound images.<sup>35</sup>

## Choroid

### Changes in the Ocular Layers Due to Hypotony

In acute hypotony, exudation into the suprachoroidal space creates an increase in the choroidal vascular pressure. This can lead to a choroidal detachment which will then exacerbate the globe hypotony (Fig. 11.53). This situation is ultrasonographically characterized by a convex border on a cross-section image that denotes the location of the choroidal detachment. This convex shape is formed between the pars plana and location of the vortex veins, both of which have strong choroidal attachments. Knowledge of the choroidal anatomic structure and its attachments can aid in ultrasound diagnosis. In addition to the pars plana and vortex veins, the choroid is firmly attached to the optic nerve. The choroid inserts at the optic nerve at a blunt angle, as compared to the retina, which has a steeper insertion. This feature can be used to help differentiate choroidal and retinal detachments of the posterior pole on ultrasound images. In addition, a choroidal detachment would begin at the ciliary body and not the ora serrata, as in a retinal detachment (Fig. 11.54). Occasionally, the detached ciliary body can compress the lens. In severe cases, choroidal detachments may meet in the center of the globe. This feature has been termed “kissing choroidals” and is typically an indication for surgical management (Fig. 11.55). In typical cases of serous choroidal detachments the subchoroidal space is acoustically silent. In contrast, an expulsive choroidal hemorrhage can be identified by the hyperechoic signal

on ultrasound that the blood clots create within the detachment (Fig. 11.56).

**FIG. 11.53** (A) Detachment of the ciliary body and the peripheral choroid due to hypotony. (B) The thickening of the ocular walls begins in the area of the ciliary body and extends to the equator, as seen on the B-scan. (C) Schematic drawing.

**FIG. 11.54** Subtotal exudative choroidal detachment. (A) In contrast to a retinal detachment, the choroidal detachment extends beyond the ora serrata; the detachment extends from the iris diaphragm to the posterior pole without reaching the optic nerve head. (B) The frontal sections depict indentations which are caused by large vessels. (C) Schematic drawing.

**FIG. 11.55** Total exudative choroidal detachment in persistent hypotony after penetrating glaucoma surgery with external fistulation. (A) The apices of the choroidal detachment touch each other in the vitreous and are seen on the echogram. This finding is commonly termed “kissing choroidals.” Strand-like structures (possibly taut vortex veins) course through

the intrachoroidal space. (B) Schematic drawing.

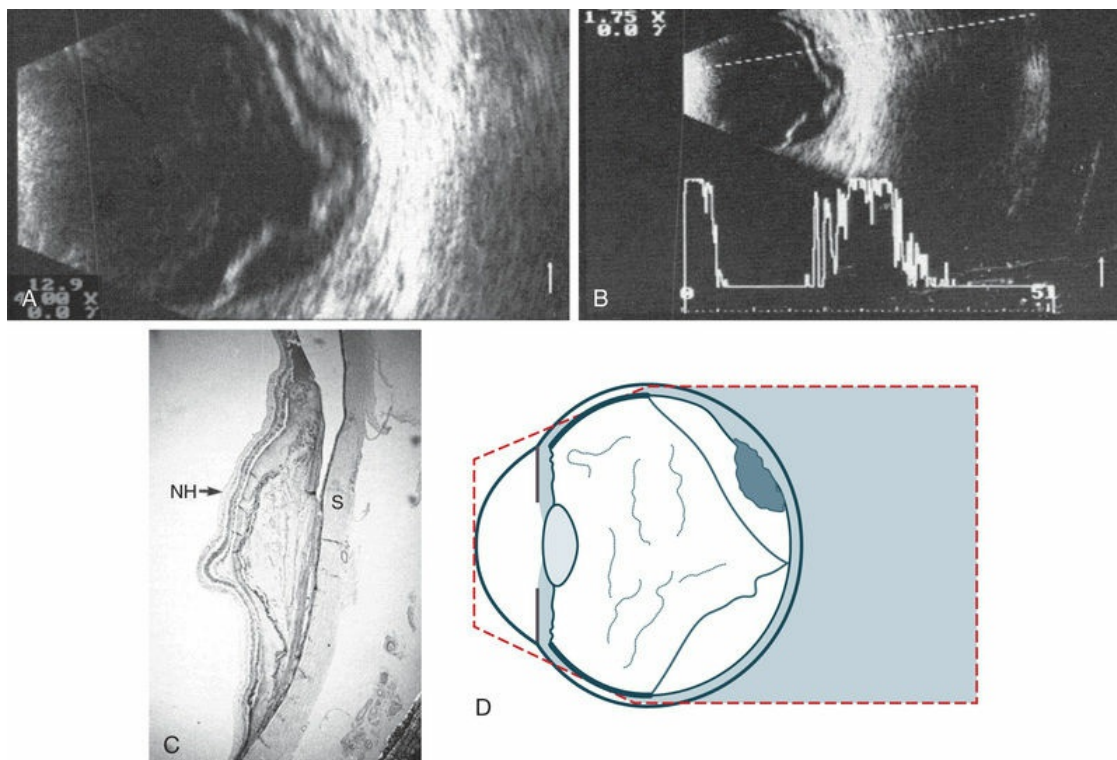

**FIG. 11.56** Extensive choroidal detachment in an eye with expulsive hemorrhage. (A) The intrachoroidal space has acquired acoustic reflectivity due to the accumulation of blood. There may be anatomical healing after the absorption of the blood, but we cannot expect visual function to improve. (B) Frontal image of the hemorrhagic choroidal detachments. (C) Schematic drawing.

In chronic hypotony with longstanding choroidal detachments, the outer layer of the globe can appear concentrically widened on ultrasound. In advanced stages, the appearance on ultrasound changes, the outer walls appear thickened, and the vitreous cavity becomes substantially reduced. In these eyes, metaplasia of the pigment epithelium can result in calcification and ossification of ocular tissue that is easily identified on ultrasound because of the total reflection of all sound waves noted on the acoustic image.

## Choroidal Neovascularization

Choroidal neovascularization is a complication seen in many eye diseases, most commonly in macular degeneration. The histologic findings include a vascularized collection of connective tissue that extends from the choriocapillaris through defects in Bruch's membrane and then into the subretinal pigment epithelial or subretinal space. This heterogeneous structure produces mixed ultrasound features, including the strong acoustic reflections from the fibrovascular membranes and dense connective tissue septa and the acoustically silent areas of exudate and subretinal fluid (Figs. 11.24 and 11.57). Peripheral choroidal neovascularization membranes can appear similar to choroidal melanomas; therefore, familiarity with the ultrasonographic features of these lesions is important, especially if vitreous hemorrhage prevents direct visualization.

**FIG. 11.57** Disciform macular degeneration with exudative retinal detachment. (A) In the cross-sectional echogram, the thickened ocular walls in the macular area appear as a strongly reflecting, layered structure. (B) The acoustic interfaces of the macular degeneration produce high signals. (C) Histologic

section of an eye with disciform macular degeneration under loupe magnification. Vascularized connective tissue scars with exudation without acoustic interfaces produce the substrate for the heterogeneous nature of the echogram. *NH*, retina; *S*, sclera. (D) Schematic drawing.

## **Choroidal Melanoma**

Evaluation of choroidal melanomas includes a comprehensive examination with ophthalmoscopy combined with ultrasound imaging. In choroidal melanomas, the signals produced within the tumor are complicated by overlapping and attenuation of echo signal with depth. Connective tissue septa and vessels vary in their prominence and interfere with the signals from the tumor tissue. Furthermore, the resolution of the image is limited because the densely packed tumor cells are separated by a considerably shorter distance than the ultrasound wavelength. A thorough understanding of the principles of ultrasonography and a strong knowledge base of the tissue complexity in metastatic processes combined with an extensive case reference aids in the image interpretation of choroidal melanomas. The interpretation of echograms in A- and B-mode is based on reports on this topic which were published by Oksala,<sup>36</sup> Baum,<sup>37</sup> Buschmann and Trier,<sup>38</sup> Till and Ossoinig,<sup>32</sup> Trier,<sup>39</sup> Coleman et al.,<sup>40</sup> and Silverman et al.,<sup>41</sup> which include data from the original scans of ocular tissues. The next section will review the principles used to image choroidal tumors and the features of a choroidal melanoma on B-mode and A-mode imaging.

### **The Characteristics of a Choroidal Melanoma on B-Mode Echography.**

In B-mode echograms, a melanoma appears as a biconvex lesion. The internal structure is relatively homogeneous so produces markedly fewer signals than the tumor surface or the sclera (Fig. 11.58). If the tumor has broken through Bruch's membrane, then a mushroom-shaped lesion, or a collar-button, can be demonstrated in cross-section and serves as a pathognomonic sign (Fig. 11.59). If present, this perforation does not necessarily occur at the peak of

the tumor; careful ultrasound examination of the entire lesion is needed (Fig. 11.60). In some sections, the collar-button of a tumor may even simulate a tumor mass lying free in the vitreous (Fig. 11.59). In addition, the collar-button portion of the lesion has unique ultrasound features due to the presence of the mass above Bruch's membrane in some places and below Bruch's membrane in other places. Previously this feature was attributed to sound attenuation, which is the continuous decay of spike altitudes in the A-mode and was called the angle kappa. However, the change in signal is most likely due to more than just an attenuation phenomenon. The features of the collar-button can be explained on the basis of echographic–histopathologic correlations (Fig. 11.61). Usually, a tumor lying immediately beneath the sensory retina reflects ultrasound more than the portion of the tumor beneath Bruch's membrane. In a collar-button, the part of the tumor growing in front of Bruch's membrane will be drained less well, leading to a dilation of the vessels in this part of the tumor.<sup>31,42</sup> This creates new acoustic interfaces with higher signal intensity, resulting in brighter dots in B-mode and higher spikes in A-mode. In the area of the tumor base, a “choroidal excavation” can be seen (Figs. 11.62 and 11.63). This excavation in the acoustic section develops at the edge of the tumor where melanoma tissue intersects the adjacent strongly reflecting intact choroid.<sup>37,43</sup>

**FIG. 11.58** Typical findings of a choroidal melanoma.

(A) In cross-section the tumor is biconvex. The diameter of the base is  $14 \times 14$  mm; elevation, 8.5 mm; calculated tumor volume, 0.75 mL. (B) With standardized A-mode, the spike amplitude within the tumor amounts to about 20% of the scleral spike. (C) Histologic section visualized under loupe magnification of a peripapillary choroidal melanoma. The reason for the low homogeneous acoustic reflectivity of a choroidal melanoma is the densely packed tumor cells, the margins of which are separated by a distance much smaller than the wavelength of ultrasound. *R*, retina; *S*, sclera; *NO*, optic nerve.

**FIG. 11.59** Large choroidal melanoma, mushroom-shaped after perforating Bruch's membrane. (A) Sagittal section. (B) In the frontal plane, one part of the tumor does not seem to have contact with the ocular outer walls, which demonstrates the principle of the necessity to image tumors in multiple planes to define the full extent of invasion. (C) Schematic drawing.

**FIG. 11.60** (A) Large mushroom-shaped choroidal melanoma with collar-button seen on fundus photography. (B) Sagittal echogram cross-section with A-mode echogram. There is markedly increased reflection in the area of the tumor peak. The part of the tumor in front of Bruch's membrane often shows dilated vessels, which act as interfaces to increase the acoustic reflectivity. (C) Histologic section through the tumor. (D) Schematic drawing. (E) Echogram from the tumor base. This image was obtained with maximal adduction of the globe, and made possible because of the far temporal location of the tumor base. Also in this direction of examination, the part of the tumor anterior to Bruch's membrane demonstrates high reflectivity. (F) Schematic drawing.

**FIG. 11.61** (A) Choroidal melanoma with eccentric perforation of Bruch's membrane. Echogram shows a mushroom-like shape of the lesion, which is nearly pathognomonic for a melanoma and therefore of great differential diagnostic value. (B) Schematic drawing.

**FIG. 11.62** (A) Small choroidal melanoma. Elevation, 2.5 mm; base, 8 × 8 mm; calculated tumor volume: 0.066 mL. The choroid at the tumor base has been replaced by tumor, which has less acoustic reflectivity and provokes a choroidal excavation echographically. (B) Schematic drawing.

**FIG. 11.63** Choroidal melanoma. (A) Elevation, 6 mm; diameter at the base, 11 × 12 mm; calculated tumor volume, 0.33 mL. The highly reflecting choroid has been replaced by the poorly reflecting melanoma, producing a choroidal excavation in the cross-section. (B) Histologic section through the margin of a choroidal melanoma. At the base, normal choroid is replaced by tumor. (C) Schematic drawing.

### The Characteristics of a Choroidal Melanoma on A-Mode Ultrasonography.

The ultrasonographic internal structure of a tumor is quantitatively best described in the echogram. An unfocused A-mode transducer can obtain a summation signal from the large tissue area,<sup>31</sup> which typically demonstrates spikes of relatively uniform amplitudes within the large biconvex tumor if the lesion has not extensively broken through Bruch's membrane (Fig. 11.58). This corresponds to the uniform histologic structure of a melanoma (Fig. 11.58). Exceptions occur when features of hemorrhage or necrosis within the tumor develop.<sup>44,45</sup>

Most melanomas consist of solid tissue; therefore, no aftermovements occur as might be expected with a large subretinal

or choroidal hemorrhage. In addition, flickering spike complexes may be seen on the A-mode echogram within the tumor itself. Various authors interpret them differently. It is assumed that they are due to blood circulating in large tumor vessels. Although the features of the ultrasound combined with a thorough clinical examination can establish the diagnosis of choroidal melanoma with enough certainty to recommend treatment, a preoperative correlation between the sonographic pattern and the histopathologic findings is currently still in debate.<sup>40,41</sup>

B-mode Doppler devices can obtain signals from the interior of the tumor by using a high-resolution power and a frequency between 7 and 20 MHz. This method is more sensitive than the visual evaluation of a time amplitude echogram<sup>46</sup> (Fig. 11.64). In some patients it was possible to determine the blood flow within the tumor using Doppler color-coding technology. In a series of 50 eyes with melanoma, Doppler shifts could be detected in all patients except one. The tumor size varied between 0.8 and 1.5 mL. Doppler imaging has also been used to study an eye with secondary glaucoma and significantly increased intraocular pressure. In this patient the tumor perforated the sclera and invaded the muscle cone (Fig. 11.65). An intraocular pressure of 45 mmHg compressed the intraocular tumor, which influenced the maximal flow velocities measured by Doppler sonography (Fig. 11.65).

**FIG. 11.64** B-mode Doppler sonography (duplex technique) of a choroidal melanoma of average size. In A-mode the occasionally observed flickering amplitudes are produced by the blood flow. They can be quantified when using a B-mode Doppler instrument of high resolution.

**FIG. 11.65** Choroidal melanoma with orbital invasion in a 65-year-old woman. Referral diagnosis was orbital cellulitis. Echographic findings include a large intraocular tumor with wide invasion of the orbital tissues (A). Remnants of the sclera can be demonstrated within the tumor in both A- and B-mode echograms because of their strong acoustic reflectivity (B). Additional findings include a total retinal detachment as seen in both images. (C) Schematic drawing of the echogram. (D,E) Doppler signal of the choroidal tumor. (D) Frequency shift from the intraocular tumor, maximum velocity: 10 cm/s. (E) Frequency shift from the extraocular tumor, maximum velocity: 2 cm/s. With Doppler technique the intraocular part of the tumor shows reduced blood flow compared to the extraocular part.

The use of Doppler ultrasonography in studying ocular blood flow in disease states is increasing; however, at the present time this method does not allow exact measurements of maximal flow velocities.

### **Determining the Volume of a Choroidal Melanoma by Ultrasonography.**

Ultrasonography produces spikes in the recorded signal when interfaces with different media are encountered. In a normal eye, the first acoustic interface after the signal passes through the vitreous is the retina. In the case of a choroidal tumor the apex is adjacent to the retina spike and the base is anterior to the scleral spike. Identifying these positions, however, can be challenging in some settings. For example, if the retina is attached to the tumor surface, no separate discrimination of the two interfaces is possible (Fig. 11.58). On the other hand, if the accompanying retinal detachment is also present over the peak of the tumor, then the retina will be imaged as a separate membranous structure lying in front of the lesion (Fig. 11.66). Then the transition between tumor and scleral must be identified. In most cases, the scleral spike is still the strongest signal even in the presence of a choroidal tumor. If the tumor breaks through the scleral barrier, the continuity of this strong signal is interrupted at the site of perforation. An exact measurement of the volume of the tumor is important when measuring the lesion height, planning a treatment, or analyzing the effect of therapy.

**FIG. 11.66** Choroidal melanoma with associated retinal detachment over the peak of the tumor. Tumor size: base, 9 × 9 mm; elevation, 3.5 mm. The detached retina lies about 2 mm in front of the tumor. The calculated tumor volume is about 150 mL. If the retinal detachment were erroneously included, the volume would be about 230 mL.

Ultrasonography is capable of providing precise measurements of tumor size. Ultrasound devices have measurement tools that can be applied in the window of the image. The examiner can use this feature to measure the height of the largest and smallest diameter of the tumor. In biconvex tumors, volume data for the tumor can be calculated from these linear measurements or it can be evaluated using special equipment designed for 3D evaluation (Fig. 11.67).

**FIG. 11.67** Example of three-dimensional rendering of the posterior segment tumor. (A) Area of interest marked. (B) Contour-finding procedure with outlining of the space-occupying lesion. (C) Surface plot for volume determination.

### The Role of Ultrasonography for Planning the Treatment of Choroidal Melanomas.

After a choroidal melanoma is diagnosed by careful clinical examination and ultrasound interpretation, the next step for the physician is to formulate a treatment plan. Radiation therapy is successfully used for the treatment of medium or small ocular

melanomas. Scleral contact radiotherapy using ruthenium-106, cobalt-90, or iodine-125 applicators shows a relatively steep decay of radiation dosage. At a distance of 8 mm from the radiation surface, only 10% of the energy is still available. In order to achieve complete tumor necrosis in this area, an application of 10 times the duration of radiation is needed. Fig. 11.68 shows the isodose curves for ruthenium-106 applicators. The aim of any radiation therapy is to destroy the tumor tissue and to spare the adjacent normal ocular tissues as much as possible. The radiation pellets are placed on custom scleral plaques that are designed to cover the full extent of the tumor. It is therefore important to have an exact measurement of the size of the tumor and have precise placement of the scleral plaque over the tumor (Figs. 11.69 and 11.70). Ultrasonography provides the most accurate measurements for this purpose. Dynamic imaging using the ultrasound B-mode can also provide information on adjacent pathology such as overlying retinal detachments, which may overestimate the total height of the tumor if not properly identified.

**FIG. 11.68** Measuring protocol for a ruthenium applicator type CCC; diameter of the emitting plane, 21 mm. At 5 mm from the applicator surface, only 25% of the scleral contact dose is still available. Because of this steep decay of effective radiation, it is critical to plan the treatment exactly.

**FIG. 11.69** (A,B) Echogram of an eye with the ruthenium-beta applicator in place. The slit between the posterior scleral surface and the applicator is filled with fluid and is less than 0.5 mm wide. The lateral extent of the applicator is marked by the sound shadow. (C) Schematic drawing.

**FIG. 11.70** (A) Ruthenium-beta applicator in place with a wide slit between the sclera and the applicator surface. On the basis of this echographic finding, the position of the applicator should be changed or the duration of the treatment has to be prolonged. Distance of the measuring marks: 1.9 mm. (B) Schematic drawing.

Serial examination with ultrasonography following treatment can be used to monitor the effect of the radiation plaque by measuring the tumor elevation, tumor base, and reflectivity of the internal tumor structure as well as by identifying the presence of tumor vessels. Fig. 11.71 illustrates the successful treatment of a choroidal melanoma that was documented echographically. In this case, after 4 months there was a marked increase in reflectivity in the internal tumor structures. Within 10 months the volume was reduced from 0.38 to 0 mL.

**FIG. 11.71** A-mode (bottom) and B-mode (top) echograms during follow-up assessments of a successfully treated choroidal melanoma. The tumor volume was reduced from 0.38 to 0 mL within 10 months. After 8 months the spikes within the tumor increased from about 40% of the scleral spike to about 90% (white arrows). (A) Before radiation, 380 mL, reflection 40%; (B) after 4 months, 230 mL, reflection 80%; (C) after 8 months, 100 mL, reflection 90%; (D) after 10 months, 0 mL, no reflection.

In some cases of successfully treated tumors, the increased reflectivity within the tumor is the only ultrasonographic parameter that changes after radiotherapy (Fig. 11.72). Increased reflectivity may demonstrate tumor necrosis; however, this may not always be the case, as some tumors remain viable even with the increase in reflectivity noted on ultrasound.

**FIG. 11.72** A-mode (bottom) and B-mode (top) echograms demonstrating the effect of brachytherapy on a choroidal melanoma. The external shape of the tumor also remains unchanged after a second series of radiation; the reflectivity of the tumor increases from about 20% of the scleral spike before radiation to about 80% after radiation (*white arrows*). (A) Before radiation, volume 250 mL, reflection 20%; (B) after 8 months, 250 mL, reflection 70%; (C) after 36 months and 22 months after second radiation, volume 250 mL, reflection 80%.

Determining blood flow by B-mode Doppler sonography is an additional parameter that could be used to monitor the treatment response in highly vascularized choroidal tumors, such as choroidal melanomas. Doppler can detect a decrease in blood flow in the necrotic mass that is left after radiation therapy. The necrotic tissue from treated tumors can be absorbed by the adjacent blood vessels, but radiation may damage these vessels and prevent the clearing of these products, which explains the residual mass on ultrasound seen after treatment with radiation: this mass is called tumefaction. This may explain the increased reflectivity of treated tumors. [Fig. 11.73](#) shows an elevated tumor before radiation.

**FIG. 11.73** (A) Choroidal melanoma with an elevation of 5 mm. Cross-sectional echogram obtained with the duplex instrument ATL mark 8. The sample volume is identified by the marks on the aiming beam. In this area Doppler spectra are obtained, indicating a high blood flow velocity (represented in the lower part of the illustration). (B) Same patient as in panel A, 4 months after radiation treatment of the choroidal melanoma with ruthenium. There is still a considerable volume of tumor remaining (maximal elevation, about 3.5 mL). No frequency shift can be obtained from the interior of the tumor when using duplex examination. The tissue lying in the guiding beam produces only a biphasic noise (illustrated in the lower part of the image).

## Metastatic Choroidal Tumors

Choroidal metastasis is a known complication of several cancers, including all types of carcinomas and sarcomas. The most frequent primary tumors are breast (40%) and lungs (29%). One study examined 230 eyes from deceased patients with known systemic carcinoma and showed that 12% of the eyes had choroidal metastasis on pathologic specimens.<sup>47</sup> Many of these tumors remained undetected at the time of death. The detection of such lesions can be a poor prognostic factor. The average survival time after treatment for choroidal metastasis is 7.4 months.<sup>48</sup> Therefore, many of these patients are not followed for extended periods of time by their ophthalmologist.

Typically carcinoma metastasis presents as a large, highly reflective thickening of the ocular outer layers. The internal acoustic properties can resemble disciform macular degeneration or a

choroidal hemangioma. A metastatic adenocarcinoma typically presents with high reflectivity from the strong acoustic interfaces from its adenoid-like histologic structure (Fig. 11.74).

**FIG. 11.74** Extensive choroidal metastatic tumor in the lower nasal quadrant. (A) On the echogram the choroid is widened to about 2.5 mm; the retina is partly detached by an exudate. The tissue inside the metastatic tumor shows high acoustic reflectivity. (B) Histologic section of a metastatic adenocarcinoma in the choroid. The gland-like structure provides good acoustic interfaces. *NH*, retina; *S*, sclera. (C) Schematic drawing.

In contrast, there are several atypical presentations of choroidal metastasis that have also been reported.<sup>49,50</sup> Pathologic examination of an eye that was enucleated because of suspicion for choroidal melanoma from ultrasound examination revealed a choroidal metastasis from small-cell bronchial carcinoma (Fig. 11.75).<sup>49</sup>

**FIG. 11.75** Histologic metastatic tumor from a small-cell bronchial carcinoma. The echogram (not shown) resembled that of a typical choroidal melanoma. Similar findings have been seen in choroidal metastases from cutaneous melanoma. *NH*, retina; *S*, sclera.

## Choroidal Hemangioma

Choroidal hemangioma may be an isolated lesion or may be associated with Sturge–Weber syndrome. Isolated hemangiomas, described as circumscribed choroidal hemangiomas, usually occur at the posterior pole. The lesions are typically diffuse, slightly

elevated, and may have indistinct margins. These features make ophthalmic interpretation of the lesion difficult and often they can be missed. However, associated features of these circumscribed lesions can include retinal detachment and secondary changes of the RPE, which makes their presence more conspicuous on exam. Ultrasonographically, choroidal hemangiomas appear as a strongly reflecting, nearly concentric widening of the outer layers of the eye (Fig. 11.76). In spite of the abundant vascularization, ultrasound images of choroidal hemangiomas do not show the circulating blood as in choroidal melanomas. Instead, the echogram of a choroidal hemangioma is similar to that of metastatic adenocarcinoma or disciform macular degeneration, which may be indicative of a slower circulation more consistent with laminar flow in the cavities of dilated blood vessels shown by Doppler ultrasonography (Fig. 11.77). In longstanding cases the epichoroidal layer may ossify and produce sound shadows. In this stage, a hemangioma may appear identical to an osteoma or a metastatic calcification of the choroid.<sup>51,52</sup>

**FIG. 11.76** Extensive choroidal hemangioma in Sturge–Weber syndrome (additional finding: total

retinal detachment). (A) Cross-sectional echogram through the area of the optic nerve head. In the lower quadrant, the ocular walls are markedly thickened. (In spite of the associated retinal detachment, the intraocular pressure was 50 mmHg by applanation.) (B) With reduced sensitivity, the scleral surface can be delineated in spite of the high acoustic reflectivity within the tumor (distance of the measuring marks, 3.1 mm). (C) Histologic section through the tumor illustrated in (A) and (B): the septa of the cavities are thin and lined with endothelium. They produce strong reflectivity within the lesion. (D) Schematic drawing.

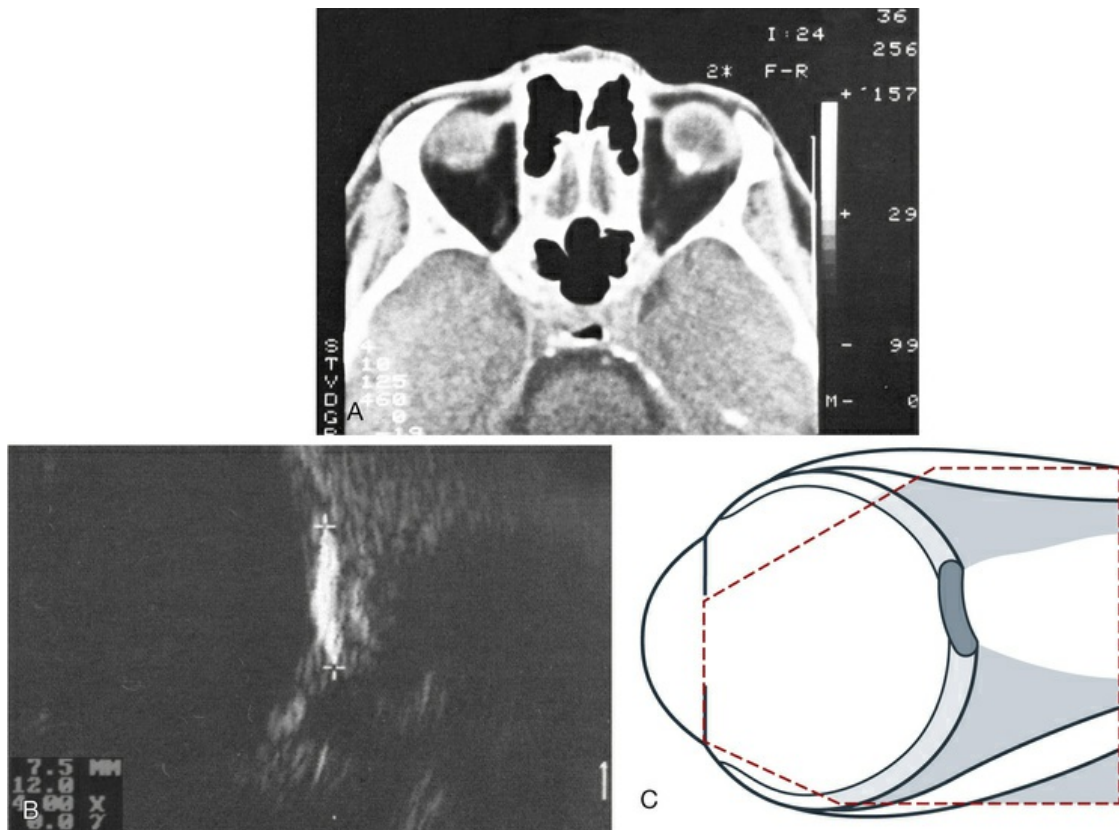

**FIG. 11.77** (A) Cross-sectional echogram of a circumscribed choroidal hemangioma in a 12-year-old boy. The tumor has an elevation of 4 mm. (B) In an A-mode echogram with S-shaped amplification the cross-sectional picture corroborates the high reflectivity of the tumor. (C) On Doppler sonography, we see blood circulating within the tumor, synchronous with the pulse. The illustrated velocity profile speaks for a relatively low resistance by the blood vessels.

## Choroidal Osteoma – Metastatic Calcifications

Choroidal osteoma is a rare condition that is characterized ultrasonographically by a localized area of high reflectivity at the outer wall (Fig. 11.78). Several conditions can mimic the appearance of a choroidal osteoma. As mentioned above, a chronic circumscribed hemangioma can ossify and resemble a choroidal osteoma.<sup>53–55</sup> In addition, several choroidal lesions can contain calcium, including ocular metastases of the choroid and the sclera<sup>51</sup> or metabolic disorders of calcium metabolism that create a localized calcium deposition within the choroid known as an osseous choristoma (Fig. 11.79).<sup>54</sup>

**FIG. 11.78** Cross-sectional echogram of the choroidal osteoma. (A) The echogram of the lesion is characterized by total reflection of the ultrasound, and shadow formation. An elevation cannot be unequivocally documented. (B) With reduced amplification it is possible to image the ossification as an isolated signal. The horizontal diameter is 11.0 mm. (C,D) Schematic drawings.

**FIG. 11.79** Metastatic calcification of the ocular walls of unknown etiology. Differential diagnosis includes choroidal osteoma. (A) A computed tomography scan was obtained because of nonophthalmologic problems. A circumscribed calcified structure within the ocular walls was found incidentally. (B) In cross-sectional echograms, a lesion of the ocular walls above the optic nerve head showed total reflection of the ultrasound signal. The lateral extension was about 7.5 mm. There was no corresponding lesion seen on fundus examination that would be typical of an osteoma. The etiology of this lesion is unknown. (C) Schematic drawing.

## Choroidal Tuberculoma

Choroidal tuberculomas are another extremely rare choroidal lesion (Fig. 11.80).<sup>56</sup> Tuberculomas can also appear similar to choroid melanoma (Figs 11.81). Images that are suggestive of choroidal tuberculomas exemplify the importance of placing the ultrasound image in context with the rest of examination of the patient in order to make the proper diagnosis. Tuberculomas are found in patients

with disseminated tuberculosis and a complete examination can identify other tuberculomas to confirm the diagnosis. Laboratory confirmation of mycobacterium by blood or sputum sampling is also helpful. In addition, these lesions should respond to antituberculous treatment.

**FIG. 11.80** Fundus picture of a 52-year-old woman with active pulmonary tuberculosis. This lesion resolved with antituberculosis treatment.

**FIG. 11.81** (A,B) Echogram of the fundus lesion shown in Fig. 11.80. (C) The lesion is characterized by low acoustic reflectivity. Tenon's space can be well demonstrated. The reflectivity corresponds to that of a choroidal melanoma. The infiltration of Tenon's space points toward inflammatory etiology.

## The Uveal Effusion Syndrome

Patients with uveal effusion syndrome can have partial or circular choroidal detachment combined with an exudative retinal detachment (Fig. 11.82). Ultrasonography is very important in this condition. It can reveal fluid in the suprachoroidal space or differentiate choroidal hemorrhage or tumor from the serous fluid seen on imaging from choroidal effusion syndrome.<sup>49,57</sup>

**FIG. 11.82** Uveal effusion syndrome in a 55-year-old woman. (A) In the axial cross-section, the retina is attached to the optic nerve head. There is an associated, strongly reflecting choroidal detachment. (B) Cross-section of image in (A). (C) Schematic drawing.

## Sclera

### Posterior Scleritis

Ultrasonography is the diagnostic method of choice for posterior scleritis.<sup>52,58,59</sup> The clinical picture is characterized by an acute loss of vision associated with folds at the posterior pole. The normal high reflectivity of the sclera will be decreased by changes in the tissue from inflammatory swelling. The result is a low reflective signal from a thickened choroid, which is suggestive of posterior scleritis. Choroid and vitreous may appear normal. Occasionally, there is a slight exudation into the subretinal space with accompanying disc edema. In 50% of the patients, fluid accumulates in Tenon's space.<sup>60</sup> This signal can be similar to a diffuse choroidal melanoma. There is one case report of an eye that was enucleated because of suspicion

of an ocular melanoma based on the finding of brawny scleral thickening (Figs. 11.83 and 11.84). This case highlights the importance of proper ultrasound interpretation in the clinical context of each patient.<sup>61</sup>

**FIG. 11.83** (A) Brawny scleritis with inflammatory infiltration of Tenon's space. This disease entity can be clinically and ultrasonographically identical to a choroidal melanoma. *T*, Tenon's space. (B) Schematic drawing. *M*, muscle.

**FIG. 11.84** Macroscopic photo of a brawny scleritis. On the basis of the ultrasonographic findings and a positive P32 test, the eye was enucleated because a melanoma was suspected.

# Ultrasound Imaging Used to Differentiate Ocular Disease

Ultrasonography is invaluable in the diagnosis of certain ocular and orbital conditions. Proper imaging with ultrasound can narrow the differential diagnosis in certain conditions and guide further workup and management. These conditions include choroidal folds (Tables 11.1–11.3 and see Fig. 11.85), leukocoria (Table 11.4 and see Fig. 11.86), and vitreous hemorrhage (Table 11.5 and see Fig. 11.87). First, choroidal folds can be from orbital masses, ocular inflammation, disc edema in an atypical presentation, or from idiopathic causes.<sup>49</sup> Next, leukocoria is a condition of a white pupil that blocks ophthalmic examination, typically diagnosed in infancy. This finding can be from retinoblastoma. Differentiating this disease from other benign causes of leukocoria is critical for providing appropriate treatment of the patient. Finally, vitreous hemorrhage may manifest from a variety of changes in the posterior globe; the urgency of treatment is dependent on the diagnosis of a retinal detachment. All of these conditions require ultrasound technology to establish the proper diagnosis. The tables listed above provide information on the differential diagnosis of each condition and ultrasound features that will help guide image interpretation.

### Choroidal Folds: Ultrasonographic Findings Helpful for Differential Diagnosis

Diagnosis		Ultrasonographic Findings
Myositis Graves orbitopathy	1	Thickened extraocular muscles
Periorbital space-occupying lesions	2	Change in the relief of the orbital wall, sound propagation into perinasal sinuses
Orbital neoplasm	3	Directly evident (it may be difficult to demonstrate a small cavernous hemangioma because of its high acoustic reflectivity)
Inflammatory orbital pseudotumor	4	Widening of normal orbital structures, low acoustic reflectivity, Tenon's space may be demonstrated
Disc edema	5	Widened dural diameter of the optic nerve
Axial hyperopia	6	Axial length below 22 mm, ocular walls concentrically thickened
Ocular hypotony	7	Ocular walls concentrically thickened
Macular degeneration		Thickening of the ocular walls in the area of the macula, high acoustic reflectivity
Scleritis	8	Circumscribed widening of the ocular walls Tenon's space apparent

For companion schematic drawing, see [Fig. 11.85](#).

**FIG. 11.85** Choroidal folds: ultrasonographic contribution to the differential diagnosis (for detail, see [Table 11.3](#)).

**TABLE 11.4**

**Leukocoria: Ultrasonographic Findings Helpful for Differential Diagnosis**

Diagnosis	Ultrasonographic Findings
<b>Normal axial length for the patient's age</b>	
Retinoblastoma	1 Widening of the ocular walls, extremely high acoustic reflectivity, shadowing effect, atypical findings possible
Congenital cataract	2 Increased reflectivity from the posterior lens surface, vitreous space empty, ocular walls normal
<b>Shortened axial length</b>	
Retinopathy of prematurity	3 In stages IV and V, beginning or complete traction detachment (normal findings in stages I–III)
Persistent hyperplastic primary vitreous (PHPV)	4 Dense strand of tissue between optic nerve head and posterior lens pole; formes frustes may occur (posterior or anterior PHPV)
Retinal anomalies	Membranes in the vitreous, atypical detachment, which in part appears solid (no typical echogram)
Fundus coloboma	5 Directly demonstrable protrusion of ocular wall, sometimes with orbital cyst (microphthalmos with cyst)
Coats disease	6 Floating crystals in the vitreous and subretinal space (fast-flickering spikes on A-mode)

For companion schematic drawing, see [Fig. 11.86](#).

**FIG. 11.86** Leukocoria: echographic contribution to the differential diagnosis (for detail, see [Table 11.4](#)).

**TABLE 11.5**

**Vitreous Hemorrhage: Ultrasonographic Findings Helpful for Establishing the Etiology**

Diagnosis	Ultrasonographic Findings
Symptomatic posterior vitreous detachment	1 Thickened detached posterior hyaloid membrane, occasionally early retinal detachment
Recently formed retinal break with torn vessel	2 Blood-covered vitreous strands converge toward the retinal break; occasionally a high-floating operculum may be detected
Proliferative retinopathy	3 Strands or membranes extending from the optic nerve head or the posterior pole, high acoustic reflectivity
Terson syndrome (vitreal hemorrhage after subchoroidal bleeding)	4 Vitreal opacities in front of the optic nerve head or behind the detached vitreal
Disciform macular degeneration	5 Widening of the ocular walls in the macular area, high acoustic reflectivity, vitreal strands extending from the macula
Choroidal melanoma	6 Biconvex thickening of the ocular wall, low acoustic reflectivity, sometimes mushroom-shaped; accompanying retinal detachment distant from the tumor

For companion schematic drawing, see [Fig. 11.87](#).

**FIG. 11.87** Vitreous hemorrhage: echographic contribution to determine the pathogenesis (for detail, see [Table 11.5](#)).

Furthermore, ultrasonography can aid in the preoperative planning and patient counselling for surgery. [Table 11.6](#) lists some of the possible ultrasonographic information and subsequent conclusions that can be obtained for operative planning ([Table 11.6](#) and see [Fig. 11.88](#)).

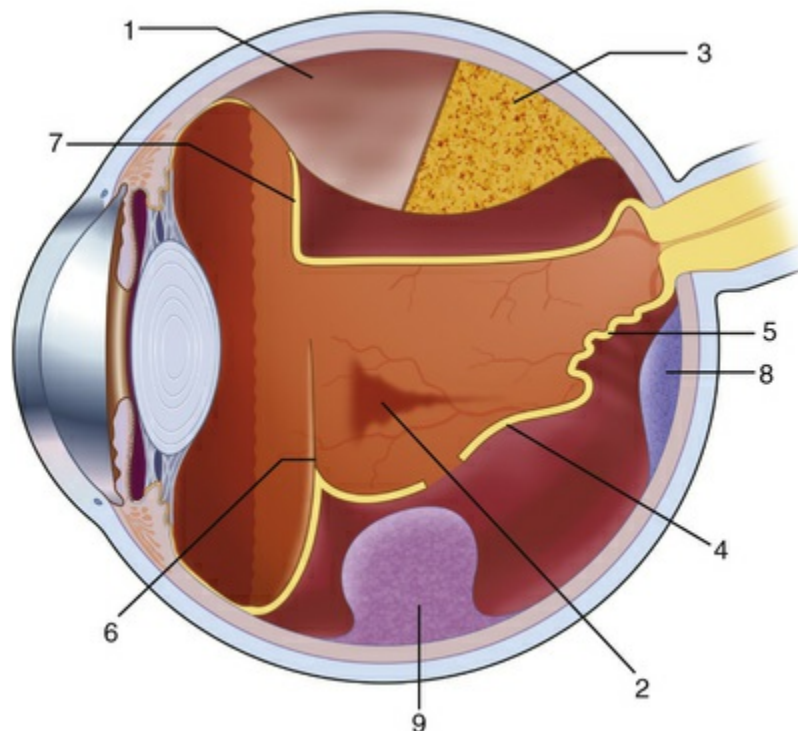

**TABLE 11.6**

**Examination Before a Vitrectomy: Ultrasonographic Findings Helpful for Planning the Operation**

Questions on the ultrasonographic examination	Consequences for planning the operation
Is the choroidal detachment including the pars plana?	1 Avoiding this area when inserting the ports
Is the posttraumatic vitreous hemorrhage associated with a detached retina?	If retina is detached, strong indication for vitrectomy
Is an intraocular foreign body demonstrable? If so, where is it in regard to ocular outer wall?	2 Choice of surgical approach, magnet extraction possible?
	<b>Estimating the prognosis</b>
Is there a choroidal detachment caused by blood?	3 Extremely poor prognosis that may not benefit from surgical intervention
Is there a free-floating retinal detachment?	4 Reattachment probable, can be achieved without tamponade from

		the inside
Is there a rigid retinal detachment? Is there a thickened retina?	5	Removal of preretinal membranes necessary
Are there vitreous strands with traction effect demonstrable?	6	Consider intraoperatively cutting the strands
Is there retinal detachment that is displaced anteriorly to be near the lens?	7	Special care indicated when entering the vitreous space
Are there thickened ocular walls in the macula that may indicate a disciform lesion from macular degeneration?	8	Poor prognosis for central vision
Are there indications of a secondary, e.g., solid retinal detachment?	9	Additional diagnostic examinations; enucleation may be necessary
Is there attached retina with minimal remaining vision?		Reconsider indication for operation, prognosis for vision extremely poor

For companion schematic drawing, see [Fig. 11.88](#).

**FIG. 11.88** Examination before a vitrectomy: echographic contribution to the planning of the operation (for detail, see [Table 11.6](#)).

## Future Developments

Many medical fields are using advances in technology to improve ultrasound images. These improvements involve the use of new

piezoelectric materials and broadband transducers.<sup>62</sup> Current and future developments can be focused on the following trends:

- Advances in the signal transmission process
- Advances in the signal reception process
- Compounding, equalization, and extended-field acquisitions
- 3D and 4D imaging<sup>63,64</sup>
- Elastographic imaging
- Fusion imaging<sup>65</sup>
- Miniaturization of units and probes, transfer, and archiving ultrasonic data.

In the field of ophthalmology new Doppler modes for analyzing retinal blood flow are currently being utilized in research initiatives. A new technique is elastographic imaging. Recently, this technique has been used to image ocular tissues in high myopia.<sup>66</sup> Patterns of elastic imaging in the vitreous cavity could be attributed to posterior vitreous detachment, whereas that of medial and lateral rectus muscles may be related to the level of muscle fiber strain. With improved resolution, higher frequencies, and spatial images on ultrasound, new frontiers in ophthalmic imaging are being reached and further research in multimodal imaging is still under way.<sup>67</sup> These advancements as well as the safety in image acquisition maintain the utility of ultrasound imaging within all fields of medicine.

## Acknowledgments

A special thank you to a number of colleagues who have been of great assistance in creating this chapter: Sönke Langner, Kirsten Franke, Beate Stroteich, Anarit Stachs, and Enrique Pfeiffer.

## **Overview**

Day vision and night vision are two separate modes of visual perception and the visual system shifts from one mode to the other based on ambient light levels. Each mode is primarily mediated by one of two photoreceptor classes in the retina, i.e., cones and rods. In day vision, visual perception is primarily cone-mediated and

perceptions are chromatic. In night vision, visual perception is rod-mediated and perceptions are principally achromatic. Historically, color vision has been studied as the salient feature of day vision and there has been emphasis on analysis of cone activities in color vision. Night vision has been studied in terms of rod activity and considerations of the shift from day vision to night vision. This chapter will review basic aspects of cone-mediated color vision and rod-mediated night vision and discuss clinical assessments of rod and cone sensitivities and color vision.

## Rod and Cone Functions

Differences in the anatomy and physiology (see [Chapter 4](#), Autofluorescence imaging, and [Chapter 11](#), Diagnostic ophthalmic ultrasound) of the rod and cone systems underlie different visual functions and modes of visual perception. The rod photoreceptors are responsible for our exquisite sensitivity to light, operating over a  $10^8$  (100 millionfold) range of illumination from near-total darkness to daylight. Cones operate over a  $10^{11}$  range of illumination, from moonlit night light levels to light levels that are so high they bleach virtually all photopigments in the cones. Together the rods and cones function over a  $10^{14}$  range of illumination. Depending on the relative activity of rods and cones, a light level can be characterized as photopic (cones alone mediate vision), mesopic (both rods and cones are active), or scotopic (rods alone mediate vision).<sup>1</sup> In the literature, the terms photopic vision and scotopic vision are used to reflect cone and rod vision, respectively. [Table 12.1](#) shows this overlapping range of rod and cone activities.

**TABLE 12.1**

**The Dynamic Range of the Human Visual System**

Visual environments	Starlight		Moonlight		Indoor lighting		Sunlight	
Photopic luminance (log cd/m <sup>2</sup> )	-6	-4	-2	0	2	4	6	8
Light category	Scotopic		Mesopic		Photopic			
Photoreceptors	Rods only		Rods and cones		Cones only			
Visual function	Rod absolute threshold		Cone absolute threshold		Rod saturation begins		Damage Possible	
	No or poor color vision				Good color vision			

Modified from Hood DC, Finkelstein MA. Sensitivity to light. In: Boff KR, Kaufman L, Thomas JP, editors. The handbook of perception and human

The distribution of rods and cones in the retina (see [Chapter 4](#), Autofluorescence imaging) is also reflected in visual function. The greatest sensitivity to light occurs in the midperiphery of the visual field, which has a predominance of rods, while high-acuity and good color vision are mediated by the fovea, which has a predominance of cones. Nonetheless, the entire retina, with the exception of a very small area within the fovea, is capable of mediating night vision, and color vision is present throughout the visual field with daylight stimulation of the entire retina. The following sections will introduce rod and cone differences in light adaptation, spectral sensitivity, and spatial/temporal sensitivity.

## Light Adaptation

Photoreceptors, whether they are rods or cones, respond well to only a small range of variations in illumination within a steady adapting background.<sup>2</sup> However, adaptation mechanisms adjust photoreceptor sensitivity so that this small range of responses is always centered near the current adaptation level, even though adaptation levels can vary over a wide range. This behavior forms the basis for the large operating range of the visual system.

It is possible to assess light adaptation behavior by measuring a threshold for the perception of an increment in light on a large, steady background field. As the background light level is increased, the increment threshold starts to increase. Rods and cones behave differently in this regard. For the rod system, as shown in [Fig. 12.1A](#), the increment threshold increases steadily over almost a thousandfold range. With further increases in background adaptation levels, an increment is not detected, no matter how much additional test light is presented as an increment, due to rod saturation. In comparison, the cone system, as shown in [Fig. 12.1B](#), shows a continuous steady increase in the increment threshold with increases in background illumination, even at light levels that

bleach almost the entire amount of available photopigment. The portion of the curve that rises linearly with illumination levels is called the Weber region (Fig. 12.1). In the Weber region, an incremental light can be detected when it is a constant proportion (i.e., the Weber fraction) of the background light level. Different photoreceptor systems have a characteristic Weber fraction. Cones have lower Weber fractions than rods. Under optimal conditions, the cone system can detect a light level difference of 1%, while rods need a light change of 20%.

**FIG. 12.1** The increment threshold functions for scotopic (rod) and photopic (cone) vision as a function of background illuminance. (A) Rod increment thresholds measured at  $9^\circ$  in the parafovea. The dashed line has a slope of 1. The portion where the curve has unit slope (in parallel to the dashed line) is the Weber region, followed at higher levels by the region of rod saturation. To the right is shown the fraction of rod photopigment bleached. The rods are saturated before there is substantial photopigment bleaching. (B) Cone increment thresholds measured at the fovea. To the right is shown the fraction of photopigment bleached. The Weber region extends to luminances (6 million trolands) that bleach virtually all the cone photopigment. (Reproduced with permission from Enoch JM.

The two-color threshold technique of Stiles and derived component color mechanisms. In: Jameson D, Hurvich L, editors. Visual psychophysics: handbook of sensory physiology, vol. VII/4. Berlin: Springer-Verlag; 1972.)

In addition to photoreceptor adaptational properties, other factors, including pupil size, the temporal and spatial summation characteristics, and photopigment depletion, can also contribute to extend the operating range of the visual system over a large luminance range. While some adaptation operates within the

photoreceptors themselves, other properties of adaptation may reflect the effects of the complex neural circuitry of the retina.<sup>2</sup>

## Spectral Sensitivity

Day vision is primarily mediated by three types of cone photoreceptors with different but overlapping spectral sensitivities. Each is identified by the relative position of the peak in spectral sensitivity. The three cone types are called the long-, middle-, and short-wavelength-sensitive (L, M, and S) cones. When overall sensitivity to light is measured at the light-adapted fovea, a broad sensitivity spectrum peaking near 555 nm is found. This sensitivity spectrum represents the combined activity of the L and M cones and is called the  $V(\lambda)$  function. When sensitivity to light is measured in the dark-adapted peripheral retina, where rods dominate, a broad-sensitivity spectrum is found with a peak sensitivity at 507 nm. This rod spectral sensitivity function is called  $V'(\lambda)$  (Fig. 12.2A). Both  $V(\lambda)$  and  $V'(\lambda)$  functions have practical significance and have been accepted by the Commission Internationale d'Eclairage (CIE) as representative of human vision relative luminous efficiency at photopic and scotopic levels. They are used to relate luminous (perceived energy of light) to radiant (emitted light) energy.

**FIG. 12.2** Spectral sensitivities of cones and rods. (A) The relative spectral luminous efficiency functions for scotopic and photopic vision adopted by the

Commission International d'Eclairage (CIE),  $V'(\lambda)$  and  $V(\lambda)$  respectively. (B) Spectral sensitivities of the S, M, and L cones derived from color-matching function.<sup>14</sup>

(Data in panel A from Wyszecki G, Stiles WS. Color science – concepts and methods, quantitative data, and formulae, 2nd ed. New York: John Wiley; 1982.)

Fig. 12.2B shows the relative spectral sensitivities of the three cone types. The S cones are most sensitive to light near 445 nm, with sensitivity declining rapidly at longer wavelengths. At 555 nm and longer wavelengths, the S cones are virtually unresponsive to light. The M and L cones have overlapping spectral sensitivities that span the entire visible spectrum. The M cones peak in sensitivity near 543 nm, while the L cones peak near 566 nm. The differential spectral sensitivity functions of the L, M, and S cones provide the foundation of early spectral processing.

## Spatial and Temporal Resolution

Compared with the cone system, the rod system has poorer spatial resolution (acuity). For an observer with 20/20 photopic acuity, scotopic acuity would be about 20/200 (10 times worse than photopic acuity). The rod system also has poorer temporal resolution, which refers to the ability to perceive a physically alternating light as steady or flickering in time. The transitional temporal frequency at which the light appears from flickering to steady is called the critical fusion frequency (CFF). CFFs increase with light adaptation level, reaching a maximum of ~20 Hz for rods and 55–60 Hz for cones. This means that flickering lights can be perceived at higher frequencies in brighter light conditions. Interestingly, dark-adapted rods can suppress cone-mediated flicker detection.<sup>3,4</sup>

## Visual Pathways for Rod and Cone Functions

### Retinal Pathways

Rod signals are conveyed by two primary retinal pathways that are

dependent on the illumination level.<sup>5</sup> One pathway is via ON rod bipolars, All amacrine cells, and ON and OFF cone bipolars. This is a temporally sluggish pathway that mediates rod vision at low scotopic light levels. The second pathway transmits rod information via rod–cone gap junctions and ON and OFF cone bipolar cells in the retina. This is a fast pathway that mediates vision at higher scotopic and mesopic light levels. A third insensitive rod pathway between rods and OFF cone bipolars has been identified in rodents but, thus far, not in primates. The significant point here is that rods and cones share neural pathways and have joint inputs to retinal ganglion cells.

## Retinogeniculate Pathways

There are three major neural retinogeniculate pathways in primates that convey retinal information to the visual cortex.<sup>6,7</sup> The pathways are named after the layers of the lateral geniculate nucleus (LGN) that receive input from distinct types of ganglion cells and project to different areas of the primary visual cortex. The magnocellular (MC) layer of the LGN receives inputs from parasol ganglion cells. The MC pathway processes the summed output of the L and M cones to signal luminance information. The parvocellular (PC) layer of the LGN receives input from midget ganglion cells. The PC pathway mediates spectral opponency of L and M cones (discussed later) to signal chromatic information. The koniocellular (KC) layer of the LGN, which receives input from small bistratified as well as other ganglion cells, detects changes in S-cone signals compared to the sum of the L- and M-cone signals. These three pathways mediate different aspects of vision, with the MC pathway mainly carrying out luminance and motion processing, the PC pathway mainly processing red–green color, acuity, and shape information, and the KC pathway mainly handling blue–yellow color processing.

The sharing of neural pathways between rods and cones implies that rods should have input to the MC, PC, and KC pathways. Indeed, physiologic studies have shown that there is strong rod input to the MC pathway, but weak input to the PC pathway.<sup>8</sup> Demonstration of rod input to the KC pathways is less clear. An

earlier study<sup>8</sup> did not find rod input to the bistratified ganglion cells in the parafovea, while two recent studies demonstrated strong rod input in the peripheral retina.<sup>9,10</sup> Fig. 12.3 shows a schematic diagram of the visual pathways conveying rod and cone inputs to the MC, PC, and KC ganglion cells, which would then produce signals that are projected into the cortex to mediate different aspects of visual perception.

**FIG. 12.3** The schematic diagram of visual pathways carrying rod and cone inputs for visual perception. *MC*, magnocellular; *PC*, parvocellular; *KC*, koniocellular; *LGN*, lateral geniculate nucleus.

## Dark Adaptation Functions: Assessment of the Shift From Day Vision to Night Vision

Measurements of detection thresholds during adaptation to darkness have produced a characteristic biphasic function with an initial segment that is attributed to cone responses and a subsequent segment attributed to rod responses. Fig. 12.4 shows a characteristic dark adaptation function measured in the peripheral retina. Thresholds decrease quickly initially and this rapid recovery is attributed to cones. Thresholds then reach a plateau in about 5 minutes and remain invariant for another 5 minutes (cone plateau, reflecting cone absolute thresholds). Then, there is a second rapid decrease in thresholds due to sensitivity recovery of the rods, referred to as the rod–cone break, to a new plateau that is reached in 40–50 minutes (rod plateau, reflecting rod absolute thresholds).

**FIG. 12.4** The time course of dark adaptation. The range of threshold sensitivities of 110 normal observers is shown. The circular points represent data of the most and least sensitive individuals. The area enclosed by the dashed lines represents 80% of this population. The cone absolute thresholds are obtained during the cone and rod plateaus, respectively. (Data from Hecht S, Mandelbaum J. The relationship between vitamin A and dark adaptation. JAMA 1939;112:1910–6.)

JAMA 1939;112:1910–6.)

The shape of the dark adaptation function depends on testing parameters, including retinal location, wavelength, and temporal and spatial characteristics.<sup>1,11</sup> The effects of these parameters on

dark adaptation curves can be understood by the differences between rods and cones in terms of their distributions, spectral sensitivity, and spatial/temporal resolution characteristics. For instance, because there are only cones in the fovea, dark adaptation measured at the fovea using a small test light reveals a rapid monophasic branch attributable to the cones. On the other hand, because the rod and cone systems have similar absolute sensitivities at long wavelengths, dark adaptation measured with long-wavelength lights is monophasic, resembling the cone function. As the test wavelength is changed to shorter wavelengths, a biphasic curve emerges because the rods show greater absolute sensitivity than cones at shorter wavelengths.<sup>12</sup>

## Clinical Evaluation Using Dark Adaptation Functions

It is known that certain retinal disorders may selectively affect rods (e.g., retinitis pigmentosa) or cones (e.g., cone dystrophies). Clinically, rod and cone functions can be evaluated electrophysiologically by measuring rod and cone electroretinograms (ERG: see [Chapter 9](#), Electrogenesis of the electroretinogram) or, psychophysically, by measuring dark adaptation functions. Dark adaptation functions quantify the ability of the rod and cone systems to recover sensitivity (i.e., regenerate photopigment) after exposure to a bright light. The recovery is faster for cones, but the absolute level of sensitivity is greatest for rods. Variations in sensitivity and sensitivity recovery times can be used to characterize retinal disorders.

Clinical evaluation using dark adaptation functions involves a measure of the cone and rod absolute thresholds and the time of the rod–cone break. Specifically, rod absolute thresholds have been used as a psychophysical supplement to ERG measurement for night-blindness evaluation. The instrument for dark adaptation rod absolute threshold measurement is called a dark adaptometer and the most widely used is a Goldmann–Weekers dark adaptometer (Haag–Streit). This instrument is old, however, and finding replacement lamps is difficult. Recently, new light-emitting diode (LED)-based, computer-controlled, dark adaptometers have become

commercially available.

## Color Vision

Color vision refers to our ability to perceive colors based on spectral variations in light absorbed by the photoreceptors. Color vision includes both chromatic discrimination and color appearance appreciation. Color-matching and color-discrimination experimental tasks are two fundamental psychophysical procedures that have provided theoretical insights into the nature of color vision and have also been developed for clinical diagnosis of color vision. Color-matching and color-discrimination results, however, do not address questions of color appearance – for example, why an object appears red. Color appearance is far more complex because it depends on not only the chromatic properties of an object but also the spatial, temporal, and spectral characteristics of the neighboring objects.<sup>13</sup> Neural processing beyond the retina is required for color appearance appreciation.

## Color Matching

### Color Matching as the Foundation for the Theory of Trichromacy

The psychophysical procedure in which an observer sets a mixture of three primary lights to match the color of a test stimulus is called color matching. It has been known since the 19th century that different colors perceived by humans can be specified by a three-variable (trichromatic) system. In the 1800s, Thomas Young and Hermann von Helmholtz proposed that there must be three kinds of physiologic entities in the eye accounting for this trichromacy and their theory is called the Young–Helmholtz trichromatic theory of color vision. We now know the basis for trichromacy is the existence of three cone types in the retina. Color matching was one of the methods to uncover the spectral sensitivity functions of the three different cone types (Fig. 12.1B).<sup>14</sup>

### Color-Matching Experimental Techniques and Data

Theoretically, a color match occurs when the photoreceptor quantal catch for the test stimulus and the quantal catch for the stimulus that is a combination of the three primary lights are the same. Color matches are unperturbed by changes in luminance levels, as long as no significant photopigment bleaching occurs, which means that the basic nature of trichromacy exists under wide variations in light levels. In a classical color-matching experiment, three spectral lights are chosen as the three primaries and the precise setting of the relative percentages of the three primaries to match a test light is the data for that match. When all three primaries are added together, they can be set to match a neutral white.

Procedurally, due to the mechanics of testing optical equipment, the spectral test color and one primary are made to appear in one field and the other two primaries appear in a second field with the two fields usually appearing as two halves of a circle. The observer's task in a color-matching experiment is to make the two fields appear identical in color. Color-matching data are usually represented in one of two ways. In the first, the amounts of energy of each primary can be plotted as a function of the test wavelength. These are called color-matching or color mixture functions. In such plots, the primary that is added to the test color is given a negative value, and the other two primaries are given positive values. The second plotting method is to normalize the value of each matching primary relative to the sum of the three primaries, leading to the sum of the normalized primaries being equal to 1. Therefore, a plot of one primary value against a second primary value is sufficient to display all the information in the color-matching data. This kind of plot is called a chromaticity diagram, which shows the relative contributions of each spectral primary needed to match any spectral light.

## **The CIE Colorimetric System**

This spectral primary-based chromaticity diagram has proven to be very useful as a generalized color specification system. However, linear transformation is needed to compare data collected with different choices of primaries. In 1931, the CIE standardized the spectral-primary-based chromaticity system by adopting three imaginary primaries ( $X$ ,  $Y$ ,  $Z$  primaries) that are out of the spectral

locus and therefore do not exist physically. The choices of the imaginary primaries were based on two important considerations: first, to ensure that the chromaticities of all physical lights have positive values and, second, to relate colorimetric functions to the previously adopted luminosity function,  $V(\lambda)$ . In the system, the color-matching function for the  $Y$  primary is identical to  $V(\lambda)$  of the photometric system as designed.

Fig. 12.5A shows the 1931 CIE chromaticity chart, in which the coordinates of the normalized  $Y$  primary [ $y = Y/(X + Y + Z)$ ] are plotted against those of the normalized  $X$  primary [ $x = X/(X + Y + Z)$ ]. The spectrum loci (their wavelengths are indicated on the graph) form a horseshoe-shaped curve. Equal-energy-spectrum (EES) light is plotted in the center, with the coordinates of  $x = 0.3333$  and  $y = 0.3333$ . A straight line connects 400 nm to 700 nm for purples, which result from mixtures of short- and long-wavelength light. All possible lights occur within the boundaries of the spectrum locus and the purple line. Highly saturated colors occur near the spectral loci and desaturated (pale) colors occur near the white point.

**FIG. 12.5** Chromaticity spaces. (A) The Commission International d'Eclairage (CIE) 1931  $x, y$  chromaticity diagram. An equal-energy-spectrum (EES) light has a coordinate of  $x = 0.3333$  and  $y = 0.3333$ . Spectral wavelengths are represented on the horseshoe-

shaped spectrum locus. All lights can be represented in this diagram. (B) The MacLeod and Boynton cone space, which plots S-cone excitation versus relative L-/M-cone excitations. In this space, the  $S/(L + M)$  chromaticity of 400 nm spectral light is normalized to be 1. In such a normalization, an EES light has a chromaticity of  $L/(L + M) = 0.665$  and  $S/(L + M) = 0.016$ . In a relative cone troland space, the  $S/(L + M)$  for an EES light is normalized to be 1. The chromaticities of the spectral loci form an “L” shape in this space. (Data in panel A from Wyszecki G, Stiles WS. Color science – concepts and methods, quantitative data, and formulae, 2nd ed. New York: John Wiley; 1982.)

The 1931 CIE system was based on the 2° field color-matching functions that were derived from color matches of many observers. The averaged color-matching function from these observers was treated as the standard. Therefore, an observer with the standard color-matching function is referred to as the standard observer. Since the color-matching data are affected by the size of the stimulus field presented to the observer, in 1964, the CIE also adopted a large-field XYZ system that was based on the 10° field standard observer color-matching functions. For large stimuli, such as those generated by Ganzfeld for ERG measurements, it is recommended to use the 1964 CIE chromaticities to reflect more accurately the large field color-matching functions.

## Cone Chromaticity Space

The CIE colorimetric system is valuable for light specifications; however, psychophysical experiments using the CIE system cannot yield results that allow easy interpretation of the underlying physiologic mechanisms. When the physiologic mechanisms of color vision are of interest, a cone chromaticity space that can represent cone stimulations, as well as the postreceptoral pathways, is preferred.

The concept of cone chromaticity space appeared in the early 20th century. It was not until 1979 that MacLeod and Boynton<sup>15</sup> published a cone chromaticity space based on modern estimates of the cone spectral sensitivities.<sup>14</sup> In the MacLeod and Boynton cone chromaticity space (Fig. 12.5B), the horizontal axis [ $L/(L + M)$ ]

represents the variation of relative L- versus M-cone stimulation at equiluminance, while the vertical axis  $[S/(L + M)]$  represents the variation of S-cone stimulation. The space normalizes  $S/(L + M) = 1$  for spectral light of 400 nm. Later, a relative cone troland space that normalizes  $S/(L + M)$  for EES light to be 1 was proposed to link cone excitations with retinal illuminance, which is measured in trolands.<sup>16</sup> Another spectral opponency space, called the DKL space, normalizes the cone chromaticity based at the EES-white to reflect both cone contrasts and postreceptoral opponency signals.<sup>17</sup> These cone chromaticity spaces are a major breakthrough for vision research because neurons in the PC and KC pathways show preferred responses to stimuli along the two axes of the cone chromaticity spaces.<sup>17,18</sup> Therefore, psychophysical experiments can be designed to infer the functions of the postreceptoral pathways by generating stimuli along the two theoretical axes.

## Chromatic Discrimination

Chromatic discrimination refers to the ability of an observer to discriminate two colors. Chromatic discrimination has been investigated using three approaches: wavelength discrimination, purity discrimination, and chromaticity discrimination (reviewed by Pokorny and Smith<sup>19</sup>). Chromatic discrimination is usually measured at a constant luminance level to avoid potential interactions between the luminance pathway (MC pathway) and the chromatic pathway (PC or KC pathway).

### Wavelength Discrimination

In a typical wavelength discrimination experiment, the stimulus consists of two equiluminant semicircular fields, one filled with a narrow band of spectral light to serve as the standard field and the other as the comparison field. The observer is instructed to change the wavelength of the comparison field to achieve a just noticeable difference (JND) from the standard wavelength. Typical wavelength discrimination thresholds, as a function of standard wavelengths, form a skewed “W” shape with two minima, one at 490 nm and the other at 580 nm.<sup>20</sup>

## Purity Discrimination

There are two ways to measure purity discrimination. The first method measures the minimum amount of spectral light the observer adds into a white field to achieve a JND from the same white in another juxtaposed field. Discrimination thresholds measured in this way are the largest at 570 nm and the smallest at 400 nm. The second method measures the minimum amount of white light added into a spectral light to achieve a JND from the spectral light. Purity discrimination thresholds measured in this way do not vary much with variations in the wavelength of the spectral light.

## Chromaticity Discrimination

Early attempts to measure chromaticity discrimination included measurement of the minimum variation needed in chromaticity to achieve a JND from any point in the CIE diagram.<sup>21</sup> Another measure of chromatic discrimination involved derived discrimination ellipses using the standard deviations of repeated color matches at a set of chromaticities in the CIE diagram.<sup>22</sup>

In modern chromaticity discrimination experiments, discrimination thresholds are obtained for test field chromaticities varied along the two cardinal axes of a cone chromaticity space in a steady adaptation field. A cone chromaticity space allows that discrimination can be mediated by the L/M cones only (L-/M-cone discrimination) or by the S cones only (S-cone discrimination).<sup>23</sup> Chromatic discrimination was found to be the best at the adaptation chromaticity and then deteriorated with increasing chromatic contrast between the test and adapting fields. Chromatic discrimination data can be explained adequately by a model based on primate ganglion cell responses in the PC and KC pathways.<sup>24</sup>

## Color Appearance

In color-matching and color-discrimination experiments, observers determine whether two colors appear the same or different but they do not determine which color is perceived. Color appearance has three perceptual dimensions: hue, saturation, and brightness. Hue is the perceptual dimension that differs from white, such as red,

orange, green, blue, yellow, purple, and pink. Saturation indicates how different the hue is from white. For instance, colors on the spectral locus are highly saturated compared with desaturated colors near white (Fig. 12.5A). Brightness is the perceptual dimension related to luminance variance.

An important feature of color appearance is that colors do not simultaneously appear red and green, nor do they simultaneously appear blue and yellow. However, colors do appear as mixtures of red and yellow or red and blue and they also appear as mixtures of green and yellow or green and blue. Further, human observers can separately abstract the qualities of redness–greenness or blueness–yellowness in an arbitrary test color. These facts have led to the concept that color appearance can be represented in a double-opponent system, with red and green placed in opposite directions on one dimension and blue and yellow placed in opposite directions in the other dimension (Fig. 12.6). Red and green are said to be opponent sensations, as are blue and yellow. This observation triggered Ewald Hering, a German physiologist, to propose the “opponent-color” theory in the late 19th century.

**FIG. 12.6** Color opponency. Theoretical curves for the first stage of opponent coding for normal 2° foveal

color vision. The (all-positive) achromatic function represents the whiteness response. Two (opponent) chromatic functions, ( $R-G$ ) and ( $Y-B$ ), represent redness–greenness and blueness–yellowness, respectively. (Reproduced with permission from Hurvich LM, Jameson D. Some quantitative aspects of an opponent-colors theory. II. Brightness, saturation and hue in normal and dichromatic vision. *J Opt Soc Am* 1955;45:602–16.)

The theories of opponency and trichromacy were two competing theories in the history of color vision research; however, the two theories have been reconciled in that chromatic processing starts with three types of cones, supporting trichromacy, and spectral responses from the cones are transmitted in bipolar and ganglion cells that have antagonistic receptive field structures, consistent with opponency. This interpretation of color vision, first proposed by von Kries in 1905,<sup>25</sup> is referred to as the two-stage or two-process model of color vision.

In a complex visual scene, the perceived color of a light (emitted from a source or reflected from an object) cannot be predicted from its spectral power distribution because the context of other nearby light affects color appearance. For instance, chromatic induction occurs when perception changes because of the presence of other lights nearby in space or time. Chromatic induction includes both chromatic contrast and chromatic assimilation. Chromatic contrast occurs when the color appearance of a test light shifts away (in terms of color opponency) from the color appearance of a nearby light. Chromatic assimilation occurs when the color appearance of a test light shifts toward the color appearance of inducing nearby light. Therefore, the color of a light seen in isolation (surrounded by darkness) is called an unrelated color while the color perceived in the presence of a complex context is called a related color; that is, its percept is related to the surrounding colors. Cortical mechanisms are likely involved in color perception in a complex scene.<sup>26</sup>

## Variations in Human Color Vision

Abnormal color vision that is either inherited or acquired is present in about 4.5% of the population. Congenital color vision defects are stationary over the lifespan and do not result from other visual

problems. These color vision defects have been studied extensively and their classification is well established based on psychophysical and genetic works. The most common are the congenital X-chromosome-linked red–green color vision defects, which have been associated with alterations in the gene sequences encoding the opsins on the X chromosome.<sup>27,28</sup> Acquired color vision defects refer to abnormalities that accompany eye diseases or drug toxicity. Acquired color vision defects are more variable and their classification is more difficult and less satisfactory. Color vision is often tested clinically with screening tests that allow identification of abnormalities and most screening tests are based on color-discrimination and color-matching abilities.<sup>29</sup>

## Color Vision Classifications

Color vision classifications are based on both the number of functioning cone types and the presence of abnormal cones. An observer with three functioning cone types is called a trichromat, an observer with two functioning cone types is a dichromat, and an observer with one functioning cone type is a monochromat (monochromacy sometimes is also termed achromatopsia in the literature since it is believed that vision based on a single cone type cannot produce color perception, assuming rods are not involved). An observer with normal color vision has three normal cone types, in terms of spectral sensitivity, and is called a normal trichromat. Observers who are said to have defective color vision have at least one abnormal cone type or are missing at least a cone type with conventional color-matching techniques. An observer with rods only (lack of any cones) is called a rod monochromat, also termed complete achromatopsia.<sup>30</sup>

X-linked color vision defects have been recognized since the 18th century and were subdivided into two qualitatively different types: protan (“red-blind”) and deutan (“green-blind”). The term “protanope” is used for a dichromat who is thought to be missing L cones and the term “deuteranope” is used for a dichromat who is thought to be missing M cones, based on color-matching characteristics using a 2° visual field in the fovea. Anomalous trichromacy is a variation in color vision that is attributed to the

presence of a cone type that is shifted in spectral sensitivity. A protanomalous observer has trichromatic color vision but the L cones have spectral sensitivity that is shifted to shorter wavelengths compared to normal L cones. A deuteranomalous observer also has trichromatic color vision but the M cones have spectral sensitivity that is shifted to longer wavelengths compared to normal M cones. A third qualitatively different type of color vision is tritan (“blue-blind”). Tritan color vision defects are thought to arise from variations in S cones.

## The Genes Encoding the Human Photopigments

It has been known for many years that the spectral sensitivities of rods and cones reflect the absorption spectra of the visual photopigments. In a major advance, the genes encoding the opsins of the human visual photopigments were cloned and mapped in the human genome in 1983.<sup>27,31</sup> The gene for rhodopsin was found on chromosome 3 and the human rhodopsin gene showed high homology (93.4%) to that of bovine rhodopsin.<sup>31</sup> A visual photopigment gene for the opsin of S cones (*OPN1SW* gene) was found on chromosome 7. A tandem array of visual photopigment genes for the opsins of the M and L cones (*OPN1MW* and *OPN1LW* genes) was found on the X chromosome. The human opsin genes show about 45% homology between rhodopsin and any of the three cone photopigment genes and between the chromosome 7 and the X-chromosome pigment genes. This similarity among the photopigment genes suggests a common ancestor. The genes on the X chromosome have a high homology to each other (about 96%), suggesting a more recent evolutionary appearance. An unexpected finding was that of multiple genes in a tandem array on the X chromosome, which has been proposed to range from 2 to 6. Nathans et al.<sup>28</sup> postulated that the multiple genes in the tandem array on the X chromosome arose as a result of unequal homologous recombination. Subsequent study has suggested there are polymorphisms among these genes in color-normal and color-defective individuals.<sup>27</sup>

The initial study of the opsin genes on the X chromosome was

based on the longstanding conventional ideas about X-linked congenital color vision defects,<sup>28</sup> that is, protanopes are missing L cones and deuteranopes are missing M cones, and that the genetics of these types of defective color vision may be based on missing genes for either L or M cones. Specifically, protanopes were thought to be dichromats who lacked an L-cone gene and deuteranopes were dichromats who lacked an M-cone gene.

The initial work with the X-chromosome opsin genes, in attempting to link color vision defects with these genes, was carried out using restriction fragment length polymorphisms (RFLPs), an early molecular genetic technique that simplified the study of DNA sequences. The initial RFLP analysis of the X-chromosome genes was done on DNA from one observer with normal color vision and a few protanopes and deuteranopes. Comparisons were carried out to determine which of the fragments found in the normal observer's RFLPs were missing in the protanopes and deuteranopes. A fragment found in the normal observer that was missing in the protanope was said to be part of the assumed missing L-cone gene. Similarly, a fragment found in the normal observer that was missing in the deuteranope was said to be part of the assumed missing M-cone gene. In the initial study, observers with dichromatic as well as anomalous trichromatic color vision defects showed the presence of hybrid genes (genes comprising the head of one type of gene and the tail of the other type of gene). The hybrid genes were said to be the basis for the altered spectral sensitivity of anomalous L or M cones associated with X-linked anomalous trichromacy (discussed previously).

Subsequent studies that have been carried out on both normal and X-linked defective color vision have their roots in the initial RFLP analysis based on the conventional idea of missing cone types and missing genes using one normal observer and a few color-defectives. The variations that have been found in subsequent studies on the visual pigment genes have correlated largely, but not absolutely, with phenotypes established by color vision testing. The current view is that the X-chromosome tandem array consists of one or more opsin genes encoding L-cone photopigment, followed by one or more opsin genes encoding the M-cone photopigment. The expression of the genes in the tandem array is believed to be

governed by a stochastic process.<sup>27</sup>

There have been advances in molecular genetic technology and in the understanding of the human genome since the initial RFLP studies of the opsin genes. Knowledge derived from the Human Genome Project, which has spurred an understanding of the scarcity of genes in the human genome, and the developing knowledge of epigenetics, such as the editing processes of microRNAs, may contribute to future studies and understanding of the genetics of color vision variations.

## Clinical Evaluation of Color Vision

### Screening Tests

Screening tests are rapid tests (requiring 2–3 minutes) and color-defective observers are identified due to their inability to see the difference between certain colors that are easily discriminated by normal observers. Screening tests can be administered to both children and adults.

### Pseudoisochromatic Plate Tests

The most commonly used screening tests are the pseudoisochromatic plate tests. First introduced by Stilling, a pseudoisochromatic plate presents a figure composed of colored dots in a background of differently colored dots. Usually, the colors are chosen so that an X-linked color-defective observer does not see the figure that is easily seen by normal observers. The cleverest designs use four sets of colors, chosen such that the normal observer sees one figure and the defective observer sees a different figure.

The majority of pseudoisochromatic plate tests (such as the Ishihara) were designed to identify observers with X-linked congenital color defects (i.e., protan or deutan color anomalies). The choice of colors was optimized to take advantage of the particular discrimination losses found in X-linked color vision defects and the tests are successful in detecting 90–95% of color-defective observers. Pseudoisochromatic plate tests cannot be used to identify acquired color vision defects, which are most likely to affect blue/yellow

color vision. More recently developed pseudoisochromatic plates (such as the HRR and SPP2 plates) have been designed specifically for acquired color vision deficiencies, including tritan (blue/yellow) anomalies.

## Other Rapid Tests of Color Vision

Other rapid tests of color vision involve sorting colored pieces. In principle, this approach can be used successfully with acquired color vision abnormalities since it does not involve the choice of a particular pair of colors that has a prediction based on common X-linked color vision defects.

## Chromatic Discrimination Ability Tests

Clinical assessment of color discrimination ability involves arrangement tests that require the observer to arrange a set of colored samples according to their similarity in color. If the samples are closely spaced in chromaticity (e.g., the Farnsworth–Munsell 100-hue test: [Fig. 12.7](#)), the task becomes one of fine chromatic discrimination. Tests involving fine chromatic discrimination are usually relatively time-consuming. If the samples are widely spaced in chromaticity (e.g., the Farnsworth panel D-15), the test evaluates color confusions that occur with defective color vision that would not be perceived by a normal observer. Tests with widely spaced colors are conducted rapidly and can even be used for screening. An arrangement test may use samples that differ only in chromaticity to test hue discrimination (e.g., the Farnsworth–Munsell 100-hue test, Farnsworth panel D-15, Farnsworth desaturated panel D-15, and Lanthony new color test), may vary in luminance only to test lightness discrimination (Verriest's lightness discrimination test), or may vary only in grayness to test saturation discrimination (Sahlgren's saturation test, Lanthony new color test). Arrangement tests are easy to administer but require the concept of abstract ordering, manual dexterity, and patience. As a result, they are rarely suitable for children under 10 years of age.

Panel 1

Panel 2

Panel 3

Panel 4

**FIG. 12.7** Examples of Farnsworth–Munsell 100-hue test error patterns in normal subjects (panels 1 and 2) and in observers with congenital (panels 3–6) and later onset or acquired (panels 7 and 8) color vision defects. Panel 1, normal with good discrimination. Panel 2, normal with poor discrimination. Panel 3, deuteranope. Panel 4, protanope. Panel 5, tritanope. Panel 6, achromat. Panel 7, retinitis pigmentosa with an acquired violet–yellow defect. Panel 8, optic neuropathy with an acquired red–green defect.

The best known of the arrangement tests is the Farnsworth–Munsell 100-hue test. The test includes 85 black plastic caps with inserted papers that vary in hue but have constant lightness and saturation. The caps are divided into four boxes with each box covering one-quarter of the color circle. Observers being tested

arrange the caps in a natural color order according to their unique perception. An error occurs if the caps are misplaced from the ideal color order. A numeric score can be calculated and displayed on a polar graph. Age norms have been prepared giving the range of the expected total error scores for an unselected population as well as the expected inter-eye variability.

Observers with congenital color vision deficiencies make characteristic errors on arrangement tests because their chromatic discrimination ability is weakened or lost on particular axes in chromaticity space. Discrimination loss in acquired color vision defects is more variable. However, following the idea that discrimination of blueness content is, to a first order, independent of discrimination of redness–greenness, it is possible to partition the caps into those where correct ordering depends on normal function of the S-cone system (caps 1 through 12, 34 through 54, and 76 through 84) and those where correct ordering depends on normal function of the M- and L-cone opponent system (caps 13 through 33 and 55 through 75). The partitioned scores can be examined to determine whether an acquired color vision defect causes a particular type of discrimination loss; i.e., the S or L/M systems.<sup>32</sup>

## **Importance of the Test Illuminant for Plate and Discrimination Color Vision Tests**

The plate and discrimination tests described above use reflective materials as colored test objects and the perceived color presented to an observer depends on the illuminating light as well as the reflective properties of the test materials. The original pseudoisochromatic plate tests were designed to be viewed under afternoon daylight in the northern hemisphere, and more recent tests have followed this design convention. Standardized illuminants (called illuminant C or illuminant D65) that closely simulate the spectra of afternoon daylight are more preferable to natural daylight, which may vary substantially in both spectrum and radiance with time of day and weather. Light sources that approximate these standard illuminants are commercially available and are suitable for use in illuminating clinical color vision tests. Most fluorescent light sources, however, do not accurately mimic

the colors produced in natural light and, therefore, they are not appropriate illuminants for color vision tests.

## Color-Matching Tests

Adjusting three primaries to match a test color is not intuitive for many observers and research experimental methods are therefore not appropriate for clinical purposes. To adapt color-matching procedures for clinical evaluation, simplified methods have been developed by using two-variable matches and rapid, less complicated tasks. The instruments that allow these matches to be carried out are called anomaloscopes and the color-matching paradigms are called equations. The equations are named after the researchers who first proposed or used them.

### Anomaloscope Color-Matching Test Using the Rayleigh Equation

In a Rayleigh match, a spectral “yellow” test field (589 nm) is presented in one-half of a circular field with an adjustable brightness. In the half field, a mixture of two “green” and “red” spectral primaries (545 and 670 nm) is presented. The mixture field can appear green (545 nm), green–yellow, yellow, orange, or red (670 nm) as the ratio of the primaries is varied. The task of the observer is to adjust the primary red–green ratio and brightness of the yellow to make the two fields appear identical. Observers with normal color vision accept a narrow range of ratios near the middle of the red–green range, but color-deficient observers will pick ratios shifted away from this range, depending on the specific deficiency. Matching abnormalities accompanying ophthalmic disease or X-linked color vision variations may include a widened matching range or acceptance of an abnormal match.<sup>33</sup>

The Rayleigh equation assesses the normality of M- and L-cone functions, since S cones are not contributing to the match because they are unresponsive to the primary wavelengths. A graphic display of the cone photopigment excitations allows the tester to evaluate which photopigments participated in an observer's match. [Fig. 12.8A](#) shows the expected yellow setting, based on the L- and M- photopigments, as a function of the red–green primary ratios.

For each photopigment, the quantal catch in cones may be characterized by a straight line in a chromaticity diagram as the red–green primary ratio is changed. Two lines show the predicted responses of the L cones alone (dashed and labeled L) and the M cones alone (dotted and labeled M). The rod photopigment is responsive at these wavelengths as well and the predicted rod response (solid and labeled Rod) is also shown. The normal match occurs at or near the intersection of the L- and M-cone settings and the matching range is narrow.

**FIG. 12.8** Graphic analysis of the Rayleigh equation and Moreland equation. (A) The Rayleigh equation. The relative light in the “yellow” (589 nm) test is plotted as a function of the proportion of the “red” (670 nm) primary. The lines are calculated from the cone and rod photopigment excitations. The line marked *LWS* represents the L-cone response of Fig. 12.2B and predicts the matching behavior of deuteranopes. The line marked *MWS* represents the middle-wavelength cone response of Fig. 12.2B and predicts the matching behavior of protanopes. The normal match (*N*) occurs at the intersection of the L and M lines. The line marked *Rod* represents the rod response of Fig. 12.2A and predicts the matching behavior of achromats. (B) The Moreland equation. The relative light in the bicolor (480 nm + 580 nm) test is shown as a function of the proportion of the 440-nm primary. The lines are calculated from the cone and rod photopigment excitations. The line marked *LWS/MWS* represents the L- and M-cone response and predicts the matching behavior of tritanopes. The line marked *SWS* represents the short-wavelength cone response. The normal match (*N*) occurs at the intersection of the L/M line with the S line. The line marked *Rod* represents the rod response and predicts the matching behavior of achromats.

Deuteranopes can make satisfactory matches throughout the L

line. A deuteranope is thought to lack functional M cones in the retinal area responding to the stimuli. Studies on the X-chromosome opsin genes in deuteranopes show that many of these observers have only a single gene that is thought to encode the L photopigment. Protanopes can make matches throughout the extent of the M line. It has been speculated that the protanope lacks functional L cones in the retinal area responding to the stimuli and genetic studies have suggested that these observers usually have only a single gene on the X chromosome that has been described as a hybrid gene composed of a piece of the normal L- and a piece of the normal M-opsin genes.

Other X-linked color-defective observers, called anomalous trichromats, have a wider range of acceptable matches that are displaced from the normal match. Such observers are trichromatic but have one cone photopigment with an abnormal spectral sensitivity. Deuteranomalous matches occur along the L line (indicating a normal L-cone photopigment) but are shifted to low red–green primary ratios. The psychophysical interpretation is that the deuteranomalous trichromat has an abnormal M-cone photopigment that is shifted so that its spectral sensitivity closely overlaps that of the normal L-cone photopigment. Protanomalous matches occur along the M line (indicating a normal M-cone photopigment) but are shifted to high red–green primary ratios. The interpretation of these psychophysical studies is that the protanomalous trichromat has an abnormal L-cone photopigment, shifted so that its spectral sensitivity closely overlaps that of the normal M-cone photopigment. Anomaloscope color matching using the Rayleigh equation is recognized as the only clinical method that allows definitive classification of the X-linked color vision defects.

Anomaloscope analysis is important in ophthalmic disease assessment since it can be used to recognize a number of clinical entities, such as rod-dominated vision characteristic of cone degenerations and incomplete and complete achromatopsias. These diseases are characterized by Rayleigh matches extending along the rod line (solid line in [Fig. 12.7A](#)). Matching abnormalities that are characteristic of choroidal disorders affecting the fovea lead to Rayleigh matches that extend along or just below the L line but are shifted to higher red primary ratios (pseudoprotanomaly). The

discrimination loss characteristic of optic nerve disorders leads to matches that widen around the normal match on the L line.

## **Anomaloscope Color-Matching Test Using the Moreland Equation**

The Moreland equation<sup>34</sup> is a match of a bicolor test field (480 and 580 nm) to a mixture of two primaries (440 and 500 nm). The test field appears blue–green to a normal observer, while appearance of the mixture field appearance ranges from violet, to blue, to blue–green, to green–blue, to green as the primary ratio is changed from mostly 440 nm to mostly 500 nm. The primary ratio is expressed in terms of the amount of the 440 nm (“violet”) primary required for the match. As with the Rayleigh equation, an observer with normal color vision can find a primary ratio and test field luminance at which both fields appear identical.

The Moreland equation assesses the normality of S-cone function. [Fig. 12.8B](#) shows the predicted function for a single photopigment to the bicolor test field as a function of the violet–green primary ratio. The L and M cones share the same line (dotted and labeled as L/M). The S-cone response crosses this on the diagonal (dashed and labeled as S). The predicted rod (solid line labeled as Rod) line has the same direction as the L- and M-cone lines. The normal match occurs at the intersection of the S-cone line with the L/M line. Both congenital and acquired color vision defects can be recognized using the Moreland equation.<sup>35</sup> The tritanope (an observer lacking S-cone function) has matches extending along the L/M line, as do observers with acquired defects that affect S-cone function. Point mutations in the S-cone opsin gene on chromosome 7 have been reported in affected individuals in tritan pedigrees.<sup>36</sup>

Patients with X-linked achromatopsia (i.e., S-cone monochromacy) have matches that extend along the S-cone line. The majority of X-linked achromat pedigrees show major deletions of the region just preceding the cone opsin tandem gene array on the X chromosome in affected individuals.<sup>37</sup> This region is thought to be a regulatory area controlling expression of the L- and M-cone opsin genes. Additionally, some X-linked achromat pedigrees show only a single abnormal gene instead of the normal tandem array. Patients with complete achromatopsia have matches extending

along the rod line.

## **Considerations in the Use of Anomaloscopes**

Even though the color-matching task on an anomaloscope is simplified compared with usual research color-matching procedures, anomaloscope testing procedures are not easily explained and an observer may require some practice before being able to complete a match. Correct use of an anomaloscope requires extensive operator training and these instruments are therefore usually found only in research centers. However, if properly used, the anomaloscope is a diagnostic instrument of great power.

## **Computerized Color Vision Tests**

Computer-controlled color vision tests have been developed using a similar principle as that used for pseudoisochromatic plate tests or discrimination ability tests (such as the FM-100 hue test).

Computerized tests are automated and therefore easy to use. Further, computerized tests can avoid the illuminating light issue that exists for reflective materials. However, the sensitivity and specificity of the computerized tests largely rely on the accurate presentation of color on computer monitors, such as cathodes ray tubes (CRTs) or liquid crystal displays (LCDs). A CRT is typically preferred over a LCD because CRTs have reliable temporal characteristics. To present color accurately, the displays have to be calibrated, including spectral distribution measurements and linearization. Caution must be taken when using a computerized color vision test that does not incorporate specific display calibration.

## **Color Assessment and Diagnosis (CAD) Test**

The CAD test was developed by Dr Barbur and coworkers at City University, London.<sup>38</sup> The web-based CAD uses a color square that moves against a flickering luminance contrast noise. The color of the square changes along different chromaticity directions. Color-defective observers have difficulty seeing the square moving, whereas normal observers easily see the square move. The web-based CAD test requires a monitor to be balanced at around 9000 K

and the ambient illumination must be kept at a minimum. It is reported that this web-based test has good sensitivity and specificity for red–green color deficiencies.<sup>39</sup>

### **Cambridge Color Test (CCT)**

The CCT is a computer-controlled, easy-to-use color vision test. The CCT was developed by Drs Mollon, Reffin, and Regan at the University of Cambridge, England.<sup>40</sup> The CCT system provides 14-bit color and luminance control on a calibrated CRT display. The stimulus is a Landolt C on an achromatic background. The chromaticity of the target C is varied along the protan, deutan, and tritan lines of a chromaticity diagram. The task is to indicate the position of the gap in the target C. A staircase procedure is used to measure discrimination thresholds along any of the three lines. The results are plotted as discrimination ellipses in a CIE space. Individuals with color vision deficiencies will have elongated discrimination ellipses along a protan, deutan, or tritan line and, therefore, this test can be used for all color vision deficiencies.

### **The Cone Contrast Test**

The cone contrast test is a rapid (about 6 min) computer-based color vision test. The test was developed by Dr Rabin and colleagues based on L, M, and S cone contrast sensitivity.<sup>41</sup> The test presents a randomized series of colored letters that are visible to a single cone type (L, M, or S) in decreasing cone contrast, and subjects are required to read the letter aloud. The letters are selected from the British Standards Institution letters that have equal legibility. The letter cone contrasts range from a clear visible contrast to a threshold level. A technician records the letters read correctly and those missed, and the number of errors (out of 20 letters) is entered into the program to determine the L, M, S cone scores. The test is able to identify the type and severity of the hereditary color vision deficiency.

### **The Portal Color Sort Test (PCST)**

The PCST is based on the FM-100 hue test but uses only 36 colored “chips,” which significantly reduces the testing time. The chips are

representative of the original 85 chips in the FM-100 hue test. The observer arranges the order of the chips according to color similarities and the computer provides automatic scores. The correlation between the PCST and FM-100 hue test is high for testing congenital color vision defects but is unknown for testing acquired defects.<sup>42</sup>

## **Smartphone/Tablet Applications for Color Vision Screening**

With the popularity of mobile communication devices (e.g., smartphones or tablets) increasing in medical settings, numerous applications have developed for these devices as tools for clinical testing/screening, patient education, or physician education and reference. Several applications use the pseudoisochromatic plate principle for color vision screening. These applications might be useful for a quick screening of color vision; however, these tools have not been validated and their sensitivity and specificity for color vision defect screening are not known. Further, there are many factors that can affect the test results. The most important is the display characteristics of the mobile device. These displays are not calibrated and they may not be homogeneous; therefore the tests for color vision screening are not necessarily “pseudoisochromatic.” Finally, the illumination in the office may impair the test reliability. Therefore, these applications need to be confirmed by comparison with other established tools for color vision screening. Recently, several studies have attempted to assess the efficacy of smartphone/tablet-based color vision tests. For example, Dain and colleagues assessed the color representation in smart phones<sup>43</sup> and evaluated the colorimetric characteristics of iPhone apps for color vision tests based on the Ishihara.<sup>44</sup> In addition, it has been shown that a tablet-based cone contrast color vision test achieved the same sensitivity and specificity as a computer-based cone contrast sensitivity test.<sup>45</sup>

## **Which Test to Use in a Clinical Setting?**

Many clinicians want to have some means of testing color vision without necessarily acquiring expensive instruments and expertise

needed for professional evaluation and diagnosis. Tests using colored papers (pigment tests) and the proper illuminant offer office clinicians the possibility of some color vision evaluation.

A screening plate test with the proper illuminant would be minimal equipment for testing color vision. Approximately 8–10% of American males have one of the X-linked color vision defects. Identification of color vision defects in children before they enter grade school allows the clinician to provide counseling to the parents. Many children with color vision defects have memories of being teased or ridiculed in the early grades and early testing allows appropriate counseling. Also, many males with color vision defects may inadvertently choose careers, for example, as pilots or firefighters, from which they will be barred due to their color vision status. It should be noted, however, that the screening plate tests that may be very useful for the common genetic color vision defects are less successful at identifying acquired color vision defects.

A more ambitious plan to test color vision in an office would be to combine a screening plate test with a test of color discrimination. A discrimination test (e.g., the Farnsworth–Munsell 100-hue test) allows the clinician to follow changes in color vision over time, such as might occur with optic neuritis. Occasionally, a clinician will see a patient who has an extremely rare form of color defect and color vision testing may be informative. For example, cerebral achromatopsia is a fascinating case that likely arises from damage to higher-order visual processes. In these cases, a more complete color vision testing (such as spectral sensitivity and saturation discrimination evaluation) should be considered and case reports would be of wide interest in the medical community. Patients should be referred to a psychophysics laboratory for more visual function testing, such as contrast discrimination evaluation.

## **New Developments in Color Vision Research**

Color vision has been studied considering genetics, evolution, physiology, and psychophysics. A few newer research areas related to color vision are provided here.

## Gene Therapy for Color Vision Defects

Drs Jay and Maureen Neitz and coworkers have carried out pioneering studies on “curing” red–green color deficiency in dichromatic adult squirrel monkeys that were missing the L-cone opsin gene at birth.<sup>46,47</sup> As gene therapy, the human L-cone opsin gene was delivered into the photoreceptor layers of the retinas of the monkeys. A few months after the introduction of the new opsin gene, these monkeys exhibited trichromatic color vision behavior with spectral sensitivity shifted, chromatic discrimination improved, and color perception enriched. A clinical trial involving gene therapy in humans would require approval from the National Institutes of Health Office of Recombinant DNA Activities (ORDA)/Recombinant DNA Advisory Committee (RAC) and the Food and Drug Administration and this would not be granted easily without a long and thorough approval process. However, the fundamental question of whether it is necessary to “cure” color deficiencies is currently the point of debate since the majority of congenital dichromats live a normal life and their quality of life is not significantly affected by having the color vision deficiency.

## Adaptive Optics (AO) Retinal Imaging System

AO was initially used in astronomy to remove the effects of atmospheric distortion to improve the performance of telescopes and laser communication systems.<sup>48</sup> An AO system has three components: (1) a wavefront sensor for ocular aberration measurement; (2) a deformable mirror for aberration correction; and (3) a control system that compares the sensor output and adjusts the deforming mirrors to achieve optimal resolution. This technology was first adopted for retinal imaging in the 1990s by Dr David Williams to reduce ocular aberrations in the eyes.<sup>49</sup> After its initial introduction, the AO imaging system was considered to have great scientific and clinical application potential because it had the capability of imaging photoreceptors, the retinal pigment epithelium, retinal blood vessels and, potentially, ganglion cells at a high magnification. For instance, AO made it possible to measure

color perception<sup>50</sup> or cell responses in the postreceptoral pathways<sup>51</sup> associated with tiny flashes of light stimulating a single cone in the eye. For color vision screening, in particular, the AO system can provide high resolution of the cone mosaic and it can show whether a particular type of cone (e.g., L cones) is missing in the retina. Combining this information with genetic studies is potentially informative because AO imaging can provide insights about cone distributions that can be related to the cone opsin genes.<sup>52</sup> (See [Chapter 7](#), Advanced imaging technologies, for more details about this topic.)

## Rod and Cone Interactions in Color Vision

Duplex theory states that rods and cones independently contribute to different aspect of visual perception. However, rods and cones share common neural pathways from the retina to the brain and this provides a neural basis for rod–cone interactions in visual function, including color vision.<sup>53</sup> Conventionally, rod vision has been considered to be achromatic. However, numerous psychophysical studies have indicated that rods contribute to color vision at either mesopic<sup>54</sup> or even scotopic light levels.<sup>55</sup> Psychophysical evidence for rod contributions to color vision comes from measurements of scotopic color contrast,<sup>56</sup> photochromatic intervals during the course of dark adaptation following a light bleach,<sup>57</sup> chromatic discrimination,<sup>58</sup> and color-matching or color-appearance methods using unique hue measurement or hue-scaling methods.<sup>59,60</sup>

Recently, rod contributions to color vision were studied using a four-primary Maxwellian-view photostimulator<sup>61</sup> that allowed independent control of rod and cone excitations at the same chromaticity, retinal locus, and light level. This new method has yielded new insights into rod contributions to color vision. Specifically, rods contribute to color percepts in a manner analogous to M-cone signals at all mesopic light levels and analogous to S-cone signals only at low mesopic light levels near cone thresholds.<sup>54</sup> Also, the strength of rod contributions is linearly related to rod contrasts.<sup>62</sup>

## Visual Acuity Tests

### Introduction

Visual acuity is the most widely used measure of visual function. In fact, visual function is often equated with visual acuity, thereby ignoring other important dimensions of visual stimuli, such as color and contrast. Visual acuity tests have proven to be useful for assessment of refractive error, screening for ocular health, following the course of eye disease, evaluating the effectiveness of medical and surgical treatment, prescribing aids for the visually impaired, and setting vision standards for employment and driving.

Given the variety of its applications, it is not surprising that many different types of visual acuity tests have evolved. Generally, these tests were developed with little concern for standardization. Since the 1980s several attempts have been made to formulate standards for test design and administration. The Committee on Vision of the National Academy of Sciences–National Research Council (NAS–NRC)<sup>1</sup> has published standards for clinical testing of visual acuity that are widely adopted in the United States, and the British Standards Institution<sup>2</sup> has published similar standards for the United Kingdom. The NAS–NRC standards are used as the basis of this chapter.

## Chart Design

### Optotypes

Most familiar acuity tests require the subject to identify letters arrayed in rows of decreasing size. The so-called Snellen acuity test is the prime example, although Snellen acuity now usually refers to a way of reporting test results rather than to any particular type of chart. To facilitate testing of young children and people unfamiliar with the Latin alphabet, other optotype tests based on the tumbling E, Landolt C, numerals, or simple pictures of familiar objects are also used. Visual acuity can also be assessed with grating patterns, but grating acuity often overestimates Snellen acuity in patients with age-related maculopathy,<sup>3</sup> typically by a factor of 2 or more.

The NAS–NRC recommends that the Landolt C test be used as the standard by which other acuity tests are compared. The Landolt C is a broken circle in which the width of the break and the stroke width are both equal to one-fifth the height of the C. The ring is shown with the break at one of four locations, and the subject responds by saying “right,” “down,” “up,” or “left,” or by pointing in the appropriate direction.

There are several advantages to the Landolt C test, including equal difficulty of all targets (unlike letters that vary in degree of difficulty), sensitivity to astigmatic refractive error, and suitability for use with illiterate subjects. However, the Landolt C test is not widely used because it has a guessing rate of 25%, so an alternative is to standardize another optotype set by comparing acuities obtained with it to Landolt C test acuities. The Sloan letters,<sup>4</sup> a set of 10 upper-case sans serif letters, are the most popular substitute. An acuity chart based on Sloan letters was developed for the Early Treatment Diabetic Retinopathy Study (ETDRS)<sup>5</sup> and is illustrated in [Fig. 13.1](#). The original ETDRS chart has been replaced by the 2000 series revised ETDRS chart that more accurately equates the difficulty of letters on all lines. The ETDRS charts are the most widely used acuity charts for clinical research.

**FIG. 13.1** The Early Treatment Diabetic Retinopathy Study (ETDRS) acuity chart. (Reproduced with permission from Ferris FL III, Kassof PA, Bresnick GH, et al. New visual acuity charts for clinical research. *Am J Ophthalmol* 1982;94:91–96.)

## Chart Layout

Careful attention must be paid to the layout of the acuity chart. The chart should follow a uniform progression of letter sizes, typically a 0.1 log unit (or 26%) reduction in size from line to line. The uniform progression ensures that a one-line loss will have the same meaning at any point on the chart and at any viewing distance. The same number of letters should appear on each line, and the spacing should be uniform, both within and between lines. The spacing requirement results in a large chart, with the letters forming an inverted triangle. The NAS–NRC recommends 8–10 letters per line, but studies<sup>6</sup> suggest that as few as three letters are required for an

accurate estimate of visual function. The ETDRS chart uses five letters per line.

Concern about uncontrolled “crowding” effects has led to further modifications of the ETDRS chart. Crowding refers to the reduced visibility of letters when they are surrounded by other letters. Crowding has a larger effect in some types of visual dysfunction, notably amblyopia<sup>7</sup> and macular degeneration.<sup>8</sup> For most acuity charts, letters at either the end of a line or at the top or bottom of the chart are less subject to crowding than are internal letters. To equalize crowding effects, contour interaction bars may be added around the perimeter of the chart.<sup>9</sup>

## Testing Procedure

### Test Distance

ETDRS charts are available for a range of test distances from 4 meters (13 feet) to 2 meters (6.5 feet) and when used at the designated distance can measure acuities from 20/10 to 20/200. However, given the logarithmic progression of letter sizes, they can be used at any distance with an appropriate correction of the reported results. For patients with very poor acuity, the clinician may resort to finger counting or hand motion. This strategy is strongly discouraged by low-vision practitioners because it can be demeaning and depressing for the patient to be left with the impression that their vision is so poor it cannot even be measured with an eye chart. Instead, it is recommended that the patient be moved closer to the chart. Using a test distance of 50 cm and appropriate refractive correction it is possible to reliably measure “counting fingers” acuity with an ETDRS chart (approximately 20/1460 ± 10%).<sup>10</sup> “Hand motions” can be measured with some electronic acuity tests (see below). Distance itself should have little effect on visual acuity, provided that the subject's accommodative state and pupil size are controlled. However, one study<sup>11</sup> found that acuity changed by as much as seven letters (more than one ETDRS line) when the test distance was reduced to less than 2 meters. The reason for this discrepancy remains unexplained.

### Luminance and Contrast

Whatever the test distance, the chart must be adequately illuminated and of high contrast. Illumination standards vary from 100 cd/m<sup>2</sup> in the United States to 300 cd/m<sup>2</sup> in Germany. Increasing chart luminance improves visual acuity in normal subjects, but reaches a plateau at about 200 cd/m<sup>2</sup>.<sup>12</sup> Various types of visual dysfunction can change the effects of luminance on acuity. For example, patients with retinitis pigmentosa may show a decrease in acuity at higher luminance, whereas patients with age-related macular degeneration often continue to improve at luminances well above the normal plateau.<sup>13</sup> A luminance standard of 100 cd/m<sup>2</sup> can be justified because it represents good room illumination for ordinary reading material. Furthermore, most of the currently proposed standards would yield the same acuity scores, plus or minus one letter (assuming five letters per line and a 0.1 log unit size progression) in normal subjects.

The relationship of visual acuity to letter contrast follows a square-root law.<sup>14</sup> For example, decreasing contrast by a factor of 2 would decrease acuity by roughly a factor of 1.4. The NAS–NRC recommends that letter contrast be at least 0.85. Transilluminated, projection, and reflective charts (wall charts) can all meet these standards, but some transilluminated charts are deficient in luminance, and some projection systems lack sufficient luminance and contrast. Accurate calibration requires a spot photometer, for which procedures are described in the NAS–NRC document.<sup>1</sup>

## **Test Administration**

Administration of visual acuity tests is simple and straightforward. However, one detail often overlooked in clinical testing is that the test must be administered in a “forced-choice” manner. Rather than allowing the patient to decide when the letters become indistinguishable, the patient should be required to guess the identity of each letter until a sufficient number of errors are made to justify terminating the test. People differ in their willingness to respond to questions when they are not confident about the answers. A person with a conservative criterion answers only when absolutely certain about the identity of the letter, whereas a person with a liberal criterion ventures a guess for any letter that is even barely discernible. These two people may receive different acuity

scores because of differences in their criteria rather than because of variations in visual function. This is not merely a theoretical concern. Several studies<sup>15,16</sup> have shown that criterion-dependent test procedures lead to inaccurate and unreliable test results. Forced-choice procedures are criterion-free because the examiner, rather than the observer, determines whether the letter is correctly identified.

## Scoring

Until recently, visual acuity tests were usually scored line by line with the patient being given credit for a line when a criterion number of letters were identified correctly. The NAS–NRC recommends that at least two-thirds of the letters on a line be correctly identified to qualify for passing. Allowing a small proportion of errors improves test reliability.<sup>17</sup> For tests that follow the recommended format of an equal number of letters on each line and a constant progression of letter sizes, it is preferable to give partial credit for each letter correctly identified. This is commonly done by counting the number of letters read correctly on the entire chart and converting this to an acuity score by means of a simple formula that values each letter as  $L/N$ , where  $L$  = difference in acuity between adjacent lines and  $N$  = number of letters per line. So for a chart with five letters per line and a 0.1 LogMAR (see below) progression from line to line (such as the standard ETDRS chart) each correct letter is worth  $0.1/5 = 0.02$  LogMAR. Although differences between scoring methods are usually small, it has been shown<sup>2,6,18</sup> that letter-by-letter scoring is more reproducible than line-by-line scoring.

The most familiar method for reporting visual acuities is the Snellen fraction. The numerator of the Snellen fraction indicates the test distance, and the denominator indicates the relative size of the letter, usually in terms of the distance at which the stroke width would subtend a visual angle of 1 minute. Thus “20/40” indicates that the actual test distance was 20 feet and that the strokes of the letters would subtend 1 minute of arc at 40 feet.

To simplify comparison of acuities measured at different distances, the minimum angle of resolution (MAR) should be used. The MAR is the visual angle corresponding to stroke width in

minutes of arc and is equal to the reciprocal of the Snellen fraction. Visual acuities are frequently converted to log<sub>10</sub> and reported as “LogMAR.” For example, 20/20 acuity corresponds to a MAR of 1 minute of arc, or a LogMAR of 0, and 20/100 acuity corresponds to a MAR of 5 minutes of arc, or a LogMAR of 0.7 (as does an acuity of 2/10 or 6/30). The MAR and LogMAR scales increase with worsening acuity. One often sees visual acuities reported as the decimal equivalent of the Snellen fraction. However acuities are more normally distributed when converted to LogMAR rather than decimal values. Moreover, decimals give the false impression that acuity scores can be equated with overall loss of visual function. For example, acuity of 0.1 (the decimal equivalent of 20/200) may misleadingly suggest that the patient has retained 10% of residual visual function.

## Near and Reading Acuity Tests

Near acuity is usually tested to evaluate reading vision. These tests are particularly important for prescribing visual aids for persons with low vision. Near acuity has been shown to be a better predictor of the optimal magnification needed by visually impaired readers than traditional distance acuity.<sup>19</sup>

Although some near acuity tests are simply reduced versions of distance acuity charts, most tests consist of printed text, either unrelated words or complete sentences or paragraphs, covering a range of sizes. Near acuity tests are even less standardized than distance acuity tests.

## Specifying Letter Size

As with all acuity tests, the most critical parameter is the visual angle subtended by the optotype. Many systems have been devised for specification of print size. One of the most common is the Jaeger J notation. Jaeger notation is based on a numeric scale (J1, J2, and so on) that follows no logical progression except that larger numbers correspond to larger print sizes. Furthermore, print with the same J specification can vary by as much as 90% from one test manufacturer to another.<sup>20</sup>

Alternatives to the Jaeger notation are the typesetter's point

system, the British N system, and the M notation introduced by Sloan. The typesetter's point is commonly used to specify letter size for printed text and is equal to 0.32 mm (1/72 inch). However, the measurement refers to the size of the metal slug that contains the letter and varies from one font to another. A study<sup>21</sup> of the effect of font on reading speed showed that the nominal sizes of printed text could be very misleading. Of four fonts, all labeled as 12 point, one was much more legible than the other three. But it turned out that the more legible font was actually larger than the others and when equated for real size there was no difference in legibility.

The British N system standardized the point size specification by adopting the Times Roman font. Sloan's M notation,<sup>4</sup> widely used in the United States, is standardized according to the height of a lower-case "x." A lower-case 1M letter subtends 5 minutes of arc at a 1-meter viewing distance and corresponds roughly to the size of ordinary newsprint. None of the print size specifications can be used for quantitative comparisons unless viewing distance is also specified. For example, 1M print read at a distance of 40 cm would be recorded as 0.40/1.00M.

## **Words Versus Continuous Text**

One issue that remains unresolved is whether near acuity tests should be based on unrelated words or meaningful text. An argument in favor of unrelated words is that contextual information promotes guessing and may lead to an overestimate of near acuity.<sup>22</sup> In addition, the presence of semantic context introduces variability because of cognitive intellectual factors that may mask the visual factors of primary concern.<sup>23</sup> On the other side it is argued that the main reason for measuring near acuity is to gain information about reading performance. Since context is normally available to the reader, a reading test that includes meaningful text will be a better indicator of everyday performance. Fortunately, reading speed for meaningful text is highly correlated with reading speed for unrelated words.<sup>24</sup>

The MNREAD test<sup>25</sup> uses meaningful text to evaluate near acuity. The test is composed of 19 standardized sentences in a logarithmic progression of sizes. Each sentence is 55 characters and the words are drawn from a controlled vocabulary. The test can be used to

measure reading acuity (the smallest print size that can be read), maximum reading speed, and critical print size (the smallest print size for maximum reading speed). The test–retest variability for the MNREAD test has been assessed in patients with macular disease<sup>26</sup> and the coefficient of repeatability was found to be greater than 65 words/minute. The high level of variability may be due, in part, to the short sentences. The International Reading Speed Test (IReST)<sup>27</sup> uses 150-word paragraphs of continuous text to measure reading speed, which should yield more reproducible measures. The IReST is available in 17 languages.

## Electronic Acuity Tests

Video-based acuity tests have been available since the 1980s, but did not become popular until the introduction of inexpensive LCD monitors in recent years. These electronic tests include computer software that can be used with the experimenter's own computer hardware (such as the Freiburg Acuity and Contrast Test (FrACT)), devices that display optotypes under operator control (such as the Test Chart 2000) and systems that administer, score, and store the results of the acuity measurement (such as the E-ETDRS and COMPlog systems).

Electronic tests offer several potential advantages over paper-based tests:

1. multiple types of test, such as acuity, contrast sensitivity, and stereoacuity, with one instrument;
2. better randomization of optotypes – each test administration can use a different arrangement of letters instead of being constrained to two or three printed charts;
3. easier standardization of luminance and contrast, although if calibration instructions are ignored, luminance and contrast errors can be greater than for paper tests;
4. the promise of advanced testing algorithms that reduce testing time and/or increase measurement accuracy and precision. Until recently, the electronic systems had not lived up to this promise,

with test times as long as or longer, and measurement accuracy and precision no better than conventional chart tests.<sup>28</sup> One test, the E-ETDRS system used in clinical trials for treatment of central retinal vein occlusion,<sup>29</sup> is reported to take longer without any increase in reliability.<sup>28</sup> But the introduction of new smartphone and tablet display technology has dramatically changed the field.

Modern high-end touchscreen displays have sufficient spatial resolution to test near the acuity limit, but the displays are susceptible to glare, require adequate warm-up time for luminance to stabilize, and must be viewed straight on.<sup>30</sup>

All of these cautions are shared by LCD computer monitors, however many of the smartphone and tablet apps are intended to be self-administered, and the user may not have the same concern for standardization as in researcher-administered testing. However, results of smartphone and tablet acuity tests do not appear to compare well to gold standard ETDRS acuity tests. Two studies looked at validity and reliability of smartphone acuity tests: the PEEK study and the Eye Phone study.<sup>31,32</sup> Both studies show that the smartphone measurements are not biased. On average, the smartphone scores differ from ETDRS or Snellen scores by 2 letters or less. But more importantly, they show, but do not comment on, the very large limits of agreement, which run to  $\pm 0.3$  LogMAR or  $\pm 3$  ETDRS lines. That is equivalent to a factor of  $\pm 2\times$  so the limit of agreement for someone with 6/12 acuity would extend from 6/6 to 6/24, which is three times higher than what is generally observed with ETDRS charts. The reasons for this poor repeatability are not discussed.

## Contrast Sensitivity Tests

### Introduction

Contrast sensitivity testing has been widely promoted as an important adjunct or even replacement for visual acuity testing. Acuity measures the eye's ability to resolve fine detail but may not adequately describe a person's ability to see large low-contrast objects such as faces. Contrast sensitivity testing was originally

developed as a research tool by engineers and vision scientists interested in characterizing normal visual function. For theoretical reasons, most investigators have used sine-wave grating stimuli, patterns consisting of alternating light and dark bars, which have a sinusoidal luminance profile. Sine-wave gratings vary in spatial frequency (bar width) and contrast. A contrast sensitivity function (CSF) is derived by measuring the lowest detectable contrast across a range of spatial frequencies.

## Utility of Contrast Sensitivity Tests

For people with normal vision, contrast sensitivity and visual acuity are correlated. However, various types of visual dysfunction, including cerebral lesions,<sup>33</sup> optic neuritis related to multiple sclerosis,<sup>34</sup> glaucoma,<sup>35</sup> diabetic retinopathy,<sup>36</sup> and cataract,<sup>37</sup> may cause a reduction in contrast sensitivity despite near-normal visual acuity. This led to the suggestion that contrast sensitivity might serve as a tool for differential diagnosis and screening. However, there is no pattern of CSF loss that is unique to any particular vision disorder. The types of CSF measured in patients with macular disease or glaucoma can be similar to the CSFs measured in cataract patients, although detailed analyses with targets of different size or at different retinal eccentricities may help distinguish between various causes of the loss. It is argued that contrast sensitivity tests are more sensitive to early eye disease than visual acuity. While this may be true, much of the apparent difference in sensitivity is due to careless measurement of visual acuity (poorly designed charts and test procedures). Even if the test were more sensitive, its lack of specificity for distinguishing between ocular and retinal/neural disorders limits its usefulness as a screening test.<sup>38</sup>

The real value of clinical contrast sensitivity testing is to gain a better understanding of the impact of visual impairment on functional ability. Several studies have demonstrated that contrast sensitivity is useful for understanding the difficulties in performing everyday visual tasks faced by older people with essentially normal vision<sup>39</sup> and by patients with retinal disease.<sup>40,41</sup> Studies have shown that contrast sensitivity loss leads to mobility problems and difficulty recognizing signs or faces,<sup>42</sup> even when adjusted for loss

of acuity.<sup>43</sup>

The association of contrast sensitivity with functional ability argues in favor of including contrast sensitivity measurements in clinical trials. Although visual acuity is the most common primary visual outcome measure, several studies have included contrast sensitivity as a secondary outcome. Considering both visual acuity and contrast sensitivity when assessing the outcomes of clinical trials may provide a more complete picture of the effects of treatment on vision than either measure alone. Examples where contrast sensitivity has been used as a secondary outcome include the Optic Neuritis Treatment Trial,<sup>44</sup> the TAP study of photodynamic therapy for age-related macular degeneration (AMD),<sup>45</sup> and the ABC trial of bevacizumab for AMD.<sup>46</sup>

## Methods

### Common Contrast Sensitivity Tests

Traditional methods for measuring contrast sensitivity require relatively expensive and sophisticated equipment – typically a computer-controlled video monitor – and employ time-consuming psychophysical procedures. However, several simpler contrast sensitivity tests have been developed primarily for clinical use. These include the Functional Acuity Contrast Test<sup>47</sup> (FACT, replacement for the popular Vistech VCTS chart) and the CSV-1000,<sup>48</sup> sine-wave grating tests in chart form, and various low-contrast optotype tests such as the Lea test,<sup>49</sup> the Pelli–Robson letter chart,<sup>17</sup> the Melbourne Edge Test<sup>50</sup> and the Mars Letter Contrast Sensitivity Test.<sup>51</sup> Examples of three of the most commonly used clinical contrast sensitivity tests are illustrated in [Fig. 13.2](#).

The design of a new letter chart for measuring contrast sensitivity. *Clin Vis Sci* 1988;2:187–200.)

With the advent of smartphone and tablet-based vision testing, there has been a re-kindling of interest in clinical contrast sensitivity testing. High-end tablets have the spatial resolution to test contrast sensitivity but many of these new displays have too small a range of contrasts to cover both normal and impaired vision. Typically the tablet displays are only capable of reproducing contrasts of 1.5 log CS units (3%) or higher, whereas the normal contrast threshold is close to 2.0 log CS.<sup>52</sup>

## Gratings Versus Optotypes

A thorough discussion of the relative merits of the various tests is beyond the scope of this chapter; however, a few salient points are worth noting. Various investigators disagree about whether measurement of an entire CSF is necessary or whether a single measure of contrast sensitivity is adequate for clinical purposes. Proponents of the sine-wave grating tests argue that visual dysfunction can cause reductions in contrast sensitivity over a limited range of spatial frequencies, which would be missed by more global measures of contrast sensitivity. On the other hand, advocates of global measures note that contrast sensitivities at specific spatial frequencies tend to be highly correlated with one another, and they maintain that overall changes in contrast sensitivity are clinically more important than subtle bumps and wiggles in the CSF. Data from large-scale studies of vision impairment indicate that global measures of contrast sensitivity are valuable predictors of difficulty in everyday life.<sup>42</sup>

## Test Design and Procedure

In order to be useful, contrast sensitivity must be measured accurately and reliably. Many of the same principles of test design previously discussed for visual acuity tests apply to contrast sensitivity tests. Most important, the test should employ a criterion-free procedure, a uniform progression of contrasts, and an adequate number of trials at each contrast to make a reliable estimate of sensitivity. Most of the optotype tests conform to good design principles and produce reliable results, with the Mars test outperforming the very popular Pelli–Robson test.<sup>53</sup> Sine-wave grating charts tend to be less reliable because they have a limited number of trials to make measurements at several spatial frequencies.<sup>54</sup>

Some of the electronic acuity testing systems can also measure contrast sensitivity, including the Vision Test 2000 and FrACT. However, it is difficult to display a wide-enough range of contrasts to measure normal thresholds, and accurate calibration of the display monitor is critical. One study found that the computer-based test was less reliable than paper charts,<sup>53</sup> presumably due to problems generating low-contrast patterns with LCD displays.

Traditionally, accurate measurement of the CSF required many hundreds of trials and an hour or more of the patient's time. However, new adaptive test procedures have reduced the number of trials to 50–100 and the testing time to 5 minutes. The dramatic reduction in number of trials is accomplished by the introduction of a sophisticated Bayesian adaptive test procedure<sup>55</sup> that fits the patient's CSF data to a model with a restricted number of free parameters (four, in this case) and uses Bayesian statistics to select the optimum spatial frequencies and contrasts to fit those free parameters. The method works well if the underlying assumptions are met – that the CSF conforms to the model and the slope of psychometric functions is constant for patients and normal controls. Limited data collected to date supports these assumptions.<sup>56</sup>

It is still to be determined, however, whether the entire CSF provides more useful information about visual function than a single measurement of peak contrast sensitivity such as the Pelli–Robson letter chart.

## **Interpretation of Clinical Versus Statistical Significance: An Example From the Literature**

One of the vexing problems with contrast sensitivity testing is how to interpret the clinical significance of test scores. After many decades of acuity testing, we have arrived at a consensus that a doubling of the MAR (increase of 0.3 LogMAR or 15 ETDRS letters) represents a meaningful change in acuity. Recent data from large population-based studies suggest that a doubling of contrast threshold (reducing sensitivity by 0.3 logCS units or six letters on the Pelli–Robson chart) has a comparable impact on task performance and quality of life.<sup>39,42</sup>

After several decades of laboratory investigation, contrast sensitivity testing is taking its place alongside visual acuity in clinical vision research. While early claims that contrast sensitivity would replace visual acuity proved to be exaggerated, this additional test does have an important role to play. Contrast sensitivity may not be particularly useful for differential diagnosis and screening, but its close association with everyday task difficulty has made it an important outcome measure for assessing treatment safety and efficacy.

## **Introduction**

Visual field testing helps correlate structural changes in the retina or elsewhere in the visual pathway with deficits in function. For example, AM was a 70-year-old woman diagnosed as having an old central retinal vein occlusion (CRVO) in the left eye and an epiretinal membrane in both eyes. She also had been treated for elevated intraocular pressure. Fluorescein angiography of the left eye showed shunting vessels around the optic nerve head, thought to be consistent with the old vein occlusion. However, progressive bilateral visual field loss ([Fig. 14.1](#)) over 2 years suggested the need for further investigation. A computed tomography (CT) scan

demonstrated a large subfrontal meningioma compressing both optic nerves (Fig. 14.2).

**FIG. 14.1** (A,B) Fluorescein angiograms of a 70-year-old woman who has had progressive loss of vision in both eyes over 2 years. She has controlled ocular hypertension and surface-wrinkling retinopathy. The history of an old central retinal vein occlusion in the left eye is supported by the slightly dilated and tortuous retinal veins and the multiple shunting capillaries on the surface of the disc (B). (C) Progressive field loss, documented in both eyes over 3 years, is inconsistent with the ophthalmoscopic appearance. A computed tomographic scan was ordered, the results of which are shown in Fig. 14.2.

**FIG. 14.2** Computed tomographic scan from the patient described in Fig. 14.1 demonstrates a large subfrontal meningioma (arrows) with bilateral optic nerve compression. Surgical resection improved sensorium but not vision.

Visual field tests can be qualitative or quantitative. They span multiple formats, from the simplest confrontation field or Amsler grid to the most advanced quantitative kinetic, static, and microperimetry. For all visual field tests, reliability and reproducibility are important. There are currently three main uses for visual field tests in patients with retinal pathology: (1) to determine the current level of visual field loss and monitor progression; (2) to evaluate the effects of treating retinal pathology on visual function; and (3) to correlate functional and structural changes in the retina.

This chapter reviews the use of visual fields and the principles of perimetry relevant to retinal disease. Visual field defects corresponding to common retinal diseases are described, with an emphasis on clinical situations for which perimetry is useful diagnostically. The value of specialized visual field testing in clinical research is also reviewed.

# Principles of Perimetry

## The Island of Traquair

The single most important concept in understanding the visual field is depicted by the island of Traquair, which is defined as a “hill of vision” surrounded by a “sea of blindness.”<sup>1</sup> The shape of the normal visual field is oval. There is decreasing sensitivity with increasing eccentricity in the field, as the elevation corresponds to the sensitivity of the field, and the flat plane corresponds to location within the field (Fig. 14.3). From the point of fixation, the field extends 60° superiorly, 60° nasally, 70–75° inferiorly, and 100–110° temporally. The blind spot is represented by a hole in the “hill” about 15° temporal to the foveal “peak.”

**FIG. 14.3** The “island,” or “hill of vision,” proposed by Traquair is surrounded by a “sea of blindness.” The height of the island represents increasing sensitivity. Using kinetic perimetry, the island is intercepted by a moving target of fixed size. Using static perimetry, a target's visibility is increased in size or luminosity until it descends on to the island. The blind spot located 15° temporal to fixation is absolute, creating a small “well” in the sensitivity contour. (Courtesy of Steven Newman, MD.)

Perimetric tests have been developed that systematically measure the level of light sensitivity in the visual field. Two basic types exist: kinetic perimetry and static perimetry. In kinetic perimetry a target is moved from outside the potentially seeing area toward the seeing area until it is detected. In static perimetry a target located within a

potentially seeing area can be increased in size or intensity until it is detected. With either method a region of vision can be defined in relation to a test stimulus of given size, hue, brightness, and uniform level of background illumination. For instance, under standardized conditions, the central visual field of about 30° can be mapped with a moving white target of 3 mm at a distance of 2 meters.<sup>2</sup>

## Methods of Visual Field Testing

There is no single best test for the evaluation of visual fields in retinal disease. Depending on the location and extent of the disease, the examiner must choose from an ever-increasing selection of sensitive qualitative and quantitative perimetric techniques.

### Qualitative Techniques

Vision may be extremely poor in many patients with widespread visual dysfunction resulting from retinal disease. In such instances visual fields may be obtained only by confrontation testing. However, this technique also may be used to detect even subtle relative field defects and scotomas. Confrontation testing is performed with the examiner facing the patient, usually at about arm's length. The peripheral vision of the patient is evaluated in relation to that of the examiner. To test the patient's right eye, the examiner occludes the right eye and aligns the left eye so that both patient and examiner share a common visual axis. The examiner then moves the hand or test object from outside the visual field toward fixation. Relative preservation of peripheral vision can be established if the examiner places both hands or two test objects in different seeing quadrants of the patient and asking the patient to identify the clearer object. Central visual function is estimated by having the patient look toward the examiner's nose or, if vision is very poor, toward the direction of the examiner's voice. The patient describes which parts of the examiner's face are missing or most clearly seen. Results are recorded either descriptively or with a simple drawing.

Although the tangent screen can be used quantitatively, it is most

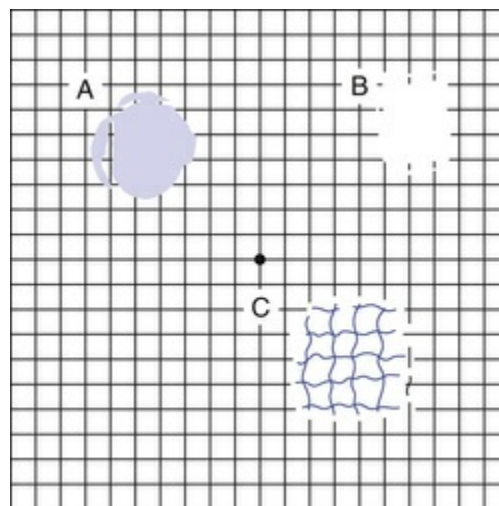

effective as a qualitative tool for estimation of visual loss in the central field. A 1-meter screen can be used to evaluate suspected midperipheral field loss, but a 2-meter screen is essential if the intent is to map central scotomas or the physiologic blind spot. The sensitivity of the test can be increased with the use of smaller test objects and by seeking subjective responses about the quality (e.g., blurry, dim, flickering, faded) of seen targets. Most important, conical visual field constriction of retinal origin can be readily distinguished from tubular fields of nonorganic visual loss by using large test objects at varying distances. With a doubling of the distance to the screen, there must be a doubling in size of the test object used. Although not routinely available or performed in a retinal specialist's office, no other form of perimetric evaluation is as effective in discriminating real from fictitious visual field constriction (Fig. 14.4).

**FIG. 14.4** A tangent screen field from a hysterical or malingering patient fails to show expansion of the visual field with doubling of both test object size and distance.

The Amsler grid is another extremely important qualitative tool for the evaluation of central vision. It is routinely used in regular self-monitoring of vision between eye exams by patients with macular degeneration or other progressive macular pathology to detect early signs of disease progression. In its original form, the patient fixates on the center dot of a white grid on a black background from a distance of 35.5 cm (14 inches) (Fig. 14.5). The patient describes the appearance of the grid pattern, especially in regard to missing areas (scotomas) and distortion (metamorphopsia). The sensitivity for detection of macular lesions can be increased with the use of red grids with or without the use of crossed polarizing lenses (Fig. 14.6) to decrease the light entering the patient's eye.<sup>3</sup>

**FIG. 14.5** The Amsler grid is viewed at 35.5 cm (14 inches), using the central dot for fixation. Regions of metamorphopsia (C), scotoma (B), and blur (A) are noted.

**FIG. 14.6** The sensitivity of the Amsler grid test can be increased by using red lines on a black background rather than black or white lines on contrasting backgrounds. Further sensitivity may be achieved by using crossed-polarizing glasses that decrease the amount of light entering the eye. (Courtesy of Alfredo Sadun, MD.)

## Quantitative Techniques

Quantitative techniques of perimetry are utilized for both diagnosis of disease and following the course of disease. Documentation of visual recovery in eyes with retinal pathology after treatment, such as retinal detachment surgery, laser therapy, antiinflammatory and anti-vascular endothelial growth factor drug therapy is becoming an important aspect of patient care. Also, quantitative records are invaluable for achieving new insights into the types of visual disturbances found in various retinal diseases.

Both Goldmann and Tübinger perimetry require examiners with a high degree of training. The Goldmann visual field (GVF) perimeter uses a kinetic strategy, although static perimetry is

possible (Fig. 14.7). It is especially useful for monitoring peripheral visual field loss and large scotomas. It has limited capabilities for the evaluation of small central scotomas. The Tübinger perimeter uses a static strategy. It is a sensitive but time-consuming less used technique for identifying small or large relative field defects once the approximate region of the field loss has been determined. Laborious Tübinger profiles are usually made only across a single meridian of the visual field, limiting its screening capabilities (Fig. 14.8).

**FIG. 14.7** The Goldmann visual field strategy developed by Armaly and Drance uses kinetic targets (*arrows*) to map the peripheral isopters and suprathreshold static targets (*dots*) to check central visual field function. (Reproduced with permission from Rock WJ, Drance SM, Morgan RW. Visual field screening in glaucoma: an evaluation of the Armaly technique for screening glaucomatous visual fields. Arch Ophthalmol 1973;89:287-90.)

**FIG. 14.8** The Tübinger perimeter produces a static profile of visual sensitivity through any chosen meridian. (Reproduced with permission from Harrington DO. The visual fields: a textbook and atlas of clinical perimetry. St. Louis: Mosby, 1981.)

Quantitative perimetry received a tremendous boost with the advent of automated, computerized methodology. Suprathreshold automated visual screeners, such as the Fieldmaster 101 and the Dicon units, did much to popularize visual field testing in the ophthalmic community. Pseudothreshold algorithms were developed for these machines to enhance their quantitative capabilities.<sup>4</sup> However, threshold perimeters, such as the Octopus and the Humphrey visual field (HVF) analyzer, surpassed the capabilities of even the Tübinger instrument. Automated, quantitative threshold perimetry is ideal for the evaluation of retinal disease. Randomized sequences for stimulus presentation within the visual field enhance the possibility of detecting small or irregular field defects. Density of points can be varied to characterize fully field losses that are either focal or diffuse. Although the HVF has the ability to test 60° of visual field, this protocol is very time-consuming. The standard protocols used are the 30-2, 24-2, and 10-2, which measure the central 30°, 24°, and 10° respectively. The choice of field is based on the region of pathology in the visual field. The dash 2 (-2) refers to protocol 2, the analysis of points on either side of the vertical and horizontal meridians rather than just on the vertical and horizontal axis as performed in protocol 1. Thus, both the 24-2 and 30-2 protocols test points 3°

from the horizontal and vertical axis as well as points at 6° intervals beyond this region in the central 24° or 30° respectively. A 10-2 protocol tests points 1° from the horizontal and vertical meridian as well as points at 2° beyond this region in the central 10° and thus is more sensitive for detecting subtle field losses in the macular region.<sup>5</sup>

Algorithms such as the Swedish interactive threshold algorithm (SITA) were developed to increase efficiency and decrease variability in the standard Humphrey strategy. SITA uses normative and real-time data from patients during the test to update estimates of thresholds and adjust presentation times of stimuli continually. Short-wavelength automated perimetry (SWAP) is a variant on the usual white light stimulus used in standard threshold testing. SWAP isolates the S-cone system (blue-yellow pathway), using a blue stimulus on a yellow background. The presence of normal, age-corrected retinal sensitivity values increase the utility in clinical testing.<sup>6,7</sup> Care must be taken when using this technique to correct for chromatic filtering effects from the crystalline lenses.<sup>8</sup> Longer test duration, increased variability, and learning effects make SWAP most applicable to conditions for which early detection has important therapeutic implications and requires careful supervision of the patient by the tester during visual field testing.<sup>9</sup> In each case, the ability to map statically determined threshold retinal sensitivity directly on to the retina with automated quantitative threshold perimetry with a high degree of accuracy is important in the evaluation of retinal disease.<sup>10</sup> This ability has further been refined by techniques such as microperimetry.

## **Microperimetry**

Macular diseases may be degenerative, hereditary, traumatic, toxic, or inflammatory. All are characterized by central visual field defects or distortion, which may be small enough to be undetected without detailed perimetry or Amsler grid testing. Ancillary psychophysical tests of visual acuity, contrast sensitivity, and color vision may be helpful in determining visual function.

Microperimetry is especially helpful for evaluating and following

macular disease. It is used to correlate anatomic pathology with function of the visual system by integrating fundus imaging and computerized threshold perimetry at specific locations in the fundus. One technique of microperimetry uses a scanning laser ophthalmoscope (SLO) (e.g., Rodenstock, Ottobrunn, Germany) to plot field defects within geographically defined regions of the retina. A modulated helium–neon laser beam of variable intensity (0–21 dB) at 633 nm projects stimuli on to the retina during ophthalmoscopy performed with an infrared diode laser at 780 nm.<sup>6,11</sup> Another type of microperimetry is Micro Perimeter 1 (MP 1, Nidek Instruments, Padua, Italy) which uses an infrared fundus camera that provides a 45° view and performs perimetry using a liquid crystal display with special software. The MP-1 allows for eye tracking and real-color fundus image acquisition. Images from other tests, such as fluorescein angiogram, can be overlaid onto the microperimetry, which is not possible in SLO microperimetry. Moreover, as SLO microperimetry is also restricted to red laser light, comparison with standard perimetry or MP-1 is difficult.<sup>11</sup>

Both the SLO and MP-1 microperimetry devices allow for kinetic and static perimetric testing of the macula and permit simultaneous observation of the retina during perimetric testing. Similar to conventional perimetry, stimulus sizes range from Goldmann size I to V and the central 15–20° of visual field can be tested in both devices. However, the MP-1 allows for a slightly larger field for testing. Rohrschneider and colleagues determined that for patients with retinal disease both the SLO and MP-1 microperimetry devices delivered comparable results, with the SLO devices providing better-resolution fundus images and the MP-1 providing better fixation analysis with more accurate real-time image alignment.<sup>12</sup> As efforts to correlate better anatomic and functional changes in the retina have advanced, more refined devices are being developed that combine techniques of visualizing the ultrastructure of the retina, such as three-dimensional spectral optical coherence tomography (OCT) and adaptive optics, with corresponding perimetric functional assessment.<sup>13,14</sup> Next generation microperimetric devices (e.g., Nidek MP-3) also feature increased automation, which should further reduce operator-related variability.

## Other Methodologies of Visual Field Testing in Retinal Disease

Perimetric tests are being developed to screen for early changes in retinal diseases affecting the macula. Rarebit testing, or the matching of test targets to receptive field sizes, has been used in select studies to assess central functional vision in a variety of retinal diseases. A compact rarebit screening test has been developed and tested in patients with age-related macular degeneration (AMD).<sup>15</sup> Preferential hyperacuity perimetry (PHP) is another screening device for detecting early visual field changes in retinal disease. PHP uses the phenomenon of hyperacuity (Vernier acuity), the ability to discern differences in the spatial location of two or more stimuli, to test one's ability to identify local distortion of a series of dotted vertical or horizontal signals. The responses are correlated to a normative database and scored to generate a probability of deviation from normal. PHP has been found to be more sensitive than Amsler grid testing for the early detection of exudative AMD in patients with intermediate AMD. Home monitoring devices using PHP have been developed and evaluated for more widespread clinical use, which allow for convenient and timely early detection of progression of AMD.<sup>16</sup> However, as with any repeated test used to follow changes over time, consistency in choice of testing method is important to accurately characterize and follow the progression of retinal diseases.

## Reliability and Reproducibility of Visual Field Tests

Anatomic, physiologic, and psychologic factors unrelated to the pathology in question can significantly affect measurement of the visual field. The nose, brow, and lid may constrict the nasal and superior fields artifactually. Numerous variables pertaining to both the patient and the environment must be controlled during testing if meaningful results are to be obtained. Even so, considerable short-term variability must be taken into account. [Box 14.1](#) outlines a list of factors that must be controlled for optimal determination of the visual field. Perimetric testing has a degree of subjectivity and

therefore ultimate reliability and repeatability of the testing rely on the patient and the test-giver.<sup>17</sup> Patients with retinal disease may be more prone to variability in testing over time, which can influence the validity of test results. Seiple and colleagues<sup>18</sup> demonstrated that for patients with retinitis pigmentosa (RP) the results of repeated HVF testing performed at different time points were two times more variable when compared to similar fields performed in normal controls despite controlling for disease progression. Microperimetry has the added advantage of real-time retinal surface monitoring with eye tracking to correct for eye movements during testing. Weingessel and colleagues demonstrated good interexaminer and intraexaminer reliability of microperimetry **Box 14.1** using the MP-1 device in eyes with and without retinal disease.<sup>19</sup>

## Variables Affecting Measurement of the Visual Field

## Perimetry in Specific Retinal Diseases

The visual fields tests described are used in patients with retinal disease to assess and catalog progression of functional visual field loss, to determine the outcomes of treatment on visual function, and to correlate functional and structural changes in the retina.

### Retinal Dystrophies

#### Retinitis Pigmentosa

Visual fields have traditionally been used to characterize and monitor the progression of visual field loss in retinitis pigmentosa (RP). However, some caution should be exercised when interpreting fields in ill RP patients. A recent study by Bittner<sup>20</sup> suggested that episodic decline in general health was correlated with simultaneous decline in visual field (VF) that was not representative of the true area of visual field loss. The earliest field defect in RP is reported to be a group of isolated scotomas 20–25° from fixation.<sup>2</sup> Eventually these isolated defects coalesce into a “ring scotoma” affecting the midperiphery of the visual field. Usually the peripheral field loss progresses and leaves a small, central island of vision. Eventually, complete visual loss may occur (Fig. 14.9).

**FIG. 14.9** Classic development of a ring scotoma with focal sparing of a peripheral temporal island seen in retinitis pigmentosa and cone-rod dystrophies. (A)

Progressive depression of peripheral visual field in a patient with cone–rod degeneration at presentation. (B) Same patient after 1 year. (C) Same patient during fourth year of follow-up. (Reproduced with permission from Krauss HR, Heckenlively JR. Visual field changes in cone–rod degenerations. Arch Ophthalmol 1982;100:1784–90.)

Characterization and comparison of specific patterns of visual field loss in genotypically and phenotypically different forms of RP such as X-linked, dominant, pericentral, and Usher syndrome, using GVF perimetry have been attempted.<sup>21–24</sup> Association of the degree of visual field loss with different genotypes in syndromic associations of RP, including Bardet–Biedl syndrome 1, has also been studied.<sup>25</sup>

HVF measurements have been correlated with contrast sensitivity in RP and were found to be a sensitive predictor for central visual function in advanced RP.<sup>26,27</sup> Perimetry has been used to test outcomes of treatments for varieties of RP, including fundus albipunctatus.<sup>28</sup> Visual fields have also been used in correlating photoreceptor anatomy and visual function in RP. Decreased retinal sensitivity on electroretinogram has been linked to visual field loss demonstrated by perimetry in RP.<sup>29</sup> Changes in GVF, HVF, and microperimetry have been correlated with anatomical changes at the cellular level using OCT and autofluorescence to identify abnormal photoreceptor morphology and damage to retinal pigment epithelial (RPE) cells.<sup>30–38</sup>

## Other Retinal Dystrophies

Perimetric changes occur in a variety of retinal dystrophies. Cone dystrophy produces progressive symmetric to slightly asymmetric central visual loss. Autofluorescence has been shown to correlate with GVF in cone and cone–rod dystrophies.<sup>39</sup> The visual fields demonstrate central scotomas with relative sparing of the fovea. A central or paracentral scotoma can also be seen in Stargardt disease (Fig. 14.10). However, microperimetry identifies two types of scotoma in patients with Stargardt disease. In one type there is a dense ring scotoma associated with stable fixation. In the second type there is a dense central scotoma associated with fixation shift. The second type is also correlated with poorer acuity.<sup>40</sup> Another

recently described microperimetric phenomenon in Stargardt disease is longitudinal decline in retinal sensitivity observed over a 2-year follow-up period.<sup>41</sup> Such microperimetric monitoring could be important in short-term follow-up as a quantitative indicator of the rate of disease progression.

**FIG. 14.10** (A) Fundus photos of a 34-year-old female patient with Stargardt disease and visual acuity of 20/30 OD and 20/40 OS. (B) OCT with disruption of the IS–OS junction (ellipsoid zone) in the same patient and (C) corresponding 24-2 HVF and (D) 10-2 HVF with paracentral scotomas corresponding to structural changes seen on imaging.

In gyrate atrophy of the retina and choroid, a rare tapetoretinal degeneration caused by an inborn error of ornithine aminotransferase activity, there is constriction of the visual field corresponding to the progressive peripheral retinal degeneration with scalloped margins (Figs. 14.11 and 14.12). Constricted GVF tests are also seen in Bietti crystalline dystrophy.<sup>42</sup> Correlations between HVF sensitivity and multifocal electroretinogram (mERG) have been documented for eyes with central areolar choroidal dystrophy and North Carolina macular dystrophy.<sup>43,44</sup> Functional changes as evidenced by perimetry and mERG have also been correlated with morphologic changes documented by fundus autofluorescence (FAF) in adult vitelliform macular dystrophy.<sup>45</sup>

**FIG. 14.11** Central (A) and peripheral (B) fundus appearance of a patient with gyrate atrophy of the retina. The visual field of this patient is shown in Fig. 14.12.

**FIG. 14.12** Thirty-degree Octopus visual field (program 31) demonstrates marked peripheral constriction, with relative sparing in the centrocecal region. In addition, there are a few more peripheral islands of reduced sensitivity. (Reproduced with permission from Feldon SE. Computerized perimetry in selected disorders of the retina. In: Whalen WR, Spaeth GL, editors. Computerized visual fields: what they are and how to use them. Thorofare, NJ: Slack; 1985.)

## Diabetic Retinopathy

The diffuse retinal ischemia associated with diabetic retinopathy would seem to make visual field assessment an ideal method for follow-up of the disease, but progressive field deterioration in diabetics does not necessarily correlate with changes in retinopathy.<sup>46</sup> Visual fields are not routinely used to evaluate this retinal disease, even though field defects may exist in the absence of observable retinopathy. Roth<sup>47</sup> found central field defects in about 40% of eyes without visible retinopathy and in all diabetic patients with retinopathy. Using frequency-doubling perimetry, Parravano<sup>48</sup> confirmed retinal impairment in type I diabetics that correlated with glycemic control, without evidence of visible retinopathy. SWAP studies on patients with early diabetic maculopathy demonstrated a correlation between the decrease in mean thresholds and the increase in size of the foveal avascular zone and the perifoveal intercapillary area. These changes were not observed with standard white-on-white perimetry.<sup>49</sup>

Microperimetric studies indicate decreased sensitivity in diabetics with retinal thickening despite the absence of frank macular edema.<sup>50</sup> In a group of patients with clinically significant diabetic macular edema, Hudson and colleagues<sup>51</sup> found that one-third had abnormal standard perimetric fields, but all patients had abnormal SWAP 10-2 fields. Further, the area of abnormal sensitivities was greater than that expected by clinical assessment. Using microperimetry, macular scotomas were also found in 74% of 19 patients with clinically significant macular edema.<sup>52</sup> SWAP sensitivity in the central 10° of visual field in diabetic patients without macular edema was significantly reduced compared to standard white-on-white perimetry.<sup>53</sup> A study of visual field defects in diabetic children without retinopathy by Mastropasqua and colleagues<sup>54</sup> suggested that retinal sensitivity was impaired in the midperiphery of the visual field proportional to the degree of microalbuminuria. Inner/outer-segment (IS–OS) junction (now termed the ellipsoid zone, EZ) disruption on OCT has also been correlated with decreased sensitivity on microperimetry in those with diabetic macular edema.<sup>55</sup>

Once diabetic retinopathy is present, visual field loss is readily documented. Gandolfo and colleagues<sup>56</sup> studied 85 eyes with nonproliferative diabetic retinopathy using the Goldmann

perimeter. They were able to identify retinal hemorrhages and exudates of at least 3–4° in diameter as localized depressions in the visual field. Macular exudation and edema caused an irregular depression and flattening of static profiles of the central field. Wisznia and colleagues<sup>57</sup> tried to correlate the degree of retinopathy with the amount of visual field loss. They hypothesized that a correlation might exist between retinal capillary perfusion and field loss. Bell and Feldon<sup>10</sup> used Octopus static perimetry to show that visual sensitivity is quantitatively correlated with retinal perfusion in nonproliferative diabetic retinopathy (Figs. 14.13 and 14.14). Utilizing standard perimetry, Federman and Lloyd<sup>58</sup> found the degree of perfusion to be more important in predicting field loss than the amount of proliferative retinopathy. This relationship between nonperfusion and regional field loss has been confirmed in other studies as well.<sup>56,59</sup>

**FIG. 14.13** Fluorescein angiogram of a patient with preproliferative diabetic retinopathy. Static sensitivities from Octopus perimetry are superimposed. Areas of good perfusion (G) have normal visual function. Areas

of intermediate perfusion (*I*) have a moderate decrease of visual function, and nonperfused areas (*P*) have complete loss of visual function. (Reproduced with permission from Bell JA, Feldon SE. Retinal microangiopathy: correlation of Octopus perimetry with fluorescein angiography. Arch Ophthalmol 1984;102:1294–8.)

**FIG. 14.14** Average sensitivity of the retina decreases with decreasing perfusion, both for diabetic retinopathy (*dots*) and for branch retinal vein occlusion (*diamonds*). (Reproduced with permission from Bell JA, Feldon SE. Retinal microangiopathy: correlation of Octopus perimetry with fluorescein angiography. Arch Ophthalmol 1984;102:1294–8.)

Lutze and Bresnick<sup>60</sup> demonstrated a correlation between the degree of retinopathy in type I diabetic patients and visual field loss using SWAP. These findings were consistent with those of Zwas and coworkers and have been confirmed in more recent studies.<sup>8,53</sup> In addition, automated perimetry was found to correlate better with severity of diabetic retinopathy than visual acuity.<sup>61</sup> A study by Agardh and colleagues demonstrated that SWAP sensitivity of visual field loss was correlated to ischemic changes in areas of macular edema, rather than to the severity of macular edema.<sup>62</sup> SWAP analysis also demonstrated a greater decrease in mean sensitivity in menstruating diabetic women who were in the luteal phase, which was not seen in menstruating control patients.<sup>63</sup> In a

study by Stavrou and Wood,<sup>64</sup> flicker perimetry appeared to be more sensitive than static perimetry in documenting early visual field changes in diabetic retinopathy, especially in a region of clinically significant diabetic macular edema.

In instances of vitreous hemorrhage and tractional retinal detachment due to high-risk proliferative diabetic retinopathy, visual acuity is often dramatically improved by vitrectomy; however, severely impaired visual fields due to extensive retinal ischemia may still preclude driving.<sup>65</sup> Moreover, the treatment of diabetic retinopathy with either panretinal or focal photocoagulation may produce visual field defects, a fact that should be considered in overall patient management.<sup>66,67</sup> In a study by Zingirian and colleagues,<sup>68</sup> isolated photocoagulation of diabetic retinopathy results in small scotomas that are difficult to isolate by kinetic perimetry. Confluent lesions measuring one to two disc diameters cause correspondingly sized scotomas with sloping margins.

Panretinal photocoagulation produces a marked concentric contraction of the visual field. Yoon et al.<sup>69</sup> demonstrate preservation of retinal sensitivity in central visual field after panretinal photocoagulation in diabetic patients. At 1 week after treatment there is significant depression, but recovery of up to 95% occurred within the ensuing 3 months. They attribute these encouraging findings to the use of burn sizes of 200  $\mu\text{m}$  or less, as recommended by Hulbert and Vernon.<sup>70</sup>

Using automated perimetry, an initial loss of sensitivity after grid laser for diabetic macular edema was seen followed by improvement.<sup>71</sup> Hudson and colleagues<sup>71</sup> followed 24 diabetic patients with macular edema before grid laser treatment and up to 12 weeks following treatment with microperimetry. They found correlation between the amount of edema and visual function in some, but not all, patients. In another study of 30 patients, 8 eyes remained stable, 15 had improved mean deviation on HVF after treatment, and laser scars corresponded to marked loss of function.<sup>72</sup>

Retinal sensitivity tested by microperimetry appears to increase after micropulse diode laser, but to decrease after modified Early Treatment Diabetic Retinopathy Study focal laser in eyes with

clinically significant diabetic macular edema. These perimetric changes are observed even though there is no difference in visual acuity or retinal thickness after either treatment.<sup>73</sup> Recent studies highlight associations between morphologic and functional alterations in diabetic macular edema using microperimetry. Microperimetry sensitivities are reduced in eyes with diabetic macular edema, and direct correlations have been made between decreased microperimetry sensitivity and increased cystoid edema, as evidenced by OCT and increased FAF.<sup>74-77</sup> Microperimetry sensitivities are increased in patients receiving intravitreal injections of ranibizumab<sup>78</sup> and triamcinolone<sup>79</sup> for diabetic macular edema when such edema is reduced.

## Other Vascular Diseases and Nondiabetic Macular Edema

Many other vascular abnormalities of the choroid and retina have been evaluated with perimetry. For example, visual field defects correspond to retinal vascular occlusions in sickle-cell disease.<sup>80</sup> Microperimetric sensitivity is decreased in sickle-cell retinopathy in areas of retinal thinning.<sup>81</sup> GVF perimetry showed a slight constriction of peripheral visual fields, though visually insignificant, a decade after diode laser retinal ablative therapy for retinopathy of prematurity (ROP) in one series. This field constriction is similar to peripheral field changes observed years after cryotherapy for ROP.<sup>82</sup> Laser ablative treatment at the earlier stage of ROP results in a slight preservation of the field when compared with eyes treated at threshold (type I ROP).<sup>83</sup>

Microperimetry has been used to document functional improvement with resolution of absolute scotomas and improvement in vision to baseline in the setting of Purtscher's retinopathy after treatment with oral steroids.<sup>84</sup> However, permanent paracentral scotoma on HVF has been reported in Purtscher's retinopathy secondary to pancreatitis.<sup>85</sup> Perimetric improvement was noted following carotid endarterectomy for clinically significant carotid stenosis.<sup>86,87</sup> Recovery of visual field loss was also seen over time using HVF and microperimetry after central and branch artery occlusions.<sup>88,89</sup> In addition, greater

decrease in scotopic macular sensitivity was shown with microperimetry fine matrix mapping of the macula in eyes with type 2 idiopathic macular telangiectasia. In similar eyes, Wong and colleagues<sup>90</sup> demonstrated correlations between microperimetry sensitivities, OCT retinal morphology, and FAF.

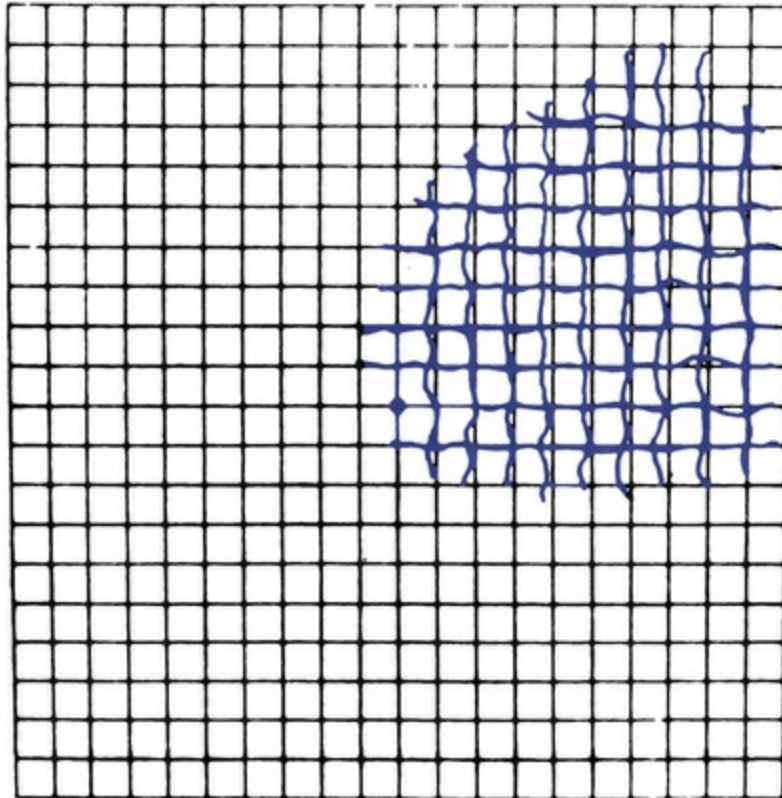

In branch vein occlusions, Bell and Feldon<sup>10</sup> have shown good correlation between residual capillary perfusion and threshold retinal sensitivity (Figs. 14.14 and 14.15). According to the Branch Vein Occlusion Study guidelines, microperimetry is useful in assessing the benefit of laser treatment. Regression of the scotoma from the foveal avascular zone was observed in one-third of patients, but in one-half of treated patients an increase in total scotoma size occurred.<sup>91</sup>

**FIG. 14.15** Fluorescein angiogram from a patient with a superior branch retinal vein occlusion. Retinal sensitivities from Octopus perimetry are superimposed to show depressed function in the area of intermediate retinal perfusion (*I*). *G*, Area of good perfusion.

After injection of intravitreal triamcinolone for treatment of branch retinal vein occlusion, improvement in macular sensitivity by microperimetry correlated with improvement in macular edema.<sup>92</sup> Visual fields may also effectively document the effects of treatments for CRVO.<sup>93</sup> For instance, microperimetry demonstrated improved central fixation and retinal sensitivity following resolution of macular edema due to CRVO after treatment with intravitreal triamcinolone acetonide. An increase in retinal sensitivity is also seen after Ozurdex intravitreal implant for macular edema after CRVO and BRVO.<sup>94</sup> Though microperimetry showed a benefit in macular function and field after radial optic neurotomy for CRVO, according to Tsujikawa and colleagues,<sup>95</sup> persistent peripheral field defects were documented by full-field perimetry corresponding to the incision site on the optic nerve head in similar eyes with CRVO that underwent the same treatment.<sup>96</sup>

Central serous retinopathy is another entity affecting the macula that can present as metamorphopsia on Amsler grid testing. There is also an accompanying mild central depression which varies in size from 2 to 5° (Fig. 14.16). The scotoma is usually substantially larger using SWAP relative to that detected with white-on-white perimetry.<sup>97</sup> HVF and microperimetry central retinal sensitivity is reduced as subretinal fluid in central serous retinopathy increases on OCT.<sup>98,99</sup> Even after resolution of edema, the majority of patients have residual Amsler and perimetric defects<sup>100–102</sup> (Fig. 14.17). Similar changes may result from other causes of fluid accumulation in the macula, such as diabetic retinopathy, Irvine–Gass syndrome, trauma (Berlin's edema), and retinal vasculitis.<sup>2,103</sup>

## Age-Related Macular Degeneration and Other Maculopathies

Macular drusen are not usually associated with any reduction of retinal sensitivity using standard techniques. However, in a prospective study using SWAP, the mean sensitivity of patients with soft drusen and early AMD is significantly lower compared to patients without drusen.<sup>104,105</sup> In this study the presence or absence of focal hyperpigmentation did not affect mean sensitivity.

Microperimetry of macular drusen demonstrated decreased overlying sensitivity in some, but not all, studies.<sup>106,107</sup>

Microperimetry is used to assess retinal sensitivities for a variety of other diseases affecting retinal function in the macula, including X-linked retinoschisis, S-cone syndrome, retinopathy of membranoproliferative glomerulonephritis type II, and atrophic maculopathy associated with spinocerebellar ataxia type 7.<sup>108-111</sup>

The relationship between microperimetric retinal sensitivity and OCT characteristics in AMD has been the subject of several studies as microperimetry is becoming more popular as a reliable functional outcome measure.<sup>112</sup> In one study<sup>113</sup> the integrity of the IS–OS junction (EZ) and drusen-associated RPE elevation correlated with retinal sensitivity, implicating these criteria as markers of retinal function in early AMD. Both nonexudative<sup>114</sup> and exudative AMD have been associated with reduced microperimetry sensitivity that correlated with a disrupted IS–OS interface.<sup>115</sup> Studies on microperimetry and OCT correlation for exudative AMD have shown similar findings.<sup>116-118</sup> In contrast, one study measured a functional deficit with microperimetry, but found a lack of correlation with the multifocal electroretinogram (greater in microperimetry) in eyes with intermediate nonexudative AMD.<sup>119</sup>

Microperimetry retinal sensitivity correlates with alterations in FAF even in early stages of AMD.<sup>120</sup> Perimetry is also used to evaluate macular retinal sensitivity after novel treatments for nonexudative AMD<sup>121-123</sup> and is more sensitive than low luminance and best corrected visual acuity in early and intermediate nonexudative AMD.<sup>112,124</sup>

Disciform subfoveal scarring from subretinal neovascularization, hemorrhage, and gliosis due to exudative AMD causes a dense central scotoma,<sup>2</sup> as shown in [Fig. 14.18](#). Detailed studies of subfoveal choroidal neovascularization in exudative AMD have been performed by microperimetry ([Fig. 14.19](#)). Of 179 eyes evaluated by Fujii and colleagues, 135 (75%) had central fixation, 42% had stable fixation, and in 28%, there was a dense central scotoma. The authors found that both central and stable fixation deteriorated over time. These fixational patterns were felt to be important in the selection of patients for macular translocation surgery.<sup>125</sup> Microperimetry has also been used to assess retinal

sensitivity after autologous RPE and choroid grafting for exudative AMD.<sup>126</sup> When microperimetry was utilized to evaluate the anatomic abnormalities associated with an absolute scotoma in subfoveal choroidal neovascularization, Tezel and associates found that the relative risk (RR) was highest in areas of chorioretinal scar (RR = 107.61) compared to areas of RPE atrophy (RR = 9.97), subretinal hemorrhage (RR = 2.88), and neovascular membrane (RR = 1.86).<sup>127</sup> The majority of patients with stable fixation preferred an area of RPE hyperplasia.

**FIG. 14.18** (A) Fluorescein angiogram of a 60-year-old patient referred for evaluation of transient right homonymous hemianopia documents disciform macular degeneration of the left eye. (B) Dense central scotoma corresponding to the fundus lesion is shown by grayscale printout from Humphrey perimeter (program 30–2).

**FIG. 14.19** A sequence of scanning laser ophthalmoscope (SLO) microperimetry shows the progressive functional deterioration in one eye with subfoveal choroidal neovascularization (CNV) secondary to age-related macular degeneration (AMD). The SLO testing demonstrated that eyes with subfoveal CNV secondary to AMD experienced a predictable and progressive loss of fixation stability, decreased central retinal sensitivity, and loss of central fixation location. A 65-year-old man presented with 20/150 vision and a 1-month history of decreased vision due to a predominantly classic subfoveal CNV secondary to AMD. (A) The SLO testing performed at presentation disclosed a pattern of predominantly central and stable fixation. (B) The balls indicate the areas where the patient could perceive the stimulus; the triangles indicate the areas where the patient could not perceive the stimulus. Each ball and triangle is color-coded to indicate the intensity of the stimulus.

The SLO microperimetry also showed a mild decrease in central retinal sensitivity. The patient elected not to receive any treatment and had a follow-up visit 4 months after initial visual symptoms. (C) An SLO test was performed and demonstrated that the fixation pattern became poor central and relatively unstable. (D) The microperimetry also showed that retinal sensitivity was markedly affected with some central areas of dense scotoma. Best corrected visual acuity at this visit was 20/200. Twelve months after onset of initial visual symptoms and no treatment, SLO microperimetry was performed and disclosed further functional deterioration. (E) The fixation became predominantly eccentric and unstable. (F) Retinal sensitivity testing demonstrated a large central area of dense central scotoma. (Reproduced with permission from Wong WT, Kam W, Cunnigham D, et al. Treatment of geographic atrophy by the topical administration of OT-551: results of a phase II clinical trial. *Invest Ophthalmol Vis Sci* 2010;51:6131–9.)

Visual field sensitivity as demonstrated by HVF 10-2 and microperimetry improved after photodynamic therapy for exudative AMD and subfoveal polypoidal choroidal vasculopathy.<sup>128–130</sup> Using the HVF macular threshold protocol, improvement in macular visual field sensitivity occurred after treatment with intravitreal bevacizumab for exudative AMD, even in cases where visual acuity had not improved.<sup>131</sup> Microperimetry in patients with exudative AMD has shown similar improvement in central retinal sensitivity after intravitreal ranibizumab,<sup>132,133</sup> bevacizumab,<sup>101</sup> and aflibercept.<sup>117</sup> However, supplementation of the micronutrient lutein did not improve microperimetric retinal sensitivity or visual acuity in AMD.<sup>134</sup>

Patients with AMD or other macular pathology are routinely instructed to monitor their visual field in each eye with an Amsler grid regularly. The higher contrast of the original white lines on a black background Amsler grid proved to be superior at detecting metamorphopsia and central vision changes compared to the modified grid, which displays black lines on a white background.<sup>135</sup> However, due to ease in photocopying, the grid with black lines on a white background is most commonly used in the office setting and provided to patients for home use.

With the increasing prevalence of AMD and the ability to treat early exudative AMD effectively, new perimetric tests that allow for patient self-monitoring of visual fields are being devised to detect early deficits. Nazemi and colleagues<sup>136</sup> developed a three-dimensional automated computer-based threshold Amsler grid test that maps the visual field and records steep slopes in areas of nonexudative AMD and shallow slopes in regions corresponding to exudative AMD. As discussed at the beginning of this chapter, the psychophysical property of hyperacuity has been used to develop a device that detects progressive maculopathy and the early onset of exudative disease in AMD.<sup>137,138</sup> The device, PreView PHP (Carl Zeiss Meditec, Dublin, CA), was evaluated as a home-based device in a multicenter trial and found to have a sensitivity and specificity of 85% to detect alterations in hyperacuity corresponding to exudative and intermediate nonexudative AMD.<sup>138</sup> Other home-based perimetric devices for patients to monitor their vision routinely are expected in the near future. With the development of better algorithms to detect early disease progression, these home devices will hopefully ensure timely sight-saving treatment.

## Epiretinal Membrane and Macular Holes

Perimetry has been used to evaluate visual fields in eyes with epiretinal membrane (ERM). Binocular correspondence perimetry, a method akin to PHP, but which uses the principle of retinal correspondence and requires binocular testing, was used to quantify metamorphopsia in eyes with ERM.<sup>139</sup> This study demonstrated focal areas of abnormal retinal correspondence in eyes with ERM compared to the normal fellow eye. Surprisingly, microperimetry revealed unimpaired central fixation in eyes with idiopathic ERM despite lower visual acuity.<sup>140</sup>

Cysts may develop in the macula without producing appreciable scotomas. In eyes with lamellar macular holes, both mean total and central microperimetric retinal sensitivity were lower than controls and were more pronounced in eyes with outer retinal layer abnormalities.<sup>141</sup> Foveal photoreceptor layer integrity was correlated with central retinal sensitivity in these eyes.<sup>142</sup>

Macular holes, however, result in dense scotomas with steep

margins (Figs. 14.20 and 14.21). Microperimetry may be helpful in predicting the outcome of macular hole surgery. In a study by Amari and associates, visual outcome correlated with the maximum sensitivity adjacent to the hole.<sup>143</sup> In another study, absolute scotomas disappeared completely in 18 of 28 eyes that achieved complete closure, became relative in five of six eyes with partial closure, and remained absolute in four eyes with atrophic closure.<sup>144</sup> Ozdemir and colleagues<sup>145</sup> suggested that MP-1 microperimetry may be more sensitive than visual acuity in measuring retinal function following closure of a macular hole with pars plana vitrectomy and internal limiting membrane (ILM) peeling. Increases in retinal sensitivity by microperimetry have also been correlated with the degree of FAF after macular hole closure.<sup>146</sup> Preoperative extent of the IS–OS junction (EZ) disruption on OCT in macular holes predicted postoperative microperimetric macular sensitivity<sup>147</sup> but final best corrected visual acuity was multifactorial. Similarly, mean retinal sensitivity before surgery also predicted prognosis after macular hole surgery.<sup>148</sup> OCT studies have shown that outer retinal layer integrity was associated with better final microperimetric sensitivity after macular hole surgery.<sup>149</sup> However, ILM peeling may reduce retinal sensitivity and significantly increase the incidence of microscotomas.<sup>150</sup>

**FIG. 14.20** Fundus photograph of an eye with a full-thickness macular hole. The visual field defect is shown in Fig. 14.21.

**FIG. 14.21** Three-dimensional reconstruction of high-density macular grid (1° spacing) documenting steep absolute central scotoma of the left eye (A) and unaffected right eye (B). Retinal sensitivity is noted on the vertical axis and position is noted on the horizontal axis. (Copyright 1983, Wesley K. Herman, MD and Joseph M. DeFaller, Alcon

Richter-Mueksch and colleagues<sup>151</sup> reported increased microperimetry retinal sensitivity without change in metamorphopsia following vitreoretinal surgery for ERM and macular hole using PHP. However, after uncomplicated repair of macular holes and ERM and using pars plana vitrectomy and ILM peeling, several investigators reported a high incidence of peripheral field defects infringing on the central visual field<sup>152-158</sup> (Fig. 14.22). A majority of studies documented postoperative field defects only after patients complained of perceived field loss. Tsuiki and colleagues<sup>159</sup> specifically compared pre- and postoperative GVF tests and found new peripheral field defects in 17 of 140 eyes postoperatively after macular hole repair. In the majority of eyes, indocyanine green (ICG) was used to enhance visualization of the ILM during peeling. In vitro studies demonstrated the toxicity of ICG exposure to human retinal cell lines.<sup>160</sup> The postsurgical visual defects are probably due to (1) toxic effects of ICG; (2) alterations in the retina, such as damage to the peripapillary nerve fibers, during the pars plana vitrectomy (PPV); or (3) mechanical damage incurred with peeling of the ILM. Damage to the nerve fiber layer from intraocular gas tamponade in cases of macular hole repair must also be considered.<sup>151</sup>

**FIG. 14.22** Goldmann and Humphrey 30-2 visual field perimetry depicting peripheral wedge-like visual field loss encroaching on the central visual field in the eyes of three patients after pars plana vitrectomy, internal limiting membrane (ILM) peeling assisted by indocyanine green staining of the ILM for external

limiting membrane. (Reproduced with permission from von Jagow B, Hoing A, Gandorfer A, et al. Functional outcome of indocyanine green-assisted macular surgery: 7-year follow-up. *Retina* 2009;29:1249–56.)

Recently, brilliant blue G dye was studied for ILM peeling,<sup>161,162</sup> and it provided improved central retinal sensitivity and quicker IS–OS junction (EZ) restoration than ICG dye.<sup>163</sup> Further studies that systematically and more accurately compare pre- and postoperative visual fields in eyes undergoing retinal surgery are needed to understand better the effects of the procedure and the adjuvant dyes or agents used to assist in the procedure on visual function.

## Toxic Retinopathies

Toxic maculopathy is epitomized by chloroquine and hydroxychloroquine retinopathy. The most characteristic field defect caused by macular involvement is a ring-like central scotoma with a small island of slightly less visual loss in its center, commonly referred to as a “bull's eye” (Fig. 14.23).<sup>164</sup> GVF and HVF perimetry document visual field changes that can persist and worsen for decades even after stopping the medications<sup>10,165–167</sup> (Fig. 14.24). 10-2 HVFs usually show paracentral changes while 24-2 fields often display central changes.<sup>168</sup> Threshold Amsler grid testing, which varies light transmission through two cross-polarizing filters, and PHP hyperacuity may be useful in screening for early functional changes due to chloroquine and hydroxychloroquine use.<sup>169,170</sup> Microperimetry also detects early macular hyposensitivity.<sup>171</sup> Lower sensitivity is often found in elderly and short statured individuals, likely due to increased toxicity of lower doses of the two drugs.<sup>172</sup>

**FIG. 14.23** (A) Fundus photos of a 65-year-old female with lupus on hydroxychloroquine (Plaquenil) 400 mg daily) for 8 years displaying perifoveal atrophy of the retinal pigment epithelium (RPE) corresponding to bull's-eye maculopathy. (B) Fundus autofluorescence in the same patient showing RPE changes as concentric rings of hypo- and hyperautofluorescence in a bull's-eye pattern. (C) Macular OCT of the patient with extrafoveal loss of RPE and the IS–OS junction (ellipsoid zone) corresponding to the bull's-eye pattern

seen clinically and to the paracentral scotoma demonstrated by the 10-2 Humphrey visual field in [Fig. 14.24C](#).

**FIG 14.24** (A) 10-2 Humphrey visual fields (HVF) at 2° spacing showing early onset of perifoveal visual field depression in both eyes in the same patient as [Fig. 14.23](#) (1999). (B) 10-2 HVF taken eight years (2007)

later displays increased concentric paracentral visual field loss at which time the patient stopped hydroxychloroquine. (C) Six years later (2013) the patient continued visual field progression with denser paracentral defects encircling the foveal region. Despite the paracentral visual field progression, best corrected visual acuity remained at 20/20 in both eyes.

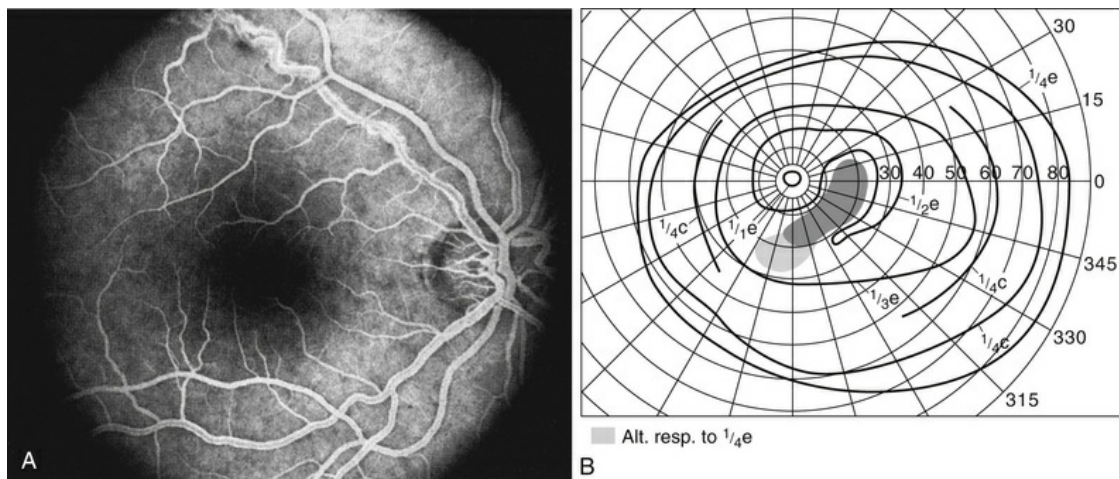

To screen for chloroquine and hydroxychloroquine toxicity HVF, 10-2 white-on-white protocol is recommended. mERG is a helpful adjunct when early perimetric changes are seen, but may not be readily available in all retina practices. Recent screening guidelines advocate the addition of high-resolution imaging, such as spectral domain OCT and FAF, to correlate functional changes with structural alterations in the photoreceptor and RPE layers.<sup>172,173</sup> Defects seen on standard automated perimetry may precede ultrastructural changes on OCT.<sup>174</sup> In one study 10% of patients had significant ring scotomas without obvious changes on OCT.<sup>175</sup> In concert with other testing modalities, early perimetric changes that may be nonspecific for macular toxicity can be validated to allow for timely changes in medication with ultimate preservation of vision.<sup>175</sup>

A number of medications are associated with retinal toxicity resulting in visual field loss. Thioridazine, a phenothiazine derivative, is a cause of pigmented maculopathy with associated central scotoma. Even in the absence of clinical tamoxifen retinopathy, SWAP fields show depressed mean deviations which correlated with duration of therapy.<sup>176</sup> Peripheral visual field loss is detected in about 30% of patients using the antiepileptic drug vigabatrin.<sup>177-180</sup> Sildenafil (Viagra) has been associated with nonarteritic ischemic optic neuropathy in individuals with preexisting cardiovascular disease.<sup>181</sup> Although visual field defects can occur in these cases, sildenafil has not been proven to cause retinal toxicity.<sup>182,183</sup>

## Infectious and Inflammatory Retinopathies

Infectious and inflammatory retinopathies exhibit visual field defects corresponding to the area of pathology. Toxoplasmosis

commonly produces focal chorioretinal destruction that causes corresponding dense, irregular, steep-margined, isolated scotomas.<sup>184</sup> More disseminated types of inflammation, such as syphilitic choroiditis, produce a more diffuse depression of visual field function. In a patient with idiopathic retinal vasculitis, the inferior arcuate field defect corresponded to leakage from the superior temporal branch vein (Fig. 14.25). A review of patients with Behcet uveitis revealed retinal nerve fiber layer defects and corresponding field defects with standard automated perimetry.<sup>185</sup> One unusual case report described the use of microperimetry to determine the focal visual loss associated with nematode-induced unilateral subacute neuroretinitis.<sup>186</sup>

**FIG. 14.25** (A) Fluorescein angiogram from a patient with idiopathic retinal vasculitis demonstrates leakage from the superotemporal retinal branch vein of the right eye. (B) Goldmann perimetry shows an inferior arcuate field defect that corresponds to the affected region of the retina.

Even without clinically evident infectious retinopathy, human immunodeficiency virus (HIV)-positive patients had significant localized as well as mean defects. These defects were more apparent in SWAP than in white-on-white automated perimetry.<sup>187</sup> Correlation of HVF perimetry with mERG in similar eyes demonstrated involvement of the inner retina and sparing of the outer retina.<sup>188</sup> Perimetric changes may also be related to HIV-related brain dysfunction.<sup>189</sup> More marked changes in retinal

sensitivity have been found in HIV-positive patients with low CD4 counts.<sup>189</sup>

In a small case series of patients with multiple evanescent white-dot syndrome, areas of decreased microperimetric sensitivity were shown to correlate with focal regions of inner and outer photoreceptor segment disruption documented by spectral domain OCT. Both the microperimetry and OCT findings changed location in keeping with the resolution and presence of new lesions during the disease course, and returned to normal by the end of clinical recovery.<sup>190,191</sup> Similar correlation between function and structure was seen in eyes with acute posterior multifocal placoid pigment epitheliopathy (APMPPE).<sup>192</sup> Field defects on static perimetry may remain after APMPPE.<sup>193</sup> Microperimetry retinal sensitivity was also found to correlate with visual acuity in both serpiginous choroiditis and birdshot chorioretinopathy. HVF in one study revealed multifocal defects (most commonly para/central scotoma coexisting with isolated defects in the nasal or temporal fields) that stabilized after 6 months of treatment in serpiginous choroiditis.<sup>194</sup> Gordon and colleagues<sup>195</sup> documented and analyzed HVF in patients with birdshot chorioretinopathy, in an attempt to determine characteristic patterns of field loss. The visual fields of this small series of patients exhibited diffuse loss, central sparing, and blind-spot enlargement. Long-term immunosuppression appeared to better maintain peripheral visual fields when compared to short-term treatment.<sup>196</sup> A study using microperimetry suggested sustained diminished retinal sensitivity even after the disease became inactive.<sup>197</sup> In addition, assessment of outcomes after valaciclovir treatment for acute zonal occult outer retinopathy using GVF demonstrated improved peripheral visual function.<sup>198</sup>

## Retinal Detachment

Typically, rhegmatogenous retinal detachments have sloping isopters on kinetic perimetry. Occasionally, this feature helps to differentiate a retinal detachment from a retinoschisis, which is characterized by dense defects with steep margins, usually located supranasally. However, longstanding retinal detachments may develop steep isopters. In the case of a shallow detachment,

assessment of the visual field may be more accurate than ophthalmoscopy in identifying the border of detached retina.<sup>2</sup>

If the detachment is longstanding, recovery of visual field sensitivity is incomplete.<sup>199</sup> Performing visual fields under conditions of both light and dark adaptation, Alexandridis and Janzarik<sup>200</sup> report that cone function returns before rod function after successful surgical reattachment of the retina. Assessment of visual fields using SWAP is a sensitive measure of functional visual improvement in the macula following surgical repair for macula-involving retinal detachment.<sup>201</sup> One study suggested that central visual field defects occur following a high percentage of retinal detachment surgeries, especially if retinotomy for drainage of subretinal fluid (12 of 14, 86%) is performed. In this study, risk of visual field loss was more frequent if the retinotomy is relatively posterior (less than 5 disc diameters from fixation).<sup>202</sup> Although visual field loss may recover initially after retinal detachment repair, GVF perimetry has shown persistent decreased visual field following scleral buckle repair of retinal detachment despite continued improvement in visual acuity.<sup>203</sup> In a recent report, microperimetry used in conjunction with spectral domain OCT and FAF demonstrated good correlation of visual function with retinal morphology after rhegmatogenous retinal detachment repair.<sup>204</sup> Another study of six eyes with metamorphopsia after macula-involving retinal detachment repair found retinal sensitivity correlated with postoperative best corrected visual acuity.<sup>205</sup>

## Tumors

Retinoblastoma and choroidal melanoma are the most common malignant intraocular tumors in children and adults, respectively. Long-term visual field defects that correspond to tumor size, location, and treatment modality have been documented in eyes with retinoblastoma.<sup>206</sup> Anterior melanomas produce localized constriction of the visual field, whereas posterior melanomas produce dense scotomas with steep borders. Only a subtle field defect, if any, is associated with choroidal nevus. Thus, fields may be important in distinguishing between these entities.

Fig. 14.26 shows the Octopus visual field superimposed on the

fundus photograph of a patient with a small melanoma of the posterior pole. In this instance, loss of sensitivity is present only in the center of the mass. Use of a finer grid pattern would have facilitated a better correlation between the pathologic process and the degree of visual loss.

**FIG. 14.26** A fundus photograph of a patient with a small malignant melanoma of the posterior pole has been superimposed on the visual field obtained by Octopus perimetry. Because of the relatively coarse ( $6^\circ$ ) grid pattern of the perimeter, sensitivity is markedly reduced only at the center of the lesion.

(Reproduced with permission from Feldon SE. Computerized perimetry in selected disorders of the retina. In: Whalen WR, Spaeth GL, editors. Computerized visual fields: what they are and how to use them. Thorofare, NJ: Slack, 1985.)

Like melanomas, choroidal metastases also produce dense scotomas with steep borders. However, in a study by Rahhal and colleagues,<sup>207</sup> HVF depression does not consistently correspond with tumor size or location. The visual fields shown in Fig. 14.27 were obtained from a patient with breast carcinoma whose fundus photograph is shown in Fig. 14.28. This patient demonstrated not

only a dense inferonasal field defect corresponding to the choroidal metastasis, but also a bitemporal field defect. Subsequent CT scan demonstrated a suprasellar mass consistent with either a pituitary adenoma or metastasis (Fig. 14.29).

**FIG. 14.27** Octopus perimetry (program 32) on the same patient as in Fig. 14.28. An inferonasal field defect in the right eye corresponds to the choroidal metastasis. There is also an unexpected dense bitemporal hemianopsia. A computed tomographic scan was requested for further evaluation. (Reproduced with permission from Feldon SE. Computerized perimetry in selected disorders of the retina. In: Whalen WR, Spaeth GL, editors. Computerized visual fields: what they are and how to use them. Thorofare, NJ: Slack, 1985.)

**FIG. 14.28** A 50-year-old patient with known breast carcinoma is referred for evaluation of a mass in the posterior pole of the right eye. The visual fields are shown in [Fig. 14.27](#). (Reproduced with permission from Feldon SE. Computerized perimetry in selected disorders of the retina. In: Whalen WR, Spaeth GL, editors. Computerized visual fields: what they are and how to use them. Thorofare, NJ: Slack, 1985.)

**FIG. 14.29** Computed tomographic scan from the patient whose visual field and fundus photograph are shown in Figs 14.27 and 14.28. A suprasellar mass is shown that is consistent with either pituitary tumor or metastasis. (Reproduced with permission from Feldon SE. Computerized perimetry in selected disorders of the retina. In: Whalen WR, Spaeth GL, editors. Computerized visual fields: what they are and how to use them. Thorofare, NJ: Slack, 1985.)

## Future of Perimetry in Retinal Disease

### Layer-by-Layer Perimetry

Enoch, along with his collaborators Lawrence, Fitzgerald, and Campos,<sup>208–210</sup> developed a clinical perimetric technique emphasizing the detection of a small luminous spot in a stationary (sustained) or flashing (transient) surround, based on analogies with the neural processing of the inner versus outer retinal layers. Graded or “sustained-like” electrical responses are obtained from the retinal receptor, bipolar, and horizontal cells. Transient or “spike” impulses are recorded from amacrine and ganglion cells. Enoch and colleagues investigated layer-by-layer perimetry in diabetic retinopathy, macular drusen, macular degeneration, and angioid streaks. However, layer-by-layer perimetry has not gained clinical acceptance. The relationship between retinal function and the testing parameters of this modality remains unconfirmed.

### Color Perimetry

Assessment of color vision may be helpful in screening for retinal disease and in separating neural from retinal causes of visual loss. Acquired diseases of the retina and choroid typically produce a tritan-like pattern of color confusion, and neural diseases typically produce a protan or deutan-like pattern of color confusion on Farnsworth–Munsell 100-hue discrimination testing.<sup>211</sup> Thus color perimetry might be used to advantage in the identification and quantitative description of certain retinal and choroidal diseases. Although color contrast might be more sensitive in finding visual

field defects, Hart and Burde<sup>212</sup> demonstrate that colored test objects used in standard techniques of perimetry may be of little clinical value over small or low-contrast white test objects for detecting scotomas in a number of optic nerve and retinal disorders. Currently there are no commercially available, standardized color perimeters.

## High-Resolution OCT and Adaptive Optics With Microperimetry

Although innovative, both layer-by-layer and color perimetry do not appear to add new scientific or clinical information relevant to the etiology, localization, or treatment of retinal diseases beyond already available more standard clinical tests such as electroretinography, electrooculography, contrast sensitivity, and fluorescein angiography. Anatomical imaging of the retina at the ultrastructural level has advanced to a high degree of sophistication, allowing correlations of structure and function at the microscopic level. Hopefully, these new research strategies will result in clinical applications that will allow earlier detection and treatment of potentially debilitating and widely prevalent retinal diseases such as AMD.

The combined spectral domain OCT and SLO, introduced in 2006 (Spectral OCT/SLO; OPKO/OTI, Miami, FL, USA) is a significant achievement in advancing retinal imaging. The enhancement in accurate and real-time image capture with this system allows for integration with microperimetry. Thus, a functional spectral OCT/SLO allows assessment of retinal morphology and function at specific retinal loci. Landa and colleagues<sup>13</sup> demonstrated the effectiveness of a three-dimensional spectral OCT/SLO topography and microperimetry in assessing functional and structural changes of the macula in a variety of retinal disease, including AMD and cystoid macular edema. Continued refinement of this functional imaging modality is expected to allow for better detection and monitoring of retinal disease.

Adaptive optics imaging of cones and other ultrastructural elements of the retina combined with ultrafine microperimetry shows promise in pinpointing finite areas of decreased retinal

sensitivity. The ability to resolve cones and rods through adaptive optics allows for the reduction in the size of retinal image and, hence, the number of photoreceptors stimulated by adaptive optics microperimetry. Using microflashes in a patient with a genetic mutation for a cone photopigment and no clinical visual deficits, Williams and colleagues at the University of Rochester detected retinal microscotomas representing early cone photoreceptor loss.<sup>213</sup> In addition, Roorda and colleagues<sup>14</sup> demonstrated correlations between healthy and unhealthy RPE and microperimetry retinal sensitivity in patients with maculopathy and normal visual acuity. The precision of testing cellular function in the retina with this modality highlights its ability to detect early loss of function of a few photoreceptors. As this focal loss of retinal function is clinically compensated by the redundancy in the visual system, it is not noticed by patients or captured by standard perimetry and visual acuity tests. Detecting very early functional and structural pathology at the photoreceptor level before its clinical manifestation would allow for a better understanding of early pathophysiology and disease course. With this knowledge, refined screening algorithms and timely interventions for vision-threatening retinal disease might be developed.

## Tele-Perimetry

Ophthalmology has not been excluded from the widespread use of smartphones and tablets over the last decade. A recent poll<sup>214</sup> indicated that 83% of ophthalmologists utilize smartphones for work. Various applications on handheld devices allow for easily accessed qualitative and quantitative visual field assessment, such as Amsler grid, tangent screen, and perimetric testing. Rigorous testing of the quality and validation of the accuracy of these digital tests is needed. A recent study<sup>215</sup> of tablet-based perimetry utilized a free peripheral vision assessment software (Visual Fields Easy) in an underserved Nepali population. Results of the study suggest that such screening could be a viable method of detecting visual field loss in places without access to healthcare or computers. Concordance between tablet-perimetry and Humphrey SITA Standard 24-2 HVF occurred 51–79% of the time. Agreement was

highest in patients having moderate to severe visual field loss. Such a screening tool could be useful in high-risk groups like African Americans and the elderly.

## Conclusions

Achromatic and static SWAP provides a cost-efficient, standardized, and reliable way to evaluate and follow visual fields in patients with retinal disease. Microperimetry seems to be a valuable tool that has been used more frequently to quantify macular function in a variety of retinal diseases. As both simple and complex visual field testing applications become available for handheld computing devices, there will be a need for these formats to be carefully assessed and validated against the gold standards. The availability of new qualitative and quantitative visual field tests will continue to inform how retinal pathology and morphology impact functional vision, which is crucial in developing and delivering effective treatments for retinal disease to preserve and restore eyesight.

## **Introduction**

Our understanding of the mechanisms by which the complex cellular assemblies of the retina develop has increased tremendously in the past 20 years. The growth of information in this field has been stimulated by the increasing use of molecular

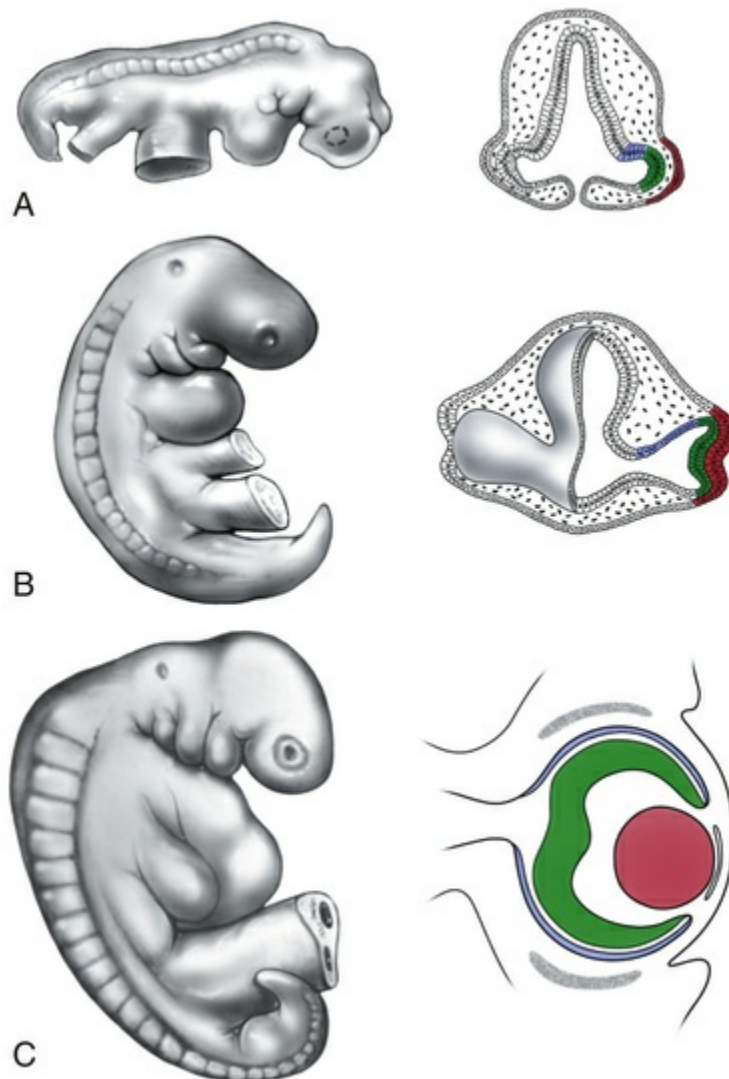

genetic methods and the identification of the genes that control eye development in a variety of species. This chapter provides an overview of the basic principles of retinal development that have been known for some time and then highlights recent data that have significantly extended these principles. It is impossible to present a comprehensive review of this dramatically expanding field in this short a space, but I hope the reader will come to appreciate the complexity of the cellular and molecular interactions that generate this spectacular tissue.

## Embryology of the Eye

The development of the eye is an extremely complex process, each step of which requires exquisite coordination among the various tissues that contribute to it. As a result, examples of inductive interactions at precise times during ocular development are numerous. Thus it is not surprising that many teratogens disrupt these processes and lead to developmental abnormalities in eye formation. In addition, there are many congenital defects in eye formation that are caused by mutations in genes critical for different stages in the process.

The retina is first recognized as the optic pit in the anterior neuroectoderm at day 23 of gestation;<sup>1</sup> a few days later (day 25) the optic vesicle can be recognized as an evagination from the diencephalon of the neural tube (Fig. 15.1). The optic vesicles initially lie immediately adjacent to the ectoderm (Fig. 15.1), but then a layer of mesenchymal cells, derived from the neural crest, becomes interposed between the ectoderm and the vesicles. The neural crest cells that surround the developing optic cup, along with the periocular mesenchyme, contribute to many ocular tissues: the corneal endothelium, the choroid, the ciliary body and the retinal vasculature (including the hyaloid artery).<sup>2</sup> During the next stage of ocular development, the optic vesicle folds in on itself, becoming the optic cup, and the lens ectoderm invaginates into the vesicle (Fig. 15.1). The resulting two tissue layers of the optic cup are the outer presumptive retinal pigment epithelium (RPE) and the inner presumptive neural retina, with the lens vesicle filling much of the interior of the cup. In humans, these dramatic morphologic

changes occur at approximately 25–35 days of gestation. The optic stalk, connecting the developing retina with the diencephalon, will form the scaffold for the growing axons of the optic nerve. The developing optic cup grows around the stalk from the dorsal sides, fusing to form the ventral (or embryonic) fissure. This fissure “closes” at day 33 in the human embryo, and incomplete closure of the fissure occurs from mutations in several different genes leading to colobomas (Table 15.1). The hyaloid artery, the major source of blood for the embryonic retina and lens, enters the eye through the ventral fissure. The hyaloid artery regresses by birth, but the central retinal artery remains. Incomplete or delayed regression of the hyaloid artery can lead to vitreal hemorrhage, and studies in mice have implicated the gene *Norrin* in this process.<sup>3</sup>

**FIG. 15.1** The retinas develop as paired evaginations from the anterior central nervous system. (A) At stage 11 (13–20 somites in humans), the optic vesicles are continuous with the ectoderm near the point of closure of the anterior neuropore. (B) By postovulatory day 26, stage 12, the neuropore has closed and continued rostral growth of the prosencephalon now results in a relative caudal displacement of the vesicles. At this time the presumptive neural retina (*green*) is in close contact with the lens ectoderm (*red*), the ventral part of the optic vesicle contributes to the optic stalk, and the dorsal region of the optic vesicle gives rise to the pigmented epithelium (*blue*). (C) By stage 15, 34 postovulatory days, the lens vesicle has completely formed, and the neural retina and pigment epithelial layers are distinct.

**TABLE 15.1**

**Key Stages of Retinal Development, Genes Associated With Those Stages, and Clinical Conditions Resulting From Their Mutations**

Age	Stage	Genes	Phenotype
3–4 weeks	Optic pit; vesicle	<i>Pax6, Sox2, Rax, Shh, Six3, Bmp7</i>	Anophthalmia
5 weeks	Optic cup patterned into RPE and neural retina	<i>Vsx2, Bcor, Maf, Pax2, Bmp4</i>	Microphthalmia
5.5–6 weeks	Neurogenesis Choroidal fissure closure	<i>Zfmx1b, Vsx2, Bcor, Maf, Pax2, Vax2</i>	Microphthalmia, coloboma
8–30 weeks	Neural retina histogenesis	<i>Aipl1, Crx, Crb1, RPE65, Gucy2d, Rpgrip</i>	Leber congenital amaurosis

RPE, retinal pigment epithelium.

## The Eye Field

Although the eye is first apparent as it evaginates from the diencephalon, this region of the embryo is already specified to give rise to the eye some time earlier.<sup>4</sup> Since much of the experimental embryology of the developing eye has been carried out in frog and chick embryos, most of the information on this process is derived from these species; however, it is likely that the process of eye development has been largely conserved throughout vertebrate

evolution, and most of what has been learned from other species is likely to be true of human eye development as well. During gastrulation, the process known as neural induction transforms a region of ectoderm into the precursors of the central nervous system (CNS), called the neural plate. Even at these early times in development, the anterior region of the neural plate is specified to give rise to the retina. This region is called the eye field. Indelibly labeling the cells in the eye field of the neural plate with vital dyes allowed embryologists of the 1920s to track the cells as they developed into the neural retina and pigmented epithelium. Additional evidence that the eye field cells were specified to produce eye tissue came from transplantation studies of these cells to ectopic locations, such as the trunk or tail of other embryos; ectopic eyes formed from the transplanted cells. In situ hybridization studies to localize these genes have shown that genes that are critical to eye development are expressed in the eye-forming regions of the neural plate before any clear morphologic differentiation into retinal structures (see below).

What makes the eye field cells capable of generating retina? In part, the eye-forming character of these cells comes from their expression of a group of proteins, called the eye field transcription factors (EFTFs), which bind to DNA and selectively activate genes important for eye development.<sup>5</sup> Among the first of these transcription factor genes to be expressed in eye development is *Pax6*. *Pax6* codes for a transcription factor that is a member of the paired class of homeodomain proteins. Transcription factors of this class are expressed very early in the development of many tissues and appear to be involved in controlling the identity of the various regions of the embryo. *Pax6* is expressed in the eye field, and continues to be expressed by both the optic vesicle and the developing lens. Mutations in this gene cause a phenotype in mice characterized by small eyes and aniridia in humans.<sup>6</sup> The homologous gene in *Drosophila*, called *eyeless*, is necessary for eye development in these animals as well.<sup>7</sup> Remarkably, misexpression of the *eyeless* gene in the larval tissue that normally gives rise to the leg causes ectopic eyes to form on the leg in the adult fly.<sup>8</sup> This result has led to the proposal that *Pax6/eyeless* is a master control gene, responsible for activating the other genes necessary for eye

development.<sup>9</sup>

More recent data have shown that *Pax6* is only one of many homeodomain proteins that are important for normal eye development in both vertebrates and invertebrates. The coordinated actions of these genes together contribute to the formation of the cells of the neural retina. These can act both as multimeric complexes and/or as part of a hierarchical pathway (Fig. 15.2). One of the key transcription factors, *Rx* (*RAX* in humans), for example, is necessary for the very earliest stages of eye formation, and targeted deletion of this gene in mice blocks eye development almost completely.<sup>10</sup> *Rx*, then, is close to the beginning of the cascade of the EFTFs. When *Rx* is expressed in retinal precursors, it then activates the transcription of *Pax6*, which then turns on many of the other EFTFs. Experimental misexpression of each of the different EFTFs can produce some ectopic eye-like structure, but coordinated misexpression of the EFTFs together (*Pax6*, *Rx1*, *Six3*, *Six6*, *Lhx2*, *Nr2e1*, and *Tbx3*), along with the anterior patterning gene *Otx2*, is sufficient to induce ectopic eye fields and eyes in amphibia at a high frequency even in nonneural regions of the animal like the belly. These experiments in frog embryos, along with others in mice, have led to the current model that EFTFs cross-regulate one another in a feedforward manner.<sup>5</sup> The fact that similar genes are critical for eye development in both *Drosophila* and vertebrates, and that mutations in these genes lead to ocular malformations, has had a major influence on the understanding of the evolution of the eye.<sup>9</sup> Although the cellular components of eyes in the various phyla are quite different, the genes that may ultimately control the expression of the phototransduction machinery may have been shared by a common ancestor.

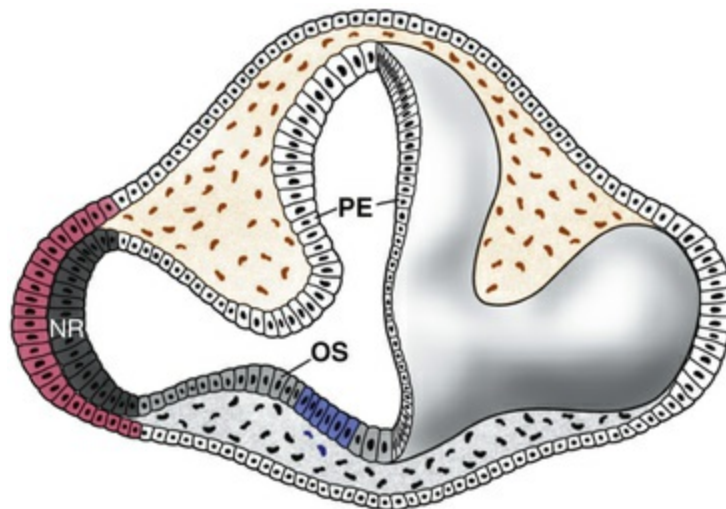

**FIG. 15.2** A network of transcription factors, in addition to *Pax6*, regulates the formation of the eye. Upper series of drawings show the neural plate stages of the *Xenopus* frog and the stages in eye field specification.

Drawings in the middle panel show the complex genetic regulatory network activated at the corresponding stages. See text for detailed descriptions of these genes. Lower panels show representative in situ hybridization for several of the eye transcription factors at the same stages as drawn above to show their localization in *Xenopus* embryos.

From left to right, the panels show *Otx2*, Stage 12; *Otx2*, Stage 13; *Otx2* (purple) and *Rx1* (red), Stage 13; and *Rx1* alone, Stage 13. (Modified with permission from Zuber ME, Gestri G, Viczian AS, et al. Specification of the vertebrate eye by a network of eye field transcription factors. *Development* 2003;130:5155–67.)

The eye field is originally continuous across the neural plate at its anterior end; however, this single field is soon split in two by a factor from the underlying prechordal mesoderm that lies immediately adjacent to the ventral midline of the neural plate. Deletion of the prechordal mesoderm results in the development of a single fused eye (cyclopia) at the ventral part of the diencephalon. The factor released by the prechordal mesoderm that suppresses

eye development in the middle of the field is thought to be a molecule called *Sonic hedgehog* (*Shh*), an extracellular glycoprotein important in several other inductive events throughout the embryo. *Shh* is released initially by the prechordal mesoderm and induces cells in the ventral diencephalon (Fig. 15.3) to produce the same factor.<sup>11</sup> This factor then acts on the neighboring cells of the ventral diencephalon to suppress eye development. Mice lacking the *Shh* gene die as embryos; nevertheless, these embryos develop to a stage where the paired optic vesicles would normally form. However, in animals lacking *Shh*, the eye field is not split at the midline and a single optic vesicle forms, resulting in cyclopia.<sup>12</sup> The conservation of these inductive signals in human development has been confirmed by the report that congenital holoprosencephaly, a condition that frequently displays varying ocular defects, including cyclopia, is caused by mutations in the *Shh* gene.<sup>12-14</sup>

**FIG. 15.3** Factors that pattern the embryonic diencephalon. *Shh* (blue) inhibits eye development in the ventral diencephalon, and fibroblast growth factor (red), in the ectoderm overlying the optic vesicle, promotes neural retinal development. *PE*, pigment epithelium; *NR*, neural retinal differentiation; *OS*, optic stalk.

## Patterning the Retinal, RPE, and

## Anterior Domains of the Optic Cup

The next stages of eye development in vertebrates also require a number of inductive interactions to coordinate the various tissues that ultimately contribute to the structure. Both the neural retina and the pigmented epithelium arise from the optic vesicle region of the neural tube. Although both are derived from the optic vesicle, these two tissues are quite distinct; the neural retina is a multilayered structure containing millions of neurons and photoreceptors, whereas the pigment epithelium is a single layer of nonneural, pigmented, cuboidal cells. The appropriate development of both of these two very different parts of the retina requires interactions with the adjacent tissues. If the optic vesicle is isolated from the surrounding epidermis and mesenchyme, differentiation is arrested at the optic vesicle stage and the eye does not form. Transplantation experiments in many species have shown that the developmental decision to develop as either a neural retinal progenitor or alternatively as a pigmented epithelial cell is regulated by factors in the microenvironment surrounding the eye. For example, if an optic vesicle is transplanted to a position in an embryo adjacent to the developing hindbrain, near the otic vesicle, a second neural retina is formed from the presumptive pigmented epithelial layer.

The distinction between the RPE and the neural retina comes about as a result of their expression of different transcription factors. The transcription factor *Vsx2/Chx10* specifies the neural retinal domain, while the basic helix–loop–helix (bHLH) transcription factor *Mitf* defines the RPE. Loss of *Mitf* leads to conversion of the RPE into a second layer of neural retina, whereas loss of function mutations in *Vsx2/Chx10* leads to a conversion of the neural retina into RPE (for review, see Fuhrmann<sup>15</sup>). *Otx2* is also required for RPE development, and expression of *Otx2*, along with the signaling molecule Wnt, can convert neural retina to RPE.<sup>16</sup> Along with these transcription factors, the specification of RPE is also controlled in part by soluble signaling molecules, which induce the outer region of the optic vesicle to adopt the pigmented cell fate instead of becoming retina. In particular, this mesenchymal tissue upregulates RPE-specific genes like *Mitf*, while downregulating

retina-specific genes. The transforming growth factor- $\beta$  (TGF- $\beta$ ) family member activin was able to mimic the effects of the extraocular tissue on the optic vesicle, which suggests an activin-like signal is required for normal RPE development.<sup>17</sup> Experiments in developing chick embryos have also implicated another TGF- $\beta$ -like signaling molecule, bone morphogenetic protein (BMP), in the process of RPE specification<sup>18</sup> and deletion of the *Bmp7* gene in mice leads to disruptions in ocular development. Another signaling molecule, *Shh*, introduced earlier in this review in the context of the eye field, is also involved in the induction of RPE cell fate in the ventral region of the optic vesicle, since inhibition of *Shh* signaling with cyclopamine in frog embryos disrupts ventral RPE development, and two strains of mice with altered *Shh* signaling do not develop ventral RPE.<sup>19</sup>

Signaling factors are also important in the specification of the neural retinal domain of the optic cup. Several lines of evidence support a critical role for fibroblast growth factor (FGF) in the development of the neural retinal part of the eye. First, FGFs are expressed in the lens ectoderm and the developing neural retinal domain.<sup>20,21</sup> Second, experimental treatment of the developing chick optic vesicle with exogenous FGFs or antibodies that block FGFs causes perturbations in the development of the retina. The optic vesicle of the chick embryo develops into an optic cup when isolated from the embryo and maintained overnight in culture. The addition of exogenous FGF to these optic vesicle cultures causes the presumptive pigmented epithelial layer to develop instead into a neural retina.<sup>21</sup> Antibodies raised against FGF cause the opposite effect and block neural retinal formation in similar optic vesicle cultures. Although it is not clear which FGFs are necessary in mammals for neural retinal specification, interruption of all FGF signaling by conditional deletion of a downstream factor in the FGF signal transduction pathway, *Shp2*, causes a loss in *Vsx2* expression and a transition of the affected region of the optic cup from neural retina to RPE.<sup>22</sup> These results are consistent with a model in which FGF promotes neural retinal specification in the optic cup, by promoting *Vsx2* expression, which represses expression or activity of *Mitf*. The outer part of the optic cup, the presumptive RPE, is then specified by *Shh*, Wnt and activin/BMP signaling, which

promotes *Mitf* expression to repress *Vsx2*<sup>15</sup> (Fig. 15.3).

## Histogenesis of the Retinal Cell Types

In the next phase of retinal development, the various classes of neurons are generated by cells that undergo repeated mitotic cell divisions. The mitotic progenitors have a relatively short cell cycle and are able to produce the hundreds of millions of cells in the human retina in a few months, from the 7th to the 24th week of gestation in humans. At the same time that many of the progenitors undergo symmetric cell divisions to enable the nearly exponential increases in cell numbers, some of the cell divisions of the progenitors result in postmitotic neurons throughout this period of histogenesis. The different types of retinal cells are not produced by the progenitor cells all at the same time. Rather they are generated in a sequence that has been conserved in all vertebrates. The sequence was first described using the <sup>3</sup>H-thymidine “birthdating” technique. Following an injection of <sup>3</sup>H-thymidine, the nucleotide is incorporated into the DNA of the retinal progenitor cells during the S phase of their cell cycle. Those cells that withdraw from the cycle after their next mitosis, and become postmitotic neurons/photoreceptors, retain a high level of label in their nucleus. Since the <sup>3</sup>H-thymidine is available for only a short period, those cells that remain in the cycle for additional cell divisions become progressively less heavily labeled. If the animal is allowed to survive to adulthood and the retina processed for autoradiography to reveal the label in the various retinal cells, those retinal cells that were generated on the day of the thymidine injection are easily identified by the large number of silver grains over their nuclei. In a typical thymidine birthdating study, injections of the nucleotide are made in pregnant animals on each day of gestation, and the number of labeled cells of the various retinal cell classes is calculated to produce a graph like the one shown in Fig. 15.4.<sup>23</sup>

**FIG. 15.4** (A,B) Each retinal cell type is generated over a slightly different time course during retinal histogenesis. Addition and integration of new cells during the histogenesis of the retina at three different ages, corresponding to the chart of thymidine birthdating of retinal cells in the monkey. *CON*, cones; *HOR*, horizontal; *PRO*, progenitor cells; *RGC*, retinal ganglion cell; *AMA*, amacrine; *MUL*, Müller; *BIP*, bipolar. (Panel B modified with permission from La Vail MM, Rapaport DH, Rakic P. Cytogenesis in the monkey retina. *J Comp Neurol* 1991;309:86–114.)

This type of thymidine birthdating analysis has been carried out in the retina in many different animals, and the sequence of cell generation is remarkably conserved among the various vertebrates. Fig. 15.4 shows the sequence of generation of the retinal cell classes in the monkey,<sup>23</sup> but a very similar graph can be produced in other vertebrates. Overall, the cell classes can be divided into two phases

of generation. In the first phase, the ganglion cells, the cones, and the horizontal cells are generated. In the second phase of histogenesis, the rod photoreceptors, the bipolar cells, and the Müller glial cells are produced by the progenitor cells.<sup>24,25</sup> Amacrine cells are primarily generated in the later phase, but many amacrine cells become postmitotic at the same time as ganglion cells are generated, so these cells do not fall as neatly into one or the other phase. Despite this seeming regularity in histogenesis, it should be noted that there are distinct central-to-peripheral gradients of histogenesis, and that peripheral retina may still be in the first “phase” at the time central retina is generating later cell types.

Even though the retinal cell types are generated in a defined sequence, multiple different types of neurons are produced at any given time in development; this has led to the current model in which the progenitors are multipotential, and can generate many different types of retinal neurons up to and including their final mitotic cell division.<sup>26,27</sup> Several methods have been developed for tracing the lineage of individual retinal progenitor cells: (1) retroviral infection of progenitors with a virus containing a reporter gene;<sup>26,27</sup> (2) direct injection of progenitors with a cell-impermeant dye;<sup>28,29</sup> (3) genetically inducing a lineage marker into specific types of progenitors based on their gene expression.<sup>30,31</sup> These methods all show that many of the mitotic progenitor cells can produce various, somewhat random mixtures of the different retinal cell classes; however, they also show that in some cases progenitors can generate only a subset of the different types of retinal cell types; for example, the progenitors that express the transcription factor *Ascl1* can produce all the different types of retinal cells except ganglion cells.<sup>30</sup>

The sequential development of the different retinal cell types has led several investigators to propose that the production of one cell class induces the progenitor cells to make the next cell type in the sequence. For example, the retinal ganglion cells, being generated first by the progenitor cells, might secrete a substance that prevents additional cells from differentiating into this fate, and at the same time instructs the progenitor cells to begin making the next cell type, the horizontal cells; the horizontal cells would then secrete a factor that instructs the progenitor cells to make cones, and so on

until all the retinal cell types have been generated. Cell culture studies have provided some support for this model: when progenitor cells from the retina are isolated from early stages of retina, they predominantly differentiate into retinal ganglion cells.<sup>32</sup> However, if these same early progenitor cells are mixed with retinal cells from later stages of development, presumably containing factors derived from the cell types generated later, the early progenitor cells will be biased to adopt later cell identities.<sup>33–35</sup> Thus the type of cell that the progenitor will produce at any particular time in development can be influenced by factors produced by the neighboring cells. There is also in vivo evidence in mice that cell-type specific feedback mechanisms control the relative ratios of retinal cells: the signaling factor *Shh*, mentioned earlier in the development of the eye field, is also expressed in the retinal ganglion cells, and this factor alters the rate of proliferation of the progenitors and their cell cycle exit, thereby controlling the addition of new ganglion cells.<sup>36</sup> However, while there appear to be feedback mechanisms within cell types for controlling their numbers, elimination of ganglion cells does not appear to affect the development of the other retinal cells drastically,<sup>37</sup> and so the evidence to date supports regulation within cell types rather than between cell types.

There is also considerable evidence that the production of the different retinal cell types from a common precursor is due to a progressive change in the progenitor cell competence, like a clock ticking through the different cell fates.<sup>38,39</sup> In this model the retinal progenitor cells change over development in the cell types they are competent to give rise to. First, the default state, as discussed above, is the retinal ganglion cell. Next, the progenitor cells shift their competence so that they are more likely to produce horizontal cells, then cone photoreceptors, and so on. A cascade of transcription factors might be responsible, with the first one setting in motion the mechanism for the production of the second, which acts to produce a third transcription factor, and so on. Recent data have shown that miRNAs are necessary in this process. Deletion of the gene that codes for the enzyme Dicer, needed to produce mature miRNAs, causes the progenitors to be “stuck” in the early state, and only generate early cell fates, like ganglion cells, cones, and horizontal

cells.<sup>40,41</sup> Three miRNAs, let7, miR-125 and miR-9 are particularly important in controlling the changing competence of the retinal progenitors.<sup>41</sup>

As the different types of retinal neurons begin their differentiation, several transcription factors are critical for the various cell fates. One transcription factor expressed by progenitors that controls the types of cells that are generated is *Pax6*. Although mutations of the *Pax6* gene cause early defects in eye development (see above), it has been possible to delete the gene specifically from the retinal progenitors at later stages of development. This leads to a loss of competence in the progenitor cells to generate anything except amacrine cells.<sup>42</sup> Deletion of a different transcription factor, *FoxN4*, produces the complementary result: all cell types develop normally, except amacrine cells.<sup>43</sup> The combination of *FoxN4* and *Pax6* is therefore able to confer progenitors with competence for all retinal cell fates. Other transcription factors that are expressed in progenitors or newly produced neurons play important roles in the production of cell diversity and/or the maintenance of this diversity as the neurons acquire their differentiated fates. For example deletion of the proneural gene *Atoh7* (*Math5*) leads to a dramatic failure in ganglion cell production;<sup>44</sup> the gene *Otx2* is expressed in the newly developing photoreceptors and genetic deletion of this gene specifically in the retina prevents the progenitors from producing photoreceptors, and instead they produce more amacrine cells,<sup>45-47</sup> the transcription factors *Ptf1a*, *NeuroD1*, and *Math3* are expressed in amacrine cells, and loss of one or more of these genes causes a loss in amacrine cells in the developing retina;<sup>48</sup> deletion of the *Nrl* transcription factor causes all the rods to develop as short-wavelength sensitive cones instead;<sup>49</sup> mutation in the paired-homeodomain gene *Chx10/Vsx2* leads to an absence of most bipolar cells;<sup>50</sup> elimination of the transcription factor *Prdm1/Blimp* causes the photoreceptors to become bipolar cells instead;<sup>51</sup> deletion in the *Ascl1* gene, another bHLH transcription factor, leads to an increase in the production of Müller glia at the expense of late-generated retinal neurons, like bipolar cells and rods.<sup>52-54</sup> Putting all these molecular interactions into a coherent network model has yet to be accomplished; moreover, integration of these transcriptional regulators with the miRNAs and signaling

factors remains a challenge.

Several cell classes that are resident in the retina are not derived from the progenitor cells in the ventricular zone, including the microglia, vascular endothelial cells, and retinal astrocytes. Microglia in the retina, like microglia elsewhere in the CNS, are derived from the blood; monocytes enter the retina through the vascular endothelial cells and become “ameboid” in morphology.<sup>55,56</sup> These highly motile, phagocytic cells digest those retinal cells that undergo apoptotic cell death (see below) during the course of retinal development. When they are first observed in development, they are concentrated in the ganglion cell layer (GCL), presumably as a result of the large number of degenerating cells in that layer. Later in development, when other types of retinal cells undergo apoptosis, microglia are found in the inner nuclear layer (INL) and outer nuclear layer (ONL). A second type of glial cell that is present in the mature retina is the astrocyte. These cells form from ventricular zone cells in other areas of the CNS, but they are not generated by the retinal progenitors; instead, the retinal astrocytes migrate along the developing optic nerve and enter the retina at the optic nerve head. The vascular endothelial cells emerge from the same point, and both the astrocytes and the endothelial cells migrate across the retinal surface, eventually covering it completely.<sup>57,58</sup>

## Inner Retinal Development

The further development of the inner retina follows a sequence similar to that described in other areas of the developing CNS. Immediately after their final mitotic division at the ventricular (scleral) surface, retinal cells migrate to their appropriate lamina. As they migrate, the different types of neurons begin to take on some morphologic features of their characteristic cell type. For example, ganglion cells begin to elongate an axon from their basal/vitreous process before their soma reaches the GCL.<sup>59,60</sup> The next phase in the differentiation of retinal neurons is the growth of dendritic processes. In the last stages of differentiation the retinal neurons make functionally active synapses with one another and express their transmitters and receptors. Although the time course of these

events overlaps considerably, this sequence is typical of most classes of retinal cells.

The development of the inner retina is led by the differentiation of the retinal ganglion cells. The morphologic development of retinal ganglion cells has been well characterized in several species, including primates, and is known to proceed through a characteristic sequence.<sup>61,62</sup> The first phase of ganglion cell morphogenesis begins as soon as the cells complete their final mitotic division at the ventricular surface of the developing retina. The vitreal process begins to resemble an axon, which extends toward the optic disc even before the migration of the cell soma from the ventricular surface. The cell soma then migrates to the vitreal surface of the retina. The molecular mechanisms that underlie ganglion cell migration are not understood; nevertheless, the laminar structure of the retina is likely the result of the selective migration and specific adhesions among the different types of retinal cell. Selective adhesive interactions are mediated by cell adhesion molecules (CAMs). It has been known for some time that interfering with CAM function, particularly the molecule known as N-cadherin, causes a disruption of the normal lamination pattern in the retina.<sup>63</sup> Although interfering with CAM function leads to a disruption in the lamination of the retina, it is still not well understood how these relatively nonselective molecules direct the particular retinal cell types to their appropriate laminae. In the developing cerebral cortex, newly generated neurons migrate to their destinations along radially arranged glial cells that span the expanding neural tube from the ventricular surface at the core of the brain to the external surface. Several different molecules have been identified that are critical in this migration, including adhesion molecules that mediate the selective attachment of the migrating neurons to the glial scaffold.<sup>64</sup> Although similar molecules may be expected to mediate the migration of ganglion cells in the retina, there is little evidence for the presence of radial glial cells in the developing retina. Müller cells could provide such a scaffold; however, these cells have not yet been generated at the time of ganglion cell migration (see above). Although some reports using ultrastructural criteria have claimed that Müller cells are present in the developing retina before they have been birthdated by

thymidine, extensive serial section reconstructions by Hinds and Hinds<sup>59</sup> failed to find any evidence for radial glial cells during the period of ganglion cell genesis. Therefore it is likely that the newly generated ganglion cells use the other retinal progenitor cells as their scaffold for migration. In fact, more recent evidence in the cerebral cortex indicates that the radial glial cells are in fact progenitor cells, consistent with the possibility that migrating neurons in the retina use the progenitors to guide their migration.

In the next phase of ganglion cell development, the cells extend dendrites to form the inner plexiform layer (IPL). These first dendrites are very simple, no more than a single primary large filopodial process, with growth cones at their ends. Ganglion cells next elaborate their dendritic arbors. The complex arbor emerges rather quickly. For many ganglion cells, the dendritic arbors initially span the entire width of the IPL, with numerous secondary and higher-order branches; however, in at least one type of ganglion cell, the cells have laminar subspecificity from the outset.<sup>65</sup> In fact, the arbors have more higher-order branches than adult ganglion cells. As the ganglion cells mature, the dendritic arbor is remodeled; the dendritic processes become restricted to a single sublamina of the IPL, depending on whether the ganglion cell will become an ON or OFF type, and the numerous tertiary processes regress. After the active phase of ganglion cell dendritic growth, the total extent of the dendritic field continues to expand, most likely as the result of the passive stretching of the retina with the continued growth of the eye.

What factors determine the extent and shape of the ganglion cell dendritic arbors? As the ganglion cells begin to send out dendrites, the amacrine cells are migrating to the inner nuclear layer; the processes of these two cell types grow on one another to begin the IPL. The dendritic arbors of ganglion cells are in part regulated by the same CAMs that mediate the lamination of the cells themselves. Kljavin et al.<sup>66</sup> cultured retinal ganglion cells on substrates of purified CAMs and found that cells grown on NCAM, L1, or N-cadherin developed distinctly different morphologies from one another. Those cells grown on N-cadherin developed a highly branched morphology most similar to that observed in vivo, whereas the cells grown on L1 developed simpler, axon-like

processes. However, these generic CAMs cannot provide the degree of specificity characteristic of the retina. To generate the sublaminae specificity, for example, at least two other types of molecule are required. Several members of the immunoglobulin superfamily of adhesion molecules (Dscam [Down syndrome CAM], Dscam1, Sidekick-1 and Sidekick-2) are required in chick retina to define the sublaminae in the IPL<sup>67</sup>; however, in the mouse retina, loss of Dscam does not interfere with sublaminae specificity. Instead, in the mouse retina, molecules known to be critical for axonal pathfinding in the CNS (Sema6A and PlexinA4) are required for sublaminae dendritic stratification of at least some types of ganglion cell and amacrine cell.<sup>68</sup> Sema6A and PlexinA4 have complementary expression patterns in the sublaminae of the IPL (Fig. 15.5B), and mice with PlexA4 knocked out have a defect in the correct sublaminae specificity of the dendrites of some types of retinal neurons; Fig. 15.5 shows the effects of loss in PlexA4 on the dendrites of the tyrosine hydroxylase-expressing dopaminergic amacrine cells. In chick retina laminae specificity of dendrites also depends on contactins, and at least five different members of this family of adhesion molecules are differentially expressed by subsets of amacrine cells. Altogether, these data indicate a growing list of candidate adhesion molecules that form an Ig-superfamily code for laminae-specific connectivity in the IPL.<sup>69</sup>

**FIG. 15.5** The tiling and lamination of dendrites are regulated by specific cell adhesion molecules. (A, left) Midget ganglion cell mosaic of human retina shows a highly regular distribution, and their dendritic arbors show no overlap. (A, right) In *Dscam* knockout mice the ganglion cells no longer tile evenly, but have fasciculated dendrites, and their cell bodies (*green*) form large clumps. (B, left) *Sema6A* (*green*) and *PlexinA4* (*red*) have complementary expression patterns in the sublaminae of the inner plexiform layer. (B, right) Tyrosine hydroxylase (TH)-expressing dopaminergic amacrine cells (*green*) in *PlexA4* knockout mice send dendrites into the wrong sublamina. (Panel A left, modified with permission from Dacey DM. The mosaic of midget ganglion cells in the human retina. *J Neurosci* 1993;13:5334. Panel A right, modified with permission from Fuerst PG, Bruce F, Tian M, et al. *DSCAM* and *DSCAML1* function in self-avoidance in multiple cell types in the developing mouse retina. *Neuron* 2009;64:484–97. Panel B, modified with permission from Matsuoka RL, Nguyen-Ba-Charvet KT, Parray A, et al. Transmembrane semaphorin signaling controls laminar stratification in the mammalian retina. *Nature* 2011;470:259–63.)

In addition to their laminar specificity, a number of studies in many different species have shown that the dendritic arbor of each

subclass of ganglion cells “tiles” the retinal surface.<sup>70</sup> Interactions among the ganglion cells control the extent of coverage of the dendrites of the various ganglion cell classes. When a region of the retina is experimentally depleted of ganglion cells, the neighboring cells will sprout dendrites into the depleted areas and thereby expand the size of their arbors considerably. In addition, when the density of ganglion cells is increased by monocular enucleation before the period of normal cell death (see below), the ganglion cells have smaller dendritic fields.<sup>71</sup> Although these data demonstrate that size of the dendritic arbor of a ganglion cell is determined by cell–cell interactions, the nature of the interactions is not clear. The ganglion cells could be competing for some dendrite-promoting factor derived from the amacrine cells, so when fewer ganglion cells are present, they can get more of the factor. Alternatively, the ganglion cells may intrinsically extend exuberant dendrites, but their growth may be limited by a phenomenon known as contact inhibition, in which a direct contact between two cells leads to the cessation of process extension because of the collapse of their growth cones. Some evidence for this latter mechanism has been provided from an analysis of the *Dscam* and *Dscaml* mouse mutants. As noted above, although these molecules are not required in mouse for sublaminar specificity, they do appear to be critical for the phenomenon of tiling of the dendrites and cell bodies via “self-avoidance.” In *Dscam* knockout mice (Fig. 15.5) the ganglion cells had fasciculated dendrites, and their cell bodies formed large clumps, instead of being spread out evenly across the retinal surface.<sup>72</sup>

The further development of the plexiform layers is a reflection of the dendritic growth and the synapse formation of the various types of retinal cell. As they mature, the bipolar cells begin to produce dendritic arborizations that can form synaptic connections with the ganglion cells. As noted above, the IPL develops before the outer plexiform layer in all species that have been studied. In most mammals, conventional synapses, between amacrine cells and ganglion cells, develop before the ribbon synapses between bipolar cells and ganglion cells. This sequence parallels the sequence of generation of these cell types, since the amacrine cells are born before the bipolar cells in vertebrate retinas. In addition, these first

synapses apparently mediate horizontal interactions among the cells of the inner retina that are important for the development of the appropriate pattern of connections between ganglion cells and their targets. Studies by Wong and collaborators in the ferret have shown that waves of activity are spread among the retinal ganglion cells through synapses in the inner retina before most of the bipolar cells have even been generated.<sup>73</sup> Thus the flow of information in the developing retina is initially horizontal and only later develops the predominantly vertical flow of information characteristic of the mature retina.

An exception to this pattern is found in the primate fovea, where there are virtually no rods at any time in development. In the fovea the first synapses observed in the IPL are the ribbon synapses between bipolar cells and ganglion cells.<sup>74</sup> In the monkey fovea, ganglion cells are born as early as 30 days of gestation, but bipolar and amacrine cells are not generated until approximately 1 week later, at E38. As described above, ganglion cells have primitive dendrites at E55, and the first synapses in the foveal IPL can be morphologically identified at this same time, approximately 2 weeks after the bipolar cells were generated. Thus in the primate fovea the vertical flow of information appears to be in place before the conventional synapses among ganglion cells and amacrine cells. This is not true of peripheral retina in the primate, where the typical mammalian pattern characteristic of rod-dominated retinas is observed. Since the connections among the ganglion cells and amacrine cells in immature retina are thought to contribute to the coordinated bursts of ganglion cell activity required for appropriate retinogeniculate connections, there may be differences in the mechanisms by which the connections from foveal ganglion cells are specified.

The development of functional circuits among the retinal cells requires synaptic transmitters and their receptors to be expressed in the appropriate cells (for review of synaptic development in the retina, see Bleckert and Wong<sup>75</sup> and Yoshimatsu et al.<sup>76</sup>). In fact, the major neurotransmitters of the retina – glutamate, gamma-aminobutyric acid, and glycine – are all localized to specific retinal neurons before development of morphologically identifiable synapses. In addition, both ligand-gated and voltage-gated

channels are present in retinal cells soon after they have been generated by the progenitor cell. For example, ganglion cells in the mouse have Na<sup>+</sup>, K<sup>+</sup>, and Ca<sup>2+</sup> channels as early as E15, only a few days after birth. The fact that these very immature neurons have both neurotransmitters and receptors allows for these molecules to act as signals to shape the development of the circuit. Although genetic suppression of bipolar cell transmitter release in mice does not affect the gross dendritic morphology of the ganglion cell dendrites,<sup>77</sup> neurotransmitters may be more important in shaping the dendrites in the outer retina (see below).

## Photoreceptor Development

When photoreceptors are first recognizable by their opsin immunoreactivity or mRNA expression, they have a very simple morphology and no outer-segment formation. Fig. 15.6 shows the simple morphology of the early differentiating cones in the monkey retina. In all vertebrates the cone photoreceptors are generated before the rod photoreceptors (see above); however, the rod photoreceptors express their specific opsin before the cones do.<sup>78,79</sup> Thus at least this aspect of rod differentiation proceeds more rapidly than that of cones. The monkey has been a particularly favorable species to study the normal pattern of photoreceptor differentiation, owing to the relatively long time course of retinal development in this species and the fact that the rod-dominated retinas of most other mammals have relatively few cones. The foveal cones of the rhesus monkey are born between gestational days E38 and E50 and first make synapses in the outer plexiform layer by E55. Thymidine birthdating studies indicate that the first foveal cones are generated on fetal day 38 (see above) but do not express their specific opsin until several weeks later at fetal day 75, well after the cones have differentiated to the point of making synaptic connections with bipolar cells (E55). This delay is a general feature of photoreceptor development in vertebrates and suggests that the factors that control opsin expression act at a later time than the factors that direct the retinal progenitor cells to the photoreceptor cell fate.

**FIG. 15.6** L/M and S cones in the fetal monkey retina. (A) Double-labeled immunohistochemical staining of a fetal day 108 parafoveal retinal section; L/M cones appear green and S cones appear red. (B) The distribution of the different types of cones across the retinal surface as a function of age. *F*, fovea; *Fwk*, fetal week. (Panel A, reproduced with permission from Burnsted K, Jasoni C, Szel, et al. *J Comp Neurol* 1997;378:117–34. Panel B redrawn with permission from Xiao M, Hendrickson A. Spatial and temporal expression of cone opsins during monkey retinal development. *J Comp Neurol* 2000;425:545–59.)

The factors that control the mosaics of cell differentiation alluded to above must also be at work in the development of the cone

mosaics. In the primate fovea the cones expressing the S (short-wavelength) opsin and those expressing the long- and middle-wavelength opsins (L/M) both are distributed in regular mosaics. In both primates and mice, the S-opsin-expressing cone photoreceptors emerge first in development.<sup>78</sup> Fig. 15.6 shows the progression of S-opsin expression from the central to peripheral retina in monkey retina. Once the S opsin cones have covered a relatively large fraction of the retinal surface, the L/M opsin cones begin their development in central retina.<sup>80</sup> The L/M opsin cone wave of development then follows that of the S opsin cones from the central retina to the periphery.<sup>81,82</sup>

Emerging evidence suggests that photoreceptor differentiation is controlled by transcription factors that promote a progenitor cell to become a photoreceptor progenitor, then either a protocone or protorod, and then further to a specific type of cone. At each stage, a different transcription factor seems to control the competence of the protophotoreceptor in its fate choices. The homeodomain transcription factor *Otx2* is the earliest factor biasing progenitor cells to become photoreceptor.<sup>45,46</sup> Conditional knockout studies show that photoreceptors do not develop in *Otx2*<sup>-/-</sup> retinas, and retroviral gene transfer of *Otx2* into retinal progenitors biases cells to become photoreceptors. *Otx2* also activates transcription of cone-rod homeobox gene (*Crx*), which is also required for expression of many photoreceptor-specific genes, including the opsins.<sup>83</sup> *Otx2*-positive *Crx*-positive protophotoreceptors then must choose to become rods or cones, and this decision is made by expression of neural retina leucine (*Nrl*) zipper transcription factor. *Nrl* expression promotes rod cell fate and inhibits cone cell fate. *Nrl*<sup>-/-</sup> retinas do not develop rods, but have many more cones than normal.<sup>49</sup> Photoreceptor progenitors not expressing *Nrl* become cones. Interestingly, the choice of cone subtype is determined by yet another transcription factor, *thyroid hormone receptor-β2* (*TRβ2*) and *RXR-gamma*,<sup>84,85</sup> which promote M-opsin expression while inhibiting the expression of S opsin. Mice deficient in the *TRβ2* gene have no M-opsin-expressing cones, but rather have only S opsin cones.<sup>86</sup>

A number of studies have used in vitro techniques to identify the factors that control photoreceptor differentiation during retinal

development. Since many of these studies have been carried out in rodents, and since rodent retinas have relatively few cones, most of the *in vitro* studies have concentrated on rod photoreceptor differentiation. The finding that rod photoreceptors do not differentiate in low-density cell cultures, but do so readily in high-density cultures or retinal explants, led to the development of several *in vitro* assays for rod differentiation factors and the identification of several signaling molecules that promote rod photoreceptor differentiation *in vitro*.<sup>87</sup> These factors are now being used to promote photoreceptor development in cultures of embryonic stem cells.<sup>88-91</sup>

The development of the outer plexiform layer and synapses between the photoreceptors, horizontal cells, and bipolar cells lags behind that of the IPL. There is good evidence that the dendrites of the cells are regulated through interactions with one another. For example, the dendritic branching of horizontal cells depends on the ratio of rods to cones. In mice, reducing cone number during development causes an increase in horizontal cell dendritic branching. The formation of ribbon synapses, specialized synaptic structures between rod and cone pedicles and horizontal cell and bipolar cell dendrites, is also dependent on the activity of the cells: inhibition of phototransduction in cones forces the cone bipolar cells instead to make synapses with rods.<sup>92</sup> Blocking transmitter release in rods causes rod bipolar cells and horizontal cells to send aberrant processes into the ONL<sup>93,94</sup> and synapse with cones. Although the specific molecular interactions that regulate OPL formation are not well understood, loss of DSCAM leads to malformation of the dendrites of some types of bipolar cells, indicating a role for this adhesion molecule in OPL formation as well as IPL development.<sup>95</sup> Recent studies show that in both mice and primates, several additional adhesion molecules are localized to cone synapses, including gamma-protocadherin, cadherin-8, MAGI2, and CASK, and these may prove to be important in the formation of these synapses.<sup>96</sup>

## Ganglion Cell Death

It has long been recognized that a considerable number of neurons

die during the development of the vertebrate CNS. The death of “excess” neurons is thought to be the result of their inability to compete effectively for a limited supply of trophic support, usually from their postsynaptic targets. Such a mechanism could ensure that presynaptic and postsynaptic populations of neurons are numerically matched during development. In the retina the phenomenon of cell death has been most thoroughly studied in the retinal ganglion cell population,<sup>97</sup> although cell death has been documented in other cell types.<sup>98</sup> A considerable fraction of the ganglion cells that are initially produced are subsequently lost during the phase of cell death. The loss of ganglion cells occurs as the axons of the cells reach the lateral geniculate nucleus and superior colliculus. The neurons in these targets presumably produce only enough trophic factor to keep less than half of the ganglion cells alive in most vertebrates and in humans. In addition to numerically matching ganglion cells and their targets, it is possible that different trophic factors are produced by the different targets, and this ensures that only those ganglion cells survive that have extended their axon to the right place.<sup>99</sup>

The trophic factors supplied by the targets are likely to be among the same molecules identified as survival factors for other cells in the nervous system. The major family of trophic molecules shown to be important for ganglion cell survival is the neurotrophins, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT3), and NT4/5. Of the neurotrophins, the best evidence indicates that BDNF and NT3 are the most important for ganglion cell survival. Both BDNF and NT3 are expressed by cells in the targets of the ganglion cells<sup>100</sup> Both of these neurotrophins promote the survival of ganglion cells when added to cell cultures of retinal cells or when injected in excess into the target during the normal period of cell death. Ganglion cells express receptors for BDNF and NT3, receptor tyrosine kinases known as trkB and trkC, respectively. These data taken together are consistent with the following model. Over twice as many ganglion cells are generated by the retinal progenitor cells than are actually needed in the adult.<sup>101</sup> These cells extend axons to the lateral geniculate nucleus and the superior colliculus and other targets. At the time the axons reach the targets, the ganglion cells express trkB

and *trkC*, and they now require activation of these receptors for their continued survival. Since the supply of BDNF and NT3 is limited, many of the ganglion cells will have an insufficient activation of their *trk* receptors, so they then initiate a program of apoptosis. Although this scheme is intellectually attractive and complies with much of the available data, evidence suggests that additional growth factors are also important in controlling the number of ganglion cells in the retina.<sup>102,103</sup>

There is evidence that transcription factors of the *Brn3* class are important for ganglion cell survival. The *Brn3* transcription factors are among a class of molecules called the *POU domain transcriptional regulators*. In the retina, the *Brn3* genes are expressed exclusively in the retinal ganglion cells. Their expression has been characterized in mouse, cat, and monkey retina, but there does not seem to be a simple relationship between the particular *Brn* gene expressed and one of the major morphologic subtypes of ganglion cells. Targeted disruption of the *Brn* genes in mice causes the loss of nearly all of the retinal ganglion cells.<sup>104–106</sup> These experiments lend support to the idea that *Brn* genes may be important for the expression of the neurotrophins or their receptors, as well as other genes critical for their survival.<sup>104,107</sup>

## Retinal Maturation

As the retina matures, nearly all of the events continue to proceed in a central to peripheral direction. Once the process of retinal histogenesis and death is complete, considerable remodeling continues, primarily in the form of retinal stretch, owing to the steadily increasing intraocular pressure. The pigmented epithelium and the scleral tissue also participate actively in the growth of the eye, as these tissues proliferate in response to increases in intraocular pressure. Because the retina matures later in the periphery, a disproportionate amount of expansion occurs in the peripheral retina. As a result, the ganglion cell density is lower in the peripheral retina than in the central retina, and the dendritic arbor size of most types of retina cells increases in extent with eccentricity because of the disproportionate retinal stretch.

The development of the fovea in primates is another important

aspect of later retinal development. The fovea is a small, avascular depression that is devoid of all cells except cone photoreceptors and Müller glia in the central part of the retina of Old World primates. Foveal development has been extensively characterized by Hendrickson and her colleagues.<sup>108-111</sup> This region is initially one of the thickest parts of the retina, and by a process of cell migration is transformed into a depression or pit. The GCL begins to thin between the 24th and 26th fetal week in humans, and the number of amacrine and bipolar cells begins to decline soon after. The loss of these cells from the fovea is not due to their death, but rather to their migration from the fovea to the surrounding retina. Since these cells already have formed synaptic connections by this time in development, the synaptic pedicles of the cones remain in contact with horizontal and bipolar cells as they migrate, which causes a dramatic elongation of the fiber of Henle. At birth, the GCL and INL are only a single cell layer thick; after birth, the GCL and INL continue to thin, but now the ONL begins to increase in thickness; by age 4, the ONL has six to seven layers of cone photoreceptor nuclei. Although the development of the fovea has been well described, little is known of the mechanisms by which the cells migrate.

## Conclusion

The past 20 years have witnessed an explosive growth in our knowledge of retinal development. The remarkable conservation of molecular mechanisms for eye development throughout evolution has allowed the use of the powerful molecular genetics of *Drosophila* to identify many of the key molecular components required for retinal differentiation. However, many aspects of retinal development remain mysterious. A better understanding, for example, of the mechanisms that control cell fate will allow better derivation of specific retinal cell types from human embryonic stem and induced pluripotent stem cells for cell replacement therapies and disease modeling. Discovery of the mechanisms that control specific synaptic connections will have implications for developmental disorders in the eye and the rest of the CNS. Elucidation of the processes of eye development will

continue to inform the way we look at retinal disease and pathology and potentially lead us to methods to recapitulate developmental processes and provide regenerative treatments of retinal disease.

## Transducin Defects and Retinal Disease cGMP and Photoreceptor Cell Physiology

### Introduction

Our visual experience is initiated by rod and cone photoreceptors in the retina. The human eye contains over 100 million rods and about 6 million cones, which are located within the outer nuclear layer of the retina and allow our visual experience to extend over 12 orders of magnitude in light intensity by splitting this range. Rod photoreceptors mediate vision under conditions of dim illumination, and allow our visual system to reach the limit imposed by the absorption of single photons.<sup>1,2</sup> Cones are less sensitive by ~100-fold, but their tremendous capacity for adaptation allows them to encode light intensities on the brightest of days.<sup>3,4</sup> Over the last two decades, our understanding of structure and function of these cells has increased dramatically. Over 150 genes have been cloned or linked to retinal diseases, and, surprisingly, as many as half of these genes are specifically expressed or highly enriched in the photoreceptor cells. Discovery of the molecular constituents of the rods and cones is progressing at an increasing rate, particularly enhanced by the availability of “complete” genomic sequences for both human and mouse. While photoreceptor genes can be identified through association with a retinal disease (linkage), information about their function does not accompany their identification.<sup>5</sup> Basic science research must then be undertaken to explain their role in both the normal, healthy photoreceptor, as well as in photoreceptor diseases.

Though much of what we know about the structure and function of photoreceptor cells has come from studying animal models of inherited blindness,<sup>6,7</sup> more recently, transgenic and knockout animal technologies have established themselves as powerful tools for understanding function and studying disease. After new photoreceptor genes are identified from patients, mutant animals can be engineered to emulate human photoreceptor pathologies. Before these molecular technologies were available, most data

about retinal disease was gleaned from the rare “informative” patient or donor retina that had surviving photoreceptors to examine.<sup>8</sup> Other major sources of information were studies of animal models that occurred through inbreeding or random inheritance of mutations in photoreceptor genes. Examples of these are the Irish setter dog,<sup>9</sup> the Briard dog,<sup>10</sup> the Abyssinian cat,<sup>11</sup> the RCS rat,<sup>12</sup> and the rd1<sup>13,14</sup> and rds<sup>15,16</sup> mouse models. Now, the ability to engineer transgenic animals has made the search for “informative” patients and naturally occurring animal models less acute – since any single gene of interest can be introduced<sup>17-19</sup> or removed<sup>20-24</sup> from the photoreceptor. However, the most instructive examples of structure–function relationships occur when there are patients and animal models with analogous mutation(s) and/or disease phenotype. Only recently has it become possible to incorporate the insights from numerous studies into biochemical pathways and mechanisms of photoreceptor function. Here, we review the principal proteins and pathways involved in rod photoreceptor structure and function, and highlight the parallelisms in cone photoreceptors.

## Photoreceptor Fundamentals

The rod and cone photoreceptors are specialized sensory neurons that contain the protein machinery necessary to convert incident light into a signal that can be interpreted by the nervous system. Rod photoreceptors are more numerous than cones in most mammalian retina, and are highly sensitive. In the fully dark-adapted state, rods can reliably report the absorption of single photons to the retinal output, and they permit our scotopic, or night, vision. Cone photoreceptors are morphologically and functionally distinct from rods and express several types of visual pigments, or opsins, whose spectral sensitivity varies based on the cones subtype. In humans, three classes of cones confer robust color vision: S-cones, M-cones, and L-cones (see [Chapter 12](#), Color vision and night vision). Cones are also less sensitive than rods and generate light responses that are temporally briefer. This allows cones to mediate our photopic, or day, vision with improved temporal resolution. The concerted action of these two types of

photoreceptors, and the retinal circuitry that carries their signals to the retinal output, ultimately underlie our rich visual experience.

Both rod and cone photoreceptors are highly polarized elongated cells that can be described as having four subcellular compartments: the outer segment (OS), the inner segment (IS), the nucleus, and the synaptic terminal (Figs. 16.1 and 16.2). The OS is where photons are captured and activation of the phototransduction cascade begins. The IS lies immediately proximal to the OS, and contains the cell's protein synthesis (Golgi apparatus and endoplasmic reticulum) and metabolic (mitochondria) machinery. Light-evoked signals are relayed passively down the photoreceptor axon (up to 75  $\mu\text{m}$  long) to the synaptic terminals in the outer plexiform layer. The structure of photoreceptor terminals is unique in the nervous system, as they contain a specialized structure called a ribbon that facilitates the release of the excitatory neurotransmitter glutamate onto second-order retinal neurons (bipolar and horizontal cells). Thus, the photoreceptor cells transduce the sensory stimulus, light, and pass on a signal to retinal circuits that carry this information to higher visual centers.

**FIG. 16.1** (A) Scanning electron micrograph of rods and cones from the African clawed frog, *Xenopus laevis*. The basic shape of the rod photoreceptor inner and outer segments can be appreciated by this surface view. The cones in this species are exceptionally short and “cone”-shaped, unlike the cylindrical appearance of cone outer segment (OS) in the mammalian retina. (B) Immunolocalization of opsin in the inner segment (IS) of the frog retina. Arrows show location of newly synthesized opsin in the Golgi apparatus (*solid arrows*) and a track of labeled vesicles (*open arrows*) from the myoid to the cilium. (C) Transmission electron micrograph of photoreceptors from the mouse retina. Note the connecting cilium between the inner and outer segments and that a large number of mitochondria are visible in this orientation. (D) High-magnification view of frog photoreceptor OSs as

viewed from the top of the disc stack. Upper left shows a single disc labeled with an anti-rod opsin antibody. The plasma membrane surrounding the disc can be observed in this section. Lower left is a cone photoreceptor OS that is not labeled by the antibody. (E) High-magnification view of frog photoreceptor OSs as viewed from the side of the disc stack. Discs are labeled with an anti-rod opsin antibody. The rim region of the disc can be observed, as well as the close packing of the individual discs within the OS. (F) Synaptic terminal of the rod photoreceptor. Directly below the nucleus is the photoreceptor spherule. Synaptic ribbons are visible in this section. (Panels D and E courtesy of Robert Molday, University of British Columbia.)

**FIG. 16.2** The fundamental organization of vertebrate rod and cone photoreceptors. Parts of the cell include: OS, outer segment; A, axoneme; CC, connecting cilium; BB, basal body; R, ciliary rootlet; M, mitochondria; G, Golgi apparatus; ER, endoplasmic reticulum; N, nucleus; S, synaptic terminal. *Insets* depict the structure of the axoneme at the level of the outer segment where microtubule structure is  $9 \times 1 + 0$  (top), and where the inner and outer segment join the microtubule structure is  $9 \times 2 + 0$  (bottom). Middle panels depict two models for outer segment (OS) disc formation. In Model 1, OS discs originate from

evaginations of the plasma membrane but become closed off and separate from the plasma membrane.<sup>56,57</sup> In Model 2, newly generated OS discs are already closed and separate from the plasma membrane.<sup>58</sup> (Modified with permission from Anderson DH, Fisher SK, Steinberg RH. ## Photoreceptor Outer-Segment Structure

The OS compartment contains all components necessary for phototransduction, which is a set of biochemical reactions that convert photon capture to a change in a cationic current at the plasma membrane. Rods have a cylindrical OS about 1.3  $\mu\text{m}$  in diameter; the OS length ranges from 25 to 45  $\mu\text{m}$ ,<sup>25-28</sup> that depends on numerous factors including the time of day, the light intensity, their location in the retina, and the animal species. The cone OS is shorter, typically half the length as rods, with a larger diameter at the base that gradually tapers towards the tip (Fig. 16.2). Mouse rod OS contains an average of 810 membranous discs, which occupy two-thirds of the volume of the OS.<sup>29</sup> The majority of the protein on these discs is rod opsin (or rhodopsin when the opsin is bound to its chromophore, 11-*cis* retinal). The density of rhodopsin on the disc membrane has been measured to be about 24,000 molecules/ $\mu\text{m}^2$ .<sup>30</sup> Despite this dense packing, rhodopsin freely diffuses in the membrane,<sup>31</sup> which facilitates its encounter with, and activation of, transducin molecules to amplify the light signal. Many G-protein-coupled receptors are known to form dimers and higher-order oligomers. Rhodopsin has been observed to form a paracrystalline array of dimers when native disc membrane is viewed under atomic force microscopy<sup>32</sup> and more recently by cryoelectron microscopy.<sup>33</sup> Whether it exists as dimers in vivo is still an area of controversy. However, it is known that rhodopsin is functional as

monomers.<sup>34</sup>

Other integral membrane proteins of the phototransduction pathway that are embedded in the discs are two isoforms of the guanylyl cyclases, RetGC1 and RetGC2, which are single-pass transmembrane proteins. Other transduction proteins, such as the G protein transducin ( $T\alpha$ ), phosphodiesterase 6 (PDE6), recoverin, and guanylyl cyclase activating proteins (GCAPs), are peripheral membrane proteins (see below).

## Proteins That Stabilize the Structure of Outer-Segment Discs

Rhodopsin is not only integral to the phototransduction cascade, it is also required for the formation and maintenance of OS discs; in the absence of rhodopsin, the OS structure is not formed.<sup>22</sup>

Peripherin and Rom-1<sup>15,35,36</sup> are two other disc membrane components that contribute to maintaining the flattened structure of the disc. Both of these proteins belong to the tetraspanin family of integral membrane proteins that form large multiprotein complexes known as the tetraspanin web or tetraspanin-enriched microdomains.<sup>37</sup> Peripherin/rds is normally found within the edge or “rim” of the disc. It self-associates to form higher-order complexes and also interacts with Rom-1.<sup>38</sup> Peripherin/rds and Rom-1 likely function as adhesion molecules that assist in keeping the discs vertically aligned, and may stabilize the disc stack with bridges to the overlying plasma membrane. Peripherin/rds is also thought to function in forming the curvature of the disc rim.<sup>39</sup>

Deletion or disruption of peripherin/rds results in malformation of discs at the OS base. The naturally occurring retinal degeneration in the mouse named “retinal degeneration, slow” (rds) has been shown to be due to a defect in peripherin/rds. The absence of peripherin/rds in the *rds/rds* mouse prevents normal development of the photoreceptor OS and leads to photoreceptor cell death.<sup>15,40</sup> Transgenic mice that lack peripherin/rds fail to form an OS. When the level is reduced, as in the heterozygous mice, large whorls of disc membrane are formed instead of an organized stack of uniform discs.<sup>15,40</sup> Mutations that affect the quaternary structure of peripherin/rds also lead to malformed discs. These observations

underscore the importance of peripherin/rds in the formation and maintenance of disc structure in the OS.

Although Rom-1 is analogous to peripherin in structure and function, its absence in rods shows a less severe phenotype than peripherin/rds knockout mice, suggesting that peripherin/rds is more critical for disc formation. Although the discs grow larger than normal sizes, photoreceptor function appears to be retained to a much higher level than when peripherin/rds is absent.

Nevertheless, abnormal Rom-1 does lead to slow and progressive photoreceptor degeneration both in mice and in humans.<sup>41</sup>

Functional differences of peripherin/rds and Rom-1 have been noted in rods and cones. Cones appear to have a lower ratio of Rom-1/peripherin,<sup>37</sup> and different peripherin/rds mutations appear to differentially affect rods and cones. For example, the C214S and N244K mutations have a greater effect on rods whereas R172W and N244H tend to cause cone-dominant diseases such as macular dystrophy.<sup>37</sup>

Transmission electron microscopy has revealed structural elements between the lamellar discs as well as between the discs and the plasma membrane that are mainly localized to the rim region and incisures of discs.<sup>42-45</sup> A recent study of OS structure using cryoelectron tomography of vitrified outer segments showed previously unobserved spacers distributed throughout the discs.<sup>30</sup> These structural elements likely maintain the proper distance between adjacent discs and between discs and the plasma membrane. The protein identities of these spacers are not known, but peripherin/rds and Rom-1 may be candidates.

Another component of the rod disc is ABCR (photoreceptor cell-specific ATP-binding cassette transporter).<sup>46,47</sup> Mutations in *ABCR* are responsible for a large variety of retinal degenerations, including Stargardt macular dystrophy, fundus flavimaculatus, some forms of cone-rod degeneration, and retinitis pigmentosa. Other *ABCR* mutations are thought to increase the risk of developing age-related macular degeneration (AMD). *ABCR* is a member of the ATP-binding cassette (ABC) superfamily. This is a large family of transmembrane proteins involved in energy-dependent transport of many different substrates across membrane "barriers." The localization of *ABCR* at the disc rim suggests that it

is involved in the movement of molecules from the disc lumen into the cytosol. This hypothesis was supported by studies in ABCR knockout mice, which show delayed dark adaptation, increased all-*trans* retinal following light exposure, and elevated phosphatidylethanolamine (PE) in the rod OS.<sup>48</sup> Biochemical analysis of retinas from ABCR knockout mice revealed accumulation of a novel complex of all-*trans* retinal and PE, termed (N-retinylidene-PE), which is not found in normal retina. Once in the cytosol, the all-*trans* retinol moves to the RPE for recycling and chromophore (11-*cis* retinal) regeneration (see [Chapter 18](#), Cell biology of the retinal pigment epithelium). The primary pathologic defect in Stargardt disease, and also in ABCR knockout mice, is accumulation of toxic lipofuscin pigments, such as A2E, in RPE cells. Thus the phenotype is remarkably similar between mice and that observed in the fundus of Stargardt patients. The animal model and further biochemical investigations<sup>41</sup> suggest that ABCR functions as an outwardly directed flippase for N-retinylidene-PE. Delayed dark adaptation is likely due to accumulation (in discs) of the non-covalent complex between opsin and all-*trans* retinal. ABCR-mediated retinal degeneration in patients may result from “poisoning” of the RPE due to A2E accumulation, with secondary photoreceptor degeneration due to loss of the ABCR support role.

Though ABCR most definitely plays a role in the structure of discs, no mutations have been conclusively associated with abnormal structural features, *per se*. In other words, it appears that mutations do not directly affect folding at the disc rim, and more likely affect the biochemical function of the transporter. In corroboration of these data, Radu and colleagues tested the effects of isotretinoin on lipofuscin accumulation in ABCR knockout mice,<sup>49</sup> a model of recessive Stargardt disease. They observed by electron microscopy that isotretinoin blocked both the formation of A2E biochemically, and the accumulation of lipofuscin pigments. Further, no significant visual loss was observed in ABCR null mice by electroretinography (when treated), and isotretinoin also blocked the slower, age-dependent accumulation of lipofuscin in wild-type mice. The results suggest that treatment with isotretinoin may inhibit lipofuscin accumulation and delay the onset of visual loss in patients with Stargardt disease and may be an effective

treatment for other forms of retinal or macular degeneration associated with lipofuscin accumulation, though “normal” visual function may be somewhat compromised by such treatment.

The presence of an OS is clearly not optional, as there are many examples of retinal disease in which the photoreceptor cell dies shortly after loss of the OS.<sup>50-52</sup> Why loss of the OS triggers rod cell death is not obvious, since all of the required cellular organelles inhabit the IS and cell body; the OS appears devoid of organelles. The necessity to maintain an OS is further surprising since photoreceptors continually replace all the OS components. In fact, the renewal of rod cell OS components is perhaps more readily seen in the photoreceptor than in any other cell in the body. The disc and plasma membrane components of the OS are completely replaced within two weeks.<sup>53,54</sup> To support this turnover there is an influx of newly synthesized proteins and lipids from the IS. These components are transported to the base of the OS, and from there discs gradually migrate towards the RPE for phagocytosis and recycling. One idea is that the high oxygen tension coming from the choroidal vasculature may interfere with the cellular machinery in the IS and nucleus of the photoreceptor, and the presence of the OS puts a protective distance between the choroid and the photoreceptor nuclei.<sup>55</sup>

## Disc Morphogenesis

Although it is known that new discs are formed at the base of the OS, the process by which these discs are formed is not fully resolved (see Fig. 16.2). One model was described in the work of Anderson, Steinberg, and Fisher (Model 1).<sup>56,57</sup> Based on morphologic studies of adult monkey rods, it was observed that the folded membrane stacks at the base of the OS are continuous with the plasma membrane of the connecting cilium, whereas the older discs are closed off and separated from the plasma membrane. From this appearance a model was proposed that the newly arrived rhodopsin-bearing vesicles fuse with the plasma membrane, and the growing membrane evaginates to form open discs. Eventually these discs pinch off and form the mature closed discs. Another model (Model 2), the “vesicular targeting model,” has been

proposed by Chuang and colleagues.<sup>58</sup> They provide molecular evidence that rhodopsin's carboxyl terminus interacts with a protein called SARA (smad anchor for receptor activation), as well as PI3P (phosphatidylinositol 3-phosphate) and syntaxin 3. In their model, the new discs are already closed and enveloped by the OS plasma membrane. Their evidence suggests that the protein–protein and protein–lipid interactions organized by SARA regulate the vesicular targeting of axonemal rhodopsin-bearing vesicles to the newly formed discs. Thus the discs grow by fusing with the rhodopsin-bearing vesicles and not from the evaginated plasma membrane. This model is more consistent with the morphology of their experimental model system, the mouse rods, which do not display open discs at the base of the OS.

The degree of translational and posttranslational control in the processes of disc formation remains an open question. The processes necessary to manage and partition the correct ratio of rhodopsin to the other proteins of the phototransduction cascade (transducin: PDE: GC: GCAP: cGMP-gated channel) in the discs are unknown. Additionally, the insertion of the structural proteins peripherin, Rom-1, and ABCR into the forming disc rim is likely to require precise instruction. How these processes combine to generate a functional OS will require extensive new investigation and methodology. It is unlikely that these complex morphogenic processes will be elucidated using static two-dimensional microscopy methods with fixed materials, the method that has yielded most of information to date. These problems may require the application of three-dimensional microscopy, in conjunction with immunocytochemical tags and fluorescent labels such as GFP, to follow the assembling proteins in preparations of living photoreceptors.

## Outer-Segment Plasma Membrane

The plasma membrane of the rod OS encloses the majority of the discs and creates a physical barrier between the discs and the cell's exterior, except perhaps for the newly formed basal discs (see [Fig. 16.2](#), Model 1). In the mammalian cone OS at least several discs are continuous with the outer plasma membrane along the OS.<sup>59</sup> This

open configuration creates additional surface area, which allows for more rapid exchange of retinoids and ions. It is clear that, in addition to its obvious role in phototransduction, the OS plasma membrane contains a rich array of specialized proteins, many of which regulate the movement of ions into and out of the OS. The best-characterized proteins of this type are the retinal cGMP-gated (CNG) cation channels. In the dark-adapted rods and cones,  $\text{Na}^+$  and  $\text{Ca}^{2+}$  flow into the OS through these channels in the plasma membrane. Calcium comprises about 10% of the dark current carried by these channels in rods,<sup>60</sup> and perhaps 20% or more in cones.<sup>61,62</sup> In both rods and cones  $\text{Na}^+$  is extruded from the IS through the  $\text{Na}^+/\text{K}^+$  pump. This flow of ions sets up the circulating dark current, of which the vast majority is carried by the  $\text{Na}^+$ . The probability of the opening of the CNG channel, which in turn determines the size of the circulating current, depends on the amount of free [cGMP], which in the dark is estimated to be 3–4  $\mu\text{M}$ .<sup>63</sup> At this concentration, the probability of channel opening is estimated to be only 0.1–0.2.<sup>64,65</sup> This underscores the impact that elevated [cGMP] can have on the number of open channels in the diseased state. The influx of  $\text{Ca}^{2+}$  through the channel is balanced by an efflux of  $\text{Ca}^{2+}$  by the  $\text{Na}^+/\text{Ca}^{2+}\text{-K}^+$  exchanger in the rod OS plasma membrane, thereby maintaining the intracellular level of  $\text{Ca}^{2+}$  at a relatively constant level.<sup>66</sup> Kaupp and colleagues<sup>67</sup> cloned the cGMP channel from bovine retina, while Pittler and colleagues<sup>68</sup> determined the primary structures of the human and mouse retinal rod cGMP-gated cation channel. These studies found that the sequence of the cGMP channel has significant similarity (59%) to the olfactory cAMP-gated channel. The retinal rod CNG channel is a hetero-oligomer composed of three alpha- ( $\alpha$ ) (CNGA1) and one beta- ( $\beta$ ) (CNGB1) subunits,<sup>69,70</sup> each with cytoplasmic amino(N)- and carboxyl(C)-termini, six putative transmembrane domains, and a pore region.<sup>15,71</sup> Mutations in *CNGA1* and *CNGB1* have been linked to disease. A point mutation in *CNGB1*<sup>72</sup> and several mutations in *CNGA1*<sup>73</sup> have been identified and linked to recessive RP in humans. The CNG channel instead of cones consists of two CNGA3 and two CNGB3 subunits.<sup>74</sup> Together, mutations in either of these genes account for ~75% of complete acromatopsia.<sup>75,76</sup>

In addition to the CNG channel, there are several other channels

and transporters in the plasma membrane that serve to regulate the intracellular contents of the OS. The best studied of these is the  $\text{Na}^+/\text{Ca}^{2+}-\text{K}^+$  exchanger (NCKX), which is the only known route for  $\text{Ca}^{2+}$  extrusion from the OS. Rods express NCKX1 whereas cones express NCKX2.<sup>77</sup> However, the lack of a clear phenotype in the cone electroretinogram in the *NCKX2* knockout mice<sup>78</sup> raises possibilities for additional *NCKX* expression in cones or yet to be discovered NCKX-independent  $\text{Ca}^{2+}$  extrusion mechanisms. The exchanger moves with every cycle 4  $\text{Na}^+$  into the OS, and in exchange, moves 1  $\text{Ca}^{2+}$  and 1  $\text{K}^+$  into the subretinal space; exchange is thus electrogenic. A mutation in *NCKX1* is associated with autosomal recessive congenital stationary night blindness in humans,<sup>79</sup> and deletion of *NCKX1* in mice resulted in malformed rod OS discs and suppressed expression and function of rod CNG channels. The rods slowly degenerated while cone function was maintained.<sup>80</sup> Other transmembrane proteins, such as the GLUT-1 glucose transporter, have been shown to be present on both rod and cone OS.<sup>81</sup>

## Outer-Segment Lipids

Docosahexaenoic acid (DHA, 22:6n-6) is the major fatty acid found in the retinal rod OS, and rod photoreceptors have higher levels of DHA than in any other membrane system examined.<sup>82</sup> Numerous studies have established that the high level of DHA in rod OS membranes provides an optimal microenvironment for rhodopsin. DHA belongs to the n-3 family of essential polyunsaturated fatty acids. These fatty acids cannot be synthesized by vertebrates and they, or their shorter chain precursors, must therefore be obtained in the diet.<sup>83</sup>

Humans with RP and dogs with progressive rod–cone degeneration (*prcd*) have lower than normal blood levels of long-chain polyunsaturated fatty acids, including DHA. In addition, *prcd*-affected dogs have lower levels of DHA in their rod OS than control animals.<sup>84</sup> The reason for the reduced level of DHA in rod outer segments of animals with inherited retinal degeneration is not known. However, the fatty acid composition of the rod OS of these animals suggests that the synthesis of DHA containing

glycerolipids is downregulated in retinas of animals with inherited retinal degenerations.

## Phototransduction

Visual transduction is initiated by the phototransduction cascade, which is perhaps the best characterized of all G-protein-coupled receptor signaling pathways. Our knowledge about phototransduction is relatively advanced because the components of this pathway are located selectively in the photoreceptor OS and can be isolated in quantities suitable for biochemical analysis. Photoreceptors can also be isolated easily for electrophysiologic measurements, either as single cells using suction electrodes ([Fig. 16.3](#)), or en masse using field potentials called electroretinograms (ERG; see [Chapter 9](#), Electrogenesis of the electroretinogram). The phototransduction cascade within rods is so robust such that single photon absorption by rhodopsin gives rise to a change in current that can be monitored by suction electrode recordings. Similarly, the remarkable ability of cone phototransduction to adapt to increases in background light intensity can also be monitored with suction electrodes. The combination of transgenic technology and electrophysiologic analysis has enhanced greatly our understanding of signal transduction within these photoreceptor cells. In particular, transgenic technologies have allowed the introduction of targeted changes into specific components of the signaling pathway. These genetically altered intact photoreceptor cells can then be subjected to electrophysiologic measurements, and their tissues can subsequently be used in biochemical or immunocytochemical assays to pinpoint the molecular mechanism behind the physiologic phenotype. Below, we summarize the current state of our understanding of phototransduction in retinal photoreceptors.

**FIG. 16.3** Suction electrode used in recording the outer-segment current. The cells in this clump of toad retina are being superfused with bicarbonate-buffered Ringer solution equilibrated with 5% carbon dioxide. A rod outer segment is carefully drawn into the glass electrode, which makes a high-resistance seal against the cell. Responses are recorded during the presentation of a stimulus, in this case a slit of focused green light.<sup>1</sup> (Modified with permission from Baylor DA, Lamb TD, Yau KW. Responses of retinal rods to single photons. *J Physiol* 1979;288:613-34.)

## Signal Activation and Amplification

A hallmark of rod phototransduction is its high sensitivity. Fully dark-adapted rods achieve sensitivity that reaches the theoretical maximum, the ability to detect individual quanta of light.<sup>1,2</sup> This high sensitivity is generated through several stages of amplification, resulting in a tremendous increase in the signal gain (Fig. 16.4). This cascade of amplification begins at the light-activated G-protein-coupled receptor rhodopsin (R). Absorption of a photon by R leads to a conformation change ( $R^*$ ), allowing it to interact with the heterotrimeric G protein transducin (T alpha ( $\alpha$ ), beta ( $\beta$ ), and gamma ( $\gamma$ )), thereby promoting the exchange of bound GDP for GTP. The complex then dissociates into  $T\alpha$ -GTP and  $T\beta\gamma$ ,

and  $R^*$  is free to activate many other transducin molecules during its catalytic lifetime.<sup>85</sup> In the subsequent step,  $T\alpha$ -GTP binds and removes the inhibitory gamma- ( $\gamma$ ) subunit of the cGMP-phosphodiesterase (PDE) so that it can now hydrolyze cGMP to 5'-GMP; the enzymatic activity of PDE (PDE\*) in turn degrades thousands of cGMP molecules. The decrease in cytoplasmic cGMP concentration then leads to closure of the cGMP-gated cation conductance channel in the rod plasma membrane, resulting in a reduction in the influx of  $\sim 1,000,000$   $\text{Na}^+$  ions.<sup>86</sup> This is a graded effect: a slight lowering in the cGMP concentration leads to closure of some channels, while a large decrease will eventually lead to closure of all channels. In this instance, the rod cell is said to be "saturated."

**FIG. 16.4** (A) The phototransduction cascade in the

rod and cone outer segment is initiated when a photon ( $h\nu$ ) strikes the visual pigment, rhodopsin in rods, and promotes it to an active state ( $R^*$ ).  $R^*$  interacts with a heterotrimeric G-protein and promotes the exchange of GTP for GDP on the alpha-subunit ( $T\alpha$ ).  $T\alpha$  in turn disinhibits a cGMP phosphodiesterase (PDE) thereby allowing the hydrolysis of cGMP and the closure of cyclic nucleotide gated (CNG) channels. The closure of CNG channels interrupts the flow of  $Na^+$  and  $Ca^{2+}$  into the photoreceptor and hyperpolarizes the membrane potential. (B) Deactivation of  $R^*$  is required to quench the phototransduction cascade.  $R^*$  deactivation is initiated by the phosphorylation Ser and Thr residues at its C-terminus by rhodopsin kinase (RK). RK is inhibited by recoverin (Rv), a process which is controlled by  $Ca^{2+}$ .  $Ca^{2+}$  concentration falls as CNG channels close during the activation of phototransduction, allowing the disassociation of RK from Rv, and subsequently the phosphorylation of  $R^*$ . The  $R^*$  catalytic activity is further quenched by the binding of visual arrestin (Arr) to phosphorylated  $R^*$ . (C) Deactivation of activated PDE ( $PDE^*$ ) requires the hydrolysis of GTP to GDP on  $T\alpha$ . To reopen CNG channels, guanylyl cyclase synthesizes cGMP from GTP, a process that is regulated by the  $Ca^{2+}$ -binding protein, guanylyl cyclase activating protein 1 and 2 (GCAPs).

In darkness, glutamate, the transmitter used by both rods and cones, is released at a steady rate because the photoreceptor's membrane potential is in a relatively depolarized state. The closure of CNG channels results in a graded hyperpolarization of the cell, leading to a decrease in glutamate release at the synapse. In this manner, the first sensation of light perception is transmitted from the photoreceptor cell to second-order cells of the retina, where signals are further processed and ultimately conveyed to the retinal ganglion cells (see [Chapter 17](#), Function and anatomy of the mammalian retina).

## Signal Deactivation

A reversal of the activation steps is required ultimately for the

photoreceptor to return to its resting state. First, the catalytically active components of the phototransduction cascade, R\* and PDE\*, must be quenched, then cGMP needs to be resynthesized (see Fig. 16.4). These events must be rapid and reproducible for the photoreceptor to maintain its high sensitivity and respond to subsequent stimuli. Our current understanding of these processes is detailed below.

### **Quenching R\*: Rhodopsin Phosphorylation**

Since the early 1980s, phosphorylation was recognized to play an important role in deactivation of R\*.<sup>87,88</sup> To determine how receptor deactivation occurs in vivo, transgenic mouse models were developed to assess the contribution of receptor phosphorylation to R\* shut-off. It is clear that rhodopsin kinase, or GRK1, is solely responsible for phosphorylating R\*, since phosphorylation of R\* does not occur in mice lacking rhodopsin kinase.<sup>89</sup> In early experiments, a rhodopsin truncation mutation, S334ter, was expressed in the photoreceptors of transgenic mice<sup>17</sup> that removed the terminal 15 amino acid residues and thus all putative Ser and Thr phosphorylation sites. Single-photon responses produced by S334ter R\* failed to shut off in a timely and stereotyped manner, indicating that this domain is important for R\* quenching. In the 1990s numerous biochemical experiments suggested that specific Ser residues on the C-terminus are crucial in R\* shut-off.<sup>90-92</sup> However, single cell recordings from transgenic mice rods expressing rhodopsin lacking native Ser or Thr residues showed that Ser-only rhodopsin generated abnormally prolonged responses whereas Thr-only rhodopsin generated responses that were only modestly slower than normal rhodopsin.<sup>93-95</sup>

### **Quenching R\*: Arrestin Binding**

Subsequent to C-terminus phosphorylation, the catalytic activity of R\* is quenched fully through by binding of visual arrestin. Arrestins are soluble cytoplasmic proteins that bind to G-protein-coupled receptors, thus switching off activation of the G-protein and terminating the signaling pathway that triggers the cellular response; the most commonly studied arrestin is  $\beta$ -arrestin. Visual arrestin exhibits exquisite specificity for binding phosphorylated

R\*. Our understanding of how this specificity is conferred emerges from extensive mutagenesis studies, and the crystal structure of visual arrestin.<sup>96-99</sup> These studies reveal that arrestin is constrained into a latent, inactive structure by a network of intramolecular interactions.<sup>96</sup> According to the current model of arrestin activation, these intramolecular constraints are released by (1) interaction with multiple phosphates on rhodopsin's C-terminus, and (2) interaction with the cytoplasmic loops of R\*. The physiologic role of visual arrestin in controlling the rod single-photon response was studied by Xu and colleagues,<sup>24</sup> who created transgenic mice lacking visual arrestin. Suction electrode recordings of photoresponses from the OS of these transgenic rods displayed a rapid, partial recovery, followed by a prolonged final recovery phase. The timing of the slow phase of shutoff is consistent with the spontaneous decay of the R\*. Thus, while R\* phosphorylation is required to terminate rapidly its catalytic activity, the full quenching of R\* activity requires visual arrestin binding. Together, these extensive studies of light responses arising from rhodopsin phosphorylation site mutants show that coordination of phosphorylation of the cluster of Ser and Thr sites, together with arrestin binding, play a pivotal role in controlling the catalytic lifetime of rhodopsin and in ensuring the reproducibility of the single photon response in rods.

## Deactivating PDE: Control of Transducin's GTPase Activity

Quenching of the phototransduction cascade also requires the shutoff of PDE\*, which occurs through the deactivation of T $\alpha$ . The GTPase activity of T $\alpha$  allows the reassociation of the inhibitory gamma-subunit to the catalytic PDE subunits,<sup>100</sup> a process that is speeded through the participation of a photoreceptor-specific RGS protein, RGS-9, and its binding partner, G $\beta$ 5.<sup>101</sup> These proteins act sequentially on T $\alpha$  to facilitate the hydrolysis of bound GTP. The physiologic role of all these proteins in the shutoff of the rod photoresponse was evaluated with transgenic mice that had alterations in each of these components. Rod photoresponses from transgenic mice expressing a PDE- $\gamma$  with an impaired ability to stimulate GTP hydrolysis<sup>102</sup> showed abnormally slowed recovery,

demonstrating the necessary role of PDE- $\gamma$  in T $\alpha$  deactivation.<sup>103</sup> Similarly, mice lacking RGS-9 showed profoundly slowed response recovery,<sup>104</sup> as do mice lacking G $\beta$ 5.<sup>105</sup> RGS-9 is anchored to photoreceptor membranes by the adaptor protein, R9AP.<sup>106-108</sup> Interestingly, human patients with mutations in *R9AP* have difficulties adapting to sudden changes in light levels that are mediated by cones,<sup>109</sup> consistent with the higher concentration of RGS-9 complex in cones compared to rods.<sup>110</sup> Together, the current data support an important role of PDE- $\gamma$ , RGS-9/G $\beta$ 5, and R9AP in T $\alpha$  deactivation, and consequently, response recovery, in both rods and cones.

## Resynthesis of cGMP: Ca<sup>2+</sup> Dependence of Guanylyl Cyclase

Recovery of the dark current also requires that cGMP is resynthesized to allow CNG channels to open. cGMP is synthesized in photoreceptor outer segments by a retinal guanylyl cyclase (RetGC), which is regulated by the protein GCAPs (guanylyl cyclase activating protein 1 and 2).<sup>111</sup> GCAPs is an EF hand Ca<sup>2+</sup>-binding protein that confers on RetGC a highly cooperative Ca<sup>2+</sup>-dependence for cGMP synthesis.<sup>112</sup> Near the dark resting Ca<sup>2+</sup> concentration RetGC's activity is inhibited, but as OS Ca<sup>2+</sup> falls in response to illumination as CNG channels close, RetGC's activity accelerates to restore the resting cGMP and reopen CNG channels. The physiologic actions of GCAPs have been evaluated in physiologic recordings. For instance, when GCAP1 is dialyzed into Gecko rods, the recovery phase of the light response is accelerated.<sup>113</sup> In addition, suction electrode recordings from rods of GCAPs knockout mice show that the Ca<sup>2+</sup>-dependence of cGMP synthesis is required to set the time course of the rod's photoresponse, and to suppress noise within the phototransduction cascade.<sup>114</sup>

## Light Adaptation

In a normal cycle of day and night, the illumination at the earth's surface varies over 12 orders of magnitude, making photoreceptor adaptation fundamentally important to the normal functioning of

the vertebrate visual system. Rod cells are able to adjust their sensitivity over 2 to 3 log units of light intensities, while cone cells exhibit no response saturation over 6 to 7 log units.<sup>3,4</sup> The switch between rod and cone function from night to bright daylight covers a large portion of vision's functional range; and downstream circuitry accounts for the remainder of the range extension. While the molecular events underlying the amplification cascade following photon capture by rhodopsin are well delineated, the mechanisms underlying photoreceptor adaptation are less well understood; however,  $\text{Ca}^{2+}$  is known to play a feedback role in the adaptation process.<sup>105,115</sup>

## **The Role of $\text{Ca}^{2+}$ Feedback**

In darkness,  $\text{Na}^+$  ions enter the OS through the CNG channels and are extruded in the IS through  $\text{Na}^+/\text{K}^+$  ATPase pumps. This steady-state influx and efflux of  $\text{Na}^+$  is largely the basis for the circulating dark current in photoreceptor cells. Similarly,  $\text{Ca}^{2+}$  enters through CNG channels in the OS, but is extruded locally by  $\text{Na}^+/\text{Ca}^{2+}$ ,  $\text{K}^+$  (NCKX) exchangers. In mouse rods the steady-state influx and efflux of  $\text{Ca}^{2+}$  holds its concentration near 250 nM,<sup>116</sup> but as light closes CNG channels  $\text{Ca}^{2+}$  entry is blocked,  $\text{Ca}^{2+}$  efflux continues, and  $[\text{Ca}^{2+}]_i$  falls. This change in  $[\text{Ca}^{2+}]_i$  is graded just like the dark current: the degree of lowered  $[\text{Ca}^{2+}]_i$  is proportional to the intensity of background light in both rods and cones.<sup>117,118</sup> This decrease in  $[\text{Ca}^{2+}]_i$  triggers a feedback signal that is necessary for light adaptation, since, when the  $[\text{Ca}^{2+}]_i$  decrease is blocked, adaptation to background illumination is greatly compromised.<sup>60,119</sup> Existing evidence suggests that this feedback is rather complex, as it orchestrates several pathways directed toward different components of the transduction machinery.<sup>120-122</sup> Here we review the role of  $\text{Ca}^{2+}$  on each of these components.

## **Adaptation Mediated by $\text{Ca}^{2+}$ -Feedback to Retinal Guanylyl Cyclase (RetGC)**

It has long been recognized that feedback controlling accelerated recovery contributes to light adaptation.<sup>112</sup> Recovery of the light response requires the resynthesis of cGMP, which is needed to

reopen the CNG channels and reestablish the circulating current. The control of cGMP synthesis by RetGC/GCAPs is central to this process. The contribution of accelerated cGMP synthesis to adaptation in rod photoreceptors was investigated in GCAPs knockout mice.<sup>23,114</sup> This work showed that the presence of GCAPs extends the sensitivity to background light in rod photoreceptors ~10-fold (Fig. 16.5), and can account for about half of the rod's capacity to adapt to background light. Recordings from cones in GCAPs knockout mice also show that GCAPs contributes to background adaptation, but to a lesser extent than it does in mouse rods.<sup>123</sup>

**FIG. 16.5** Sensitivity as a function of background light was measured from mouse rod photoreceptors using suction electrodes (see Fig. 16.3). Sensitivity was calculated from dim flash responses as the peak response amplitude divided by the flash strength. Flash sensitivity ( $S_F$ ) in the presence of increasing background light ( $I_B$ ) was normalized against the flash sensitivity in darkness ( $S_F^D$ ) and is plotted for the rods of several transgenic mice with particular elements of the phototransduction cascade altered. These mice include wild-type ( $\bullet$ ), mice lacking recoverin ( $\blacksquare$ ), mice where the calmodulin binding site on the CNG channels has been eliminated ( $\blacktriangle$ ), mice lacking

guanylyl cyclase activating proteins 1 and 2 ( $\circ$ ), and mice where both the calmodulin binding site on the CNG channel and guanylyl cyclase activating proteins 1 and 2 have been eliminated ( $\square$ ). The dashed line shows the predicted decline in sensitivity as a function of background light intensity if rods displayed no light adaptation. The solid line is best-fitting Weber–Fechner function for wild-type rods, and shows that light adaptation extends the sensitivity of rod photoreceptors to 100-fold higher background light levels. Rods from mice lacking recoverin, or the calmodulin-binding site on the CNG channels, show little deviation from wild-type rods, indicating that these proteins do not play a significant role in light adaptation. However, in mice lacking guanylyl cyclase activating protein 1 and 2, light adaptation is impaired, but not absent, even when the calmodulin-binding site on the CNG channel is also eliminated (red dashed line). The remaining mechanisms that control light adaptation in rod photoreceptors remain unidentified.

Background light produces a recoverin-dependent modulation of activated-rhodopsin lifetime in mouse rods. *J Neurosci* 2010;30(4):1213-20.)

## Recoverin and Control of Rhodopsin Kinase

The accelerated response recovery that mediates light adaptation is also achieved through the speeded deactivation of  $R^*$ . The first step in the quenching of  $R^*$  activity is the phosphorylation of its C-terminus by rhodopsin kinase, a process that is believed to be regulated in a  $Ca^{2+}$ -dependent manner by the protein recoverin. Recoverin is a highly conserved  $Ca^{2+}$ -binding protein found in both rod and cone photoreceptors. *In vitro*, recoverin binds and inhibits rhodopsin kinase when it is  $Ca^{2+}$ -bound, and accelerates rhodopsin kinase activity as  $Ca^{2+}$  is removed.<sup>124,125</sup> Since  $[Ca^{2+}]_i$  is high in darkness, it has been suggested that, under dark-adapted conditions, recoverin prolongs the catalytic activity of  $R^*$  by inhibiting rhodopsin phosphorylation. Early evidence in experiments that introduce recombinant recoverin into Gecko and salamander rods indicated that recoverin prolongs the light

response.<sup>126,127</sup> However, recoverin's effect was most prominent at  $\text{Ca}^{2+}$  concentrations outside the rod's physiologic range ( $>1 \mu\text{M}$ ). The  $\text{Ca}^{2+}$  requirement for rhodopsin kinase inhibition by recoverin in reconstituted biochemical assays was similarly high.<sup>124</sup> These results placed into doubt the role of recoverin in mediating light adaptation. Suction electrode recordings from the rods of transgenic mice lacking recoverin, however, reveal a response speeding.<sup>128</sup> This speeding effect is exacerbated in rods that lack recoverin, but also have a reduced expression of rhodopsin kinase.<sup>129</sup> Thus, in the physiologic range of  $\text{Ca}^{2+}$  concentrations recoverin can influence  $R^*$  lifetime. Despite this effect on  $R^*$  lifetime, recoverin appears to play a relatively minor role in rod light adaptation (Fig. 16.5).<sup>128</sup> In cone photoreceptors, however, recoverin appears to contribute to sensitivity over a wider range of light intensities,<sup>130</sup> a fact perhaps not totally surprising given experiments from salamander L cones show that  $R^*$  lifetime dominates the light response.<sup>131</sup>

## Feedback Regulation of the cGMP-Gated (CNG) Channel

Another target of the  $\text{Ca}^{2+}$  feedback is the CNG channel itself. In vitro data have shown that the presence of  $\text{Ca}^{2+}$ -calmodulin causes a decrease in the apparent affinity of the CNG channels for cGMP.<sup>132</sup> This effect is reversed in light when  $[\text{Ca}^{2+}]_i$  is low, such that more channels tend to open despite the lowering of cGMP levels. However, the role of CNG channel modulation in intact rods remains controversial, because based upon the measured effect of  $\text{Ca}^{2+}$  on the apparent affinity of the channel for cGMP and the intracellular range of cGMP concentration, it has been predicted theoretically that the channel contributes little to the overall adaptive behavior of the rod photoreceptor.<sup>121</sup> The site that confers  $\text{Ca}^{2+}$ -calmodulin sensitivity has been identified in the beta-subunit of the CNG channel.<sup>133,134</sup> Transgenic mice with this  $\text{Ca}^{2+}$ -binding site disrupted show little influence on the light response or in the adaptive features of rod phototransduction,<sup>129</sup> consistent with previous conjecture (see Fig. 16.5). The role of CNG channel modulation in cones, however, may be more profound than for rods. For instance, the cones of the ground squirrel demonstrate

strong  $\text{Ca}^{2+}$ -dependent modulation of the CNG gated-current in the normal range of  $\text{Ca}^{2+}$  concentrations, while the rods of the same species do not.<sup>135</sup> In addition,  $\text{Ca}^{2+}$  concentration varies over a larger dynamic range in cones than rods<sup>118</sup> allowing the recently identified protein, CNG-modulin, to regulate cone sensitivity more profoundly.<sup>136,137</sup>

## Other ( $\text{Ca}^{2+}$ -Independent) Adaptation Mechanisms: Protein Translocation

A mechanism operating at a longer timescale (minutes rather than seconds) that may contribute to regulating photoreceptor cell performance is the light-driven redistribution of specific signal transduction proteins between the compartments of the photoreceptor cell. The immunoreactivity of both  $\text{T}\alpha$  and visual arrestin is known to redistribute in rods in response to light.<sup>138-141</sup> Visual arrestin immunostaining predominates at rod ISs, as well as at the outer nuclear layer and outer plexiform layers of dark-adapted retinas, and shifts to rod OSs upon light exposure.  $\text{T}\alpha$  immunoreactivity shifts in the opposite direction in response to light.<sup>140-142</sup> Quantitative measurements show that bright light exposure is required to trigger translocation: for visual arrestin the threshold is 1000 rhodopsin excitations per rod per second, a light intensity at the upper limits of rod vision; for  $\text{T}\alpha$  at least 10,000 rhodopsin excitations is required.<sup>143</sup> Sokolov and colleagues confirmed the physiologic movement of  $\text{T}\alpha$  by combining serial tangential cryosectioning of the retina with Western blot analysis, and demonstrated that such movement may help to extend the range of light intensities in which the rods are able to operate.<sup>144</sup> More recent evidence indicates that movement of  $\text{T}\alpha$  to synaptic terminal enhances synaptic transmission in the light-adapted state.<sup>145</sup> Similarly, visual arrestin movement may regulate rod performance under varying light environments.

Our current understanding of protein translocation is that it occurs by diffusion. In the case of  $\text{T}\alpha$ , the lipid modifications on the alpha- and gamma-subunits act synergistically to anchor  $\text{T}\alpha$ -GDP on the membrane. Upon activation, the subunits dissociate and become solubilized.<sup>146</sup> In an elegant set of experiments, Lobanova

and colleagues showed that light threshold can be shifted to either a lower or higher light intensity using mutant mice whose GTPase-activating (GAP) complex is enhanced or decreased.<sup>147</sup> Their data suggests that when the GAP complex is saturated, T $\alpha$ -GTP can escape the OS compartment and diffuse to the IS. Whether such a mechanism also governs cone translocation is uncertain. It has been observed that cones contain a higher concentration of GAP proteins,<sup>110,148</sup> a reason that could explain a much higher threshold for cone T $\alpha$  translocation.<sup>149</sup> However, others have observed that cone T $\alpha$  readily translocates.<sup>150</sup> In the case of rod arrestin, its interaction with microtubules restricts its location to the IS in the dark. Light exposure creates its high-affinity binding partner, R\*, which drives its movement towards the OS.<sup>151</sup>

It has become increasingly clear that Ca<sup>2+</sup>-dependent light adaptation results from the sum of multiple mechanisms that act at different sites in the phototransduction cascade. While biochemical experiments have identified the Ca<sup>2+</sup> sensitive steps in the phototransduction cascade, a full understanding of how these steps contributes to visual adaptation requires a method that critically evaluates the timing, as well as the strength, of feedback modulation under physiologic conditions. Given the complexity of Ca<sup>2+</sup> feedback, coupled with the possibility that other adaptation mechanisms may overlay on this feedback regulation, visual adaptation, particularly in cones, remains one of the least understood areas in phototransduction. This complexity is being unraveled by the systematic removal of Ca<sup>2+</sup> feedback pathways in vivo using mouse genetics, and by measuring the resultant change in adaptation with electrophysiologic measurements. The molecular mechanism behind the observed phenotype can then be confirmed by biochemical experiments. Using this approach, the Ca<sup>2+</sup> feedback loops can be evaluated independently, as well as in sum, since the mice can be bred to combine the individual components (see Fig. 16.5). Eventually, as each and every Ca<sup>2+</sup>-dependent pathway is peeled away, the remaining (perhaps Ca<sup>2+</sup>-independent) pathways will be revealed.

## Dark Adaptation

The process of *light adaptation* described above represents the mechanisms that desensitize phototransduction during steady background light. Despite the push toward desensitization by these mechanisms, several of which depend on the ROS  $\text{Ca}^{2+}$  concentration, there is a simultaneous pull toward sensitization. Adaptive mechanisms that pull the system toward the “dark” state (collectively coined “*dark adaptation*”) play a crucial role in sensitivity maintenance. Dark adaptation has been classically studied by exposing dark-adapted subjects, or animal retinas, to bright light that bleaches (i.e., causes a *cis* to *trans* isomerization of retinal) the visual pigment and depresses sensitivity, and then observing the recovery with time. While cones recover sensitivity within seconds to minutes, rods take tens of minutes to recover to levels comparable to the dark-adapted state.<sup>152</sup> This slow recovery is attributable to many biochemical processes within rods that quench phototransduction activity fully and reestablish the dark-adapted condition. Among these is the rapid and continuous turnover of the visual pigment, which in rods requires tight apposition with the RPE. Additionally, mechanisms that reset the distribution and state of phototransduction proteins are critical to establish sensitivity. These mechanisms include the decay of long-lasting visual pigment intermediates, such as MetaIII rhodopsin (reviewed in [reference 153](#)), and reversing the light-dependent movement of proteins such as  $\text{T}\alpha$ , recoverin, and arrestin back to their respective compartments (reviewed in [reference 143](#)). The clinical importance of dark adaptation is manifest in pathologic perturbations of this process that lead to a number of blinding eye diseases, including retinal degeneration and diseases of retinoid deficiency.

## Differences Between Rod and Cone Phototransduction

What factors underlie the specialized functions of rods and cones? This remains a very important problem in phototransduction. Investigation of rod phototransduction has benefited from rod-dominated species where biochemical and physiologic assays are robust. The relatively low number of cones in most mammalian species has made a biochemical analysis of cone phototransduction

less fruitful, although use of carp<sup>154-156</sup> and the Nrl knockout mouse (that generates a cone-dominant retina) have proven useful.<sup>157</sup> As described above, some quantitative differences may arise for differential modulation of components of the phototransduction cascade. In addition, differences in their characteristic morphology may play a role in setting the response properties. For example, the discontinuous and invaginating OS plasma membrane in cones provides greater surface area for ion exchange and chromophore recycling. To facilitate pigment regeneration in cones, two sources of 11-*cis* chromophore are available: the classic visual cycle within the retinal pigmented epithelium that also supplies the rods, and a newly discovered source within the Müller cells that supplies chromophore only to cones.<sup>158</sup> Also important may be their signal transduction cascades: molecular cloning has revealed that phototransduction in the vertebrate rods and cones are regulated by structurally homologous but distinct groups of signaling proteins. Therefore, it is reasonable to assume that the phototransduction in rods and cones is qualitatively similar, and that quantitative differences in the transduction steps underlie the characteristic rod and cone behavior. For example, R\* may activate more rod T $\alpha$  molecules than cone opsin R\* in activating cone T $\alpha$  (see [reference 155](#)), resulting in a higher gain and a larger response amplitude.

To determine the roles of rod and cone phototransduction proteins in setting the response properties of the photoreceptor cells, transgenic technology has recently been used to express rod components in cones, and vice versa. For example, Kefalov and colleagues<sup>159</sup> expressed an L-cone opsin in *Xenopus* rods, and rhodopsin in *Xenopus* cones. They surprisingly found that the activation of rhodopsin and L-cone opsin within the same cell yielded nearly identical photoresponses. In addition, similar photoresponses were observed in mouse rods transgenically expressing an S-cone pigment.<sup>147</sup> These results collectively rule out the visual pigment from being a major contributor to rod-cone functional differences. Similar experiments have also addressed the role of T $\alpha$ . Mao and colleagues showed no functional differences in mouse rods wherein rod T $\alpha$  was substituted by cone T $\alpha$ . They found that rod and cone T $\alpha$  generated similar photoresponses initiated by either rhodopsin or the short-wave cone opsin.<sup>160</sup>

Finally, the expression of cone PDE in rod PDE null mice (*rd1/rd1*) shows a modestly light-adapted phenotype consistent with a higher measured basal PDE activity and faster PDE deactivation.<sup>161</sup> All these studies demonstrate that the difference between the photoresponses of rods and cones is unlikely to be determined by the strong modulation of a few factors, but likely requires more modest changes in many components of the phototransduction cascade.

## Inner Segment and Connecting Cilia

### Inner Segment

The functional role of the inner segment (IS) can be appreciated by examination of its unique anatomy, which is highly specialized to fuel the high energy and protein synthesis requirements of the photoreceptor. The metabolic functions of the IS are constantly and highly active, generating most of the rod cell's energy as well as being the primary site for synthesizing new proteins. The proximal portion of the IS, termed the myoid, contains the endoplasmic reticulum and Golgi apparatus, while the distal portion, termed the ellipsoid, is densely packed with elongated mitochondria that are aligned circumferentially along the axis of the rod cell (see Fig. 16.2). This unique arrangement of mitochondria may enhance the wave-guiding properties of the photoreceptor.<sup>162</sup> Cones have a larger IS and more mitochondria, perhaps reflecting their higher metabolic needs. In addition, the distribution of mitochondria may optimize the optical properties of cones.<sup>162</sup> This photoreceptor cell compartment is structured for high O<sub>2</sub> consumption, as well as for glycolysis at very high rates.<sup>163</sup> One major metabolic demand comes from the extrusion of Na<sup>+</sup> from the cytoplasm by the Na<sup>+</sup>/K<sup>+</sup> pump at the IS plasma membrane, which balances the influx of Na<sup>+</sup> through the cGMP-gated channels at the OS. In darkness, these pumps operate at a very high rate to accommodate the high fluxes generated by many open channels in the OS, setting up the “dark” circulating current.<sup>164</sup> The rate that these pumps can operate at is related to the supply of ATP<sup>165</sup> generated by the mitochondria in the ellipsoid. This ATP synthesis rate is coupled with the O<sub>2</sub> delivery to

the IS, which is completely supplied by the choroidal circulation. Paradoxically, due to the energy consumption required for establishing the dark circulating current, as well for tonic neurotransmitter release at the synapse in darkness (see below), the rod photoreceptor cell consumes more energy in darkness than in light.<sup>163,164</sup> Another major metabolic need is a high rate of protein synthesis that occurs in the myoid region of the IS to meet the demand of high levels of phototransduction proteins at the OS. In particular, each rod contains  $\sim 5 \times 10^7$  rhodopsin molecules, of which 10% at the tip of the OS is phagocytosed by the RPE before light onset each day. To maintain homeostasis,  $\sim 5 \times 10^6$  molecules are synthesized daily and added to the base of the OS. Similar events occur in cones, although they express about half the amount of visual pigment as rods. As with other cells, the soluble and peripheral membrane proteins are made in the cytosol, while the transmembrane proteins are made in the endoplasmic reticulum. To facilitate the speed of molecular collisions, many of the phototransduction proteins are associated with the membrane through lipid modifications and protein–protein interactions. These interactions are dynamic, with functional complexes forming and dissociating on the membrane surface on a rapid timescale. For example, the rod  $T\alpha$  is heterogeneously acylated at the amino-terminal glycine residue while the gamma-subunit is carboxyl-methylated and prenylated at the cysteine residue. PDE6 $\alpha$  and rhodopsin kinase are farnesylated, while PDE6 $\beta$  is geranylgeranylated.<sup>166,167</sup> In some instances, the lipid modification is exposed as a consequence of a change in protein structure. An example is recoverin that, upon binding calcium, exposes its amino-terminal myristoyl group.<sup>168</sup> GCAP1 and GCAP2 are also calcium-binding proteins that are myristoylated, but exposure of their lipid group is not regulated by calcium binding. These proteins are complexed with RetGCs and regulate their activity in a calcium-dependent manner.

## **Targeting of Phototransduction Proteins From the Inner Segment to the Outer Segment**

How phototransduction proteins traffic from the IS, the site of synthesis, to the OS, the site of phototransduction, is an area of

active research. This question is made more important by the fact that defective trafficking can cause photoreceptor cell death. For example, a cluster of naturally occurring mutations on rhodopsin's carboxyl-terminus causes autosomal dominant retinitis pigmentosa in human patients.<sup>169</sup> These mutations do not affect the biochemical properties of rhodopsin with respect to its ability to bind 11-*cis* retinal and form a visual pigment, nor its ability to activate T $\alpha$  following photon absorption in reconstituted systems.<sup>170-172</sup> The underlying defect remained a mystery until these mutants were expressed in transgenic mice, whereupon it was observed that they were mis-localized throughout the cell and caused retinal degeneration.<sup>173-175</sup> It is now known that the VxPx motif at the rhodopsin's carboxyl terminus is important for sorting of rhodopsin into transport carriers from the trans-Golgi network towards the connecting cilium en route to the OS.<sup>176</sup> This is a recognition site for transport proteins that include the small GTPase Arf4, ASAP1, Rab11, and FIP3.<sup>177</sup> The VxPx motif is also present in cone opsins. Other integral membrane proteins contain their own trafficking motif. These motifs have been identified in peripherin/rds<sup>178</sup> and the cGMP-gated channel in rods.<sup>179</sup> Often a defect in transport of one transmembrane protein does not affect transport of others, suggesting that transport occurs independently.

Trafficking of membrane-associated proteins to the OS may occur through their interaction with transmembrane proteins as they are delivered out of the trans-Golgi network. It was also recently discovered that membrane-associated phototransduction proteins are transported by prenyl- or acyl-chain binding proteins. For example, rhodopsin kinase and cone PDE6 $\alpha'$  require PrBP/ $\delta$ , which contains a binding site for the prenyl group, for transport to the OS,<sup>180</sup> while the alpha-subunit of rod transducin requires UNC119, which binds acyl chains.<sup>181</sup> Thus diverse mechanisms are responsible for correct targeting of phototransduction proteins from the IS to the OS compartment.

## The Connecting Cilium

A slender nonmotile connecting cilium that is 0.3  $\mu\text{m}$  in diameter connects the IS to the OS. The microtubule-based axoneme of the

connecting cilium lacks the central microtubule pair of the motile cilium. The arrangement is a  $9 \times 2 + 0$  microtubule structure towards the base of the cilia, where the doublet microtubules are attached to the plasma membrane via Y-shaped linkers,<sup>182</sup> extending proximally from the vertically arranged basal body is the ciliary rootlet (Fig. 16.2). The doublet microtubules transition to a  $9 \times 1 + 0$  singlet microtubule arrangement more distally from the basal body and continue through much of the OS (Fig. 16.2). The axoneme arises from basal bodies which, together with the centrioles, act as microtubule organizing centers of the photoreceptor cell. The connecting cilium is the site of tremendous vectorial flow of lipids and proteins from their site of synthesis in the IS to the OS. It has been estimated that 2000 opsin molecules are transported every minute from the IS to the OS.<sup>183</sup> As post-Golgi carrier vesicles are delivered to the connecting cilium, proteins destined for the OS need to be sorted between the disk lamellar region, the disk rim region, and the plasma membrane in the OS. How the protein cargo is sorted at this point is not understood fully, but is thought to involve recognition of the specific trafficking motif displayed on the protein cargo by their cognate transport complex that also include the intraflagellar transport (IFT) particles.<sup>183</sup> The IFT particles associate with the post-Golgi carrier vesicles at the base of the cilium and transport them along the connecting cilium to the OS. IFTs are large protein complexes that move along the axoneme by motor proteins and may be viewed as conveyor belts that deliver different cargos to their respective destination.

Ciliary proteins are receiving increased attention because of their association with human retinal disease. They belong to a wide spectrum of diseases associated with defective ciliary function, collectively called ciliopathies.

Actin and myosin are two proteins common to many cells in the body. Both myosin and actin filaments are localized to the photoreceptor connecting cilium and IS. Disruption of either of these proteins causes retinal degeneration.<sup>184</sup> Actin depolymerization promotes disc overgrowth and photoreceptor death,<sup>185</sup> and myosin mutants appear to have defects in the transport of molecules from the IS to the OS. Myosin defects cause

numerous diseases, including Usher syndromes that affect both hearing and vision.<sup>186,187</sup>

*RP1* (retinitis pigmentosa-1) is responsible for 5–10% of all retinitis pigmentosa (RP) cases.<sup>188</sup> *RP1* is a large protein localized to the connecting cilium in both rods and cones and is especially concentrated at the site of nascent OS disks. *RP1* has recently been shown to bind microtubules suggesting that this interaction may stabilize microtubules in the axoneme.<sup>189–191</sup> An *RP1* knockout mouse model shows that discs are misshapen, overgrown, and fail to align properly.<sup>189</sup> This phenotype correlates well with ERG abnormalities in *RP1* patients.

Mutations in the retinitis pigmentosa GTPase regulator gene (*RPGR*)<sup>192</sup> cause X-linked retinitis pigmentosa-3 (RP3), a severe and progressive retinal dystrophy. Antibodies localize *RPGR* and a related protein *RPGRIP* (*RPGR* interacting protein) in connecting cilia of rods and cones and in the cilia of airway epithelia.<sup>193</sup> An *RPGR* knockout mouse (an animal model of RP3)<sup>194</sup> demonstrated mislocalization of opsin in cones, and reduced quantities of rhodopsin in rods prior to photoreceptor degeneration. These data suggest a role for *RPGR* in maintaining the polarized distribution of proteins between the IS and the OS through the connecting cilium.

Centrins are calcium-binding proteins associated with centrosome-related structures. The mammalian rods and cones express four centrin isoforms; three of these (Cen1p-3p) are in the connecting cilium and three (Cen2p-4p) are in the basal body.<sup>195</sup> These centrins may participate in the alignment of the photoreceptor OS. Inasmuch as centrins were shown to interact with transducin in a calcium-dependent manner, they have been proposed to regulate the light-dependent translocation of T $\alpha$  from the OS to the IS.<sup>195</sup>

The ciliary rootlet, first recognized over a century ago, is a prominent structure originating from the basal body at the proximal end of a cilium. Rootlets appear to be particularly robust in retinal photoreceptors, extending from the basal bodies to the synaptic terminals, anchoring ER membranes along their length. Recent studies indicate that rootlets are composed of a structural protein, aptly named rootletin. Rootletin protofilaments are bundled into variably shaped thick filaments within the cilium.<sup>196</sup>

Additional proteins, such as TULP1,<sup>197,198</sup> cadherin,<sup>199</sup> and myocilin,<sup>200</sup> are associated with the connecting cilium, several of which are known to be associated with rod photoreceptor disease. Collectively, genes that affect ciliary trafficking account for a large portion (~25%) of all genetic loci that influence photoreceptor degeneration.<sup>201,202</sup> This suggests, not surprisingly, that the highly specialized connecting cilium is a complicated structure connecting the IS to OS, and that there will undoubtedly be additional proteins associated with this unique subcellular structure.

## Nucleus

The nucleus contains the primary genome of the photoreceptor and is responsible for the initiation of genetic programs in the cell. As a result, the nucleus is the target for gene therapy protocols designed to correct genetic defects in the photoreceptor. Rods and cones differ in their nuclear features. The nucleus of the rod photoreceptor is more round and is stained darker by nucleophilic stains due to the presence of a large clump of heterochromatin. Nuclei of cones are larger and oval in shape, with one to several clumps of heterochromatin and a larger amount of lightly staining euchromatin. Like most cells, photoreceptors also contain a second, non-nuclear genome in the mitochondria. Biochemical pathways linking photoreceptor cell death, the nucleus, and the mitochondria of the IS are beginning to come into focus.

## Photoreceptor Synaptic Terminal

The light response generated by the phototransduction cascade in the OS is passively relayed to the synaptic terminal, called a spherule for rods and a pedicle for cones, where it modulates the rate of glutamate release onto second-order retinal neurons (see Fig. 16.6). Since open CNG channels leave the membrane potential of photoreceptors relatively depolarized in darkness, these synapses support a high level of  $\text{Ca}^{2+}$  influx and thus a high level of glutamate release. Light activates the phototransduction cascade leading to the closure of CNG channels, the hyperpolarization of the membrane potential, and a reduction in  $\text{Ca}^{2+}$  influx, which in

turn reduces glutamate release. This reduction in glutamate release constitutes the “light response” that is passed to the retinal circuitry.

**FIG. 16.6** Glutamate release from photoreceptor cells occurs at a specialized synaptic terminal, called a spherule for rods, and a pedicle for cones. Depicted is a slice through a rod spherule. Glutamate release is facilitated by a specialized structure called a synaptic ribbon, which binds glutamatergic vesicles and brings them to the plasma membrane. Vesicle fusion then occurs as L-type calcium channels near the release site allow the influx of  $\text{Ca}^{2+}$ , allowing glutamate (black dots) to be released into the synaptic cleft where it can be sensed by rod bipolar cells (*RB*) and horizontal cells (*HC*). Both rod bipolar cells and horizontal cells make an invaginating synapse with the photoreceptor cells.

To allow high levels of glutamate release, the photoreceptor synaptic terminals house a specialized synaptic structure, called a

ribbon, which is composed of the protein ribeye.<sup>203</sup> While the exact function of the ribbon has not been fully identified, studies where the ribbon has been photoablated show that the initial release of vesicles is not affected but subsequent release is greatly reduced.<sup>204,205</sup> These results support the prevailing view that the ribbon is required to tether glutamatergic vesicles and acts like a conveyor belt to bring these vesicles to the active zone, where they promote vesicle priming and fusion with the plasma membrane to release glutamate into the synaptic cleft<sup>204,206</sup> (Fig. 16.6). While the spherules of rods contain only one ribbon (i.e., one release site) in mammalian species,<sup>207</sup> the cone pedicles contain many ribbons whose numbers vary by species. In mice, for instance, cone pedicles contain ~10 ribbons,<sup>208</sup> while pedicles in other species like ground squirrels may contain ~15 or more ribbons.<sup>209</sup> Primate cone pedicles may also contain in excess of 25 ribbons.<sup>210,211</sup> Multiple ribbons in each cone pedicle allow the output of the cone to be relayed to many classes of cone bipolar cells (see Chapter 17, Function and anatomy of the mammalian retina).

Compared to conventional central synapses, photoreceptor cells release glutamate in the absence of the stimulus. Such a configuration places fundamental constraints on the mechanisms that regulate glutamate release. For instance, the persistent depolarization of photoreceptors in darkness would cause many types of ion channels to desensitize. To allow robust control of glutamate release with changes in membrane potential, a  $\text{Ca}_v1.4$  channel located close to the active zone in the rod spherule and cone pedicle allows the  $\text{Ca}^{2+}$  influx that regulates release. These L-type  $\text{Ca}^{2+}$  channels display little voltage or  $\text{Ca}^{2+}$ -dependent desensitization,<sup>212,213</sup> and thus are ideal to support continuous glutamate release in darkness. In addition, in rod spherules these channels associate with the modulatory  $\text{Ca}^{2+}$ -binding protein, CABP4.<sup>214</sup> The association of  $\text{Ca}_v1.4$  with CABP4 shifts the voltage sensitivity of  $\text{Ca}_v1.4$  to more hyperpolarized membrane potentials.<sup>214,215</sup> This allows the gating of  $\text{Ca}_v1.4$  channels to be modulated robustly over the rod photoreceptor's the physiologic voltage range.

Additional control of glutamate release may also involve the interaction of other proteins with the synaptic machinery. For

instance, visual arrestin serves to quench fully phosphorylated rhodopsin in the rod OS, but has been shown to interact with N-ethylmaleimide-sensitive factor (NSF) at the rod spherule to increase the turnover rate of SNARE complexes.<sup>34</sup> Similarly, the protein recoverin, which serves as a modulator of rhodopsin phosphorylation in the rod OS, has a separate action in the rod spherule that increases the magnitude of the reduction in glutamate release onto rod bipolar cells.<sup>216</sup> Lastly, the translocation of transducin to rod spherules appears to sensitize glutamate release to rod bipolar cells.<sup>145</sup> Overall these forms of modulation may be controlled by the light-dependent translocation of these components,<sup>139,216</sup> or in the activity of signaling cascades initiated by metabotropic glutamate receptors in the photoreceptor terminal.<sup>217,218</sup> Finally, the control of Ca<sup>2+</sup> homeostasis in photoreceptor terminals can also modulate glutamate release.<sup>219-221</sup>

It should be noted that a majority of our understanding of the structure and function of ribbon synapses has emerged from the study of rod photoreceptors in the amphibian retina, particularly the salamander. However, the characteristics of glutamate release in cones can also be studied in this same species and reveal characteristics that are tuned for the faster kinetics of the light response in cones (reviewed in [reference 222](#)). Furthermore, since the cone photocurrent is difficult to saturate, increased vesicle turnover and recruitment is required to maintain the high level of glutamate release.<sup>223,224</sup> Ultimately, the mechanisms that produce these functional distinctions between rod spherules and cone pedicles remain largely unidentified and are currently under investigation.

## Photoreceptor Dysfunction and Disease

As of August 2016, a total of 316 genes and loci have been identified to cause retinal diseases (RetNet, <http://www.sph.uth.tmc.edu/RetNet/>). The majority of these genes affect rod and cone function that includes ciliary trafficking, visual cycle, lipid metabolism, among others.<sup>201</sup> Here we emphasize the

relationship between defective phototransduction components and retinal degeneration.

## Rhodopsin Mutations

More than 100 different mutations of rhodopsin have been associated with autosomal dominant and recessive retinitis pigmentosa (adRP and arRP) and autosomal dominant congenital stationary night blindness (CSNB).<sup>225</sup> This phenotypic heterogeneity points to diverse disease mechanisms arising from the same gene product. In the case of adRP, it has been proposed that some mutations lead to misfolding of the opsin protein, which then accumulates in the endoplasmic reticulum and elicits the unfolded protein response.<sup>226</sup> The accumulation of misfolded opsin may also interfere with the sorting and trafficking of normal proteins destined for the OS or other parts of the cell.<sup>227</sup> This may result in a pathologic mechanism where the cell cannot replenish other required proteins that do not harbor mutations.

Other rhodopsin mutations appear to affect trafficking of rhodopsin from the IS to the OS. As mentioned previously, mutations involving the last five carboxyl amino acids, such as P347A, P347S, or S344ter, allow rhodopsin to appear to fold normally and to function normally in terms of T $\alpha$  activation and deactivation by phosphorylation and visual arrestin binding. Yet, mutations in these residues cause adRP. Several lines of evidence suggest that the C-terminus of opsin contains a signal for vectorial transport of newly synthesized opsin toward the OS. In a retinal cell-free system, it was demonstrated that a monoclonal antibody to the C-terminal domain of rhodopsin inhibited post-Golgi vesicle formation and arrested newly synthesized rhodopsin in the trans-Golgi network.<sup>228</sup> A wild-type C-terminal peptide, but not a mutant peptide bearing the mutation at the P347 position, can also block this process.<sup>229</sup> Another line of evidence comes from an *in vivo* model where a truncation mutant, S344ter, was expressed in the photoreceptors of transgenic mice. Antibodies that specifically recognize the truncated opsin showed strong immunoreactivity in the IS, indicating a block in the transport to the OS.<sup>175</sup> However, some truncated opsins are also cotransported with the full-length

protein to the OS. The role of the rhodopsin C-terminal domain in vectorial transport was also investigated in MDCK cells.<sup>230</sup> This cell line exhibits polarized structure when it is grown on a porous support. When transfected into this cell line, wild-type opsin was transported to the apical membrane surface, whereas an opsin mutant lacking the terminal 32 amino acids was not.

## Constitutive Phototransduction and Retinal Disease

It is thought that constitutive phototransduction causes some forms of retinal disorders. Unabated signal flow can arise from different steps in the visual cascade. For example, certain mutations in rhodopsin, particularly those that affect the salt bridge between Lys-296 and Glu-113 (such as A292E and G90D), can lead to constitutive activity.<sup>231</sup> The interaction between Lys-296 and Glu-113 constrains the chromophore-free opsin to an inactive conformation.<sup>232</sup> Disruption of this bond leads to an opsin conformation that can support T $\alpha$  activation. This activity is suppressed when the mutant opsin is regenerated with the chromophore 11-*cis* retinal. In the case of G90D and A292E mutations, light exposure leads to formation of opsin that can still activate the visual cascade. This can lead to impairment of visual function because the transduction machinery is overwhelmed by this constitutive activity. Patients carrying these mutations suffer from night blindness because phototransduction in rods cannot be fully quenched.<sup>233,234</sup> However, in the instance of the rhodopsin K296E mutation, no evidence of constitutive activity was observed when it was expressed in rod photoreceptors of transgenic mice; instead, it was found bound to arrestin.<sup>235</sup> It was found subsequently that stable rhodopsin/arrestin complex is toxic, and rod photoreceptor survival can be prolonged if such a complex is prevented in transgenic mice that lack visual arrestin and T $\alpha$ .<sup>236</sup> Toxicity of the rhodopsin/arrestin complex appears to arise from its ability to recruit endocytic proteins, since preventing this interaction had a long-term rescuing effect on K296E-induced retinal degeneration.<sup>237</sup>

Defective shut-off can also be caused by the lack of visual arrestin

or rhodopsin kinase. These genes are mutated in patients diagnosed with the recessive genetic disorder Oguchi disease,<sup>238,239</sup> a non-progressive disorder characterized by early onset and stationary night blindness. These mutations are thought to cause a loss of function in the visual arrestin or rhodopsin kinase gene. Because of the inability to shut off signal flow, the rod photoreceptor becomes saturated even at very low light levels, leading to night blindness. Interestingly, some patients with the visual arrestin gene mutation also suffer from RP, pointing to a potential causal role between constitutive signal flow and photoreceptor cell death. Using the visual arrestin knockout mouse model, Chen and coworkers demonstrated that the absence of visual arrestin in the rod photoreceptor does lower the threshold for light damage.<sup>240</sup> The pathway leading to cell death is initiated by endoplasmic reticulum stress and induction of the unfolded protein response.<sup>241</sup> Therefore, protection from light exposure is an important preventive measure to prolong photoreceptor cell survival in those instances where constitutive signal flow is the disease mechanism.

## Transducin Defects and Retinal Disease

Transducin is composed of three subunits: alpha ( $\alpha$ ), beta ( $\beta$ ), and gamma ( $\gamma$ ). Extensive genetic screening has revealed mutations only in the rod  $T\alpha$ .<sup>242</sup> The associated disease is autosomal dominant congenital stationary night blindness. The mutation is in the position homologous to that affected by the oncogenic mutation in p21ras, a small G-protein. It is therefore hypothesized that this mutation may affect  $T\alpha$  deactivation, leading to the night blindness phenotype. Interestingly, mice that lack rod  $T\alpha$  have normal retinal structure, indicating that this abundant visual G-protein has no structural function in the photoreceptor, and that signal flow is not a prerequisite for rod photoreceptor cell survival.<sup>20</sup>

## cGMP and Photoreceptor Cell Physiology

Cyclic-GMP gates the open probability of CNG channels with a high cooperativity. The probability of open channels is only 0.1 in the dark-adapted rod, which carries the dark circulating current composing of ~85%  $\text{Na}^+$  and 15%  $\text{Ca}^{2+}$  that enters the rod outer

segment. Therefore a small increase in the level of free cGMP can profoundly affect the open probability of CNG channels. This will in turn influence the ion influx, including  $\text{Ca}^{2+}$ , which may directly and/or indirectly trigger photoreceptor cell death.

One of the first characterized mutations affecting components in the phototransduction cascade is the null mutation in the beta-subunit of *PDE6*, leading to the rapid retinal degeneration phenotype in the *rd1* mouse.<sup>13,14</sup> The complete PDE6 enzyme is made up of two catalytic chains ( $\alpha$  and  $\beta$ ), each associated with an inhibitory chain ( $\gamma$ ). Since both alpha- and beta-subunits are necessary for the formation of a functional phosphodiesterase holoenzyme, the mutation in either subunit renders the holoenzyme inactive. The gamma-subunit is important for inhibition of the catalytic subunits and is also necessary for structural stability of the holoenzyme.<sup>243</sup> Farber and Lolley<sup>244</sup> showed that photoreceptor cell death is preceded by an accumulation of cGMP in the retina, which is consistent with the role of this enzyme in degrading cGMP. Mutations in genes encoding all three PDE subunits (*PDE6A*, *PDE6B*, *PDE6G*) have been found to be associated with autosomal recessive retinitis pigmentosa in humans. RetGCs are responsible for synthesizing the cGMP that is necessary for reopening of the CNG channel leading to recovery of the dark current. Two membrane forms of RetGCs are expressed specifically in the retina of several mammalian species, including humans.<sup>245-248</sup> Whereas other membrane cyclases are activated by the binding of peptide ligands to their extracellular domains, the activity of RetGCs is controlled by interaction with GCAPs through their intracellular domain.<sup>249,250</sup> Because the extracellular domain of RetGCs is situated in the enclosed and seemingly inaccessible intradiscal space, it is questionable whether the extracellular domain serves as a receptor. The retinal cyclases are therefore termed “orphan” receptors because no ligands have yet been identified. Although two forms of RetGCs are expressed in the photoreceptor layer, there is evidence that they are not functionally redundant. First, they appear to be expressed at different levels in different photoreceptors. For example, it was observed that RetGC1 immunoreactivity is stronger in cone OS than in rod OS,<sup>251</sup> RetGC2, on the other hand, is expressed in the rod

OS,<sup>252</sup> but evidence for cone expression is lacking. Second, RetGC1 and RetGC2 behave differently biochemically in terms of their regulation by GCAPs: RetGC1 is regulated by both GCAP1 and GCAP2, whereas RetGC2 is regulated by GCAP2 but not by GCAP1.<sup>116,246,249–251</sup> In humans mutations in RetGC1 are linked to autosomal recessive Leber congenital amaurosis<sup>253</sup> and dominant cone–rod dystrophy.<sup>254</sup> No mutation in *RetGC2* has been associated with human blindness.

Another naturally occurring mutation that is expected to increase intracellular cGMP concentration is the Y99C mutation in *GCAP1*, a mutation that causes cone dystrophy in an autosomal dominant manner.<sup>255</sup> This mutation renders GCAP1 capable of stimulating RetGC, independent of Ca<sup>2+</sup> concentration.<sup>113,256</sup> Constitutive activity of RetGC may therefore lead to an accumulation of intracellular cGMP. In addition to the Y99C mutation, nine other heterozygous mutations in the gene encoding *GCAP1* (*GUCA1A*) have been linked to autosomal dominant cone dystrophy, cone–rod dystrophy, or macular degeneration.<sup>257–261</sup> Many of these mutations are found in the Ca<sup>2+</sup> binding domain. Mutations involving *GCAP2* have also been linked to autosomal dominant retinitis pigmentosa<sup>262</sup> and macular dystrophy.<sup>263</sup>

This hypothesis of cell death pathway through excessive number of open channels by elevated cGMP has been strengthened in a mouse model wherein the absence of CNG channels delayed retinal degeneration associated with elevated cGMP.<sup>264</sup> In support of this idea, survival of rd1 photoreceptors, whose mutation in *PDE6* beta leads to buildup of cGMP, was enhanced when the mutation was put into a CNG channel knockout mouse background.<sup>264</sup> This observation motivates effort to synthesize small molecules that specifically block the CNG channel as a means to prolong photoreceptor cell survival.<sup>265</sup> A loss of RetGC1, on the other hand, is expected to lead to lowered cGMP levels. This might be functionally equivalent to constant light and may lead to cell death. However, further experiments will be needed to evaluate rigorously the relationship between cGMP concentration and retinal degeneration.

**Conclusions**

The vertebrate retina forms a thin sheet of neural tissue at the back of the eye that converts light to an electrical signal. The neural retina is approximately 100–200  $\mu\text{m}$  thick, depending on the species, and represents a triumph of miniaturization.<sup>1</sup> The retina is a spatial information processor built upon a mosaic of rod and cone photoreceptors, which are the light-responsive elements that initiate

signaling using graded electrical signals.<sup>2</sup> The spatial information content is preserved through the lateral geniculate nucleus, retinotopically mapped on to area V1 (area 17) of the primary visual cortex and from there on to a number of higher visual processing areas. There is considerable processing both within the retina as well as in higher brain structures and we interpret these electrical signals as vision. While vision is an analog system, a rough approximation to a digital system would result in a resolution in excess of 500 megapixels. Although initially conceived to be a simple model for the brain, more probably, the retina approaches limits imposed by metabolism, blood flow, and diffusion. This pressure to pack more function into a small volume of neural tissue leads to increased complexity.

## Visual Illusions and Multiple Channels

Vision appears to be deceptively simple only because we are very good at it: with few exceptions, a large portion of the mammalian brain is devoted to vision. A moment's thought reveals that vision must dovetail neatly with such high-order processes as image storage and retrieval, forms of learning and memory essential to comparison and recognition. However, even in the retina, it is easy to demonstrate the presence of multiple processes using well-known visual illusions.

At first glance, [Fig. 17.1](#) looks like a random array of large pixels with three bright areas. Now, screw up your eyes, glance aside or look at it from the other side of the room, and suddenly you may recognize da Vinci's Mona Lisa. The bright areas are the face, chest, and hands. But why does the image seem to be more recognizable when visual input is distorted? The high-spatial-frequency components have been removed by greatly reducing the pixel number. What detail does remain is a confusing array of boxes. However, this detailed view can be blurred by squinting, which removes the high-frequency components, leaving an easily recognized low-acuity version. So this is a direct demonstration that the visual system operates on at least two channels of information at different spatial scales simultaneously. In fact, there is empirical evidence that vision is composed of at least 15 parallel channels or

streams of information that are transmitted simultaneously throughout the visual system. It is the purpose of this chapter to describe the functional anatomy of the retina that leads to the formation of some of these independent channels of visual information.

**FIG. 17.1** Parallel pathways. A highly filtered image,  $13 \times 20$  pixels, of a well-known icon containing mostly low-spatial-frequency information. At first, it may be hard to recognize because it is natural to focus on the pixel edges. However, if you squint to blur the image, the true identity of the picture may suddenly become

more obvious. This is a direct demonstration that the visual system carries several parallel streams of visual information with different spatial properties. For more details, see the text.

## The Retina Is a Piece of Brain

Like the rest of the central nervous system (CNS), the retina is embryologically derived from the neural tube. It is formed from the same components as the rest of the CNS and like all other sensory systems has specialized structures, photoreceptors that transduce environmental energy into electrical potentials. As such, one can divide the retina in two parts:<sup>3</sup> (1) the sensory retina, concerned with phototransduction of light by rod and cone photoreceptors; and (2) the neural retina, consisting of more typical interneurons (bipolar, horizontal, and amacrine cells) and projection neurons (ganglion cells) that carry out the first steps in processing visual information.

The retina has been characterized by Dowling as an approachable part of the brain,<sup>4</sup> because it is a ready-made brain slice with few barriers to the penetration of drugs or antibodies. In addition, its natural stimulus, light, is easily controlled and the same stimuli can be presented either to the intact animal or to the retina removed from the eye and placed in vitro. This chapter focuses on processing in the mammalian retina. However, many of the pioneering studies in retinal function were initially performed in fish and amphibian retina. In particular, the salamander retina has been a longstanding model because its large cells enhance the ease of electrophysiologic recording.

## Neuronal Communication: Chemical and Electrical

In the retina, as in the rest of the CNS, the dominant form of communication between neurons uses chemical neurotransmission. Pulses of neurotransmitter (commonly the amino acids glutamate, gamma-aminobutyric acid (GABA) and glycine plus acetylcholine

(ACh), dopamine, and serotonin) are released from a presynaptic neuron and diffuse across the narrow synaptic cleft to bind to one of a variety of postsynaptic receptors. Receptors can be ion channels themselves or can be linked via intracellular mechanisms to ion channels. Depending on the ion selectivity (anion or cation), the opening or closing of the channels produces a hyperpolarization or a depolarization of the postsynaptic cell.

Many neurons also are directly connected via electrical synapses known as gap junctions.<sup>5-9</sup> Gap junctions are named after the narrow gap formed by docked hemichannels, or connexons aligned on either side of two cell membranes. Each hemichannel is built from six connexins that surround a central pore, forming an intercellular channel, which passes ions and small molecules ( $\leq 1$  kDa). Gap junctions are not static pores; they are modulated by light and contribute to neural processing.

## The Retina Is a Layered Structure

The retina is a beautifully layered structure in which three layers of neurons can be visualized without staining (Fig. 17.2). The outer nuclear layer (ONL) contains the cell bodies of photoreceptors, both rods and cones. The inner nuclear layer (INL) contains the cell bodies of horizontal, bipolar, amacrine, and radial glial (or Müller) cells. The ganglion cell layer (GCL) contains displaced amacrine and ganglion cells. Ganglion cells are the projection neurons of the retina: their axons form the optic nerve and project to a variety of subcortical nuclei. The three nuclear layers are separated by two synaptic (plexiform) layers that contain the dendrites and synapses. The outer plexiform layer (OPL) lies between the ONL and the INL. This is where the photoreceptors, horizontal, and bipolar cell dendrites interact. The inner plexiform layer (IPL) separates the INL and the GCL and this is where the bipolar cell axons, amacrine, and ganglion cells interact. When we speak of the retina, outer or distal refers to the scleral side of the retina and inner or proximal refers to the vitreal side of the retina.

**FIG. 17.2** Primate retina. A vertical section through the macaque retina taken with differential interference contrast optics. The retina is a layered structure with two synaptic or plexiform layers sandwiched by three nuclear layers: the outer nuclear layer, inner nuclear layer, and ganglion cell layer. Although many fine details, such as cone pedicles, are visible, individual neurons must be stained to see their dendritic fields and specific connections. *Longer arrows*: cones; *smaller arrows*: cone pedicles. (Courtesy of S.C. Massey.)

The functional stratification of the retina extends to the IPL, which is organized according to the polarity of bipolar cell inputs.<sup>10</sup> Since the time of Cajal, the IPL has been divided into five layers: 1 and 2 for sublamina a and layers 3–5 for sublamina b. In mammalian species, there are 9–11 morphologic types of bipolar cell, plus the rod bipolar cell, which terminate at different depths in the IPL.<sup>11–13</sup> The polarity of a bipolar cell response is determined by the differential expression of postsynaptic glutamate receptors on their dendrites. The dendrites of OFF cone bipolar cells carry  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate receptors and they ramify in sublamina a of the IPL.<sup>14</sup> In contrast, ON cone bipolar cells and rod bipolar cells express mGluR6 receptors and their axons ramify in sublamina b.<sup>15–17</sup> The separation of ON and OFF pathways appears to be a fundamental principle of retinal organization, which is reflected throughout the visual system.<sup>18,19</sup>

There is a wealth of evidence to support the functional division of the IPL into ON and OFF sublaminae. For example, cholinergic

amacrine cells (ChACs), also known as starburst amacrine cells on account of their unique morphology, are present as mirror-image pairs.<sup>20</sup> The conventionally placed ChACs have somas in the innermost layer of the INL. They have OFF responses to light stimulation and ramify in sublamina a. In contrast, the displaced ChACs reside in the GCL, produce ON responses, and ramify in sublamina b. Likewise, alpha ganglion cells are present as paramorphic pairs such that the dendritic trees of OFF alpha ganglion cells are stratified in sublamina a to receive input from OFF bipolar cells while ON alpha ganglion cells ramify in sublamina b to make contact with ON bipolar cells.<sup>21,22</sup> In primate retina, both midget and parasol ganglion cells are present as paramorphic pairs, which conform to the stratification rules of the IPL. ON/OFF directionally selective (DS) ganglion cells produce both ON and OFF responses of short latency, indicating direct input, and they are bistratified with dendrites in sublaminae 2 and 4, coincident with the cholinergic bands.

The ON and OFF stratification of the IPL is a fundamental tenet of retinal organization which applies to many, if not most, cell types. However, several exceptions to this rule have now been identified. For example, the dopaminergic amacrine cells (DACs) stratify predominantly in sublamina a, the OFF layer, yet they apparently produce ON responses to light.<sup>23,24</sup> Likewise, the intrinsically photosensitive retinal ganglion cells (ipRGCs), which stratify in sublamina a of the primate retina, were all ON cells.<sup>25</sup> These cell types, among others, receive input from ON bipolar axons as they traverse sublamina a of the IPL. These axonal ribbons provide a set of inputs that break the stratification rules of the IPL. Thus, there is an additional accessory ON sublayer in the outer portion of the IPL<sup>26,27</sup> (see sections on [DACs](#) and [ipRGCs](#)) ([Table 17.1](#)).

---

**TABLE 17.1**  
**Cellular and Synaptic Layers of the Retina**

---

Layer	Contains:
Outer nuclear layer (ONL)	Photoreceptors, rods, and cones
Inner nuclear layer (INL)	Horizontal cells, bipolar cells, amacrine cells, Müller cells
Ganglion cell layer (GCL)	Ganglion cells, displaced amacrine cells

Outer plexiform layer (OPL)	Photoreceptors talk to horizontal cells and bipolar cells
Inner plexiform layer (IPL)	Bipolar cells talk to amacrine cells and ganglion cells

GCL, ganglion cell layer; INL, inner nuclear layer; IPL, inner plexiform layer; ONL, outer nuclear layer; OPL, outer plexiform layer.

## Gross Retinal Morphology

### The Fovea

When a peripheral visual stimulus gets our attention, we automatically focus the retinal image in the center of our gaze. In the primate retina this central region of highest visual acuity is known as the fovea. Here there is a depression in the retina, known as the foveal pit, where cone photoreceptor density is highest and there are no rods. The pit results from the lack of overlying neurons (Fig. 17.3). Instead, cone axons, Henle fibers, run obliquely to cone pedicles away from the fovea where the bipolar and ganglion cells connected to the central cones are “piled up” in an annular zone with the GCL 6–8 cells thick. The foveal structure is thought to maximize sensitivity because light cannot be scattered by passing through other retinal layers. It also optimizes acuity by packing the maximum number of cones and reducing their size. In human retina, the peak cone density approaches 200,000/mm<sup>2</sup> and the ONL is slightly thicker to accommodate these extra cells.<sup>28</sup> There are no blood vessels in the fovea, and in the central fovea there are no blue cones. The low density of blue cones lowers their acuity,<sup>29</sup> to match the blurring caused by chromatic aberration in the lens.<sup>30</sup> Other mammals have an area centralis (cat) or a visual streak (rabbit, swine) with similar high cell density but these structures lack the central depression. A consequence of the exclusion of rods from the fovea is that in dark-adapted conditions, say looking for a dim star, it is necessary to look slightly off the visual axis to focus the image in the region of high rod density.

**FIG. 17.3** The fovea and distribution of rods and cones in the human eye. (A) This cross-section of the macaque retina shows the foveal pit, a specialization of the primate retina. In this region, the cones are smallest and their packing density reaches a maximum. There are no rods. At the fovea, ganglion cells and other retinal layers are reduced for maximum sensitivity and acuity. *PE*, pigment epithelium; *OS*, outer segments; *ONL*, outer nuclear layer; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *GCL*, ganglion cell layer. (B) Rod and cone density across the retina. Note how the cones peak at the fovea. Rod density falls to zero at the fovea but reaches a maximum around 5 mm outside the fovea. There are no photoreceptors at the point where the optic nerve leaves the eye, also known as the blind spot. (Panel A, courtesy of Louvenia Carter-Dawson. Panel B, modified with permission from Wandell BA. *Foundations of vision*. Sunderland, MA: Sinauer Associates, 1995.)

## The Blind Spot and How to Find It

There are no photoreceptors where the optic nerve exits the eye and

so any image that falls on this region cannot be processed by the retina. Curiously, we do not perceive a hole in the visual scene because the visual system fills in. To demonstrate the blind spot, hold the page level at normal reading distance. Look at the O in [Fig. 17.4](#), and then close your right eye. The X on the left should disappear because the image of the cross falls on the optic nerve head. You can reverse this demonstration: look at the X, then close the left eye to make the O disappear. Remember, the blind spot is nasal to the fovea. The light rays cross over at the lens so the blind spot is lateral to the point of focus.

**FIG. 17.4** How to find the blind spot. To demonstrate the blind spot, hold the page level at normal reading distance. Look at the O in the figure, then close your right eye. The X on the left should disappear because the image of the cross falls on the optic nerve head. You can reverse this demonstration: look at the X, then close the left eye to make the O disappear. Remember, the blind spot is nasal to the fovea. The light rays cross over at the lens so the blind spot is lateral to the point of focus.

## Painting the Retina – Techniques to Label and Visualize Retinal Neurons

The major landmarks of the retina, two synaptic layers sandwiched between three nuclear layers, are obvious even in the unstained section of macaque retina shown in [Fig. 17.2](#). In fact, there is an immense amount of detail present in this image. For example, individual cones can be seen with their descending axons terminating in a row of cone pedicles in the OPL. However, the somas of all the other retinal neurons are indistinguishable and the

details of their structures cannot be visualized. One goal of vision scientists is to have a complete map of all the interconnections between the retinal neurons so that the functional outputs can be fully understood. To uncover the hidden pathways and circuits through the retina, we need to stain specific cell types selectively (Fig. 17.5), so that we can differentiate between rod and cone pathways, for example. Furthermore, it is very useful to visualize several cell types at once so that the number and position of one cell type relative to another can be determined. This can be achieved by confocal microscopy, which permits the simultaneous acquisition of three or more different labels in addition to providing improved resolution and three-dimensional visualization (Fig. 17.5). With care, confocal microscopy can be used to visualize both chemical and electrical synapses in the retina.<sup>31</sup> It has been used to measure changes in intracellular calcium concentration of single neurons or dendrites in response to stimulation with visible light.<sup>32,33</sup> One disadvantage of these methods is that individual synapses cannot easily be visualized because of the inherent resolution limits of confocal microscopy. However, high-throughput electron microscopy methods have been developed that allow three-dimensional reconstruction of blocks of retina, albeit in fixed tissue. By careful analysis and multiple staining approaches it is possible to identify all the synapses and cells to which an individual neuron makes connections.<sup>34</sup>

**FIG. 17.5** Quad labeling of the rabbit retina. In this vertical section, multiple antibodies were used to label different cell types. Red, calbindin, shows horizontal cells, large somas high in the inner nuclear layer (*INL*) adjacent to the outer plexiform layer (*OPL*). Also in red, an ON cone bipolar cell with a single axon descending to sublamina 4 of the inner plexiform layer (*IPL*). Green, protein kinase C (*PKC*), shows multiple rod bipolar cells descending to sublamina 5 of the IPL where they have prominent terminals. Blue, choline acetyltransferase (*ChAT*), labels starburst amacrine cells, one in the INL and two in the ganglion cell layer. These cells make two dense bands in the IPL. Pink, tyrosine hydroxylase (*TOH*), shows the plexus of dopaminergic processes, mostly in sublamina a, adjacent to the amacrine cell layer. There are also a few processes in the middle of the IPL. As well as staining multiple neurons, this figure demonstrates that the IPL is highly stratified with each cell type at a distinct depth. Ten to 12 distinct layers can be found in the IPL. (Courtesy of W. Li and S.C. Massey.)

The mainstay of structure, function, and morphology studies is immunocytochemistry, which can be used to stain structural components, enzymes, neurotransmitters, synaptic proteins, and postsynaptic receptors (Fig. 17.5). Primary antibodies are currently available for many of these components. Secondary antibodies

conjugated to an ever-increasing variety of fluorochromes are readily available as standard reagents and allow for multiple staining. Single neurons can also be filled with fluorescent dyes via glass microelectrodes. Diffusible tracers such as Neurobiotin can be used to label a network of coupled cells.<sup>5</sup> The optic nerve can be back-filled with fluorescent dyes, which in one useful variant are concentrated in vacuoles that explode when excited to release dye, which diffuses throughout the dendritic structure of individual ganglion cells.<sup>35</sup> Certain ganglion cell types can be selectively labeled by stereotactically injecting a central target with retrograde tracers.<sup>36</sup> Individual neurons of all types can be randomly labeled with ballistic particles coated with fluorescent dyes or DNA to synthesize a specific marker.<sup>37</sup> Finally, there is increasing use of transgenic animals such as mice engineered to express green fluorescent protein (GFP) variants under the control of a specific promoter.<sup>38</sup>

## Six Major Neuronal Cell Classes

The retina contains six major neuronal classes. Photoreceptors are located in the ONL and can be subdivided into rods and cones. Bipolar cells take the signals from photoreceptors and transmit them to the inner retina. Horizontal cells and amacrine cells are laterally extensive interneurons in the outer and inner retina, respectively. Ganglion cells receive input from bipolar and amacrine cells and form the output from the retina. In addition, interplexiform cells share many properties with amacrine cells but project back to the outer retina. Finally, the radially oriented Müller cells are the predominant glial cells (Table 17.2).

**TABLE 17.2**

### Major Cell Types in the Retina

Neuronal Types	Role	Types
Photoreceptors	Rod and cones	2
Horizontal cells	Lateral interneurons, OPL	2
Bipolar cells	Vertical connection	10–12
Amacrine cells	Lateral interneurons, IPL	~30
Ganglion cells	Output neurons	~40
Interplexiform cells	Feedback, IPL to OPL	?

IPL, inner plexiform layer; OPL, outer plexiform layer.

## Classification of Retinal Cells

Although the retina contains six major neuronal cell classes, these may be further divided into many distinct subtypes for a total of about 80 different neurons. Cells of a given type form nonrandom mosaics across the retina.<sup>39</sup> A single type shares essential morphologic features and uses the same neurotransmitter(s). Furthermore, they ramify at a characteristic depth in the retina and make stereotyped synaptic connections, including the same type and number of postsynaptic cells, and even the same number of synapses.<sup>40,41</sup> As we learn more about neuronal circuits and the functional anatomy, we see repeated patterns across the retina, and we are reminded that it is a two-dimensional array of recurring circuits.

The classification of retinal neurons, which dates back to the work of Cajal more than a century ago, is not a simple matter.<sup>42</sup> However, it is important that we are at least aware of all the major cell types in the retina. Even a basic understanding of a circuit cannot be achieved if critical parts are missing. Classification is complicated by the large number of different cell types, the low probability of obtaining rare types, variation in size with eccentricity, and the normal morphologic variation within a cell type. While the staining and sampling issues have largely been resolved by modern methods, the question of what constitutes a separate cell type, as opposed to subtle differences between examples from the same type, is still a problem. The resolution lies partly in understanding the significance of some morphologic features and partly in considering more variables, i.e., independent criteria to classify a specific cell type. Finally, as a kind of parity check, it is necessary to consider the properties of a whole population for a given cell type to see if it is consistent.

Neurons may be classified into unique cell types on the basis of several properties: (1) their morphology, meaning the size, shape, and complexity of their dendritic arbores; (2) the depth within the IPL that their dendrites ramify; (3) their electrophysiology,

particularly their excitatory and inhibitory inputs; (4) their biochemistry, particularly with regard to the different neurotransmitters used to communicate between neurons and structural proteins or receptors; (5) the pattern of connections with other neurons, which should be consistent for a unique cell type; and (6) the properties of the whole population for a specific cell type.

## Photoreceptors

### Cones

The mammalian retina contains two types of photoreceptor: rods and cones.<sup>43</sup> Rods account for 95% of all photoreceptors. They are numerous, with slender outer segments, densely packed and specialized for high sensitivity under dark or starlight conditions. Cones are larger, with tapering outer segments, and they are found in the top row of the ONL (Figs. 17.2 and 17.3). Cones make up only ~5% of photoreceptors<sup>28,43</sup> but they provide high-acuity color vision in daylight conditions when photons are abundant. This versatile combination of rods and cones and their associated circuits covers an intensity range of around 10 log units from the darkest night to bright sunlight.<sup>44</sup> While the average visual scene has a range of intensities covering 2–3 log units, the continual adaptation of retinal sensitivity slides this operating range through the entire range of light intensities. This is a critical function of the retina because outside the normal operating range we are functionally blind. Common examples include the inability to see momentarily when entering a dark cinema or driving into the setting sun. Much of the adaptation takes place in photoreceptors but, as we shall see below, this is accompanied by major changes in the neural pathways through the retina. This is arguably the most important function of the retina, after light detection itself.

There are approximately 5 million cones in the human retina and 190,000 in the mouse retina.<sup>45,46</sup> Cones make up approximately 5% of the total photoreceptors in humans, compared to 2.8% in the mouse,<sup>47</sup> so we are all rod-dominated in terms of absolute numbers. One exception is the ground squirrel, which is truly cone-dominated. Importantly, cones are not evenly distributed. In

human retina, there is a massive peak at the fovea (Fig. 17.3) where the density reaches around 200,000/mm<sup>2</sup>, approximately 100 times the density in the periphery.<sup>28,45</sup> This is the region of maximum acuity, although the peak density slightly exceeds experimentally measured visual acuity due to blurring by the optics of the eye.<sup>48-50</sup> Where the ganglion cell axons gather to form the optic nerve there are no photoreceptors and their absence from this location is the cause of the blind spot (Fig. 17.3).

Cones support color vision and, in Old World primates and humans, there are three classes: blue, green, and red. They are maximally sensitive to 430, 530, and 561 nm light, respectively.<sup>51-53</sup> Other mammals, including cats, rabbits, and rodents, have an evolutionary ancient form of color vision based on green and blue cones only. The presence of red and green cone opsins in a tandem array on the X chromosome is thought to be due to a recent gene duplication and underlies the preponderance of color blindness among males.<sup>54</sup> Using adaptive optics to correct for blurring in the lens and cornea, the distribution of red, green, and blue cones can be mapped in the living human eye.<sup>55</sup> Surprisingly, the distribution of cones was random and clumpy (Fig. 17.6). In addition, there appears to be enormous variation in the red/green cone ratio among individuals with normal color vision.

**FIG. 17.6** The mosaic of red, green, and blue cones in the human retina. This image, taken from a human subject using adaptive optics, shows the distribution of the three cone classes. Blue cones make up a small fraction, <10%, but make a regular mosaic. Red and green cones have a clumpy, random distribution. In this subject, the red cones outnumber the green cones but this ratio is highly variable, even in subjects who have normal color vision. (Courtesy of Austin Roorda; after Roorda A, Williams DR. The arrangement of the three cone classes in the living human eye.

Nature 1999;397:520–2.)

Blue cones are present as a minority: they make up approximately 10% of the cone population (Fig. 17.6). This is not enough to support high acuity but calculations show that the blue cone density is sufficient to support the reduced resolution caused by visual aberration at the blue end of the spectrum.<sup>30</sup> At the very center of the fovea, blue cones are absent.<sup>28,56</sup> The fact that this is not readily apparent is due to the relatively poor spatial acuity of color vision compared to the luminance-driven pathways.

Red and green cones cannot be differentiated morphologically and the red and green cone opsins are so closely related that they are also indistinguishable. However, blue cones can be mapped with a selective antibody against blue cone opsin<sup>29,57</sup> or by their selective accumulation of certain dyes.<sup>56</sup>

## Rods

The ONL contains photoreceptor cell bodies, both rods and cones.<sup>43</sup> Even in the cone-dominated human retina, rods far outnumber cones, by a factor of 20 : 1, so they account for most of the ONL except at the fovea. The human retina contains approximately 100 million rods, and they pool signals to provide high sensitivity for dark-adapted vision, say starlight, which appears monochromatic. A lack of color vision is the hallmark of rod-mediated vision. Rods are absent within 350  $\mu\text{m}$  of the fovea but reach a peak density in an annular region at about 20° eccentricity (Fig. 17.3). This does not match the area of maximum scotopic acuity, which occurs around 5°,<sup>58</sup> so it has been suggested that another component of the rod pathway, such as the AII amacrine cells, present at a much lower density, forms a bottleneck to limit acuity<sup>59,60</sup> (see below).

## Cone Pedicles and Rod Spherules

Cones and rods make contact with bipolar and horizontal cells in the OPL. Cone axons descend through the massed ranks of rod somas in the ONL to terminate in a two-dimensional array of cone pedicles at the OPL (Fig. 17.7). Near the fovea in primate retinas, the cone axons are splayed out radially so that the pedicles form an annular array around the center (Fig. 17.7B). Cones form two specialized contacts, ribbon synapses and flat contacts, with postsynaptic neurons. Ribbon synapses are so named because of electron-dense structures at invaginations where they contact depolarizing (or ON) bipolar and horizontal cells (Fig. 17.8). Cone pedicles also make flat contacts along the base of the pedicle with hyperpolarizing (or OFF) bipolar cells. Rod axons also descend to form synapses with a single type of depolarizing bipolar cell as well as horizontal cells. The terminals of rods are called spherules, and, similar to cones, they use a ribbon synapse. In contrast to cones, there is only a single invagination in each, containing two rod

bipolar and two horizontal cell dendrites.

**FIG. 17.7** Primate cones. (A) Vertical section of macaque retina shows cones stained with an antibody against cone arrestin. The outer segments of a few cones, <10%, have been double-labeled with an antibody against blue cone opsin. From each cone, an axon descends to the cone terminal or pedicle. (B) Whole-mount view shows how the axons run obliquely away from the fovea to terminate in an annulus of cone pedicles. (C) Close to the fovea, the cone pedicles form a tightly packed array connected by very fine telodendria. The dark regions within each pedicle are the invaginations penetrating from beneath. (D) More peripherally, the cone pedicles are widely spaced and connected by longer telodendria which are the sites of

cone-to-cone coupling. (Antibody donated by Peter MacLeish, images courtesy of J. O'Brien and S.C. Massey.)

**FIG. 17.8** Laminated postsynaptic structure of the cone pedicle. (A) Cross-section of a single cone pedicle contains synaptic ribbons and synaptic vesicles. Horizontal cell dendrites (red) invaginate the cone pedicle deeply and laterally. ON cone bipolar dendrites (green) assume a central position beneath the ribbon. (B) Whole-mount view, in the plane just below the multiple synaptic ribbons, shows the relative positions of horizontal and ON bipolar processes. The OFF bipolar contacts are beneath this plane of focus.

(C) Electron microscopic view of a cone pedicle. *Arrowheads* mark synaptic ribbons. Horizontal cell processes (*H*) are lateral, ON bipolar dendrites (*star*) central. OFF bipolar cells (*asterisk*) form basal synapses away from the synaptic ribbon. Beneath each cone pedicle lies a snake's nest of postsynaptic processes. There are also specialized desmosome-like contacts of unknown function between horizontal cell processes (*small arrows*).

(Reproduced with permission from Haverkamp S, Grunert V, Wässle H. The cone pedicle, a complex synapse in the

Each cone pedicle is 6–8  $\mu\text{m}$  in diameter and, near the fovea, contains 20 synaptic ribbons and, in the periphery, around 40.<sup>61</sup> Cones release glutamate constantly in the dark, and the synaptic ribbons are thought to support this high rate of release. As we will describe further below, the multiple ribbon and flat synapses on each cone pedicle form connections with many different types of bipolar cell.

A sense of the complexity of these synapses can be obtained by labeling some of the individual components. Antibodies reactive against a vesicle protein such as synaptophysin provide a way to label photoreceptor terminals in the OPL, because photoreceptor axon terminals are filled with vesicles. To visualize the synaptic ribbons, antibodies to kinesin II can be used. Finally, antibodies to the mGluR6 receptor, which is located on the dendritic tip of the depolarizing bipolar cells, mark one of the postsynaptic processes. When visualizing just the cone pedicle, there are a number of indentations or invaginations (Fig. 17.8). Within each invagination, horizontal cell dendrites are lateral and high, approaching the synaptic ribbons. ON cone bipolar cell processes are central but slightly lower at the synaptic ribbon. In contrast, OFF bipolar dendrites form basal synapses with the cone pedicle at a distinctly lower level. Staining a piece of retina for synaptophysin, kinesin II, and mGluR6 begins to show the complexity of the structures (Fig. 17.9). Rod spherules contain a single large horseshoe-shaped ribbon with two bipolar cell dendrites nestled within. The cones have numerous and slightly smaller ribbons with each also nestled against an mGluR6-labeled dendrite. What is not visible are the horizontal cell dendrites that also invaginate, but are slightly lower than the bipolar cells.

**FIG. 17.9** Synaptic structure of rod spherules and cone pedicles. (A) The terminals of rods and cones are packed with synaptic vesicles and contain synaptic ribbons. An antibody against synaptophysin (green), a synaptic vesicle protein, labels rod spherules which appear round (some are outlined to the lower right) and cone pedicles which are polygonal (larger outlines). Each rod spherule contains a single large synaptic ribbon which is curved like a horseshoe, stained with an antibody against kinesin II (red). The cone pedicles contain a complex of smaller synaptic ribbons (also red). (B) The dendritic tips of rod bipolar and ON cone bipolar cells can be marked with an antibody against the glutamate receptor, mGluR6 (blue). The central invagination of each rod spherule contains a pair of mGluR6-positive rod bipolar dendrites. At each cone pedicle, there are a number of

finer ON bipolar dendrites. (C) The rod bipolar dendrites (blue) are nestled within the horseshoe formed by the synaptic ribbon (red) at each rod spherule. At the cone pedicles, the ON bipolar dendrites also approach closely to the cone synaptic ribbons. (D) A triple-label image showing rod spherules and cone pedicles (green, some outlined), synaptic ribbons (red) and the postsynaptic bipolar dendrites tagged for the glutamate receptor mGluR6 (blue). Scale bars = 10  $\mu\text{m}$ . (Courtesy of W. Li and S.C. Massey.)

Around 10–12 cone bipolar cells plus multiple horizontal cell dendrites contact each cone, so under the pedicle there may be as many as 200 postsynaptic processes.<sup>62</sup> In fact, the cone pedicle may be the most complex synaptic structure in the brain. The distribution of postsynaptic processes under the cone pedicle is laminated in a stereotyped fashion (Fig. 17.8).<sup>61,62</sup>

The fundamental problem for rods is to detect a small brief hyperpolarization due to a single photon against a noisy background of thermal noise and the stochastic nature of transmitter release.<sup>63,64</sup> One strategy is to minimize background variation by maintaining a high sustained-release rate in the dark. The synaptic terminal of a rod, or rod spherule, is about 2  $\mu\text{m}$  in diameter and contains a very large synaptic ribbon (Fig. 17.9), a specialization thought to be associated with a high rate of transmitter release. The spherule is packed with synaptic vesicles, containing the neurotransmitter glutamate, to support sustained transmitter release. There is a single invagination (imagine a closed fist and insert a finger between thumb and forefinger to make a pocket) containing a tetrad of processes, two from horizontal cells and two rod bipolar dendrites.<sup>65</sup> This structure brings the postsynaptic processes close to the release site and may prevent spillover to adjacent rods. These anatomic specializations appear to reduce variation in rod signaling so that small single-photon responses can be detected with high reliability.

## Photoreceptor Coupling

While the synapses between photoreceptors and second-order neurons are extremely complex, there are still additional

connections between photoreceptors. These take the form of electrical coupling, mediated by gap junctions. Close to the fovea, the cone pedicles are densely packed, almost touching, and connected by very fine processes known as telodendria (Fig. 17.7C).<sup>43</sup> Rod terminals are either absent or displaced slightly higher, towards the outer segments, in this region. More peripherally, the cone pedicles are widely spaced and the telodendria are much more prominent (Fig. 17.7D). The contact points between telodendria of neighboring cones are the sites of connexin (Cx)36 gap junctions, which mediate electrical coupling between cones.<sup>66,67</sup> Recordings between neighboring cones also show that they are coupled.<sup>66,68</sup> This may seem puzzling at first because it should lead to a loss of acuity and blurring. However, the cone array actually oversamples the signal so this leads to little or no loss. Instead, the coupling is thought to reduce noise, which is random, while the light-driven signals, which are correlated between close neighbors, will be reinforcing. It has been calculated that this may improve the signal-to-noise ratio by 77% – a large gain for little loss.<sup>69</sup> Coupling between red/green cones is indiscriminate, which may reflect the close absorption curves of red and green cones.<sup>68</sup> Morphologically, blue cone pedicles are slightly smaller than those of red/green cones and they have only a few withered dendrites, which rarely touch neighboring cones.<sup>70</sup> Hence, blue cones are not coupled into the red/green network.<sup>66,68</sup> This may serve to preserve spectral information in the color pathways.

There are also gap junctions between cone pedicles and rods.<sup>71</sup> These allow rod signals to enter cones, and rod-mediated signals can be detected in second-order neurons that are thought to be connected exclusively to cones.<sup>72</sup> Responses with the signature of rod origin have also been recorded in primate cones.<sup>73</sup> Because rods far outnumber cones, the influence of many rods on a single cone may be substantial. It is now thought that rod–cone coupling forms an alternative rod-driven pathway that may be important at intermediate light intensities, in the mesopic range.<sup>74,75</sup> This influence may relate to the enhancement of cone electroretinogram (ERG) amplitudes in humans and mice by light adaptation, where the cone ERG gradually increases in amplitude following the onset of a steady adapting field.<sup>76–79</sup> Blocking gap junctions inhibits this

effect in the mouse retina. In the human, however, the adaptation dependence of these changes has a photopic (cone) signature. Rod-cone coupling also is very dynamic and influenced by circadian rhythms, increasing at night and decreasing during the day, due to the influence of dopamine.<sup>80-82</sup>

## **Photoreceptors Release Glutamate in the Dark**

The first intracellular recordings from cones were surprising because they showed that photoreceptors hyperpolarize in response to light.<sup>4</sup> This means they are relatively depolarized and release their neurotransmitter, glutamate, in the dark. From the viewpoint of signal information, the sign of the photoreceptor response makes no logical difference; photoreceptors produce graded responses modulated around the mean light level. When a photon is absorbed, the visual pigment is activated and then a cascade of other biochemical events is triggered.<sup>83</sup> This is known as phototransduction and it leads to the closure of a cGMP-gated cation channel in the cell membrane to produce hyperpolarization and a reduction in the release of glutamate.<sup>84</sup> The postsynaptic responses to light are in fact due to a decrease of glutamate release. Thus, glutamate uptake also plays a key role in retinal neurotransmission because the clearance of glutamate must be rapid to provide a fast postsynaptic response to light.<sup>85</sup> The hyperpolarizing light response of photoreceptors is now well established and it is supported by studies of vesicle turnover, which is much higher in the dark.<sup>86</sup> Furthermore, synaptic blocking studies produce the appropriate responses in the different second-order neurons and there is a stereotyped array of distinct glutamate receptors associated with specific cell types. Glutamate, with its library of postsynaptic receptors, seems particularly suitable to orchestrate the large variety of postsynaptic responses at the cone pedicle.

Rods operate in a manner essentially similar to cones: they hyperpolarize in response to light increases, albeit there are many molecular differences. However, everything about the rod pathway in the retina is designed for maximum sensitivity. This is reflected in the anatomic details and synaptic connections of rods.<sup>64</sup> Rods can respond to single photons, obviously the design limit, with a binary

(all or nothing) signal, but visual threshold requires a signal in 5–10 rods. Depending on the species, about 20–100 rods converge on to a single rod bipolar cell<sup>87,88</sup> and this high convergence also contributes to the high sensitivity of the rod pathway. If 100 rods converge to a single rod bipolar cell and 100 rod bipolar cells converge to a ganglion cell, then the absolute threshold for vision is determined by the product, approximately 1 photoisomerization per 10,000 rods.

## Second-Order Neurons: Horizontal and Bipolar Cells

Rods and cones make synaptic connections with bipolar and horizontal cells. Horizontal cells are laterally extensive interneurons located in the outer row of the INL, adjacent to the OPL. They respond to diffuse light with a large hyperpolarization. This is the same as cones so we say that the input is sign-conserving. It appears to be mediated by excitatory glutamate receptors of the AMPA subtype, which have been located on horizontal cell dendrites.<sup>89,90</sup> In most mammals there are two morphologic types of horizontal cell, but only one in rodents.<sup>91–93</sup> In all species, horizontal cells are extensively coupled, which dramatically increases the size of the receptive field. In [Fig. 17.10](#) the entire A-type horizontal cell network in the rabbit retina has been labeled by injecting several cells with a diffusible tracer, Neurobiotin, which readily passes through gap junctions.<sup>94</sup> A-type horizontal cells are axonless and have a large irregular shape, giving rise to many fine terminals that contact every cone pedicle within the dendritic field. A high-resolution image shows how fine horizontal cell dendrites converge at cone terminals while ignoring the numerous rod spherules ([Fig. 17.10](#)). The cone terminals were marked by the labeling of two different glutamate receptors, GluR5, which marks the basal contacts of certain OFF bipolar cells,<sup>95</sup> and mGluR6, which is expressed by ON cone bipolar cells<sup>17,96</sup> (see below). It should be noted that the three labels are nonoverlapping at the cone terminal, consistent with the presence of three separate neurons, horizontal cells, ON cone bipolar cells, and OFF cone bipolar cells, which all converge independently at the cone pedicles ([Fig. 17.10](#)).<sup>62</sup>

**FIG. 17.10** A-type horizontal cells in the rabbit retina. The coupled matrix of A-type horizontal cells following the intracellular injection of Neurobiotin (green) in the rabbit retina and the rod/cone mosaic is shown by labeling postsynaptic glutamate receptors, GluR5 (blue) and mGluR6 (red). The A-type horizontal cells contact every cone in the frame. The high-resolution images (right) show that the fine horizontal cell dendrites (green) converge at individual cone pedicles. The green, red, and blue labels are not colocalized. They label independent neuronal structures: horizontal cells, ON bipolar cells, and OFF bipolar cells, respectively. (Courtesy of F. Pan and S.C. Massey.)

B-type horizontal cells in the rabbit retina are smaller and radially symmetrical (Fig. 17.11). While the somatic dendrites of the B-type horizontal cell also contact cones, each cell gives rise to a long axon that meanders randomly before branching into an elaborate terminal structure (Fig. 17.11C).<sup>94</sup> The electrotonic length of the axon was thought to isolate the somatic region from the axon terminal whose branches contact rods instead of cones,<sup>97</sup> but there is now evidence that at high light levels rods may play a role by acting as relays to transmit horizontal cell surround information to cones.<sup>98</sup> B-type horizontal cells are also coupled by gap junctions and so are the axon terminals (Fig. 17.11B).<sup>94,99–101</sup> For both types of horizontal cell, as the cell density falls with eccentricity, the dendritic field size increases so that an even coverage of 6–8 is maintained across the retina. B-type horizontal cells are always

smaller and more numerous – two to three times the A-type density.<sup>94</sup>

**FIG. 17.11** B-type horizontal cells in the rabbit retina. (A) A single B-type horizontal cell filled with Lucifer Yellow contacts all the cone pedicles (white outlines) within its dendritic field. *Arrow* shows the axon leaving the frame. (B) When B-type horizontal cells are filled with Neurobiotin, the coupled network is revealed. (C) Fine details of the elaborate axon terminal of a B-type horizontal cell. Each terminal varicosity contacts a rod spherule. (Panel A, courtesy of W. Li and S.C. Massey; panels B and C, reproduced with permission from Mills SL, Massey SC. A series of biotinylated tracers distinguishes three types of gap junction in retina. *J Neurosci* 2000;20:8629–36.)

In primates, there are also two kinds of horizontal cell, both axon-bearing, but the H2 only contacts cones and the axon is not well developed.<sup>102</sup> H1 is a large, well-coupled cell that contacts all red/green cones but not blue cones.<sup>103</sup> H2 has a smaller soma and finer dendrites that make sparse contacts with red/green cones but densely innervate blue cone pedicles.<sup>103</sup> Recording from both horizontal cell types shows that they receive sign-conserving inputs from both red and green cones (plus blue for H2).<sup>103</sup> The wiring of the H2 horizontal cell suggests it plays a role in blue/yellow (red+green) processing.

In central retina, there are four times as many H1s as H2s, decreasing to twice as many in peripheral retina.<sup>104</sup> Increasing size with eccentricity compensates for decreasing density so coverage for both types is 3–5 evenly across most of the retina. The peak density for H1 horizontal cells reaches about 18,000/mm<sup>2</sup> near the fovea. This is an order of magnitude higher than rabbit retina. Packer and Dacey<sup>105</sup> have recorded from many primate H1 cells and they make the interesting observation that central cells are not only smaller but less coupled, perhaps because they overlap less. Thus, the H1 receptive field in the fovea may be small enough, 20–30 μm, to match the receptive field surround of midget ganglion cells.

Horizontal cells are extensively coupled by gap junctions and their molecular identity has been determined for many species. In the rabbit retina, the gap junctions between A-type horizontal cells are labeled with an antibody against Cx50 at many contact points in the matrix (Fig. 17.12).<sup>106</sup> Some of the gap junction plaques are very large and the unitary conductance of Cx50 channels is also high. This explains why A-type horizontal cells form an electrical syncytium. B-type horizontal cells are not labeled for Cx50. These gap junctions have different properties so they are likely to be assembled from different connexins. In rodents, there is only one type of axon-bearing horizontal cell.<sup>107</sup> In a Cx57 knockout mouse, these cells are no longer coupled.<sup>108</sup> This suggests that multiple neuronal connexins are present in the retina and that Cx57 gap junctions may be responsible for coupling in axon-bearing horizontal cells. The situation in the primate retina is still unknown but future progress should make it possible to test theories concerning horizontal cell coupling.

**FIG. 17.12** Gap junctions between A-type horizontal cells. A-type horizontal cells are extensively coupled, as observed following Neurobiotin injection (red). An antibody against connexin 50 (green) labels gap junctions in the matrix of A-type horizontal cells. Some large plaques are located at the crossing of two major dendrites (yellow). The background mosaic of cone pedicles is marked by GluR5 labeling (blue). (Reproduced with permission from O'Brien JJ, Li W, Pan F, et al. Coupling between A-type horizontal cells is mediated by connexin 50 gap junctions in the rabbit retina. *J Neurosci* 2006;26:11624–36.)

## Horizontal Cell Function

There is general consensus that horizontal cells provide negative-feedback signals to cones and rods. This can be seen when a full field light flash, which hyperpolarizes photoreceptors and reduces their glutamate release. This causes a sustained hyperpolarization in the horizontal cells, which rest at a relative depolarized membrane potential in the dark. Upon hyperpolarization, horizontal cells send a feedback signal to the photoreceptors that shifts the activation function of their calcium channels to more

negative potentials increasing their calcium current and their glutamate release.<sup>109</sup> This is a sign-inverting signal and forms the basis for the antagonistic center/surround receptive field of bipolar cells.

## The Feedback Mechanism

The mechanism responsible for horizontal cell feedback to cones has been hotly debated for the past two decades. Initially it was proposed that horizontal cell feedback to photoreceptors utilized a GABAergic mechanism.<sup>110-112</sup> This hypothesis was based on the observations that horizontal cells synthesize and release GABA<sup>89,113-116</sup> and that photoreceptors express GABA<sub>A</sub> receptors.<sup>111,117-120</sup> More recently, results indicate that mammalian horizontal cells release GABA via a vesicular mechanism,<sup>121-123</sup> although pharmacologic manipulation of GABA input has yielded conflicting results.<sup>109,124-127</sup> It may be that GABA modulates the strength of the negative feedback signal by acting on cones and horizontal cell GABA receptors, but is not the basic feedback signal.<sup>128,129</sup>

Both an ephaptic<sup>125,130</sup> and a pH-based mechanism<sup>126</sup> for this feedback pathway have been proposed. The ephaptic feedback mechanism is a purely electrical signal, mediated via connexin hemichannels found at the tips of the horizontal cell dendrites that invaginate at the cone synaptic terminal (Fig. 17.13). The connexin hemichannels act as large nonselective ion-channels and current flows through them into the resting ( $\sim -40$  mV) horizontal cell in the dark. Through the feedback pathway photoreceptors sense this as a local depolarization. Horizontal cell hyperpolarization to light increases the current through the hemichannels and the extracellular space, producing an even larger local depolarization in the photoreceptor near their calcium channels. As described above, this leads to an increase in calcium current and glutamate release. A role for hemichannels in this process is supported by pharmacologic and genetic manipulations.<sup>131,132</sup>

**FIG. 17.13** General organization of the cone synaptic terminal. (A) Electron microscopic image of the zebrafish cone synaptic complex, with characteristic synaptic ribbons (*R*) and deep invaginations. The black staining is present in horizontal cell dendrites which terminate close to the synaptic ribbons. Labeling was performed with a GFP antibody in a transgenic zebrafish expressing GFP via the Cx55.5 promoter in horizontal cells. (B) Electron microscopic image of synaptic triad in goldfish showing the location of connexin hemichannels. The membrane of the tips of horizontal cell (*HC*) dendrites, close to the synaptic ribbon (*R*), are stained with an antibody against Cx26.

(Modified from Kamermans et al. *Science* 2001;292:1178-1180.)

The pH-based feedback mechanism also has considerable experimental support. Here acidification of the extracellular space inhibits photoreceptor calcium channels<sup>133</sup> and feedback is modulated by altering the pH in the synaptic cleft, which modulates the calcium current.<sup>126,134</sup> The mechanism for the pH modulation was highly unexpected and involves release of ATP into the synaptic cleft via pannexin-1 channels located close to the connexin hemichannels at the tips of the horizontal cell dendrites. The ATP is hydrolyzed by the ecto-ATPase NTPDase1 and ADA into inosine, which generates protons and phosphate groups. This forms a pH buffer with a pKa of 7.2, which acidifies the synaptic cleft,<sup>134</sup> and has been directly measured.<sup>135</sup> Light-induced hyperpolarization of horizontal cells leads to a closure of pannexin channels at the tips of the horizontal cell dendrites, reduction of ATP release, leading to a reduction of the pH buffer and producing

a slow alkalization in the synaptic cleft. This disinhibits the photoreceptor calcium current and increases glutamate release from cones.

Recent evidence indicates that both ephaptic and pH mechanisms may function in parallel<sup>134</sup> and that the feedback signal consists of these two components with differing kinetics: a superfast component provided by the ephaptic mechanism and a slow component provided that is ATP/pH mechanism.<sup>134</sup> Layered on this is modulation by GABA, which acts to suppress feedback in the dark-adapted retina.<sup>128,136-138</sup> Because both horizontal and bipolar cells express GABA receptors,<sup>139-141</sup> horizontal cells may use feedforward GABAergic signaling to bipolar cells as well.<sup>142</sup>

## Horizontal Cell Function

An important question is why horizontal cell feedback to cones requires two different mechanisms? To answer this question, we have to consider how horizontal cells contribute to visual signaling. As pointed out by Sterling, reading high-contrast images in bright artificial light is one thing,<sup>143</sup> but in the natural scenes in the outside world visual objects often have very low contrast compared to their background. Here what is needed is a way to subtract the common background (which has little information) and amplify the remaining signal to enhance the visibility of small, low-contrast details.

At least in part, this role is accomplished by horizontal cells in the outer retina. Horizontal cells have large receptive fields and are well suited to estimate mean luminance of a scene. This information is fed back to photoreceptors in the negative feedback described above so that the photoreceptor output can signal local deviations in light intensity. Because our eyes are always moving we need to consider how to extract small, low-contrast details moving against the background. When horizontal cell feedback is slow, the receptive field surround it creates should lag temporally behind the center response in bipolar cells. This will create blur. However, with an added superfast ephaptic feedback this should not happen. What about the function of the slow pH mechanism? Responses of neurons become more and more transient when going from the

outer retina to the inner retina. This transience represents temporal redundancy reduction. The essence of a mechanism that reduces temporal redundancy is that it is slow. The ATP/pH system fulfills those requirements.

Horizontal cells also have an impact on color vision, because they are connected to more than one cone type. This means that the feedback signal cones receive will have a different spectral sensitivity than the spectral sensitivity of the cones themselves.<sup>144</sup> The consequence is far reaching. It means that the brain never has access to pure cone signals. The signals will always be modified by horizontal cell action and thus by the other spectral cone types. The output of a cone will depend on the spectral composition of the global illumination. Why would this be an advantage? It has been proposed that these chromatic interactions at the photoreceptor/horizontal cell level lead to phenomena like “color constancy” and “color induction.”<sup>145,146</sup>

## Bipolar Cell Function

Bipolar cells receive input from photoreceptors and then conduct the visual signal to the inner retina. They are excitatory interneurons, using glutamate as a neurotransmitter, specialized for sustained transmitter release, with terminals containing synaptic ribbons, similar to those of photoreceptors, only smaller. There are approximately 9–12 kinds of cone bipolar cell in the mammalian species that have been studied thoroughly, i.e., primates, rabbits, cats, rats, and mice (Fig. 17.14).<sup>12,147–153</sup> In contrast to the cone bipolar cells, there is only one type of rod bipolar cell, which is morphologically and physiologically distinct from the cone bipolar cells. Rod bipolar cells are numerous – three times the density of any diffuse cone bipolar type. However, there are around 10 types of cone bipolar cell so, in total, they outnumber the rod bipolar cells by a factor of three to four.

**FIG. 17.14** Bipolar cells. Top: Lucifer Yellow-filled examples of bipolar cell types in the rat retina. Bottom: Drawings of Golgi-impregnated bipolar cells from the primate retina. Note the presence of midget bipolar cells in the primate retina. In both species, it may be observed that the main difference between cell types is the depth of stratification in the inner plexiform layer. OFF bipolar cells terminate in sublamina a and ON bipolar cells stratify at a deeper level, in sublamina b. *OPL*, outer plexiform layer; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *GCL*, ganglion cell layer; *RB*, rod bipolar cells; *FMB*, flat midget bipolar; *IMB*, invaginating midget bipolar. (Top panel, reproduced with permission from Harveit E. Functional organization of cone bipolar cells in the rat retina. *J Neurophysiol* 1997;77:1716–30, with permission from the authors and the American Physiological Society. Bottom panel, reproduced with permission from Boycott BB, Wassle H. Morphological classification of bipolar cells of the primate retina. *Eur J Neurosci* 1991;3:1069–88.)

Cone bipolar cells are difficult to identify in a retinal slice preparation. Once filled with a tracer they can be distinguished by the locations of their somas in the INL, by the morphology of their

dendritic and axon terminals, and by the depth of termination in the IPL. An increasing number of selective antibodies are now available to aid in the identification of specific cone bipolar cells.<sup>133-136</sup> In addition, several transgenic reporter mouse lines that mark specific types of bipolar cells have been created.<sup>154-156</sup>

There is a major functional division in the cone pathway that arises at the first synapse and is preserved in all higher visual centers. The retina is divided into ON and OFF channels served by ON and OFF cone bipolar cells (Fig. 17.14). The ON pathway is optimized to detect increases in intensity and the OFF pathway decreases in intensity. Reflecting the importance of depth in the retina, these two types of bipolar cells terminate at different levels in the IPL. OFF bipolar cells ramify in the top half, sublamina a, where they synapse with OFF ganglion cells. ON bipolar cells descend further in the IPL to sublamina b, where they synapse with ON ganglion cells. ON and OFF bipolar cells produce opposite signals in response to changes in light intensity. But how is this achieved if both bipolar types contact the same cones? The short answer is via different postsynaptic receptors and, indeed, glutamate produces opposing responses in ON and OFF bipolar cells.<sup>15,157,158</sup> This simple trick, dividing the cone signal into ON and OFF components, is thought to double the dynamic range of the retina. Half the bipolar cells carry signals greater than the local mean and the other half dimmer than the average.

## OFF Cone Bipolar Cells

The dendrites of OFF bipolar cells branch in the OPL and contact every cone within the dendritic field at basal synapses (Fig. 17.15). OFF bipolar cells, like cones themselves, are hyperpolarized by light. So these are sign-conserving excitatory synapses, shown by a + in Fig. 17.15A, served by ionotropic glutamate receptors, i.e., conventional glutamate receptors of the AMPA/kainate type.<sup>159-161</sup> Thus, the dark release of glutamate from cones holds OFF bipolar cells at a relatively depolarized potential and the reduction of glutamate release in response to light produces a hyperpolarization in OFF bipolar cells. In this regard, the photoreceptor/OFF bipolar cell synapse is similar to the photoreceptor/horizontal cell synapse.

**FIG. 17.15** ON and OFF pathways. (A) The opposite responses of ON and OFF cone bipolar cells are generated by the expression of different glutamate receptors. OFF bipolar cells are depolarized by glutamate, the photoreceptor transmitter, hence the + for a sign-conserving synapse. ON bipolar cells are hyperpolarized by glutamate, hence the - for a sign-inverting synapse. This unusual receptor is called the mGluR6 receptor. It is selectively activated by the glutamate analog 2-amino-4-phosphonobutyrate, and it is responsible for the separation of ON and OFF signals through the visual system. Furthermore, the inner retina is functionally stratified. OFF bipolar cells ramify in sublamina a and ON bipolar cells descend to sublamina b. Both bipolar cell types use glutamate and they make excitatory synapses with amacrine and ganglion cells. *IPL*, inner plexiform layer; *GC*, ganglion cell. (B) The image shows an OFF bipolar cell that was filled with Lucifer Yellow (green). In whole mount, with the focus at the outer plexiform layer, fine dendrites extend to contact every cone within the dendritic field. The positions of rod and cone terminals are marked with a combination of glutamate receptor antibodies mGluR6 (red) and GluR5 (blue). (Panel B reproduced with permission from Li W, Keung JW, Massey SC. Direct synaptic connections between rods and OFF cone bipolar cells in the rabbit retina. *J Comp Neurol* 2004;474:1–12, with permission of the authors and Wiley-Liss, a subsidiary of John Wiley.)

Recordings from cone and OFF bipolar cell pairs in the ground squirrel, which has very large cones particularly suitable for recordings, has shown that three different OFF bipolar cells use three different glutamate receptors – one AMPA receptor and two kainate receptors (Fig. 17.16).<sup>159</sup> These receptors have different affinities for glutamate and kinetics of activation, desensitization, and deactivation and therefore generate synaptic conductances that vary in time course: fast AMPA receptors are well suited to convey transient signals, while the slower kainate receptors may transmit sustained responses.<sup>159</sup> In ground squirrel retina, OFF cone bipolar cell response properties dovetail very well with the differential distribution of glutamate receptors at the cone pedicle complex, and therefore, ionotropic glutamate receptor expression has been suggested to contribute to the separation of cone signals into different temporal processing channels that encode different bandwidths of the cone signal.<sup>90,95,162</sup> All three OFF bipolar types terminate in sublamina a, as expected, but each one branches at a different depth within the OFF sublamina (Fig. 17.16). Thus, the division of the visual signal into different channels, for delivery to different addresses in the IPL, begins at the first synapse in the retina.

**FIG. 17.16** Different OFF bipolar cells and rod/cone mosaic. (A) Three bipolar cells from the ground squirrel filled with different-colored dyes. The two OFF bipolar cells have responses mediated by different classes of glutamate receptor and they stratify at different levels, or addresses, in the inner plexiform layer. (B) A single ON bipolar cell type in the rabbit retina stained for the calcium-binding protein (CABP) calbindin (red). For comparison, the more numerous rod bipolar cells are stained for protein kinase C (PKC) (blue). The calbindin bipolar cell (*CB*) has an axon that descends to sublamina b where it is narrowly stratified just above the rod bipolar terminals (*RB*). This is a different address in the inner plexiform layer. In the outer plexiform layer, horizontal cells (*HC*) are also stained for calbindin. (C) Staining for mGluR6 receptors (red) mark the tips of rod bipolar cells where they enter the rod spherule. A small cluster of ON cone bipolar dendrites is also lightly marked at each cone pedicle.

**GluR5 receptors (blue) mark OFF bipolar cell basal contacts at each cone pedicle.** (Panel A, reproduced with permission from DeVries Sh. Bipolar cells use kainite and AMPA receptors to filter visual information into separate channels. *Neuron* 2000;28:847–56. Panel B, reproduced with permission from Massey SC, Mills SL. A calbindin-immunoreactions cone bipolar cell type in the rabbit retina. *J Comp Neurol* 1996;366:15–33, with permission of the authors and Wiley-Liss, a subsidiary of John Wiley. Panel C, courtesy of F Pan and SC Massey.)

Differences in the temporal features of bipolar cell responses have been observed in a number of species,<sup>160,163–165</sup> but recent studies of OFF bipolar cells in mouse and primate, however, indicate that transmission at cone → OFF bipolar cell synapses is mediated exclusively by kainate receptors.<sup>160,161</sup> Therefore, the different temporal kinetics of different OFF bipolar cells in these two species, unlike the ground squirrel, must be generated via circuit mechanisms.

## ON Cone Bipolar Cells

The dendrites of ON bipolar cells invaginate into the cone pedicle and approach the synaptic ribbons in a central position. ON bipolar cells are depolarized by light. This is opposite to the cone signal so we refer to this as a sign-inverting synapse, hence the minus sign at the cone/ON bipolar cell synapse in [Fig. 17.15](#). The dark release of glutamate from the photoreceptors holds ON bipolar cells relatively hyperpolarized. Light turns off the cone transmitter, and the decrease of glutamate release produces a depolarization in ON bipolar cells. Bipolar cells obey the division of the IPL and so ON bipolar cells are stratified in sublamina b ([Fig. 17.14](#)).

A hyperpolarizing response to glutamate is unusual and this is an unusual receptor, which is only expressed in the retina. It has now been identified as mGluR6, one in a series of eight metabotropic glutamate receptors, so called because activation of these receptors turns on an intracellular signaling cascade.<sup>166,167</sup> The mGluR6 receptor is selectively activated by glutamate or the glutamate analog 2-amino-4-phosphonobutyrate (APB).<sup>15</sup> Activation of the mGluR6 receptor leads to the closure of a cation channel, producing a hyperpolarization in ON bipolar cells. Light

decreases glutamate release from photoreceptors and produces the opposite response. The cation channel is now known to be the transient receptor melastatin 1 (TRPM1) channel.<sup>168-170</sup> The exact mechanism by which mGluR6 activation closes TRPM1 is not known, but it does not seem to use a cyclic nucleotide-mediated mechanism.<sup>171,172</sup> While the details of the mechanisms remain uncertain, the signal inversion that occurs at the ON bipolar mGluR6 receptor underlies the separation between ON and OFF channels throughout the visual system.

Labeling the retina with an antibody against the mGluR6 receptor stains a narrow band at the level of bipolar dendrites in the OPL.<sup>17,96</sup> In whole mount, the distribution of mGluR6 labeling shows a distinct pattern with two types of terminals (Fig. 17.16C). There are lightly labeled mGluR6-positive clusters of fine ON cone bipolar terminals at each cone pedicle and bright mGluR6-positive terminals, which insert into each rod spherule. These are the terminal dendrites of rod bipolar cells. This mGluR6 pattern also provides a simple way to map the location of rod and cone terminals in the outer retina. All ON bipolar cells, which include ON cone bipolar cells, blue cone bipolar cells, and rod bipolar cells, express mGluR6 at the tips of their dendrites.<sup>17</sup>

A variety of responses may be produced by the different types of ON cone bipolar cell due to modulation of the mGluR6 cascade or to the action of calcium channels or amacrine cells at the bipolar cell terminal,<sup>173</sup> and it is clear that different temporal processing channels exist in the ON as well as in the OFF pathway.<sup>160,163-165,174,175</sup> These differences might arise from diversity in intrinsic conductances (e.g., some bipolar cells express voltage-gated channels that generate transient conductances), the dynamics of neurotransmitter release from bipolar cell synapses, and lateral inhibitory (i.e., circuit-level) interactions that modulate bipolar cell responses.<sup>176-183</sup>

## **Midget Bipolar Cells**

The primate retina is unusual in that the central retina is dominated by midget bipolar cells. Within the central 10 mm, there is one OFF midget bipolar cell and one ON midget bipolar cell for each cone. In this area, they account for more than 80% of all cone bipolar

cells.<sup>149,184</sup> Midget bipolar cells have very small dendritic fields and receive input from single cones and make output to single midget ganglion cells. This is the so-called private line, one cone to one midget bipolar cell to one midget ganglion cell. The ON midget bipolar cells invaginate the cone pedicle, ramify in sublamina b of the IPL, and contact ON midget ganglion cells. OFF midget bipolar cells make flat or basal contacts with cones and terminate in sublamina a where they contact OFF midget ganglion cells. Most investigators think this specialization of the primate retina was designed to achieve maximum acuity at high cone density. It may also, by virtue of the single cone connections, which are automatically color-coded, serve red/green color vision.

### **Blue Cone Bipolar Cells**

In general, diffuse cone bipolar cells contact every cone within the dendritic field and this gives them a characteristic appearance. However, in the primate retina, one bipolar cell type is distinctly different in that it has long dendrites that bypass many cones to seek out only blue cones.<sup>185,186</sup> The dendrites are labeled for mGluR6 and the axon descends deep into sublamina b so the blue cone bipolar cells are ON cells.<sup>17,153</sup>

### **Rod Bipolar Cells**

In contrast to the cone bipolar cells, there is only one morphologic type of rod bipolar cell. They are numerous, with a mop-head of fine dendrites that may receive input from as many as 80–120 rods in the rabbit retina (Fig. 17.17A).<sup>88</sup> This very high convergence contributes to the sensitivity of the primary rod pathway. A single dye-injected rod bipolar cell is shown in Fig. 17.17B. The dendrites branch profusely but avoid the cone pedicles within the dendritic field. Instead, all the terminal dendrites invaginate a rod spherule and they are double-labeled for mGluR6. Only one terminal at each rod spherule comes from this rod bipolar cell. The other half of each mGluR6 doublet is claimed by another unlabeled rod bipolar dendrite. Thus, each rod contacts two different rod bipolar cells.<sup>96</sup> Each rod bipolar cell gives rise to a long slender axon that descends to sublamina 5 of the IPL (Fig. 17.17). Physiologically, rod bipolar cells give ON responses to light stimulation and this is consistent

with the labeling for mGluR6 and the depth of stratification.<sup>13,187</sup> Rod bipolar cells do not usually contact ganglion cells directly. Instead, the primary output of rod bipolar cells is to AII amacrine cells, which pass on the rod signal, or to S1 and S2 amacrine cells<sup>40,187</sup> that provide a powerful negative-feedback signal to rod bipolar terminals (Fig. 17.18; see below). More than 90% of the rod bipolar output is on to these amacrine cells.

**FIG. 17.17** Rod bipolar cells and contacts in the rabbit retina. (A) There is a single morphologic type of rod bipolar cell that can be stained with antibodies against

protein kinase C (PKC). (B) A single rod bipolar cell (RBC) from the rabbit retina, filled with Lucifer Yellow (green), focus at the outer plexiform layer, has a spray of fine dendrites that contact many rod spherules (red puncta). (C) At higher resolution, mGluR6 receptors, which stain the dendritic tips of the rod bipolar cells (red), are doublets where they enter into the rod spherule invagination. The general rule is that each pair of rod bipolar dendrites at a rod spherule originates from different rod bipolar cells. A cone pedicle, marked by a cluster of dimmer, finer ON cone bipolar dendrites, is also outlined (*dashed line*). (Panel A, courtesy of W. Li and S.C. Massey. Panels B and C, reproduced from Li W, Keung JW, Massey SC. Direct synaptic connections between rods and OFF cone bipolar cells in the rabbit retina. *J Comp Neurol* 2004;474:1–12, with permission from the authors and Wiley-Liss, a subsidiary of John Wiley.)

**FIG. 17.18** The primary rod pathway. (A) There is only one type of rod bipolar cell (rod B), which produces ON responses to light and terminates at the bottom of the inner plexiform layer (IPL) in sublamina 5. Rod bipolar cells express mGluR6 receptors and are hyperpolarized by glutamate released from rods at a sign-inverting synapse, marked with a minus sign. Rod bipolar cells release glutamate and are connected to All amacrine cells and S1/S2 amacrine cells via

excitatory receptors, marked by a plus sign. In turn, S1/S2 amacrine cells make inhibitory reciprocal synapses mediated by  $\gamma$ -aminobutyric acid, back on to the rod bipolar terminal. (B) Vertical section of macaque retina: the All amacrine cells, stained for calretinin (green) descend around the rod bipolar cell axons (protein kinase C, red) as they descend through the IPL. *Arrow* marks fainter staining of cone bipolar cell DB4 at a different level in the IPL. (Panel B reproduced with permission from Massey SC, Mills SL. Antibody to calretinin stains All amacrine cells in the rabbit retina: double-label and confocal analyses. *J Comp Neurol* 1999;411:3–18.)

The high convergence allows the rod bipolar cell to collect signals from many rods but is also potentially noisy. However, the rod-to-rod bipolar synapse has a nonlinearity by which small signals are thresholded.<sup>188</sup> The price for this is that many small signals are rejected but the reduction in noise is worth it. Some near-threshold signals may be lost but when a photon signal is captured it has a high signal-to-noise ratio and is transmitted very reliably.<sup>189</sup>

## Multiple Rod Pathways

Rods are utilized under low light conditions and provide information over 5 log units. It is now clear that there are at least three pathways, referred to as primary, secondary, and tertiary, by which rod signals reach ganglion cells (Fig. 17.19). They are thought to process signals under slightly different conditions, the primary being the most sensitive and the tertiary being the least sensitive.

**FIG. 17.19** Rod and cone pathways. The primary rod pathway (rod → ON bipolar cell → All amacrine cell) provides an excitatory input to All amacrine cells, which are electrically coupled to cone ON bipolar cells and inhibit cone OFF bipolar cells. The secondary rod pathway (rod → cone → bipolar cell) arises from electrical coupling between rods and cones and allows the flow of rod signals into the cones and glutamate release into the cone ON and OFF bipolar cells. The tertiary rod pathway (rod → OFF bipolar cell) is a direct glutamatergic input from rods to cone OFF bipolar cells. Note that the secondary and tertiary pathways are in principle independent of the primary pathway. Red arrows indicate sign-inverting synapses, and green arrows indicate sign-preserving synapses.

(Modified with permission from van Genderen MM, Bijveld MM, Claassen YB, et al. Mutations in TRPM1 are a common cause of complete congenital stationary night blindness. *Am J Hum Genet* 2009;85:730–6.)

The primary rod pathway utilizes rod bipolar cells, which make ribbon synapses with two postsynaptic amacrine cells in sublamina 5 of the IPL (Fig. 17.18). One of these postsynaptic neurons is the AII amacrine cell, and the other is either an S1 (A17 in the cat) or S2 amacrine cell (Fig. 17.18).<sup>40,187</sup> These two wide-field GABA amacrine cells both make reciprocal synapses with rod bipolar terminals and thus provide another stage of negative feedback. The conspicuous terminals of rod bipolar cells literally plug into holes in the

meshwork of dendrites provided by these amacrine cell types. Rod bipolar cells, like other bipolar cells, release glutamate, and the contact points with the AII matrix are covered with glutamate receptors of the AMPA subtype (Fig. 17.20).<sup>190,191</sup> The glutamate receptors of S1/S2 amacrine cells have not been completely clarified, but the A17 (probably the S1 equivalent in the rodent) uses a Ca<sup>2+</sup>-permeable AMPA glutamate receptor via L-type Ca<sup>2+</sup> and Ca<sup>2+</sup>-activated potassium (BK) channels<sup>192</sup> to modulate feedback inhibition on to the rod bipolar cell and control glutamate release at this synapse. On the rod bipolar cell the postsynaptic targets are the GABA<sub>A</sub> and GABA<sub>C</sub> receptors.<sup>193-195</sup>

**FIG. 17.20** Rod bipolar input to AII is mediated by glutamate receptors. (A) The matrix of AII amacrine cells in the rabbit retina, stained for the calcium-binding protein calretinin (green), is decorated with punctate glutamate receptors (red) of the  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) subtype. (B) The AII dendrites carefully wrap around the rod bipolar terminals (blue) at this level. Critically, the glutamate receptors only occur at the contact sites between rod bipolar cells and AII amacrine cells (red + green + blue = white). Intervening sections of AII dendrite, between rod bipolar terminals, have no glutamate receptors. This indicates that AMPA receptors are located at synaptic contacts between rod bipolar cells and AII

**amacrine cells.** (Reproduced from Li W, Trexler EB, Massey SC.

Glutamate receptors at rod bipolar ribbon synapses in the rabbit retina. *J Comp Neurol* 2002;448:230–48, with permission from the authors and Wiley-Liss, a subsidiary of John Wiley.)

So, there are two obvious questions: how do rod signals reach ganglion cells and, if there is only one type of rod bipolar cell, how are both ON and OFF signals generated in dark-adapted conditions? The answer lies in the way the rod pathway is integrated into the cone pathways via the AII amacrine cell (Fig. 17.19). AII amacrine cells are glycinergic neurons and they also make conventional inhibitory glycinergic synapses with the axon terminals of OFF cone bipolar cells in sublamina a via alpha 1 glycine receptors.<sup>196</sup> In turn, the AII itself is modulated by a glycinergic input at synapses expressing alpha 3 glycine receptors.<sup>197</sup> Their distal processes make electrical synapses or gap junctions with ON cone bipolar cells in sublamina b and provide a direct, presumably sign-conserving, input signal to the ON cone bipolar cells.<sup>41,198,199</sup> Thus, while the cone pathways split via different postsynaptic glutamate receptors in the outer retina, the rod pathway bifurcates at the level of the AII amacrine cell. It is often said that the rod signals piggyback on the cone pathways.

The rod bipolar → AII amacrine cell synapse also plays a fundamental role in rod-mediated vision.<sup>187,200–202</sup> It acts as a high-pass filter, accelerating the time courses of slow rod responses to increase the reliability of their encoding by postsynaptic circuits.<sup>200,203</sup> Therefore, the timing of transmission shapes ganglion cell responses and retinal circuit output.<sup>204</sup> The RB → AII synapse also is the primary site of neural gain control during rod-mediated vision: when light is scarce and few rods are activated, the synapse amplifies small rod inputs so that they are transmitted reliably; as background light intensity increases, the gain of transmission is lowered by a use-dependent reduction in the size of the readily releasable vesicle pool so that the circuit avoids saturation.<sup>202,204–209</sup>

AII amacrine cells themselves are well coupled by gap junctions, as can be demonstrated by injecting a single AII amacrine cell with the diffusible tracer Neurobiotin, which passes through gap junctions to label all the coupled cells.<sup>199,210</sup> Fig. 17.21 shows that many AII amacrine cells are coupled as well as an overlying group,

consisting of four or five different types, of ON cone bipolar cells. The AII-to-AII gap junctions occur preferentially at dendritic crossings (Fig. 17.22) and AII coupling is absent in a Cx36 knockout mouse.<sup>211</sup> Coupling in this complex heterocellular network is modulated by dopamine and, perhaps more importantly, by light.<sup>212</sup> The underlying mechanism is by phosphorylation of Cx36, and this regulation can be achieved on a cell-by-cell basis.<sup>213</sup>

**FIG. 17.21** Coupling between All amacrine cells and ON cone bipolar cells. This three-dimensional reconstruction from a series of confocal images shows the result of injecting a diffusible tracer, such as Neurobiotin, into an All amacrine cell in the rabbit retina. A matrix of coupled All amacrine cells (khaki), all with the characteristic morphology, is labeled. In addition, the tracer also spreads into a complex of ON cone bipolar cells (blue) which consists of 3–5 types.

(Courtesy of E.B. Trexler and S.C. Massey.)

**FIG. 17.22** All/All gap junctions contain connexin (Cx)36. A confocal image of the All dendrites (red) in sublamina b of the inner plexiform layer. Staining for Cx36 (green) shows that Cx36 plaques are abundant in the All matrix. Image analysis indicates that there is a high probability of a Cx36 plaque when two All dendrites cross. (Reproduced from Mills SL, O'Brien JJ, Li W, et al. Rod pathways in the mammalian retina use connexin 36. *J Comp Neurol* 2001;436:336–50, with permission from the authors and Wiley-Liss, a subsidiary of John Wiley.)

Gap junctions are bidirectional, meaning that electrical signals and tracers can pass through them in either direction.<sup>214,215</sup> One consequence is that glycine from the AII amacrine cell can enter ON cone bipolar cells and indeed most ON bipolar cells contain glycine, even though they use glutamate as a neurotransmitter. The source of the bipolar cell glycine was definitively established by blocking gap junctions with carbenoxolone. This changed the labeling pattern for glycine, which was subsequently diminished in bipolar cells.<sup>167</sup> Another more relevant consequence of bidirectional coupling is that not only do rod signals pass into the cone pathways but, in fact, cone signals can pass from ON bipolar cells into the AII network. The implication is that the AII network can also influence

cone signals. This has been demonstrated in a number of studies that reveal AII act as inhibitory interneurons during cone-mediated vision.<sup>216-218</sup> In addition, transmission at the rod bipolar → AII amacrine cell synapse, by resetting the membrane potential of postsynaptic AII, can alter the membrane potential of coupled ON bipolar cells and thereby regulate transmission at their synapses.<sup>207</sup>

The importance of these gap junction pathways has been elegantly demonstrated by the development of a Cx36 knockout mouse.<sup>211</sup> In these animals, filling an AII amacrine cell with Neurobiotin yielded only one cell: there was no coupling without the expression of Cx36. In contrast to the wild type, in the knockout animals no rod signals are detectable in recordings from ON ganglion cells. In the absence of Cx36 gap junctions, rod level signals do not pass into the ON cone pathways. Of course, the OFF pathways are not dependent on transmission via gap junctions and so rod-driven OFF signals are maintained. One obvious explanation is the absence of AII/ON bipolar gap junctions, described above. However, the Cx36 knockout may also interfere with rod/cone coupling in the outer retina. In fact, both these pathways must be missing to eliminate the transmission of rod signals to ON pathways. In either case, this is the first time that a gap junction connection has been shown to be essential for the function of a neuronal pathway in the mammalian CNS.

In the rabbit retina, the gap junctions between one type of ON cone bipolar cell that is selectively labeled by antibodies against the calcium-binding protein calbindin also involve Cx36.<sup>219</sup> However, the properties of AII/bipolar gap junctions are different from AII/AII gap junctions,<sup>199</sup> suggesting that the bipolar side of the gap junction is different in some way, perhaps due to phosphorylation or even the expression of a different connexin by bipolar cells. There is some evidence that bipolar cells express Cx36.<sup>211</sup> However, there is convincing evidence that in some ON bipolar cells the coupling is mediated by Cx36 (AII)/Cx45 (BC) heterotypic gap junctions.<sup>220</sup>

## **Secondary and Tertiary Rod Pathways**

The primary rod pathway is used under threshold conditions such

as starlight<sup>143,187</sup> and it is absolutely dependent on synaptic transmission between rods and rod bipolar cells via mGluR6 receptors. However, when these synapses are blocked with APB it was still possible to record rod level signals in OFF ganglion cells.<sup>221</sup> This alternative pathway was attributed to rod/cone coupling, for which there is both anatomic and physiologic evidence. This second rod pathway runs from rods via gap junctions to cones and then into cone bipolar cells and ganglion cells in the usual way (Fig. 17.19). It has been suggested that this pathway operates in mesopic conditions of intermediate light intensity, though the primary rod pathway utilizing rod bipolar cells likely continues to function throughout the operating range of rod vision.<sup>74,204</sup>

This pathway has also been reported for the mouse retina. However, the rod-driven responses persisted even in a transgenic mouse line in which cones were eliminated.<sup>222</sup> The absence of cones would seem to rule out rod/cone coupling as a pathway. Therefore, a third rod pathway was proposed involving direct connections between rods and OFF cone bipolar cells and subsequently these connections were found.<sup>223,224</sup> This pathway was first thought to be a specialization of the rodent retina but it has now been identified in cats and rabbits.<sup>96,225</sup> It also is present in the ground squirrel, where a specific type of OFF bipolar cell, the b2, was shown to contact rods and provide a means for rods to provide fast photoreceptor signaling.<sup>226</sup> Thus, this third rod pathway may be a general feature of the mammalian retina.

It has been suggested that the rod → OFF bipolar pathway operates at high mesopic/low photopic conditions, around the transition from rod to cone vision. In general, the different rod pathways may be designed to cover different intensity ranges and perhaps they are selectively connected to specific ganglion cell types but, as yet, there are no data on this point. There is physiologic evidence from the mouse retina that different ganglion cell types have different intensity response functions but the ganglion cell types have not been identified and the contributing pathways are unknown.<sup>211</sup> The function of these novel retinal pathways under different light intensities is an important and active area of current research.

## Amacrine Cells

Amacrine cells form a morphologically and physiologically diverse group of mostly inhibitory interneurons. Approximately 30 types of amacrine cell have been identified morphologically in mammalian retina (Fig. 17.23).<sup>227–229</sup> The cell bodies of the amacrine cells are primarily located in the innermost portion of the INL, unofficially known as the amacrine cell layer. Amacrine cells are also found in the GCL, where they are known as displaced amacrine cells. Most are GABAergic medium- to wide-field cells<sup>47,230</sup> and many recognized classes of amacrine cells are found in both layers. In fact, in the mouse retina, more than half the cells in the GCL are amacrine cells. In general, the three major connections made by amacrine cells are feedback inhibition to bipolar cell terminals, feedforward inhibition to ganglion cells and serial inhibitory connections where amacrine cells are the postsynaptic targets of other amacrine cells.<sup>231</sup>

**FIG. 17.23** Amacrine cell morphology. This figure shows the comparative morphology of 24 distinct amacrine cell types from the rabbit retina. (Reproduced with permission from Masland D. Neuronal diversity in the retina. *Curr Opin Neurobiol* 2001;11:431–6.)

Amacrine cells can be divided by their dendritic arbor size into narrow- (<200  $\mu\text{M}$ ) and wide-field. The narrow-field amacrine cells are generally glycinergic and frequently provide inputs across the ON/OFF strata in the IPL.<sup>232</sup> Wide-field amacrine cells are mostly GABAergic.<sup>229,230,233–235</sup> Some provide lateral inhibition within a substratum<sup>232</sup> and others provide reciprocal feedback.<sup>195</sup> They are involved in surround inhibition<sup>236</sup> or contrast adaptation.<sup>237</sup> Several of the wide-field cells also release catecholamines or other

neuropeptides.<sup>238</sup> The best characterized in this group are the dopaminergic wide-field amacrine cells that are involved in light adaptation, and those releasing ACh.

In a large population of rabbit amacrine cells, acquired randomly using modern imaging methods, 24 different morphologic types were identified (Fig. 17.23).<sup>227,228</sup> Similar studies have been extended to the mouse, where several groups have identified large numbers of narrow-, medium-, and wide-field amacrine cells.<sup>229,230,233–235</sup>

The most numerous amacrine cell type is the AII amacrine cell, approximately 11%, while other relatively common types, such as the ChACs, make up 3–5% of the total population. Half of the amacrine cells are narrow-field, with coverage factors around 1. Many of these are broadly stratified, which suggests they may interconnect the ON and OFF substrata. Approximately a quarter of the amacrine cells are wide-field and narrowly stratified with very high coverage – as high as 100–500. A cell with an overlap this high forms an extremely dense plexus of fine dendrites that blankets the entire retina. Examples are S1 amacrine cells, DACs, and starburst amacrine cells (see below). Thus, in the rabbit retina, the identification of all the amacrine cell types, started so long ago by Cajal and his contemporaries, is now almost complete. The mouse is probably the next best characterized because of the array of genetic tools that can be used for their analyses.

The reasons for such a variety of amacrine cells are unknown. However, two functions seem to be commonly repeated. First, all bipolar cell terminals seem to receive GABA-mediated negative feedback. In the case of the rod bipolar cell, feedback is mediated by two amacrine cell types, S1 and S2.<sup>239</sup> Bipolar cells (approximately 10 types) are narrowly stratified and if different amacrine cells mediate feedback to each one, this could account for 10–20 different cell types. Secondly, about half the ganglion cells (approximately eight types) are coupled to one or two amacrine cell types by gap junctions.<sup>240–242</sup> Again, if different amacrine cells are coupled to each ganglion cell type, this could account for 10–15 types. These two groups need not be mutually exclusive and doubtless amacrine cells have many functions. In another calculation, we estimate there are 15 ganglion cell types forming independent circuits or channels. If each channel required two amacrine cells, that would produce a

total of 30 amacrine cell types. While necessarily vague, these simple estimates indicate the variety of amacrine cell types may not be extravagant.

General functions attributed to amacrine cells include feedback inhibition, surround inhibition, some forms of adaptation, signal averaging, and noise reduction.<sup>243,244</sup> In a rapid eye movement or saccade, the visual image does not blur. This is because a wave of inhibition sweeps the inner retina, like a vertical blank on a television screen. In one study, the inhibitory wave associated with saccades was attributed to wide-field amacrine cells.<sup>245</sup> However, in terms of specific connections and neuronal circuits, the functional anatomy of amacrine cells, it has only been possible to study a few types, four of which are selected below. We know almost nothing except the shape of 75% of the amacrine cells, not their connections, physiology, or circuit functions – in other words, little more than Cajal knew 100 years ago. As the means of targeting, imaging, and recording from visually identified cell types improves, we can expect further progress in this area.

An example of these new approaches was demonstrated by Knop and colleagues,<sup>246</sup> who used a GFP transgenic mouse line that marked a type 2 wide-field amacrine cell. They characterized the inputs, stratification, and physiology of the cell, showing it was ON-OFF and GABAergic and that its function was maintained over a wide range of light adaptation conditions. A major goal of visual neuroscientists is to characterize fully all the amacrine cells and integrate their function into the retinal circuitry. Several amacrine cells have been studied extensively, and their characteristics are described below.

## **All Amacrine Cells**

The AII amacrine cell, also known as the rod amacrine cell, is the most numerous of the amacrine cells, accounting for 11% of the total. It is correctly written with a Roman numeral, which is retained from an early classification scheme, while other numbered amacrine cells use Arabic numerals. AII amacrine cells have a distinctive bistratified morphology, which makes them easy to identify, even in retinal slices.<sup>246</sup> The soma protrudes into the IPL and turns into a thick axon that descends to sublamina b of the IPL

and branches into an overlapping matrix.<sup>247</sup> This is the site of glutamate input from rod bipolar cells (Fig. 17.21) and output, via gap junctions to ON cone bipolar cells. There are also fine dendrites, which terminate in lobules in sublamina a. At this level, AII amacrine cells make glycinergic inhibitory contacts with OFF cone bipolar cells, although input from AII ACs appears not to modulate OFF bipolar cell membrane potential during rod bipolar pathway mediated visual signaling.<sup>248</sup> AII ACs also receive input from OFF cone bipolar cells at this level, the function of which is unclear.<sup>187</sup>

Primate AII amacrine cells are similar in morphology to those of other mammalian species.<sup>59,60</sup> The density of rods reaches a maximum at about 20° from the fovea but psychophysical measurements in humans indicate that, in dark-adapted conditions, the maximum acuity occurs at approximately 5° from the fovea, a substantial mismatch. The rod pathway for maximum acuity is thought to be rods → rod bipolar cells → AII → midget bipolar cells → midget ganglion cells (Fig. 17.19). There is good evidence that AII amacrine cells contact midget bipolar cells and other ganglion cell types are too sparse to support the maximum resolution. Now, rods and rod bipolar cells far outnumber AII amacrine cells so they will not present a limit to scotopic acuity. In addition, both ON and OFF midget bipolar cells and ON and OFF midget ganglion cells have a 1 : 1 : 1 correspondence with the tightly packed cones of the central retina. That leaves the AII amacrine cell as the lowest density, the bottleneck, in the pathway. In macaque retina, the peak density of AII amacrine cells is about 5000 cells/mm<sup>2</sup> around 5°, which matches the peak of dark-adapted acuity. If we consider the mosaic of AII amacrine cells and, from sampling theory, calculate the maximum resolution for such an array, we find that it closely matches the peak acuity from psychophysical experiments. Together, these results indicate that the density of AII amacrine cells sets the limit of dark-adapted resolution in central retina.

The AII amacrine cell network seems to be very important since it is found in all mammalian retinas. In general terms, the AII amacrine cell network is thought to reduce noise by canceling out random events that are not correlated and by reinforcing light-driven events that are synchronized.<sup>249,250</sup> Coupling is also strongly

modulated by dopamine,<sup>212</sup> and processes from the DACs make a ring around the neck of each AII where it protrudes into the IPL (Fig. 17.24). Of course, we think that dopamine is the general signal for light adaptation and, in fact, light itself seems to modulate the strength of coupling in the AII network.<sup>251</sup> Disrupting the AII network interrupts the rod-driven ON pathways, as described above. However, even in the rod-driven OFF pathways, which are not routed via AII amacrine cell gap junctions, the sensitivity is reduced by approximately 1 log unit in the Cx36 knockout mouse.<sup>251</sup> This indicates that coupling in the AII amacrine cell network adapts to ambient lighting conditions to optimize rod signaling over a large dynamic range.

**FIG. 17.24** Dopaminergic amacrine cells form a dense matrix. The matrix of dopaminergic dendrites, stained for tyrosine hydroxylase (green), blankets the retina.

There are many small varicosities surrounding All amacrine somas, stained for calretinin (red). (Courtesy of

S.C. Massey.)

The AII amacrine cells also appear to have a day job.<sup>216,217,252</sup>

During the day, dark objects that approach the viewer activate a particular class of ganglion cells. An important component of the circuit is the AII amacrine cell. However, unlike in the dark, the information flow is effectively reversed. Depolarization of cone ON bipolar cells results in depolarization of the AII through gap junctions, which increases inhibition by the AII amacrine cell on to OFF bipolar cells. This is a crossover inhibition pathway by which ON channels inhibit OFF pathways.<sup>182</sup> The dual use of the AII amacrine cell depending on lighting condition maximizes circuit efficiency.

## **S1 and S2 Amacrine Cells**

The S1 amacrine cell of the rabbit retina (A17 in the cat) is a wide-field GABA amacrine cell with straight radiating dendrites decorated with prominent varicosities (Fig. 17.25A). The S2 GABA amacrine cell is smaller, the dendrites are more tangled, and the varicosities are smaller but more numerous (Fig. 17.25B).<sup>253,254</sup> Both cell types contribute to a dense overlapping meshwork at the level of the rod bipolar terminals (Fig. 17.26). These large cells are relatively numerous so the dendritic overlap is huge with coverage factors as high as 500. Although the rabbit retina contains little endogenous serotonin, for some unknown reason these cells take up serotonin. Therefore, they are sometimes known as indoleamine-accumulating amacrine cells and this provides a simple way to label the entire population. Electron microscopy shows that S1/S2 amacrine cells make reciprocal synapses with rod bipolar terminals, i.e., they receive input at a rod bipolar ribbon synapse and nearby they synapse back on to the rod bipolar terminal.<sup>40</sup>

**FIG. 17.25** (A) S1 and (B) S2 amacrine cells filled with Lucifer Yellow, from the rabbit retina. These amacrine cells have prominent varicosities, which are synaptic structures, along slender dendrites. (Reproduced with

permission from Zhang J, Li W, Trexler EB, et al. Confocal analysis of reciprocal feedback at rod bipolar terminals in the rabbit retina. *J Neurosci* 2002;22:10871–

82.)

**FIG. 17.26** S1/S2 matrix. (A) The S1/S2 matrix (green), stained by serotonin uptake, from whole-mount rabbit retina. (B) Rod bipolar terminals (blue) fill holes in the S1/S2 matrix. (C) All dendrites (red) also contact the same rod bipolar terminals. (D) Merged triple-label image shows S1/S2 processes and All dendrites surrounding every rod bipolar terminal. (Reproduced with permission from Zhang J, Li W, Massey SC. Confocal analysis of reciprocal feedback at rod bipolar terminals in the rabbit retina. *J Neurosci* 2002;22:10871–82.)

The varicosities contain presynaptic markers; they are wrapped around rod bipolar terminals (alternating with AII dendrites) and opposed by synaptic ribbons and GABA receptors (Fig. 17.27). In fact, the varicosities are synaptic sites. Confocal analysis of double-label material shows that every varicosity is in synaptic contact

with a rod bipolar terminal.<sup>254</sup> This means that the functional role of the S1/S2 amacrine cells is to provide a level of GABA-mediated negative feedback to rod bipolar terminals. This is their job and they do nothing else; they have no output to any other cell besides the rod bipolar cell.

**FIG. 17.27** S1 synapse on a rod bipolar terminal. This three-dimensional reconstruction shows a single varicosity from an S1 amacrine cell (green) wrapped around a rod bipolar terminal (blue). The transparency has been adjusted so we can see through these structures. GABA<sub>C</sub> (red) receptors are found on the surface of the rod bipolar terminal, including at the interface with the S1 (red + green + blue = white). This is an example of locating a synaptic structure by confocal microscopy. (Courtesy of W. Li and S.C. Massey.)

S1/S2 amacrine cells carry about 300 and 500 varicosities, respectively, and the density of varicosities has been calculated as 330,000/mm<sup>2</sup>. Each rod bipolar terminal receives input from about 25 S1 and 50 S2 varicosities. They are both apposed by GABA<sub>A</sub> and

GABA<sub>C</sub> receptors.<sup>255</sup> Thus, the inhibitory input to bipolar terminals will have two components: a large sustained component from GABA<sub>C</sub> receptors, which are only expressed by bipolar terminals, and rapid initial transient input from GABA<sub>A</sub> receptors, which are more widespread.<sup>155,193,236,256–258</sup> The S1 and S2 amacrine cells clearly have different spatial and coupling properties.<sup>239</sup> Hence, the S2 input dominates within 200 μm and provides an inhibitory signal that matches the size of the surround recorded from AII amacrine cells. The larger, well-coupled S1 amacrine cell may provide a more distant network or global signal. This analysis suggests that the presence of both S1 and S2 amacrine cells is not redundant: each cell contributes different components of lateral inhibition in the rod pathway. Together, these components will summate to modulate the spatial and temporal properties of rod bipolar output. Further, each of the synaptic sites of S1 (A17) amacrine cells may operate independently of the whole. This is possible because each varicosity appears electrically isolated from its neighbor.<sup>195</sup> In conjunction with the cable properties of the A17 neurites the outputs are compartmentalized, keeping individual reciprocal synaptic dyads independent.<sup>192,195,259</sup> Such local processing has an important consequence: it allows a single A17 to process upwards of 500 signals independently of each other. This represents a large increase in processing power based on what amounts to parallel circuits in a single cell.<sup>195</sup>

It should be emphasized that the reciprocal feedback described at the rod bipolar terminal is, in fact, a general case. It is likely that the terminals of all bipolar cells make reciprocal synapses with GABA amacrine cells and bipolar terminals are literally surrounded by GABA-positive profiles. In the mouse retina, as well as other species, GABA<sub>C</sub> receptors, a postsynaptic target of feedback inhibition, are expressed on cone ON and OFF bipolar cells. The current mediated by this receptor is slow and sustained, making it a likely target of feedback control on the cone bipolar cells, as it does in rod ON bipolar cells. The absence (in GABA<sub>C</sub> receptors knockout mice) or pharmacologic block of this receptor increases both the spontaneous activity and gain of ON-center ganglion cells relative to wild-type.<sup>256,260,261</sup>

There seem to be GABA<sub>C</sub> receptors on all bipolar cell terminals, although the density for each cell type varies.<sup>256–258</sup> If each bipolar cell type, with its unique address, had one GABA amacrine cell type, that would account for 10–12 of the amacrine cell types. The “sharing” of some broadly stratified amacrine cells would tend to reduce this number while those cases, like the rod bipolar cell, which receive feedback inhibition from two amacrine cell types, will inflate it. In either case, negative feedback provides greater stability, increased frequency response, and a wider bandwidth at the level of bipolar cell terminals. A major role for at least some of the multiple types of GABA amacrine cells is to provide negative feedback for all bipolar cells.

## Dopaminergic Amacrine Cells

A small number of amacrine cells, less than 0.1%, contain dopamine. To make up for their low density, these cells have very long axon-like processes that can run for millimeters across the retina.<sup>262</sup> The net result is a dense high-coverage plexus of dopaminergic dendrites, which covers the entire retina. Most of the plexus is in sublamina 1, adjacent to the INL, but there are minor bands in sublaminae 3 and 5 of the IPL. In some species, particularly fish, the dopamine neurons project to the OPL. In other words, they are interplexiform cells. In the rabbit retina, a few stunted processes run towards the OPL but they do not form a plexus. In the macaque retina, some dopaminergic dendrites run into the INL where they surround the somas of AII amacrine cells (Fig. 17.24).<sup>60</sup>

Electron microscopy shows that the dendrites in layer 1 receive direct bipolar input at ribbon synapses, many of which appear to be monads, as opposed to the usual dyadic arrangement with two postsynaptic processes.<sup>263</sup> Yet, recordings from GFP-labeled cells in the mouse retina have shown that DACs produce a variety of light responses: ON transient, ON sustained, and light independent.<sup>23,24</sup> But how do these ON responses arise if most dopaminergic processes are stratified in the OFF sublamina? If DACs are ON cells, then they break the rules of stratification for the IPL.

Several different mechanisms have been proposed to overcome this difficulty. For example, it has been shown that ON bipolar

inputs to the DACs occur on the minor bands in layer 3.<sup>264</sup> However, it is also clear that there are bipolar ribbon inputs to the DAC in sublamina 1.<sup>263</sup> Most recently, it has been suggested that the melanopsin-containing ipRGCs may provide an input to the DACs, because the sustained features of the DAC response and the spectral signature match those of the melanopsin ganglion cells. Furthermore, the light-evoked DAC response is maintained when photoreceptors degenerate, although transient light responses are blocked by APB, suggesting they arise from the ON bipolar pathway. In addition, melanopsin ganglion cell dendrites that ramify in sublamina a also have ON responses, thus breaking the stratification rules themselves. Most recent evidence suggests that many ON cone bipolar cells make axonal ribbon or ectopic synapses as their axons descend through stratum 1 (Fig. 17.28). These axonal ribbons provide ON excitatory input via AMPA-type glutamate receptors to DACs (and to ipRGCs) in the OFF layer of the IPL. Thus, axonal ribbons break the stratification rules of the IPL and provide an additional accessory ON sublayer in the outer IPL.<sup>26,27</sup>

**FIG. 17.28** Dopaminergic amacrine cells, stained with an antibody against tyrosine hydroxylase (TOH: blue), receive ectopic, axonal ribbon synaptic input. (A) The dopaminergic dendrites run in sublamina a. At this level, ON cone bipolar cells, labeled with an antibody against calbindin (red), are passing through so the descending axons appear as dots. However, they are nearly all immediately adjacent to the dopaminergic dendrites (*arrows*). (B) At higher magnification, it can

be seen that synaptic ribbons (green) also occur at these contact points. Thus, the arrows show ON synaptic input, via axonal ribbons, in sublamina a, the OFF layer of the inner plexiform layer. (Reproduced with permission from Hoshi H, Liu WL, Massey SC, et al. ON inputs to the OFF layer: bipolar cells that break the stratification rules of the retina. *J Neurosci* 2009;29:8875–83.)

In the mouse retina, DACs also contain GABA<sup>265</sup> but DACs from the rabbit retina do not display a GABA signature.<sup>34</sup> Dissociated DACs are spontaneously active<sup>266</sup> and, in contrast to GABA, dopamine seems to be steadily released in a paracrine fashion to diffuse throughout the retina.<sup>267</sup> Dopamine levels are higher in the daytime and seem to be under circadian control. The most recent work indicates that the DACs themselves express clock genes.<sup>268–271</sup> This is appropriate because dopamine is intimately involved in the diurnal rhythms associated with the processes of light and dark adaptation. Dopamine acts at a variety of sites in the retina, many of which seem obviously linked to light or dark adaptation.<sup>272</sup> For example, it dramatically reduces coupling in the AII amacrine cell network<sup>212,213</sup> and, in the outer retina, it promotes cone input to second-order neurons. Conversely, in the dark, when dopamine is absent, photoreceptor coupling is increased via a D2 receptor mechanism.<sup>81,82</sup> By controlling rod/cone coupling, it seems that dopamine in the light, or its absence in the night, presets rod and cone pathways as appropriate for the lighting conditions.<sup>80,273</sup>

A role for D1 receptors has recently been shown to be critical in the GABAergic control of the rod ON bipolar cell circuit that enhances light sensitivity and increases the dynamic range of their responses at dim-light levels.<sup>274</sup> The location of this control remains to be discovered and could occur via a novel dopaminergic to GABAergic amacrine serial synapse in the IPL or a horizontal cell-mediated input modulated by dopamine in the outer retina. The retina is like a self-optimizing network controlled, at least in part, by the circadian release of dopamine.

## **Starburst Amacrine Cells**

The ChACs, also known as starburst amacrine cells (SACs) on account of their unique morphology, form two mirror-symmetric

populations on either side of the IPL in all mammals.<sup>20</sup> They are the only source of ACh in the retina. In whole-mount view, they are radially symmetric with dendrites radiating from the soma in all directions (Fig. 17.29). The bipolar cell inputs, via AMPA-type glutamate receptors, occur all along the branches, but the outputs seem to be restricted to the varicosities in the terminal third of each dendrite. The cells in the INL produce OFF responses and stratify in sublamina a while the displaced SACs are ON cells branching in sublamina b. They are relatively numerous wide-field amacrine cells. Consequently, they have a very high coverage factor and in cross-section their dendrites form two continuous bands in the IPL that look like train tracks in cross-section (Fig. 17.29). This is a very dense, narrowly stratified matrix of overlapping dendrites that are cofasciculated with the direction selective (DS) ganglion cell types.<sup>275,276</sup>

**FIG. 17.29** Starburst amacrine cells. (A) The somas of displaced starburst amacrine cells stained with 4',6-diamidino-2-phenylindole (DAPI). This method is used to target this cell type. (B) A single starburst amacrine cell, filled with Lucifer Yellow. (C) A section of retina stained for choline acetyltransferase (red) showing conventional and displaced somas and two bands in the inner plexiform layer. *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *GCL*, ganglion cell layer. (Courtesy of S.C. Massey.)

SACs also contain GABA.<sup>277</sup> In fact, we should probably think of these cells as wide-field GABA amacrine cells, which also contain ACh. The presence of two classical neurotransmitters in the same cell is unusual and it has aroused a great deal of interest. The

release of both transmitters seems to be dependent on calcium, which indicates a conventional mechanism using synaptic vesicles. But GABA and ACh release have a differential sensitivity to calcium. This implies that the two transmitters may be released from different populations of vesicles, but whether cotransmission occurs at the same sites is unknown.<sup>278</sup>

The SACs have been a focus of attention because they seem to be directly involved in neuronal circuits that produce DS responses in certain ganglion cells. DS ganglion cells were discovered nearly 50 years ago and, although the mechanism has been under intense investigation, the details have still not been fully resolved. However, SACs are in the middle of the puzzle. Ablating them, in a mouse line engineered to respond to an immunotoxin, blocked DS responses in ganglion cells.<sup>279</sup> Furthermore, optokinetic nystagmus, a type of reflex eye movement elicited by a moving stimulus, was also blocked. This combination of physiologic and behavioral data provides convincing evidence that SACs are required for directional selectivity and optokinetic eye movements.

SACs also are found at the same depth as the bistratified ON/OFF DS ganglion cells, which are the most sensitive of all ganglion cells to ACh. But cholinergic input alone is not sufficient to produce DS responses.<sup>280</sup> Rather, the mechanism seems to depend on asymmetrical GABA inhibition that comes from the SACs. In dual recordings, stimulating a starburst amacrine cell on the null side produced an inhibitory GABA input to DS ganglion cells.<sup>278,281</sup>

Furthermore, calcium imaging by two-photon microscopy showed that individual dendrites of SACs can themselves produce directional responses, even though recordings from the soma do not.<sup>33</sup> The dendrites respond better to a centrifugal stimulus, moving away from the soma, than a centripetal stimulus, towards the soma. The directional signals are due to the intrinsic morphologic properties of SACs and a voltage gradient generated by the asymmetric distribution of voltage-dependent channels.<sup>282,283</sup> Most recently, crowd sourced 3D reconstruction (Eyewire) has shown that the OFF layer of starburst dendrites receive input from two bipolar cell types, one sustained and one transient, and this may contribute to the directional asymmetry.<sup>284</sup> In addition, there is GABA-mediated starburst-to-starburst inhibition, which may

enhance or fine-tune the DS responses.<sup>278</sup> These important results confirm a long-held suspicion that there is a great deal of local processing among amacrine cell dendrites and it suggests that SACs are the source of directional signals in the retina.

Given that SACs generate directional signals, they release GABA, and they synapse directly with ON/OFF DS ganglion cells, then the final requirement for specific wiring is that individual starburst dendrites with the appropriate directional asymmetry are connected to ON/OFF DS ganglion cells with the same orientation of the null/preferred axis. (Remember, there are four subsets of ON/OFF DS ganglion cells with different axes, roughly aligned with the four main compass points.) By a combination of calcium imaging to identify the directional preferences combined with serial block-face electron microscopic imaging to reconstruct the underlying retinal circuits, the specific synaptic connections have now been identified.<sup>285</sup> Starburst dendrites with a specific orientation make synaptic connections, identified by varicosities containing presynaptic machinery, with ON/OFF DS ganglion cells with an antiparallel null axis. Thus, preferred excitation in starburst dendrites can provide the GABA input for null inhibition to ON/OFF DS ganglion cells. Often, the starburst dendrites and the ON/OFF DS ganglion cell dendrites are oriented nearly parallel and it is well known that these two cell types are cofasciculated at the level of the two cholinergic bands. Once a local DS response is generated in the ganglion cell, dendritic spikes propagate to the soma with a high probability of generating somatic spikes.<sup>286</sup> After 50 years, the neuronal circuitry underlying directional selectivity has finally been revealed. How this arises developmentally and what the role is for cholinergic input are further important questions that remain.

Finally, the network of SACs appears to play a key role in retinal development.<sup>287</sup> Imaging of neonatal retina shows the presence of calcium waves, which propagate across the retina and elicit bursts of firing in all ganglion cells. These waves apparently are not required to establish directional selectivity, which arises independently of both waves and visual experience.<sup>288</sup> However, in one model, wave activity is thought to promote the development of ganglion cell connections in a retinotopic manner. The cholinergic

plexus is present surprisingly early in development and, in the early stages, the calcium waves are blocked by cholinergic antagonists.<sup>289–291</sup> This suggests that spontaneous activity in the ChACs may initiate the calcium waves. This was thought to be light-independent; however, it now appears that light input via ipRGCs (light-sensitive ganglion cells: see below) is required for aspects of the spiking that are important for retinogeniculate segregation.<sup>292</sup>

## Ganglion Cells

Ganglion cells are the output neurons of the retina, and they receive input from bipolar cells, at ribbon synapses, via AMPA-type glutamate receptors.<sup>293</sup> In addition, there are even more amacrine cell inputs, through conventional synapses and via gap junctions, which are thought to tune ganglion cell properties in a complex way that is not well understood. Ganglion cells mostly obey the stratification rules governing the inner retina. Thus OFF ganglion cells receive input from OFF bipolar cells in sublamina a and ON ganglion cells receive input from ON bipolar cells in sublamina b. There are a few ON/OFF types of ganglion cell, such as the famous DS type, and they are bistratified.

Ganglion cell axons run across the vitreal surface of the retina and unite to form the optic nerve. Unlike many other retinal neurons, ganglion cells produce conventional action potentials suitable for transmission over the relatively long distance to the brain. The vast majority of ganglion cells use the excitatory neurotransmitter glutamate to communicate with higher visual centers. Everything you see about the visual world comes to you through the responses of ganglion cells. If they don't signal it, you don't see it! If there are about 30–40 ganglion cell types (see below) and the coverage factors range from one to three, then the total coverage of the retina by the whole ganglion cell population is about 50–100. In other words, each point on the retina is covered by at least 50 ganglion cells. The number of ganglion cells in each human retina is approximately 1.5 million, equal to the number of axons in each optic nerve. In macaque, there are 1.8 million,<sup>143</sup> in rabbit, 380,000,<sup>294</sup> and in mouse retina approximately 60,000

ganglion cells.<sup>47</sup> The actual number of cells has a large genetic component, which produces up to threefold variation in numbers, as demonstrated by quantitative analyses of a large number of mouse strains.<sup>295</sup>

Ganglion cells are physiologically and morphologically diverse. They can be classified by many physiologic and anatomic criteria, including size, response, receptive field, color, bandwidth, ON or OFF, conduction velocity, morphology, branch pattern, stratification, coupling, coverage, and central projections. Earlier estimates are in the range of 15–20 different ganglion cell types. However, the most recent report suggests there are as many as 40 ganglion cell types in the mouse retina.<sup>296</sup> Importantly, this is based on an unbiased sample of 11,000 ganglion cells, obtained by calcium imaging of electroporated retina. Specific ganglion cell types were extracted mathematically by cluster analysis and verified by complementary genetic and anatomical methods. This analysis suggests that the number of ganglion cell types, and therefore the number of channels via which the mouse eye talks to the mouse brain, is substantially greater than previously realized using purely anatomical methods.<sup>296</sup> We think the number of distinct types is extremely important because each ganglion cell type is thought to represent an independent visual channel, perhaps with a specific central target. An important goal now is to characterize fully each RGC type with respect to physiology and synaptic connections. An understanding of the central projections of each ganglion cell type will be necessary before we have a true understanding of the visual process.

New tools by way of transgenic mouse lines that express a marker protein such as GFP in a single type of cell are becoming available.<sup>38,297–301</sup> A particularly striking example of the power of this approach was the ability of Michal Rivlin-Etzion and colleagues to show that two ON/OFF DS RGCs with similar direction selectivity had different projection patterns to the brain. These data suggest there are at least eight ON/OFF DS RGCs with indistinguishable dendritic arbors. If a similar situation arises with other classes of RGCs then the number of independent cell types may increase dramatically, also increasing the number of visual channels leaving the retina. In fact, the total number of ganglion cell types has not yet

been determined for any species. Seemingly rare cell types that account for a small fraction of the total, e.g., ipRGCs, make up less than 1%, but may be split into five subtypes with different morphology and different central projections, further adding to the types of RGCs. There seems to be general agreement that the number of ganglion cell types will be more than 20 and as high as 40.<sup>296</sup> Genetic methods will be increasingly important and they have been used to identify several new ganglion cell types, increasing the anatomical cell count to 30.<sup>302</sup>

The importance of depth in the IPL was emphasized when Roska and Werblin showed that at least 10 ganglion cell types, most narrowly stratified at different depths, received distinct physiologic inputs in the rabbit retina.<sup>303,304</sup> Apparently, the IPL contains a stack of parallel versions of the visual scene coded by depth. Each layer receives a different combination of excitatory and inhibitory inputs to produce at least 10 spatiotemporal channels. Ganglion cells with transient or sustained responses were located at different levels of the IPL. Some ganglion cells received inhibitory inputs that originated in another layer. This type of vertical inhibition could be carried by narrow-field amacrine cells, many of which are broadly stratified.<sup>228</sup> The functional anatomy of the IPL is very precise. In the rabbit retina, OFF and ON alpha ganglion cells are stratified just below the two cholinergic bands (Fig. 17.30).<sup>10,218</sup> They are separated by as little as 1–3  $\mu\text{m}$  but they are clearly different addresses serving different ganglion cells with distinct morphologic and physiologic properties. If a single stratum can be as narrow as this, there is certainly room for a dozen or more different layers within the IPL, each serving one or more different ganglion cell types.

**FIG. 17.30** Stratification of the inner plexiform layer.

(A) The dendrites of an OFF alpha ganglion cell (green) lie above the cholinergic a band (red). (B) The dendrites of an ON/OFF directionally selective ganglion cell are bistratified and lie within the two cholinergic bands (green + red + yellow). (C) The dendrites of an ON alpha ganglion cell lie immediately below the lower cholinergic b band. This is at the same depth as the terminals of calbindin bipolar cells (blue), so green + blue = cyan. Thus, the inner plexiform layer can be very finely divided into different layers which are actually different addresses for synaptic interactions. (Courtesy of W. Li and S.C. Massey.)

## Does Each Ganglion Cell Type Represent a Visual Channel?

The simple answer to this question is yes, we think so. However, we still do not have a definitive value for the number of channels and, for those ganglion cell types that have been classified morphologically, it is not always clear which physiologic class they belong to. The correspondence between functional anatomy and physiologic type is only partially complete.<sup>305</sup> But, it is increasingly apparent that the characteristic responses of the different ganglion cell types represent the diversity of parallel bipolar cell pathway outputs modified by lateral inhibitory interactions; the interplay between vertical excitatory and lateral inhibitory pathways generates the ~20 distinct computations represented by the ganglion cell classes.<sup>4,152,306</sup>

Several recent studies have revealed unexpected complexity within ganglion cells' receptive fields by identifying interactions between excitatory bipolar cell and inhibitory amacrine cell circuits that expand the signaling capacity of ganglion cells. For example, strong, local synaptic inhibition can act to make some ganglion cells sensitive primarily to spatially homogeneous stimuli.<sup>307</sup> Local inhibition also is responsible for a phenomenon termed "sensitization," in which a ganglion cell responds more strongly to a low contrast stimulus following exposure to a high contrast one. A subset of ganglion cells in both the salamander and mouse retinas

exhibit sensitization, which is thought to arise from activity-dependent changes in the balance of local excitation and inhibition.<sup>308,309</sup> Presumably, such spatially tuned synaptic drive permits ganglion cells to encode visual stimuli more precisely.<sup>310</sup> Recent work also has yielded the surprising findings that retinal circuit function is not static, but rather can change with ambient light intensity. For example, some inhibitory circuits are not activated well by rod stimulation, and this makes some ganglion cells' receptive field structure intensity-dependent.<sup>311</sup>

A problem that has yet to be adequately resolved is what features of the functional responses of the ganglion cells are the ones that set individual classes apart. In fact, function alone is probably not sufficient and projection pattern, axon diameter, and terminal morphology may also be important. Regardless, it is widely believed that the retina, with the ganglion cells as the output, produces a large set of neural codes, most of which have not been deciphered, that are transmitted to the brain in parallel both on a temporal scale and to a variety of central structures. These are the visual channels, some of which carry different versions of Mona Lisa (see Fig. 17.1), where we began. The extent to which visual perception represents retinal processing is uncertain, but increasing insight into both retinal and cortical neural computation will permit this issue to be clarified in the future.<sup>312</sup> Below are some examples of different ganglion cells/visual channels that we are beginning to understand.

In a few cases, a particular ganglion cell type seems to have a specific role. Midget ganglion cells in the primate retina are a good example. There are two types, ON and OFF, which are broadly stratified towards the middle of the IPL. Midget ganglion cells are numerically dominant in central retina, where they may account for as many as 95% of all ganglion cells.<sup>184</sup> Importantly, we know that in central retina there is a 1 : 1 : 1 correspondence from cones → midget bipolar cells → midget ganglion cells. Beyond 2 mm or 10°, the midget ganglion cells form separate dendritic clusters that receive input from multiple midget bipolar cells. Sampling theory, based on the density of midget ganglion cells, closely predicts the curve describing a psychophysical measure of human acuity, except close to the fovea where the cone pedicles are laterally displaced.<sup>313</sup>

Thus, it seems clear that midget ganglion cells transmit a high-acuity version of the visual scene from the center of your gaze, the central retina. The 1 : 1 : 1 ratio also means that individual midget ganglion cells will be color-coded according to the type of cone at the beginning of the chain. Midget ganglion cells project to the parvocellular layers of the lateral geniculate nucleus which also carry color signals. Midget ganglion cells are a specialization of the primate retina, perhaps the final point in the relentless survival-driven goal of maximum acuity. There is no exact match in other mammalian species but an equivalent role could be played by beta ganglion cells in the cat retina. In the rabbit retina, there are neither midget nor beta ganglion cells but an ON and OFF pair of relatively small ganglion cells, G4, which are rather broadly stratified toward the middle of the IPL.<sup>314</sup> These are at least morphologically similar. Consistent with the idea that the midget/beta cells are a specialization of animals with a fovea or foveal-like specialization, the rodent retina lacks these types of ganglion cells.

Some of the most convincing evidence that ganglion cells carry specific channels of visual information comes from comparative anatomy, where it can be seen that certain ganglion cell types recur frequently across species. Perhaps the best example is the alpha ganglion cell, which has been reported in many mammalian retinas.<sup>315</sup> Alpha ganglion cells have large somas, come in paramorphic ON and OFF pairs, make up less than 5% of all ganglion cells, and have a large dendritic field with a characteristic radiate branching pattern (Fig. 17.31). In the rabbit retina, alpha ganglion cells are narrowly stratified just below the cholinergic bands. Physiologically, they have transient nonlinear (Y-like) properties, they respond to stimuli of high temporal frequency and project to the magnocellular layers of the lateral geniculate nucleus. Their responses are not color-coded. Alpha ganglion cells seem well suited for detection of low luminance contrast over large areas of the visual field, such as a blurred copy of the Mona Lisa. Their occurrence over such a wide range of species suggests they play a fundamental role common to the visual needs of many animals, e.g., detection of motion. Parasol ganglion cells in the primate retina and A-type cells of rodents have similar properties, although whether they correspond exactly to alpha cells is an open question.

There appear to be wide-field ganglion cells in the primate retina that are morphologically closer to alpha ganglion cells in other species.<sup>316</sup>

**FIG. 17.31** Dye-injected ganglion cells in the rabbit retina. The white cell is an ON/OFF directionally selective ganglion cell surrounded by four much larger transient ON DS ganglion cells. These two ganglion cell types have obviously different dendritic morphology. In addition, the transient ON DS ganglion cells form a nonrandom mosaic. There are also some dye-coupled amacrine cells in the background.

(Reproduced with permission from Hoshi H, Tian LM, Massey SC, et al. Two distinct types of ON directionally selective ganglion cells in the rabbit retina. *J Comp Neurol* 2011;519:2509–21.)

The ON/OFF DS ganglion cells of the rabbit retina, reported by Barlow and Levick nearly 50 years ago,<sup>317</sup> are one of the best characterized of the retinal ganglion cells. In these ganglion cells, a bar moving in the preferred direction through their receptive field produces a strong burst of spikes, but the same stimulus moving in the opposite direction produces little or no response. As first shown by Amthor and colleagues,<sup>318</sup> bistratified cells fasciculate extensively within the two bands of starburst amacrine cell processes and they have a distinct retroflexive branching pattern (Fig. 17.32). DS ganglion cells are exquisitely sensitive to nicotinic cholinergic agonists but, surprisingly, directional selectivity is not

dependent on this cholinergic input.<sup>280</sup>

**FIG. 17.32** ON/OFF directionally selective ganglion cell. A single ON/OFF directionally selective ganglion cell was dye-injected with Neurobiotin and then, using the confocal microscope, the two dendritic fields were imaged and color-coded. Note the retroflexive branching pattern which fills most of the available space, in contrast to the branch pattern of the alpha ganglion cell above. (Reproduced with permission from Kittila CA, Massey SC. Pharmacology of directionally selective ganglion cells in the rabbit retina. *J Neurophysiol* 1997;77:675–89.)

Paired recordings showed that SACs on the null side of the DS ganglion cells provide asymmetric GABA inhibition to DS ganglion cells.<sup>281,319</sup> The source of the GABAergic input is from SACs, which

contain GABA as well as ACh.<sup>277</sup> Individual dendrites of the SACs generate directional responses due to their intrinsic properties and this is the origin of directional signals in several other types of DS ganglion cells.<sup>33</sup> This difference is consistent with recent morphologic results using an extensive three-dimensional reconstruction of functionally identified DS ganglion cells by serial block-face electron microscopy that showed specific inhibitory inputs from starburst dendrites with the appropriate orientation.<sup>285</sup>

At present, four ganglion cell types with different null/preferred axes have been described, one of which is dye-coupled and shows a precise dendrite-to-dendrite tiling pattern with a coverage close to 1.<sup>320</sup> DS cells with the other preferred axes are thought to tile the retina independently so that if the dendrites of two DS ganglion cells overlap, they must have different preferred directions. They can also be differentiated by molecular markers and have slightly different central projections.<sup>321</sup> The four null/preferred axes are aligned with the extraocular muscles<sup>322</sup> so it is often suggested that the ON/OFF DS cells play a role in the control of eye movements. Cells with a similar morphology have been noted in mouse and rat,<sup>323,324</sup> cat (the iota cell),<sup>325</sup> and even primate retina.<sup>316</sup> In the mouse two posteriorly tuned, essentially morphologically identical DS cells have been defined that have subtle receptive field differences, and different central projection patterns.<sup>301</sup> If each compass point is duplicated in the same manner, this would predict there should be a total of eight ON/OFF DS ganglion cells. It is not unreasonable to assume a similar situation will exist in most other mammals.

There is another DS cell in the rabbit retina that has interesting properties. Its dendrites are monostratified in the ON starburst band and have a similar retroflexive branch pattern. They also receive specific null-side inhibition from SACs.<sup>326</sup> However, these ON DS cells respond to much slower movements and its three variants have different null/preferred axes, which are aligned with the semicircular canals.<sup>327</sup> Consistent with the hypothesis that DS ganglion cells are critical to eye movement control, the ON DS ganglion cells project to the medial terminal nucleus of the accessory optic system.<sup>327,328</sup> Ganglion cells with a strikingly similar morphology have been reported in mouse, rat, and primate retina.<sup>316</sup> The value of this comparative anatomy becomes clear

when we consider an experiment in the mouse retina. When SACs are ablated, DS responses in ganglion cells are abolished and the optokinetic nystagmus is also blocked.<sup>279</sup> This is a type of reflex eye movement involved with tracking moving objects with the same velocity range as the ON DS ganglion cell. It suggests that ON DS cells provide the input to a system for tracking or stabilizing the retinal image. At least one gene associated with an eye movement disorder is exclusively expressed in SACs, which provide the directional input to the ON DS ganglion cell.<sup>300</sup>

A second type of ON DS ganglion cell has recently been identified in the rabbit retina.<sup>328-330</sup> This cell type, originally reported by Ackert and colleagues,<sup>331</sup> is distinct from the cell described above in terms of morphology and dendritic stratification, just above the lower band of ChAC processes. If the SACs are the source of directional signals in the retina, it is not clear how DS signals are generated in this cell type. Finally, in a stunning example of a cell type-specific molecular marker, a whole population of ganglion cells from the mouse retina was stained using a junctional adhesion molecule B (JAM-B)-driven GFP mouse line.<sup>299</sup> This procedure identified a uniform population of ganglion cells with asymmetrical dendritic trees aligned dorsal to ventral. A similar OFF cell type, G3 in the Masland catalog, has been reported for the rabbit retina.<sup>314,332</sup> In the mouse, this cell type has been characterized as OFF DS, although in the rabbit retina it was identified as orientation-selective.<sup>333</sup> If it is truly DS, then the mechanism may be unusual because it does not stratify with the SACs. Together, these observations suggest that there may be multiple circuits to generate directional signals.<sup>334</sup>

## **A Ganglion Cell for the Control of Pupil Diameter and Circadian Rhythm**

It has long been known that certain visually driven activities persist in mice where rods and cones have completely degenerated. These apparently blind mice retain pupillary light reflexes as well as circadian rhythms and a similar profile has been reported in totally blind humans.<sup>335</sup> It was concluded that these reflexes are driven by connections separate from the usual image-forming pathways. This issue was resolved when a set of ganglion cells were found to

express an additional visual pigment called melanopsin. They form a relatively sparse mosaic (only 2000 per mouse retina) with loopy dendrites (Fig. 17.33) in sublamina a and b and they respond with a slow sustained discharge dependent on the light intensity.<sup>36</sup> Even when these cells are isolated, they still produce light responses.<sup>336</sup> In other words, the melanopsin-containing ganglion cells are intrinsically photosensitive and they are referred to as ipRGCs.

**FIG. 17.33** Melanopsin ganglion cell ectopic inputs. (A) Low-resolution picture shows melanopsin ganglion cells in the rabbit retina have sparse randomly arranged dendrites. (B) Staining certain ON cone bipolar cells with an antibody against calbindin showed that the descending axons were frequently adjacent to the melanopsin-positive ganglion cells. These are the sites of axonal ribbon inputs which provide ON input to melanopsin ganglion cells that stratify in sublamina a of the inner plexiform layer. (Reproduced with permission from Hoshi H, Liu WL, Massey SC, et al. ON inputs to the OFF layer: bipolar cells that break the stratification rules of the retina. *J Neurosci* 2009;29:8875–83.)

The melanopsin-containing ganglion cells project to the suprachiasmatic nucleus (SCN), the brain's circadian pacemaker.<sup>36,336</sup> Labeled axons were also found in the olivary pretectal nucleus (OPN), which is involved with the circuit controlling pupil diameter. These are referred to as nonimage-forming pathways. In mice lacking melanopsin, photoentrainment

of the circadian rhythm and the control of the pupillary light reflex were attenuated at high light intensities.<sup>337</sup>

However, melanopsin ganglion cells also receive the usual rod and cone inputs, which can drive these circuits at low light intensities. The M1 subtype is stratified in sublamina a but it still has ON-driven light responses due to the presence of ectopic or axonal ribbon synapses from ON cone bipolar cells as they traverse sublamina a (Fig. 17.33).<sup>27,28,338</sup> In crossbred mice with photoreceptor degeneration as well as no melanopsin, the pupillary light reflex and the photoentrainment of the circadian clock were completely eliminated.<sup>339</sup> The conclusion is that, at low irradiance, the normal rod/cone inputs drive these circuits but at higher light levels the intrinsic melanopsin system drives these accessory visual functions. These experiments provide anatomic, physiologic, and behavioral evidence that the ganglion cell type defined by the expression of melanopsin forms a specific channel in the mammalian visual system that is connected to the SCN and the OPN among other targets. This is a prime example that different ganglion cell types provide parallel channels in the visual system that serves specific functions.

Based on a combination of morphology and physiology, five subtypes of melanopsin-containing ganglion cells, M1–M5, have been identified in the mouse retina.<sup>340,341</sup> The M1 subtype is the only one stratified in sublamina a; it contains the most melanopsin and has strong intrinsic photoresponses and relatively weak rod/cone input. M2 cells have dendrites in sublamina b but less melanopsin and weaker intrinsic responses. M3 cells are bistratified and do not form a uniform population.<sup>342</sup> M4 and M5 cells have very low levels of melanopsin and correspondingly weak intrinsic responses.<sup>340</sup> Using combinations of markers, the M1-class ipRGCs can be further divided into two types, one projecting to the shell of the OPN, which is required for the pupillary light reflex, and one targeting the SCN, required for circadian photo entrainment.<sup>301</sup> This Brn-3b-negative group of M1 ipRGCs comprises approximately only 10% of all melanopsin ganglion cells. Thus, the specific nonimage-forming visual pathway that resets the circadian clock every morning consists of only 200 ganglion cells.<sup>343</sup> It is very surprising that a distinct visual pathway can be formed by such a small

number of cells.

The roles of non-M1 types are still unclear, but they may contribute to light avoidance in mouse pups, sleep regulation, and, in humans, the light sensitivity of migraine and seasonal affective disorder.<sup>340</sup> The activity of ipRGCs is also important for retinogeniculate segregation, which is now known to involve light sensitivity prior to function of the photoreceptors.<sup>292</sup>

## Color Vision and Ganglion Cells

Humans are trichromatic, with red, green, and blue cones. Color vision provides an additional variable to improve visual discrimination. It is organized into two opponent systems, red–green and blue–yellow (where yellow = red + green).<sup>344</sup> Hence, there are no red/green hues and no mixtures of blue and yellow; they are said to be color-opponent. The blue–yellow system is found widely in mammals and is thought to be older on an evolutionary timescale.<sup>54</sup> In primates, once the midget system had reached maximum resolution in the 1 : 1 : 1 pathway, a comparatively recent gene duplication produced red and green pigments. By reason of the connection with a single cone, midget ganglion cells are automatically color-coded.

Midget ganglion cells are concentrically organized as red–green or green–red. The center input is spectrally pure because of the 1 : 1 : 1 connection with single cones. There has been some controversy concerning the origin of the color-opponent surround, whether it is spectrally pure, and whether it arises from the outer or inner retina. Recent recordings from midget ganglion cells in the primate retina indicate that the surround is chromatically mixed. In other words, it is the average of the surrounding cones. On average, the ratio of red to green in the surround was approximately 50%.<sup>345</sup> Furthermore, both center and surround inputs modulated an excitatory conductance with a reversal potential around 0 mV. This means that the surround signal does not arise from amacrine cell inhibition in the inner retina. Rather, the color opponency must be generated in the outer retina by horizontal cell feedback.<sup>345</sup> Horizontal cells are suitably wired to provide the spectrally mixed surround signal because they contact both red and green cones indiscriminately.<sup>346</sup> Enhanced buffering to block pH-dependent horizontal cell feedback

eliminated both the spatial and chromatic surround of midget ganglion cells. Although the exact mechanism of horizontal cell feedback is controversial, this strongly indicates that color opponency is produced by horizontal cell feedback in the outer retina.<sup>131,345</sup> Finally, neither GABA nor glycine antagonists blocked the surround inputs. Thus inhibition in either the outer or inner retina is not required. Nor does horizontal cell feedback in the primate retina depend on GABA or glycine.<sup>345</sup>

Large-scale multielectrode array recording has also been used to analyze the color inputs to primate ganglion cells.<sup>347</sup> Hundreds of ganglion cells may be recorded simultaneously and then sorted by spike size and shape to identify individual ganglion cells. Types of ganglion cells may be identified by their receptive field sizes, center/surround organization, and the mosaic properties by which they tile the retina. Using a fine-grained textual stimulus, local hot spots were found within each receptive field that matched the distribution of the underlying cone array. The spectral characteristics of each hot spot, recorded in several nearby ganglion cells, were used to identify each cone locus as red, green, or blue, and then the contributions of each individual cone were mapped to the overlying array of ganglion cells. Parasol ganglion cells sampled uniformly from red and green cones but not blue cones. In contrast, many midget ganglion cells showed color-opponent responses. As above, the surrounds were spectrally mixed but the center inputs to both ON and OFF midget ganglion cells had a small nonrandom tendency to sample from more red or green cones.<sup>347</sup> Obviously, in central retina, where midget bipolar cells may contact a single cone, this would provide a spectrally pure center with a mixed color-opponent surround. Intellectually, we understand that tracing back from ganglion cells through the retinal circuitry must lead to cones. However, the direct demonstration of ganglion cell sampling from the complete array of identified cones is an experimental triumph. These experiments indicate that parasol ganglion cells are not color-coded while color signals are carried by the midget ganglion cells.

In contrast to the red–green system, the circuits underlying blue–yellow opponency have been relatively well described. Some of this success is due to the morphologic details that make cells in the blue pathway more recognizable. This begins with blue cones

themselves, which can be labeled with antibodies against blue cone opsin.<sup>57</sup> Red and green cone opsins are so close they cannot be discriminated by current antibodies. In addition, blue cone pedicles are noticeably smaller, with fewer telodendria.<sup>70</sup> The blue cone bipolar cells can also be recognized because of their long dendrites, which bypass many cones in search of the blue ones.<sup>186,348,349</sup> Blue ON cone bipolar cells have direct input to a small bistratified ganglion cell that gives blue ON/yellow OFF responses.<sup>350</sup> Blue–yellow small bistratified ganglion cells have also been identified in multielectrode array recordings from primate retina. These experiments suggested that most of the color opponency arose in the outer retina.<sup>351,352</sup> Further physiologic evidence suggests that blue–yellow color opponency originates in the outer retina.<sup>353</sup> Indeed, blue cones themselves are blue–yellow color-opponent, indicating that the yellow-opponent signal is generated by horizontal cell feedback.<sup>354</sup>

In nonprimate mammalian retina, blue-driven ganglion cells were reported as monostратified ON cells.<sup>355</sup> This is quite different from the small bistratified blue–yellow ganglion cell of the primate retina. The color opponency of this monostратified ganglion cell could arise in the outer retina, as suggested for primate retina.<sup>352,354</sup>

## Gene Therapy to Cure Color Blindness

Mice are dichromats, expressing a short-wavelength photopigment and a single medium-wavelength pigment on the X chromosome. Jacobs and colleagues<sup>356</sup> showed that adding a human long-wavelength photopigment allowed mice to have a form of color vision. This idea has been extended to primates and could potentially be used in humans. About 5–8% of the population has red–green color blindness, because they lack either the long- or middle-wavelength visual pigments. Some squirrel monkeys also are dichromats and recently Mancuso and colleagues<sup>357</sup> showed that adding a third photopigment, using gene therapy approaches could restore color discrimination, even though the monkeys had been dichromats since birth.

## New Tools to Identify Ganglion Cell Types

The lack of genetic markers for individual ganglion cell types is a major handicap. As shown above, classification schemes that rely on morphology are very difficult to implement and there is a less-than-perfect mesh with physiology and biochemistry. This is not a minor issue: the comparatively recent flood of information about ipRGCs depends in large part on the identification of this cell type(s) due to the expression of melanopsin. Mouse lines with GFP-labeled melanopsin ganglion cells, knockout mouse strains, and melanopsin antibodies have all been developed. This one simple attribute allows the identification of melanopsin-containing ganglion cells for recording, filling, manipulating, or deleting. Thus, the connections, subtypes, physiology, light responses, and central projections of the ipRGCs have been uncovered, obtaining essentially a full description of this nonimage-forming pathway and its functions in the pupillary light reflex and circadian entrainment.

However, new molecular techniques are starting to provide a way to mark certain ganglion cell types as a complete population. Thus, it is becoming possible to study a specific ganglion cell type as opposed to a spectrum of mixed cell types with variable properties. One research group has screened a library of bacterial artificial chromosome (BAC) transgenic mice with GFP expressed under the control of different promoters. In particular, they looked for GFP expression in a nonrandom mosaic. This is one of the known properties of specific ganglion cell types, which tile the retina in a uniform manner.<sup>39</sup> In calretinin-enhanced GFP (EGFP) mice, a mosaic of large ganglion cells, stratified in sublamina a, with OFF transient responses to light was found. Collectively, these properties identify the GFP-labeled cells as OFF  $\alpha$  ganglion cells.<sup>298</sup> Centrally, this specific ganglion cell type projects to both the superior colliculus, an area integrating sensory input and guiding visual attention, and the dorsal lateral geniculate nucleus, a relay station on the way to the visual cortex. Furthermore, the axonal projections in both areas are precisely organized in columns at a specific laminar depth. Importantly, disrupting cholinergic retinal waves during development prevented the columnar organization of

OFF  $\alpha$  ganglion cell axons.<sup>298</sup> This suggests that spontaneous activity during retinal development controls the development of a retinotopic map. It is worth repeating that these experiments were made possible because a genetic marker for a single ganglion cell type, the OFF  $\alpha$  ganglion cell, was identified.

In a cadherin-3 GFP mouse line, a small percentage of ganglion cells was labeled, some of which also expressed melanopsin. They also contained cadherin-6 and projected to nonimage-forming visual nuclei such as the ventral lateral geniculate nucleus, the intergeniculate leaflet, and the OPN. These nuclei, known targets of ipRGCs. Importantly, in cadherin-6-deficient mice (cadherin-3/GFP crossed with a cadherin-6 knockout), the cadherin-3-labeled ganglion cells failed to innervate the appropriate visual nuclei. Instead, the GFP-labeled axons projected through and past their usual targets. These experiments, utilizing genetically labeled mouse lines, indicate that cadherin-6 is necessary for certain ganglion cell types to recognize their synaptic targets and form functional circuits.<sup>358</sup>

As mouse lines in which different cell types are labeled by molecular methods become widely available, the methods to differentiate among retinal cell types will continue to expand. One group has published a “genetic address book” of retinal cell types.<sup>38</sup> Moreover, several groups have used GFP-labeled cell types to develop single-cell expression libraries for specific cell types.<sup>321,359</sup> This advance in technique is likely to be a game-changer. It will enable a molecular fingerprint to be developed for each cell type, as well as identifying the transcription factors and signaling molecules which govern development and circuit connections.<sup>360</sup> In particular, a transcription factor-based code was used to sort the cells into relevant groups. Perhaps this methodology will provide the definitive answer to how many ganglion cell types are present in the mammalian retina. Finally, by correlating these single-cell libraries against a database of gene mutations associated with visual system disorders, it may be possible to identify defects arising in specific cell types or circuits. For example, an eye movement disorder was correlated with SACs, which may be the source of DS signals required to control reflex eye movements.<sup>317</sup>

# Clinical Relevance of Functional Anatomy

As we have seen, the retina is fundamentally organized as a layered structure. This applies not only to the major cellular and synaptic layers but particularly within the IPL, where the level of stratification is an address. It appears that stratification at the appropriate depth in the IPL allows a ganglion cell to receive input from a certain set of bipolar and amacrine cell processes. The sum of these inputs to a particular type of ganglion cell forms a single channel in the visual system. The overall complexity appears daunting but it may be broken down into a repeated set of stereotyped local circuits, which are strictly governed by a set of rules concerning position and appropriate synaptic partners. Below we discuss briefly some obvious examples where the basic layering and organization of the retina are disrupted, with important clinical consequences.

In glaucoma, the basic defect is in the GCL. Increased intraocular pressure apparently induces programmed cell death in retinal ganglion cells. Factors involved may include anoxia, reduced axonal transport, and excess glutamate, leading to excitatory damage known as excitotoxicity. Ganglion cells appear to be particularly sensitive while other retinal neurons such as amacrine cells are unaffected. [Fig. 17.34](#) shows a retinal section from the same eccentricity of a control macaque eye compared to the operated eye with experimentally induced high intraocular pressure. All retinal layers appear normal, with the exception of the GCL, which is severely depleted compared to the control eye. The absence of retinal ganglion cells may be correlated with dramatically reduced visual acuity, especially in the peripheral retina.<sup>360</sup>

**FIG. 17.34** Depletion of ganglion cells in glaucoma. (A) Control retina, near central, as shown by the depth of ganglion cell somas. (B) While the rest of the retina is normal, the ganglion cell layer has been severely depleted by experimental glaucoma. *GCL*, ganglion cell layer; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *ONL*, outer nuclear layer; *OPL*, outer plexiform layer. A large number of photoreceptor mutations, often in the phototransduction cascade, lead to photoreceptor degeneration in conditions such as retinitis pigmentosa (RP). The defect often arises in rods but eventually both rods and cones degenerate. Whether this occurs because rods secrete a maintenance factor for cones, or via rod/cone coupling, known as the bystander effect, or due to the accumulation of cellular debris is a matter of debate beyond the scope of this chapter. However, photoreceptor degeneration has severe consequences for the organization of the remaining retina. The neural retina apparently requires input from the sensory retina to maintain its well-organized structure. When the neural retina has been deafferented, the second-order neurons, such as rod bipolar cells, produce new dendrites and sprout profusely, making many inappropriate contacts.<sup>3,361</sup> Many neurons develop novel processes that invade other layers where they proliferate to produce tangled microneuromas. Glial cells are extensively remodeled; there is mass

neuronal migration and almost total disruption of the layered structure of the retina. [Fig. 17.35](#) shows examples from two rodent lines and a human RP case. In each case, the resulting tangle of misplaced cells and inappropriate contacts is essentially unrecognizable as a section of retina. The basic layered organization of the retina has been destroyed. One consequence of this neural reorganization is that the remaining retina is unlikely to retain sufficient organization to operate in any kind of coherent manner. Thus, in the absence of photoreceptors, strategies aimed at stimulating the remaining neural retina by means of a retinal implant seem unlikely to succeed, unless the process of retinal remodeling can be controlled.

**FIG. 17.35** Disruption of retinal organization following photoreceptor degeneration. (A) Control retina: a theme map shows the well-organized, layered structure of the normal retina. (B,C) Rodent retina following photoreceptor degeneration shows severe disruption of the normal layered structure. Many cells have migrated to inappropriate locations. (D) A human retinitis pigmentosa case where the organization of the neural retina has been severely disrupted. *RCS*, Royal College of Surgeons; *SD*, Sprague–Dawley. ACs,
